Library of Congress Cataloging-in-Publication Data

Encyclopedia of hydrological science/editor-in-chief, Malcolm G. Anderson.
p. cm.
ISBN 0-471-49103-9 (cased) – ISBN 0-470-84894-4 (obook)
1. Hydrology – Encyclopedias. I. Anderson, Malcolm G.
GB655.E527 2005
551.48′03 – dc22

2005022541

British Library Cataloguing in Publication Data

A catalogue record for this book is available from the British Library
ISBN 10: 0-471-49103-9 (HB)
ISBN 13: 978-0-471-49103-9

Typeset in 9½/11½ pt Times Roman by Laserwords Private Ltd., Chennai, India.
Printed and bound in Great Britain by Bath Press, Bath, UK.
This book is printed on acid-free paper responsibly manufactured from sustainable forestry in which at least two trees are planted for each one used for paper production.

Contributors

Michael B Abbott
Knowledge Engineering B.V. Belgium and UNESCO-IHE Delft, Delft, The Netherlands

Richard G Allen
Department of Civil Engineering and Department of Biological and Agricultural Engineering, University of Idaho, Kimberly, ID, US

William M Alley
United States Geological Survey, Office of Ground Water, San Diego, CA, US

Doug Alsdorf
Department of Geological Sciences, Ohio State University, Columbus, OH, US

Mustafa S Altinakar
Laboratoire de Recherches Hydrauliques, Ecole Polytechnique Fédérale, Lausanne, Switzerland

Jaime M Amezaga
Centre for Land Use and Water Resources Research, Institute for Research on the Environment and Sustainability, University of Newcastle, Newcastle upon Tyne, UK

Ulf Andrae
Research Department, European Centre for Medium-Range Weather Forecasts, Reading, UK

George W Annandale
Engineering and Hydrosystems Inc., Denver, CO, US

Aronne Armanini
Department of Civil and Environmental Engineering, University of Trento, Trento, Italy

Geoffrey L Austin
Department of Physics, The University of Auckland, Auckland, New Zealand

Roni Avissar
Department of Civil and Environmental Engineering, Duke University, Durham, NC, US

Bruce Aylward
Deschutes Water Exchange Program, Deschutes Resources Conservancy, Bend, OR, US

Vladan Babovic
DHI Water & Environment, Agern Alle, Hørsholm, Denmark

Darren L Bade
Center for Limnology, University of Wisconsin, Madison, WI, US

Andy Baker
School of Geography, Earth and Environmental Sciences, The University of Birmingham, Birmingham, UK

Lawrence E Band
University of North Carolina, Chapel Hill, NC, US

András Bárdossy
Universität Stuttgart, Institut für Wasserbau, Stuttgart (Vaihingen), Germany

Luis A Bastidas
Department of Civil and Environmental Engineering/Utah Water Research Laboratory, Utah State University, Logan, UT, US

Paul D Bates
School of Geographical Sciences, University of Bristol, Bristol, UK

Jacob Bear
Department of Civil and Environmental Engineering, Technion – Israel Institute of Technology, Haifa, Israel

Roger Beckie
Department of Earth and Ocean Sciences, University of British Columbia, Vancouver, BC, Canada

Anton Beljaars
Research Department, European Centre for Medium-Range Weather Forecasts, Reading, UK

Kenneth E Bencala
United States Geological Survey, Menlo Park, CA, US

Sandra L Berry
Formerly of: Cooperative Research Centre for Greenhouse Accounting, Research School of Biological Sciences, Institute of Advanced Studies, The Australian National University, Canberra, Australia & Currently at: School of Resources, Environment and Society, Faculty of Science, The Australian National University, Canberra, Australia

Richard A Betts
Hadley Centre for Climate Prediction and Research, Exeter, UK

Keith J Beven
Department of Environmental Science, and Lancaster Environment Centre, Lancaster University, Lancaster, UK

Charon Birkett
Earth Science Interdisciplinary Center, University of Maryland, College Park, MD, US

David M Bjerklie
United States Geological Survey, Hartford, CT, US

Günter Blöschl
Institute for Hydraulic and Water Resources Engineering, Vienna University of Technology, Vienna, Austria

Axel Bronstert
Institute for Geoecology, University of Potsdam, Potsdam, Germany

James D Brown
Universiteit van Amsterdam, Nieuwe Achtergracht, Amsterdam, The Netherlands

Ross D Brown
Meteorological Service of Canada, Dorval, QC, Canada

LA Sampurno Bruijnzeel
Department of Hydrology and Geo-Environmental Sciences, Vrije Universiteit, Amsterdam, The Netherlands

Reto Burkard
University of Bern, Bern, Switzerland

Timothy P Burt
Department of Geography, University of Durham, Durham, UK

Jim M Buttle
Department of Geography, Trent University, Peterborough, ON, Canada

Ian R Calder
Centre for Land Use & Water Resources Research, University of Newcastle, Newcastle upon Tyne, UK

Terri Camesano
Department of Chemical Engineering, Worcester Polytechnic Institute, Worcester, MA, US

Claire L Campbell
Centre for Ecology and Hydrology, Edinburgh, UK

Pamela L Campbell
ETI, St Petersburg, FL, US

Liz Chalk
Environment Agency, North East Region, York, UK

Alfred TC Chang
NASA/Goddard Space Flight Center, Greenbelt, MD, US
†Deceased May 26, 2004

Deborah V Chapman
Environmental Research Institute and Department of Zoology, Ecology and Plant Science, University College Cork, Cork, Ireland

Thomas N Chase
Cooperative Institute for Research in Environmental Sciences, University of Colorado, Boulder, CO, US

Limin Chen
Civil and Environmental Engineering Department, Syracuse University, Syracuse, NY, US

Bernard Chocat
INSA de Lyon, URGC Hydrologie Urbaine, Villeurbanne Cedex, Lyon, France

Robin T Clarke
Instituto de Pesquisas Hidráulicas, Porto Alegre RS, Brazil

T Prabhakar Clement
Department of Civil Engineering, Auburn University, Auburn, AL, US

Cory C Cleveland
Institute of Arctic and Alpine Research, University of Colorado, Boulder, CO, US

J Graham Cogley
Department of Geography, Trent University, Peterborough, ON, Canada

Frederick S Colwell
Biological Sciences Division, Idaho National Laboratory, Idaho Falls, ID, US

Josefino C Comiso
NASA/Goddard Space Flight Center, Greenbelt, MD, US

Dennis L Corwin
USDA-ARS, George E. Brown, Jr. Salinity Laboratory, Riverside, CA, US

Justin F Costelloe
CRC for Catchment Hydrology and Department of Civil and Environmental Engineering, The University of Melbourne, Victoria, Australia

Alan P Covich
Institute of Ecology, University of Georgia, Athens, GA, US

Christopher B Craft
School of Public and Environmental Affairs, Indiana University, Bloomington, IN, US

Susanne Crewell
Meteorological Institute, University of Munich, Munich, Germany

Jacob H Dane
Department of Agronomy and Soils, Auburn University, Auburn, AL, US

Lisa S Darby
NOAA Environmental Technology Laboratory, Boulder, CO, US

Jorge Soares David
Instituto Superior de Agronomia, Tapada da Ajuda, Lisboa, Portugal

Bruce Davison
Environment Canada, National Hydrology Research Centre, National Water Research Institute, Saskatoon, SK, Canada

John Dearing
Department of Geography, University of Liverpool, Liverpool, UK

William E Dietrich
Department of Earth and Planetary Science, University of California, Berkeley, CA, US

S Lawrence Dingman
Earth Sciences Department, University of New Hampshire, Durham, NH, US

Kim N Dirks
Department of Physiology, The University of Auckland, Auckland, New Zealand

Stefan H Doerr
Geography Department, University of Wales, Swansea, UK

Shawan Dogramaci
Department of Environment, Salinity and Land Use Impacts Branch, Resource Science Division, East Perth, Australia

Albertus Johannes Dolman
Department of Hydrology and Geo-Environmental Sciences, Faculty of Earth and Life Sciences, Vrije Universiteit, Amsterdam, The Netherlands

Brendan Dooher
Environmental Restoration Division, Lawrence Livermore National Laboratory, Livermore, CA, US

Charles A Doswell III
University of Oklahoma, Norman, OK, US

Charles T Driscoll
Civil and Environmental Engineering Department, Syracuse University, Syracuse, NY, US

Ian G Droppo
National Water Research Institute, Environment Canada, Burlington, ON, Canada

Matthias Drusch
European Centre for Medium-Range Weather Forecasts, Reading, UK

Ralph Dubayah
Department of Geography, University of Maryland, College Park, MD, US

Wolfgang Durner
Institute of Geoecology, Department of Soil Physics, Braunschweig Technical University, Braunschweig, Germany

S Eden
US Climate Change Science Program Office, Washington, DC, US

Anthony C Edwards
Formerly of: Catchment Management Group, Macaulay Institute, Aberdeen, UK & Currently at: Nether Backhill, Aberdeen, UK

William E Eichinger
IIHR Hydroscience and Engineering, University of Iowa, Iowa City, IA, US

Michael B Ek
National Centers for Environmental Prediction/Environmental Modeling Center, Suitland, MD, US

Brenda Ekwurzel
Global Environment Program, Union of Concerned Scientists, Washington DC, US

J Bryan Ellis
Urban Pollution Research Centre, Middlesex University, Enfield, UK

Theodore A Endreny
Program in Hydrological Systems Science & Engineering, State University of New York College of Environmental Science and Forestry, Syracuse, NY, US

Anthony W England
University of Michigan, Ann Arbor, MI, US

Alan Ervine
Department of Civil Engineering, University of Glasgow, Glasgow, UK

Werner Eugster
Swiss Federal Institute of Technology, Zürich, Switzerland

Souheil M Ezzedine
University of California, Lawrence Livermore National Laboratory, Livermore, CA, US

Roger A Falconer
Cardiff School of Engineering, Cardiff University, Cardiff, UK

Kathy Fallon-Lambert
Ecologic: Analysis and Communications, Quechee, VT, US

Graham D Farquhar
Cooperative Research Centre for Greenhouse Accounting, Research School of Biological Sciences, The Australian National University, Canberra, Australia

Ty PA Ferré
University of Arizona, Tucson, AZ, US

Massimiliano Ferronato
University of Padova, Padova, Italy

Jonathan W Finch
Centre for Ecology and Hydrology, Wallingford, Oxfordshire, UK

Andrea I Flossmann
Laboratoire de Météorologie Physique/OPGC, Université Blaise Pascal/CNRS, Aubière Cedex, France

Hannes Flühler
Institute of Terrestrial Ecology, Swiss Federal Technical University at Zürich, Schlieren, Switzerland

Tim Forsyth
Development Studies Institute, London School of Economics and Political Science, London, UK

James L Foster
NASA/Goddard Space Flight Center, Greenbelt, MD, US

Luigi Fraccarollo
CUDAM and Department of Civil and Environmental Engineering, University of Trento, Trento, Italy

Janet Franklin
San Diego State University, San Diego, CA, US

James K Fredrickson
Biological Sciences Division, Pacific Northwest National Laboratory, Richland, WA, US

Sherilyn C Fritz
Department of Geosciences & School of Biological Sciences, University of Nebraska, Lincoln, NE, US

John Gallant
Butler Laboratory, Commonwealth Scientific and Industrial Research Organisation, Land and Water, Canberra, Australia

Giuseppe Gambolati
University of Padova, Padova, Italy

John HC Gash
Centre for Ecology & Hydrology, Wallingford, Oxfordshire, UK

Charles P Gerba
Department of Soil, Water and Environmental Science, University of Arizona, Tucson, AZ, US

Thomas W Giambelluca
Geography Department, University of Hawaii at Manoa, Honolulu, HI, US

Timothy R Ginn
Department of Civil and Environmental Engineering, University of California, Davis, CA, US

Christopher J Gippel
Fluvial Systems Pty Ltd, Stockton, Australia

Scott J Goetz
Woods Hole Research Center, Woods Hole, MA, US

Jaime Gómez-Hernández
Department of Hydraulics and Environmental Engineering, Universidad Politécnica de Valencia, Valencia, Spain

Barry E Goodison
Meteorological Service of Canada, Downsview, Canada

David C Goodrich
Southwest Watershed Research Center, ARS USDA, Tucson, AZ, US

Lars Gottschalk
Department of Geosciences, University of Oslo, Oslo, Norway

Walter H Graf
Laboratoire de Recherches Hydrauliques, Ecole Polytechnique Fédérale, Lausanne, Switzerland

Rodger B Grayson
CRC for Catchment Hydrology and Department of Civil and Environmental Engineering, The University of Melbourne, Victoria, Australia

Vincent Guinot
Hydrosciences Montpellier, Université Montpellier 2, Montpellier Cedex 5, France

Hoshin V Gupta
Department of Hydrology and Water Resources, The University of Arizona, Tucson, AZ, US

Dorothy K Hall
NASA/Goddard Space Flight Center, Greenbelt, MD, US

Michael J Hall
Department of Water Engineering, UNESCO-IHE, Delft, The Netherlands

Robin L Hall
Centre for Ecology and Hydrology, Wallingford, Oxfordshire, UK

John Hallett
Division of Atmospheric Sciences, Desert Research Institute, Reno, NV, US

Matthew C Hansen
Geographic Information Science Center of Excellence, South Dakota State University, Brookings, SD, US

R Michael Hardesty
NOAA Environmental Technology Laboratory, Boulder, CO, US

David Harding
Geodynamics Branch, NASA/Goddard Space Flight Center, Greenbelt, MD, US

Holly C Hartmann
Department of Hydrology and Water Resources, The University of Arizona, Tucson, AZ, US

Bent Hasholt
University of Copenhagen, Copenhagen, Denmark

Richard W Healy
United States Geological Survey, Denver, CO, US

Marius Heinen
Alterra, Wageningen, The Netherlands

Henry Hengeveld
Meteorological Service of Canada, Toronto, ON, Canada

Gerard BM Heuvelink
Wageningen University, Wageningen, The Netherlands

Larry D Hinzman
Water and Environmental Research Center, Institute of Northern Engineering, University of Alaska, Fairbanks, AK, US

Regine Hock
Department of Physical Geography and Quaternary Geology, Stockholm University, Stockholm, Sweden

Forrest Hoffman
Oak Ridge National Laboratory, Oak Ridge, TN, US

Fred Hoffman
Environmental Restoration Division, Lawrence Livermore National Laboratory, Livermore, CA, US

Albert AM Holtslag
Meteorology and Air Quality Wageningen University, Wageningen, The Netherlands

Ekkehard Holzbecher
Humboldt Universität, Inst. of Freshwater Ecology (IGB), Berlin, Germany

Jan W Hopmans
Department of Land, Air and Water Resources, University of California, Davis, CA, US

Bryn Hubbard
Institute of Geography and Earth Sciences, University of Wales, Aberystwyth, UK

Alfredo R Huete
Department of Soil, Water and Environmental Science, University of Arizona, Tucson, AZ, US

George J Huffman
Science Systems and Applications, Inc. and NASA/Goddard Space Flight Center Laboratory for Atmospheres, Greenbelt, MD, US

George A Isaac
Cloud Physics and Severe Weather Research Division, Meteorological Service of Canada, Toronto, ON, Canada

Thomas J Jackson
USDA ARS Hydrology and Remote Sensing Lab, Beltsville, MD, US

Peter Jansson
Department of Physical Geography and Quaternary Geology, Stockholm University, Stockholm, Sweden

Mathieu Javaux
Department of Environmental Sciences and Land Use Planning, Université Catholique de Louvain, Louvain-la-Neuve, Belgium and Agrosphere Institute, (ICG-IV), Forschungszentrum Jülich GmbH, Jülich, Germany

Graham Jewitt
School of Bioresources Engineering and Environmental Hydrology, University of KwaZulu-Natal, Pietermaritzburg, South Africa

H Gerald Jones
INRS-ETE, Environnement, Université du Quebec, Sainte-Foy, QC, Canada

Julia Jones
Department of Geosciences, Oregon State University, Corvallis, OR, US

Andreja Jonoski
Department of Hydroinformatics and Knowledge Management, UNESCO-IHE Institute for Water Education, Delft, The Netherlands

Per Kallberg
Research Department, European Centre for Medium-Range Weather Forecasts, Reading, UK

George Kallos
Atmospheric Modeling and Weather Forecasting Group, School of Physics, University of Athens, Athens, Greece

Douglas L Kane
Water and Environmental Research Center, Institute of Northern Engineering, University of Alaska, Fairbanks, AK, US

Maarten Keijzer
DHI Water & Environment, Agern Alle, Hørsholm, Denmark

Richard EJ Kelly
University of Maryland, Baltimore, MD, US

Andreas Kemna
Agrosphere Institute (ICG-IV), Forschungszentrum Jülich GmbH, Jülich, Germany

Soon-Thiam Khu
Centre for Water Systems, School of Engineering, Computer Science and Mathematics, University of Exeter, Exeter, UK

John S Kimball
Department of Ecosystem and Conservation Sciences, NTSG University of Montana, Missoula, MT, US and Flathead Lake Biological Station, Division of Biological Sciences, The University of Montana, Polson, MT, US and Numerical Terradynamic Simulation Group, The University of Montana, Missoula, MT, US

Mike Kirkby
School of Geography, University of Leeds, Leeds, UK

Mary Beth Kirkham
Department of Agronomy, Kansas State University, Manhattan, KS, US

Randal D Koster
NASA/Goddard Space Flight Center, Greenbelt, MD, US

Bommanna G Krishnappan
Aquatic Ecosystem Impacts Research Branch, National Water Research Institute, Environment Canada, Canada Centre for Inland Waters, Burlington, ON, Canada

Charles Kroll
Environmental Resources and Forest Engineering, SUNY College of Environmental Science and Forestry (ESF), Syracuse, NY, US

Jacob Cornelis Jan Kwadijk
WL Delft Hydraulics, Delft, The Netherlands

James W La Baugh
United States Geological Survey, Office of Ground Water, Reston, VA, US

Rob Lamb
JBA Consulting – Engineers & Scientists, Skipton, North Yorkshire, UK

Luca G Lanza
Department of Environmental Engineering, University of Genoa, Genoa, Italy

Michele Larcher
CUDAM and Department of Civil and Environmental Engineering, University of Trento, Trento, Italy

Andrew RG Large
Centre for Land Use and Water Resources Research, University of Newcastle, Newcastle upon Tyne, UK

RG Lawford
International GEWEX Project Office, Silver Spring, MD, US

George Leavesley
United States Geological Survey, Denver, CO, US

Graham Leeks
Centre for Ecology and Hydrology, Wallingford, Oxfordshire, UK

Michael Lehning
WSL, Swiss Federal Institute for Snow and Avalanche Research SLF, Davos Dorf, Switzerland

Dennis P Lettenmaier
Department of Civil and Environmental Engineering, University of Washington, Seattle, WA, US

Gro Lilbæk
Centre for Hydrology, Department of Geography, University of Saskatchewan, Saskatoon, SK, Canada

Binliang Lin
Cardiff School of Engineering, Cardiff University, Cardiff, UK

Harry F Lins
United States Geological Survey, Office of Ground Water, Reston, VA, US

Kai Lipsius
Institute of Geoecology, Department of Soil Physics, Braunschweig Technical University, Braunschweig, Germany

Yongqiang Liu
Forestry Sciences Laboratory, USDA Forest Service, Athens, GA, US

Keith Loague
Department of Geological and Environmental Sciences, Stanford University, Stanford, CA, US

David Long
Electrical and Computer Engineering Department, Brigham Young University, Provo, UT, US

Charles H Luce
Rocky Mountain Research Station, Boise, ID, US

Henrik Madsen
River & Flood Management, DHI Water & Environment, Hørsholm, Denmark

David R Maidment
Department of Civil Engineering, University of Texas, Austin, TX, US

Jiri Marsalek
National Water Research Institute, Burlington, ON, Canada

Philip Marsh
NWRI Saskatoon, Saskatchewan, SK, Canada

G Richard Marzolf
United States Geological Survey, Office of Ground Water, Reston, VA, US

Michael D Mastrandrea
Interdisciplinary Program in Environment and Resources, Stanford University, Stanford, CA, US

Joseph R McConnell
Division of Hydrologic Sciences, Desert Research Institute, University and Community College System of Nevada, Reno, NV, US

Steven C McCutcheon
Faculty of Engineering and Warnell School of Forest Resources, University of Georgia on assignment from the US EPA National Exposure Research Laboratory, Athens, GA, US

Kyle C McDonald
Water and Carbon Cycles Group, Science Division, Jet Propulsion Laboratory, California Institute of Technology, Pasadena, CA, US

Jeffrey J McDonnell
Department of Forest Engineering, Oregon State University, Corvallis, OR, US

Brian McGlynn
Department of Land Resources and Environmental Sciences, Watershed Hydrology Laboratory, Montana State University, Bozeman, MT, US

Ian G McKendry
Department of Geography, The University of British Columbia, Vancouver, BC, Canada

James P McKinley
Chemical Sciences Division, Pacific Northwest National Laboratory, Richland, WA, US

Diane M McKnight
Institute of Arctic and Alpine Research, University of Colorado, Boulder, CO, US

Walt McNab
Environmental Restoration Division, Lawrence Livermore National Laboratory, Livermore, CA, US

David Meko
Laboratory of Tree-Ring Research, University of Arizona, Tucson, AZ, US

Guillermo F Mendoza
New York Department of Environmental Protection, Flushing, NY, US

Michel Meybeck
Sisyphe/CNRS, University of Paris, Paris, France

Hans Middelkoop
Department of Physical Geography, Utrecht University, The Netherlands

Anthony W Minns
Marine & Coastal Management, WL Delft Hydraulics, Delft, The Netherlands

Glenn E Moglen
Department of Civil and Environmental Engineering, University of Maryland, College Park, MD, US

Hans-Martin Münch
Agrosphere Institute (ICG-IV), Forschungszentrum Jülich GmbH, Jülich, Germany

Arthur E Mynett
WL Delft Hydraulics & UNESCO-IHE and Delft University of Technology, Delft, The Netherlands

Mark Nearing
Southwest Watershed Research Center, Tucson, AZ, US

Kirk E Nelson
Department of Civil and Environmental Engineering, University of California, Davis, CA, US

School of Geography, Politics and Sociology, University of Newcastle, Newcastle upon Tyne, UK

Mary Nichols
Southwest Watershed Research Center, Tucson, AZ, US

Peter Nienow
Institute of Geography, University of Edinburgh, Edinburgh, UK

Bart Nijssen
Departments of Hydrology and Water Resources/Civil Engineering and Engineering Mechanics, University of Arizona, Tucson, AZ, US

John R Nimmo
United States Geological Survey, Menlo Park, CA, US

Robert Oglesby
NASA/Marshall Space Flight Center, Huntsville, AL, US

Atsumu Ohmura
Swiss Federal Institute of Technology (ETH), Zürich, Switzerland

J Philip O'Kane
Environment Institute, National University of Ireland, Cork, Ireland

Taikan Oki
International Center for Urban Safety Engineering, Institute of Industrial Science, University of Tokyo, Tokyo, Japan

Dani Or
Department of Civil and Environmental Engineering, University of Connecticut, Storrs, CT, US

Thomas C Pagano
Department of Agriculture, Natural Resources Conservation Service, Portland, OR, US

Anthony John Parsons
Department of Geography, University of Leicester, Leicester, UK

Gareth Pender
School of the Built Environment, Heriot–Watt University, Edinburgh, UK

Norman E Peters
United States Geological Survey, Georgia Water Science Center, Atlanta, GA, US

Birgit Peterson
Department of Geography, University of Maryland, College Park, MD, US

Roger A Pielke Sr
Department of Atmospheric Science, Colorado State University, Fort Collins, CO, US

Alain Pietroniro
Environment Canada, National Hydrology Research Centre, National Water Research Institute, Saskatoon, SK, Canada

Rachel T Pinker
Department of Atmospheric and Oceanic Science, University of Maryland, College Park, MD, US

John W Pomeroy
Centre for Hydrology, Department of Geography, University of Saskatchewan, Saskatoon, SK, Canada

Rajiv Prasad
Environmental Technology Division, Pacific Northwest National Laboratory, Richland, WA, US

Terry D Prowse
Department of Geography, National Water Research Institute of Environment Canada, University of Victoria, Victoria, BC, Canada

Ioannis Pytharoulis
Atmospheric Modeling and Weather Forecasting Group, School of Physics, University of Athens, Athens, Greece

Peter A C Raats
Wageningen University and Research Centre, Wageningen, The Netherlands

Paolo Reggiani
Inland Water Systems, Foundation Delft Hydraulics, Delft, The Netherlands

Thomas E Reilly
United States Geological Survey, Office of Ground Water, Reston, VA, US

Ken Renard
Southwest Watershed Research Center, Tucson, AZ, US

Philippe Renard
Centre for Hydrogeology, University of Neuchâtel, Neuchâtel, Switzerland

Joshua Rhoads
Department of Geography, University of Maryland, College Park, MD, US

Jeffrey E Richey
School of Oceanography, University of Washington, Seattle, WA, US

Jerry C Ritchie
United States Department of Agriculture, Agricultural Research Service Hydrology and Remote Sensing Laboratory, Beltsville, MD, US

Professor Coen J Ritsema
Soil Science Center, Wageningen, The Netherlands

John Roads
Scripps Institution of Oceanography, UCSD La Jolla, CA, US

John Roberts
Centre for Ecology and Hydrology, Wallingford, Oxfordshire, UK

Dale M Robertson
United States Geological Survey, Water Science Center, Middleton, WI, US

Franklin R Robertson
NASA/Marshall Space Flight Center, Huntsville, AL, US

Mark Robinson
Centre for Ecology and Hydrology, Wallingford, Oxfordshire, UK

Michael L Roderick
Cooperative Research Centre for Greenhouse Accounting, Research School of Biological Sciences, The Australian National University, Canberra, Australia

Dan Rosbjerg
Environment & Resources DTU, Technical University Denmark, Kongens Lyngby, Denmark

Steven W Running
Department of Ecosystem and Conservation Sciences, NTSG University of Montana, Missoula, MT, US

John Ruprecht
Department of Environment, Salinity and Land Use Impacts Branch, Resource Science Division, East Perth, Australia

Jasmine E Saros
Department of Biology, University of Wisconsin, La Crosse, WI, US

Dragan Savic
Centre for Water Systems, School of Engineering, Computer Science and Mathematics, University of Exeter, Exeter, UK

Ted A Scambos
National Snow and Ice Data Center (NSIDC), University of Colorado, Boulder, CO, US

Marcel G Schaap
Department of Environmental Sciences, University of California, Riverside, CA, US

Timothy D Scheibe
Environmental Technology Directorate, Pacific Northwest National Laboratory, Richland, WA, US

Jaap Schellekens
Inland Water Systems, Foundation Delft Hydraulics, Delft, The Netherlands and Earth and Life Sciences, Vrije Universiteit Amsterdam, Amsterdam, The Netherlands

C Adam Schlosser
Joint Program on the Science and Policy of Global Change Massachusetts Institute of Technology, Cambridge, MA, US

Thomas J Schmugge
Formerly of: USDA/ARS Hydrology & Remote Sensing Lab, Beltsville, MD, US & Currently at: College of Agriculture, New Mexico State University, Las Cruces, NM, US

Stephen H Schneider
Department of Biological Sciences, Stanford University, Stanford, CA, US

Gerrit Schoups
Department of Land, Air and Water Resources, University of California, Davis, CA, US

Jan Seibert
Department of Physical Geography and Quaternary Geology, Stockholm University, Stockholm, Sweden

Boris Sevruk
Institut für Atmosphäre und Klima (ETH), Zürich, Switzerland

Martin Sharp
Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, AB, Canada

Chris A Shuman
NASA/Goddard Space Flight Center, Greenbelt, MD, US

W James Shuttleworth
Department of Hydrology and Water Resources, University of Arizona, Tucson, AZ, US

Martin J Siegert
Bristol Glaciology Centre, School of Geographical Sciences, University of Bristol, Bristol, UK

Adrian Simmons
Research Department, European Centre for Medium-Range Weather Forecasts, Reading, UK

Jirka Šimůnek
Department of Environmental Sciences, University of California, Riverside, CA, US

Murugesu Sivapalan
Formerly of: Centre for Water Research, Department of Environmental Engineering, University of Western Australia, Crawley, Australia & Currently at: Department of Geography, University of Illinois, Urbana, IL, US

Michael C Slattery
Institute of Environmental Studies, Texas Christian University, Fort Worth, TX, US

David Smiles
CSIRO Land and Water, Canberra, Australia

Roger E Smith
Civil Engineering Department, Colorado State University, Fort Collins, CO, US

Dimitri P Solomatine
UNESCO-IHE Institute for Water Education, Delft, The Netherlands

Shaul Sorek
Ben Gurion University of the Negev, J. Blaustein Institutes for Desert Research, Sede Boker, Israel

Soroosh Sorooshian
Department of Civil and Environment Engineering, University of California, Irvine, CA, US

Manfred Stähli
Swiss Federal Research Institute WSL; Water, Soil, and Rock Movements, Birmensdorf, Switzerland

Fritz Stauffer
Swiss Federal Institute of Technology, Zurich, Switzerland

Matthias Steiner
Princeton University, Princeton, NJ, US

Guus S Stelling
Department of Civil Engineering, Technical University of Delft, Delft, The Netherlands

Grahame Stephens
Atmospheric Sciences, Colorado State University, Fort Collins, CO, US

David A Stonestrom
United States Geological Survey, Menlo Park, CA, US

Hans von Storch
Institute of Coastal Research, GKSS Research Centre, Geesthacht, Germany

Julienne Stroeve
National Snow and Ice Data Center, University of Colorado, Boulder, CO, US

Zhongbo Su
International Institute for Geo-Information Science and Earth Observation (ITC), Enschede, The Netherlands

Alexander Y Sun
CNWRA, Southwest Research Institute, San Antonio, TX, US

Ne-Zheng Sun
Department of Civil and Environmental Engineering, University of California, Los Angeles, CA, US

Peter W Swarzenski
United States Geological Survey, St Petersburg, FL, US

Christina L Tague
San Diego State University, San Diego, CA, US

Pietro Teatini
University of Padova, Padova, Italy

Axel Tillmann
Agrosphere Institute (ICG-IV), Forschungszentrum Jülich GmbH, Jülich, Germany

Ezio Todini
Department of Earth and Geo-Environmental Sciences, University of Bologna, Bologna, Italy

Sylvia S Tognetti
Consultant, Environmental Science and Policy

G Clarke Topp
Agriculture and Agri-Food Canada, Ottawa, ON, Canada

Alan R Townsend
Institute of Arctic and Alpine Research, University of Colorado, Boulder, CO, US

Martyn Tranter
Bristol Glaciology Centre, School of Geographical Sciences, University of Bristol, Bristol, UK

Ilja Tromp-van Meerveld
Ecole Polytechnique Fédérale de Lausanne, School of Architecture, Civil & Environmental Engineering, Lausanne, Switzerland

Taro Uchida
Research Center for Disaster Risk Management, National Institute for Land & Infrastructure Management, Asahi, Tsukuba, Japan

Michael H Unsworth
Atmospheric Sciences Group, College of Oceanic and Atmospheric Sciences, Oregon State University, Corvallis, OR, US

Sakari Uppala
Research Department, European Centre for Medium-Range Weather Forecasts, Reading, UK

Fernanda Valente
Instituto Superior de Agronomia, Tapada da Ajuda, Lisboa, Portugal

Marnik Vanclooster
Department of Environmental Sciences and Land Use Planning, Université Catholique de Louvain, Louvain-la-Neuve, Belgium

J Vanderborght
Agrosphere Institute, (ICG-IV), Forschungszentrum Jülich GmbH, Jülich, Germany

Harry Vereecken
Agrosphere Institute (ICG-IV), Forschungszentrum Jülich GmbH, Jülich, Germany

Anne Verhoef
Department of Soil Science, The University of Reading, Reading, UK

Arre Verweerd
Agrosphere Institute (ICG-IV), Forschungszentrum Jülich GmbH, Jülich, Germany

Adri Verwey
WL Delft Hydraulics, Delft, The Netherlands

Pedro Viterbo
Research Department, European Centre for Medium-Range Weather Forecasts, Reading, UK

Huib J de Vriend
WL Delft Hydraulics, Delft, The Netherlands

Jasper A Vrugt
Formerly of: Institute for Biodiversity and Ecosystem Dynamics – Physical Geography, University of Amsterdam, Amsterdam, The Netherlands & Currently at: Earth and Environmental Sciences Division, Los Alamos National Laboratory, Los Alamos, NM, US

Thorsten Wagener
Formerly of: Department of Hydrology and Water Resources, The University of Arizona, Tucson, AZ, US & Currently at: Department of Civil and Environmental Engineering, Pennsylvania State University, University Park, PA, US

Desmond E Walling
Department of Geography, University of Exeter, Exeter, UK

Markus Weiler
Departments of Forest Resources Management and Geography, University of British Columbia, Vancouver, BC, Canada

Micha Guido Franciscus Werner
WL Delft Hydraulics, Delft, The Netherlands

Andrew W Western
CRC for Catchment Hydrology and Department of Civil and Environmental Engineering, The University of Melbourne, Victoria, Australia

Robert G Wetzel
Department of Environmental Sciences and Engineering, The University of North Carolina, Chapel Hill, NC, US
† Deceased April 18, 2005

Sue White
Institute of Water and Environment, Cranfield University, Silsoe, Bedfordshire, UK

Mark Wigmosta
Environmental Technology Division, Pacific Northwest National Laboratory, Richland, WA, US

Peter de Willigen
Alterra, Wageningen, The Netherlands

Ian Willis
Department of Geography, University of Cambridge, Cambridge, UK

Ming-ko Woo

School of Geography and Geology, McMaster University, Hamilton, ON, Canada

Ross Woods

Catchment Processes and Water Resources Group, National Institute of Water and Atmospheric Research, Christchurch, New Zealand

Brian D Wood

Environmental Engineering, Oregon State University, Corvallis, OR, US

Peter C Young

Centre for Research on Environmental Systems and Statistics, Lancaster University, Lancaster, UK and Centre for Resource and Environmental Studies, Australian National University, Canberra, Australia

Paul V Zimba

United States Department of Agriculture, Agricultural Research Service Catfish Genetics Research Unit, Stoneville, MS, US

Preface

The field of hydrological science deals with the occurrence, distribution, movement, and properties of water on the earth. The science of hydrology holds a unique and central place in the field of earth system science, intimately linked with other water-related disciplines such as meteorology, climatology, geomorphology, hydrogeology, and ecology. Beyond basic scientific interest, water quantity and water quality have become two of the most pressing environmental issues of our time. The first comprehensive hydrological studies began in the late 1600s with Pierre Perrault's field studies of the hydrological cycle and Edmund Halley's experiments on evaporation. However, it was not until the mid-1850s that Henry Darcy quantified the hydraulics of groundwater flow and the linear relation between velocity and hydraulic gradient. Since then, and especially through the latter twentieth century, knowledge generation in the hydrological sciences exploded with new discoveries in each of the components of the hydrological cycle. Despite scientific and technological advances, the field of hydrological sciences has been highly fragmented across the engineering-science interface, between basic and applied studies, mathematical and descriptive work, and field and laboratory investigations. Such fragmentation has left many aspects of the hydrological cycle and its underlying mechanics still poorly understood. Such understanding is an essential prerequisite for hydrological prediction and for defining the level of uncertainty around these predictions.

The Encyclopedia of Hydrological Sciences (EHS) is the first definitive research-level multivolume encyclopedia in the hydrological sciences where the full scope of research in the field of hydrological sciences is distilled – from engineering approaches to basic science, from process studies to mathematical modeling, and from field investigations to the laboratory. EHS thus provides an inclusive reference source for the field, defining what we know, what we think we know, and what we need to know about the future. EHS brings together information on hydrological processes from the sub-catchment to the global scale with a focus on research-level analysis.

We have organized the encyclopedia into 17 themed parts that cover the breadth of current major research activity in the field. The 203 articles in EHS have been written by 316 authors from 22 countries, all experts in their fields. Each article has been peer-reviewed and then edited by an Associate Editor, each among the top scientists in their sub-disciplines. We have tried to organize EHS to maximize ease of use for its readers. Each of the five volumes contains a table of contents. The last volume contains a subject index pertaining to the complete work.

The accompanying online version of the Encyclopedia includes hypertext links to appropriate software sites. The online format extends the usefulness of EHS through rapid search capability, and facilitates both updating and subsequent expansion of text material. The hard copy version of EHS is a foundational set of knowledge that will be progressively tuned in the online version, both tracking the core science foci and delivering the latest research findings.

We owe a considerable debt to the author and editor team, colleagues who are among the most active research workers in their respective fields. The Associate Editors of the 17 themed parts have managed both procurement of articles and the substantive review process that such a project demands. Such activity has been supported throughout the project life by staff at John Wiley; in particular, we acknowledge the support given to us by Sally Wilkinson, who has overseen the project from conception, whilst Sue Amesbury has given unfailing support to ourselves, the Associate Editors, and authors. Her contribution has been pivotal in ensuring timely delivery of the project.

We hope that EHS will provide both a sound comprehensive platform of current knowledge and also clear pointers to future research directions in the field.

Malcolm G Anderson
Editor-in-Chief

Jeffrey J McDonnell
Senior Advisory Editor

Abbreviations and Acronyms

1-NAA	1-Naphthylacetic Acid
2-D	Two-Dimensional
3-D	Three-Dimensional
3DVAR	Three-Dimensional Variational Method
3G	Third-Generation
4DDA	4-Dimensional Data Assimilation
AABW	Antarctic Bottom Water
ABA	Abscisic Acid
ABL	Atmospheric Boundary Layer
ABRACOS	Anglo-Brazilian Climate Observation Study
ACLs	Agent Communication Languages
ACPs	Atmospheric Circulation Patterns
ACSYS	Arctic Climate System Study
AD	Automatic Differentiation
ADC	Areal Distribution Curve
ADCP	Acoustic Doppler Current Profiler
ADCs	Analog-to-Digital Converters
ADEOS	Advanced Environmental Observation Satellite
ADV	Acoustic Doppler Velocimeters
ADZ	Aggregate Dead Zone
AEM	Airborne Electromagnetic Systems
AERI	Atmospheric Emitted Radiance Interferometer
AET	Actual Evapotranspiration
AFI	Antecedent Flow Index
AFM	Atomic Force Microscopy
AFORISM	EU Funded Flood Forecasting Research Project
AFOSM	Advanced First-Order Second-Moment
AGBM	Above-Ground Biomass
AGCMs	Atmospheric General Circulation Models
AGNPS	Agricultural Nonpoint Source
AI	Artificial Intelligence
AIC	Akaike's Information Criterion
AIRS	Atmospheric Infrared Sounder
ALMA	Assistance for Land Surface Modelling Activities
ALOS	Advanced Land Observing System
ALW	Earth Life Sciences and Research Council
AMI	Active Microwave Instrument
AMIP	Atmospheric Model Intercomparison Project
AMMA	African Monsoon Multidisciplinary Analysis
AMO	Atlantic Multidecadal Oscillation
AMS	Accelerator Mass Spectrometry
AMSR	Advanced Microwave Scanning Radiometer
AMSR-E	Advanced Microwave Scanning Radiometer – Earth Observing System
AMSU	Advanced Microwave Sounding Unit
AMV	Active Mixing Volume
ANC	Acid-Neutralizing Capacity
ANN	Artificial Neural Network
ANOVA	Analysis of Variance
ANPP	Aboveground NPP
ANSWERS	Areal Nonpoint Source Watershed Environmental Response Simulation
AO	Arctic Oscillation
AOSIS	Alliance of Small Island States
APAR	Absorbed PAR
APN	Asia–Pacific Network for Global Change Research
ARF	Area Reduction Factor
ARIMA	Auto Regressive Integrated Moving Average
ARM	Atmospheric Radiation Measurement
ARMA	Auto-Regressive Moving Average
ARMAX	Auto-Regressive Moving Average Exogenous
ARM-SGP	Atmospheric Radiation Measurement Southern Great Plains
ARPS	Advanced Regional Prediction System
ARS	Agricultural Research Service
ARX	Autoregressive Exogenous Variables Models
ASA	Aggregated Simulation Areas
ASAR	Advanced Synthetic Aperture Radar
ASB	Alternatives to Slash and Burn
ASCE	American Society of Civil Engineers
ASDC	Atmospheric Sciences Data Center
ASL	Atmospheric Surface Layer
ASTER	Advanced Spaceborne Thermal Emission and Reflection Radiometer
ATOVS	Advanced TIROS Operational Vertical Sounder
ATSR	Along Track Scanning Radiometer
AVHRR	Advanced Very High Resolution Radiometer

AVIRIS	Airborne Visible/Infrared Imaging Spectrometer
BAHC	Biological Aspects of the Hydrologic Cycle
BALTEX	The Baltic Sea Experiment
BARE	Bayesian Recursive Estimation
BAS	Bulk Atmospheric Similarity
BASINS	Better Assessment Science Integrating Point and Nonpoint Sources
BATEA	Bayesian Total Error Analysis
BATS	Biosphere Atmosphere Transfer Scheme
BBM	Building Block Methodology
BEA	Bureau of Economic Analysis
BFI	Baseflow Index
BIC	Bayesian Information Criterion
BLUE	Best Linear Unbiased Estimator
BMPs	Best Management Practices
BMBF	German Federal Ministry of Education and Research
BMWP	Biological Monitoring Working Party
BNF	Biological Nitrogen Fixation
BOA	Bottom of the Atmosphere
BOD	Biochemical/Biological Oxygen Demand
BOR	Bureau of Reclamation

PART 1

Theory, Organization and Scale

1: On the Fundamentals of Hydrological Sciences

GÜNTER BLÖSCHL

Institute for Hydraulic and Water Resources Engineering, Vienna University of Technology, Vienna, Austria

Although there is no universal theory in hydrology that starts from first principles, the various branches of hydrology show numerous common threads. They relate to the nature of the processes including their space–time variability, the general principles of hydrological measurements, and the types of methods for representing hydrological processes in a quantitative way, either statistically or deterministically. The purpose of this article is to provide some common ground for this Encyclopedia to highlight the particularities of the hydrological sciences.

WHAT ARE THE FUNDAMENTALS IN HYDROLOGY?

Hydrology is the science that deals with the waters above and below the land surfaces of the Earth; their occurrence, circulation and distribution, chemical and physical properties, and their interaction with their environment, including their relationship to living beings (NRC, 1991). Owing to its central focus on water, the science of hydrology holds a unique place in the field of earth system science, intimately intertwined with other water-related disciplines such as meteorology, climatology, geomorphology, hydrogeology, and ecology. As an applied science, hydrology is highly relevant to the management of the world's water resources and water quality and for the prediction and mitigation of water-related natural hazards such as floods and droughts. Thus, hydrology is an exciting field of study.

What now are the theoretical underpinnings of hydrology, what are the fundamentals? In many disciplines, a treatise on the fundamentals starts with a universal "big picture" theory on which there is consensus among scientists. From theory one would then move into the specific questions of how to measure, how to conceptualize more specific processes and how to model them. The theory would give guidance on all of these and would be further developed on the basis of feedbacks from them. Hydrology is different in this respect from some other natural sciences. There is no universal theory of hydrology that starts from first principles. There are different concepts for different parts of the hydrologic cycle and different spatial and temporal scales. The various branches of hydrology, however, do show remarkable parallels. The nature of hydrological variability is remarkably similar for different processes and the measurement techniques available to probe them have similar characteristics as well. Both have distinctly shaped the descriptive and predictive methods that have evolved in this discipline over the years and they ultimately control the accuracy of hydrological predictions. The common threads of the various hydrological subdisciplines may hence be a useful starting point for a presentation of fundamentals in the hydrological sciences. These are the subject of **Part 1: Theory, Organization and Scale** of this Encyclopedia. The objective of Part 1 and this chapter in particular, is to provide some common ground for the remainder of the Encyclopedia and to bring out some of the hydrological concepts that are common to them.

HYDROLOGICAL PROCESSES – WATER CYCLES AND WHY ORGANIZATION IS AN ISSUE

The most influential concept in hydrology has undoubtedly been the water cycle that links the movement of water on the Earth's surface with subsurface waters and water in the atmosphere. It not only provides a general layout

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

of the main mechanisms but also allows formulation of how much water there is in the different compartments (in the atmosphere, on the land surface, and in the subsurface) and how fast the exchange takes place (*see* **Chapter 2, The Hydrologic Cycles and Global Circulation, Volume 1**; **Chapter 25, Global Energy and Water Balances, Volume 1**; **Chapter 29, Atmospheric Boundary-Layer Climates and Interactions with the Land Surface, Volume 1**; **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2**; **Chapter 103, Terrestrial Ecosystems, Volume 3**; and **Chapter 173, Global Water Cycle (Fundamental, Theory, Mechanisms), Volume 5**). Obviously, the movement of water is more complex than an exchange of water between different boxes. In fact, one could argue that there are many water cycles, as water moves around at many space and time scales. There is a multitude of different pathways (*see* **Chapter 4, Organization and Process, Volume 1**; **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2**; **Chapter 80, Erosion and Sediment Transport by Water on Hillslopes, Volume 2**; and **Chapter 113, Hyporheic Exchange Flows, Volume 3**). Water may fall as rain in the same regions as it is evaporated, a process termed *local moisture recycling*, and water may remain much longer in the ground in some places than in others, so there are huge differences in the time scales as well. The global water cycle is linked to the global energy cycle through evapotranspiration on the land surface. Understanding the water cycle is also a key element in understanding fluxes of matter (e.g. nutrients, sediments) that are driven by the water fluxes (*see* **Chapter 79, Assessing Uncertainty Propagation Through Physically based Models of Soil Water Flow and Solute Transport, Volume 2**; **Chapter 80, Erosion and Sediment Transport by Water on Hillslopes, Volume 2**; and **Chapter 96, Nutrient Cycling, Volume 3**).

One of the fascinating observations on hydrological processes is their astounding variability at all scales, in both space and time. At the smallest scales of interest in hydrology, water fluxes and composition may vary between individual pores of the soil, and climate and hydrological processes vary over continental scales as well. Infiltration may vary over seconds and groundwater tables may vary over decades and more. Within these limits, variability abounds (*see* **Chapter 3, Hydrologic Concepts of Variability and Scale, Volume 1**, **Chapter 7, Methods of Analyzing Variability, Volume 1**). Virtually any quantitative approach to this problem requires the selection of a limited set of spatial and temporal scales. Any particular choice of time and space scales has a major influence on which aspects of this hydrological variability are perceived (*see* **Chapter 8, Fractals and Similarity Approaches in Hydrology, Volume 1**; **Chapter 9, Statistical Upscaling and Downscaling in Hydrology, Volume 1**; and **Chapter 134, Downward Approach to Hydrological Model Development, Volume 3**).

Hydrological variations are driven by variations in physiographic factors such as climate, soils, vegetation, topography, geology, as well as by human activity. These externally driven variations then propagate through hydrological systems (Sivapalan *et al.*, 2001), leading to an extremely rich variety of hydrological patterns apparent at different temporal and spatial scales, in different physical settings. This means that the patterns of variability are linked to their causal processes. Although Schumm (1991) notes that due to nonlinearities multiple processes can lead to the same form, patterns and form should be able to provide an indication of the processes that have led to them. Examining patterns will hence assist in making more representative measurements and more accurate predictions (*see* **Chapter 8, Fractals and Similarity Approaches in Hydrology, Volume 1**, **Chapter 9, Statistical Upscaling and Downscaling in Hydrology, Volume 1**).

The drivers also imply that the variability one encounters in hydrology is usually not fully random but organized in various ways (Gutknecht, 1993). Types of organized variability include continuity (Baird, 1996) in time and space which is often related to storage processes. Another type is the presence of zones with boundaries between them (Woo, 2004). Still another type of organization that seems to exist at all scales is preferential flow – in the voids of the soil, in macropores, and in both porous and hard rock aquifers at a range length-scales (*see* **Chapter 9, Statistical Upscaling and Downscaling in Hydrology, Volume 1**; **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2**; and **Chapter 147, Characterization of Porous and Fractured Media, Volume 4**). On the land surface, preferential flow occurs from micro rills to streams in the landscape (Rinaldo *et al.*, 1993). The counterpart to preferential flow in the time domain is episodic behavior, that is, a concentration of activity over short periods or events in a range of processes including runoff, erosion, and sediment transport. Other types of organization include self-similar organization, where small-scale variability looks similar to large-scale variability; the observation that extremes or outliers occur more often than would be expected on the basis of standard statistical distributions (Hurst, 1951; Mandelbrot and Wallis, 1968); and periodic variability at diurnal, annual, and multiannual scales (*see* **Chapter 3, Hydrologic Concepts of Variability and Scale, Volume 1**). Clearly, these organized patterns are linked to the processes that drive and modulate them.

The presence of spatial and temporal organization in hydrologic variability has important ramifications for measurements. If it were not for surface runoff concentrated in streams, it would be almost impossible to measure the water flowing from a catchment area. On the other hand, preferential flow in the soils and aquifers tends to

make point samples unrepresentative. Organization also has important ramifications for representing the variability in a quantitative way. The presence of organization or patterns in hydrological systems has been seen as an indication that they are, what Dooge (1986) refers to as *middle number systems* or *systems of intermediate complexity*. In these systems, there are too many components to be dealt with by classical (deterministic) mechanics and just not enough components to be dealt with by statistical methods similar to those of statistical mechanics. Thus in hydrology, both statistical and deterministic methods are appropriate depending on the type of variability one means to capture as well as the questions one asks. This type of system behavior also means that interactions of processes will be important at many scales (*see* **Chapter 4, Organization and Process, Volume 1**) such as interactions between surface water and groundwater (*see* **Chapter 113, Hyporheic Exchange Flows, Volume 3**); between soils, vegetation, and the atmosphere (*see* **Chapter 12, Co-evolution of Climate, Soil and Vegetation, Volume 1**); between land surface hydrology and terrestrial ecosystems at large (*see* **Chapter 101, Ecosystem Processes, Volume 3**, **Chapter 103, Terrestrial Ecosystems, Volume 3**); between evaporation and flood generation (*see* **Chapter 122, Rainfall-runoff Modeling: Introduction, Volume 3**; Sivapalan *et al.*, 2005); between floods and stream morphology (*see* **Chapter 86, Measuring Sediment Loads, Yields, and Source Tracing, Volume 2**); between snow processes and boundary-layer atmospheric processes (*see* **Chapter 160, Energy Balance and Thermophysical Processes in Snowpacks, Volume 4**); between catchment hydrology and soil development (*see* **Chapter 4, Organization and Process, Volume 1**); and between runoff and landscape evolution (*see* **Chapter 4, Organization and Process, Volume 1**). Not all the feedbacks will be apparent to an observer, as often observations are limited to a set of scales that reveal only a few of the many processes that are present in the hydrological environment (*see* **Chapter 6, Principles of Hydrological Measurements, Volume 1**, **Chapter 9, Statistical Upscaling and Downscaling in Hydrology, Volume 1**).

FUNDAMENTAL EQUATIONS – ARE THERE ANY?

Yes, there are fundamental equations in hydrology and the most important one is the mass balance of water over a given volume and time interval. This is termed *the water balance equation*. It is so central to hydrology that some observers have noted that the task of hydrology is to solve the water balance equation. The classic example of its application is the estimation of the average evapotranspiration of a catchment over a long period from rainfall and streamflow measurements, but it is widely applied at a range of space and time scales. The water balance equation is the only equation that can be called a *hydrological equation* in its full right and is applicable to the scales hydrologists are interested in.

Another fundamental equation is energy balance, which is mainly used when interfacing with the atmospheric sciences and plays a key role in hydrology in the context of evaporation and snow processes. The remaining balance equation of classical mechanics, momentum balance, is mainly used in representing open channel flow in a fluid mechanics context (*see* **Chapter 5, Fundamental Hydrologic Equations, Volume 1**, **Chapter 135, Open Channel Flow – Introduction, Volume 4**). These balance equations – fundamental as they are – are not sufficient to fully describe the dynamics of hydrologic systems. Hence additional equations, termed *empirical flux laws*, are needed. Most of them have four characteristics:

1. Many of the flux laws used in hydrology are based on flux–gradient type relationships. Examples are Darcy's law (water flux in aquifers – hydraulic potential gradient), Fick's law (matter flux both in aquifers and in surface waters – concentration gradient); the flux-gradient method (vertical water vapor flux in the atmosphere – vapor pressure gradient); and the Chezy equation (water flux in surface waters – energy gradient).
2. Most of them have some element of empiricism, although derivations from more fundamental laws are possible. For example, Darcy's law can be derived from the Hagen–Poiseulle equation for laminar flow in capillaries. The assumptions in the derivations may imply that their applicability is limited to particular conditions, which may not always be clear. Through simplifications additional empiricism may creep in. In the Darcy example, the geometry of soil pores is far more complex than a bundle of tubes. Thus, an empirical element will usually be involved in the flux laws, for example, through empirical parameters in the flux – gradient relationships.
3. Most of the flux laws have been taken from other disciplines such as fluid mechanics, soil physics, and the atmospheric sciences, and hence
4. Many of them apply to the point scale, that is, a sample size that is small relative to the systems hydrologists are interested in. They have been derived for minute control volumes that are amenable to laboratory experiments and the application of continuum mechanics (Hubbert, 1956), rather than for the objects of interest in hydrology (catchments, aquifers, river reaches, regions, etc.). In principle, equations can be formulated for lumped systems at larger scales and catchment models are a good example (*see* **Chapter 10, Concepts of Hydrologic Modeling, Volume 1**). However, repeatable experiments under exactly controlled conditions are not possible at these scales, which challenges the universality of these equations. Another example is the stream order laws of Horton (Horton, 1945) and

other authors that describe the statistical characteristics of the map view patterns of stream networks. While important in fluvial geomorphology they have had limited influence on the hydrological sciences themselves.

Out of the four points listed, the fourth is probably the most important one for hydrology as a science (Blöschl and Sivapalan, 1995). Point scale equations can be straightforwardly extended to catchments, aquifers, reaches, and so on *provided* the boundary conditions are known and the media characteristics are known spatially (e.g. uniform) at the scale of the equations. This means there may be finer scale variability such as grains and voids not resolved by the equations, but at larger scales where the equations apply the media are considered uniform. For example, the mass balance equation for small volumes in aquifers can be combined with Darcy's law, which gives a diffusion type differential equation. It is then possible to use concepts from continuum mechanics to solve for the variable of interest (e.g. hydraulic head), given the initial and boundary conditions (*see* **Chapter 5, Fundamental Hydrologic Equations, Volume 1**).

The challenge in the hydrological sciences is that hydrological systems are never completely uniform in terms of their parameters, fluxes, and states and are often not even approximately uniform. Although there are ways of dealing with their variability – either explicitly through distributed (deterministic) models or implicitly through upscaling methods – it is not a straightforward exercise. Additional assumptions need to be made about the variability, both in space and time and, often most importantly, about the nature and locations of the flow paths, but much of this information may be "unknowable" in practice (Savenije, 2001). One is then far removed from the fundamental equations and on the "thin ice" of models for a particular application. This is also one of the reasons why models generally need to be calibrated to the particular site of interest (Freeze and Harlan, 1969).

There are two classical paradoxes in hydrology – dispersion in the subsurface tends to deviate from Fick's law (Levy and Berkowitz, 2003), and runoff events mainly contain old (pre-event) water (Kirchner, 2003). Both paradoxes are related to small-scale equations not being applicable at the larger hydrological scale because of media heterogeneities (*see* **Chapter 13, Pattern, Process and Function: Elements of a Unified Theory of Hydrology at the Catchment Scale, Volume 1**, **Chapter 152, Modeling Solute Transport Phenomena, Volume 4**).

The issues of heterogeneity relate to the empirical flux laws but not to the balance equations as the latter are valid at any scale. Issues of heterogeneity also arise in specifying initial and boundary conditions from measurements. Notwithstanding these problems, point scale equations along with continuum mechanics are an essential basis for hydrology (*see* **Chapter 5, Fundamental Hydrologic Equations, Volume 1**) both for understanding system dynamics and for making quantitative predictions.

HYDROLOGICAL MEASUREMENTS – WHY SIZE MATTERS

With the exception of the laboratory case, experiments are not repeatable under exactly the same boundary and initial conditions in hydrology; it is nature that does the experiments (Dunne, 1998; Zehe and Blöschl, 2004). Because of this, observations generally depend on the climatic and hydrological context. From the 1960s, there have been numerous national and international programs, initially on experimental catchments, to examine similarities and differences across different climatic and hydrological conditions (*see* **Chapter 121, Intersite Comparisons of Rainfall-runoff Processes, Volume 3**, **Chapter 203, A Guide to International Hydrologic Science Programs, Volume 5**). These programmes have provided valuable insights but generalizing the findings beyond the areas of interest has always been difficult (*see* **Chapter 133, Rainfall-runoff Modeling of Ungauged Catchments, Volume 3**). Each aquifer, catchment, and river reach – in fact each episode – seems to have particularities that cannot be specified in full detail. Because of this, in addition to going into process detail for a single site (which has been the traditional approach), contrasting different catchments and different aquifers based on what has been termed *comparative hydrology* has recently been singled out as an important avenue to progress in hydrology (*see* **Chapter 3, Hydrologic Concepts of Variability and Scale, Volume 1**, **Chapter 121, Intersite Comparisons of Rainfall-runoff Processes, Volume 3**), with the eventual goal of a common method for assessing and quantifying hydrological similarity.

A key to the progress in the natural sciences is the ability to measure variables to an accuracy that is useful and at the scales one is interested in. This is another challenge in hydrology as, in many instances, the processes of interest are of a scale that is not directly amenable to the measurement techniques available (Klemeš, 1983). Most measurements are collected by point samples, while processes occur over catchments, aquifers, and landscapes. In the time domain, one is often more interested in (temporal) averages (e.g. sediment and nutrient loads) than in the snapshots as can be obtained in dedicated experiments (*see* **Chapter 92, Water Quality Monitoring, Volume 3**). Because of this, much of hydrology is constrained by measurement techniques (*see* **Chapter 122, Rainfall-runoff Modeling: Introduction, Volume 3**). This is particularly the case for spatial distributions which are more difficult to sample than time series (Grayson and Blöschl, 2000), especially for hydrological dynamics that take place beneath the ground surface.

Over the years, hydrologists have developed ways of dealing with the space–time variability and the scale incompatibility of measurements in various ways. The most efficient methods have been ways of aggregating the variability by prudent measurements. The classical examples are measurements of runoff from catchments that aggregate the within-catchment variability and pumping tests of aquifer transmissivities that aggregate the subsurface hydraulic variability within the depression cone (Anderson, 1997). More elaborate measurements require either laboratory analyses with typical sample sizes of 1 dm^3, although tracer experiments and irrigation/flume experiments can deal with somewhat larger scales of tens of meters. Because of this, the sampling design in terms of the space and time scales is critically important for capturing the natural variability in a representative way in addition to ensuring the accuracy of the instruments (*see* **Chapter 6, Principles of Hydrological Measurements, Volume 1**). In long-term monitoring, where networks are operated by national hydrographic services, space and time scales are usually large, while in dedicated field experiments organized by groups of scientists, space and time scales tend to be small, although, recently, a number of large-scale field experiments have been undertaken (*see* **Chapter 203, A Guide to International Hydrologic Science Programs, Volume 5**). In the latter, remote sensing methods play an important role as they are able to sample at finer spatial scales and wider areas than has been traditionally possible in hydrology (*see* **Chapter 47, Sensor Principles and Remote Sensing Techniques, Volume 2**). With recent advances in monitoring techniques from small-scale computer tomography to large-scale remote sensing methods as well as better logistics (*see* **Chapter 6, Principles of Hydrological Measurements, Volume 1**), measurements are increasingly able to capture wider scale ranges, but a scale problem remains for which statistical (nonprocess-based) and deterministic (process-based) upscaling methods have been developed (*see* **Chapter 9, Statistical Upscaling and Downscaling in Hydrology, Volume 1**, **Chapter 11, Upscaling and Downscaling – Dynamic Models, Volume 1**).

THE STATISTICAL APPROACH – STATISTICS, SELF SIMILARITY, AND UP/DOWNSCALING

There are two types of approaches to representing hydrologic systems, statistical, and deterministic. In both of them, data play an important role and both of them have their merits. The statistical approach is warranted if random variability (i.e. variability we are unable to interpret/predict in detail) prevails (*see* **Chapter 7, Methods of Analyzing Variability, Volume 1**; **Chapter 9, Statistical Upscaling and Downscaling in Hydrology, Volume 1**; **Chapter 10, Concepts of Hydrologic Modeling, Volume 1**; and **Chapter 125, Rainfall-runoff Modeling for Flood Frequency Estimation, Volume 3**). It represents the bulk information (frequency, distribution, dependence) not the details (spatial and temporal occurrence, dynamics). In the statistical approach it is not usually possible to take causal processes into account, which renders the extrapolation potential more limited than that of the deterministic approach, but extrapolation may not be needed for the application at hand and it is the main method used in many applied hydrologic problems. On the other hand, the statistical approach may be able to deal with systems that are too complex to be dealt with in a deterministic way.

A range of statistical techniques for representing variability are in use in hydrology. Typical steps in a sequential analysis of statistical variability are (i) looking at the data, (ii) analyzing the statistical distribution of the data, (iii) analyzing the first and second order moments (including an analysis of statistical dependence), and (iv) analyzing the data by more elaborate methods such as series expansion (*see* **Chapter 7, Methods of Analyzing Variability, Volume 1**). In these steps increasingly more complex descriptions are introduced. The second moments (variance and correlation coefficients) are of particular importance in hydrology as they are a measure of spread and hence variability of a variable. The classical example is the representation of the spread of a plume of concentration by the second moments. In a temporal (and spatial) context, the second moments can be used to represent the continuity of correlated time series (and correlated random fields) through correlation functions or variograms. In the time domain, the correlations can be used for stream flow forecasting (time series analysis), in the space domain for spatial estimation using geostatistical methods (*see* **Chapter 9, Statistical Upscaling and Downscaling in Hydrology, Volume 1**). Series expansions go a step further by representing the variable of interest by a sum of deterministic functions of random variables. To the latter type of methods belong spectral analysis, wavelet analysis, principal component analysis, and empirical orthogonal functions. Their main value in hydrology lies in the reduction of the dimensionality of the system to assist in identifying the main controls if the patterns are not apparent in large data sets (*see* **Chapter 7, Methods of Analyzing Variability, Volume 1**).

The presence of patterns or organized variability is not always considered a favorable property in statistical analyses. They can involve nonstationarity, outliers, non-Gaussian (non-normal) behavior, and thresholds, which are all characteristics commonly encountered in hydrological data but not compatible with the usual statistical methods (*see* **Chapter 9, Statistical Upscaling and Downscaling in Hydrology, Volume 1**). This is particularly an issue when extreme values (floods, precipitation extremes, low flows, extreme concentrations) are analyzed by statistical methods (*see* **Chapter 37, Rainfall Trend Analysis:**

Return Period, Volume 1; **Chapter 125, Rainfall-runoff Modeling for Flood Frequency Estimation, Volume 3**). Analyses of extremes are of particular relevance in applied hydrology and water resources management. On the other hand, organization tends to produce striking similarities across scales. Little wiggles look like big ones, statistically, and short ones like long ones. The remarkable thing is that whatever hydrologic variable is examined, it more often than not turns out that there exists similarity to the same variable examined at a different scale, at least over a certain range of scales. This is termed *self similar or fractal behavior* (*see* **Chapter 8, Fractals and Similarity Approaches in Hydrology, Volume 1**) and is related to the more general observation, that there is variability at all scales with the strength of variability (e.g. quantified in terms of the second moment) increasing with scale. In the past decades, statistical fractals have been widely used in many branches of hydrology, as they are appealing because of three main reasons. First, they deal with the presence of variability over a wide range of scales, which is consistent with observations. Second, this type of behavior can be related, at least qualitatively, to the dynamic behavior of nonlinear systems, which is an interesting paradigm for hydrological processes. Third, and perhaps most important for practical applications, fractal concepts lead to parsimonious descriptions of rainfall, landscapes, drainage networks, geologic media, and so on. This means that the statistical models only involve a few parameters and these can be estimated more robustly than the more numerous parameters of traditional concepts. Some of the fractal methods are based on the first and second moments (*see* **Chapter 7, Methods of Analyzing Variability, Volume 1**) but others involve more complex descriptions.

Statistical methods, including fractal concepts, can be used efficiently to address the scale incompatibility of hydrological processes, measurements, and predictions. They lend themselves to transferring information between various scales, for example, between point scale measurements and catchment scale prediction; or large-scale model output and small-scale predictions. These methods are termed *upscaling and downscaling methods* (*see* **Chapter 9, Statistical Upscaling and Downscaling in Hydrology, Volume 1**). The first generic task of upscaling/downscaling is to derive the statistics of a variable at one scale from the statistics of the same (or another) variable at another scale. Methods range in complexity from regressions between the variables at different scales to upscaling theory of stochastic hydrogeology (*see* **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**). The second generic task is to generate spatial patterns (or time series) given the statistical characteristics of the variable one means to represent. This can be either through interpolation between a number of samples or, alternatively, various disaggregation methods where one is interested in obtaining a number of realizations of the variable of interest that all exhibit the same statistics as the data. Some of these methods focus on the second moments by making use of correlation functions or variograms (*see* **Chapter 7, Methods of Analyzing Variability, Volume 1**, **Chapter 9, Statistical Upscaling and Downscaling in Hydrology, Volume 1**).

A range of statistical methods are available for upscaling point rainfall to catchments, for disaggregating rainfall in time, for downscaling the output of global circulation models to the scale of catchments, to relate the flood characteristics of catchments of different sizes, to transfer soil moisture across scales both in a catchment and climate modeling context, and for characterizing and generating subsurface media (*see* **Chapter 9, Statistical Upscaling and Downscaling in Hydrology, Volume 1**). One of the more general observations used in many of the statistical upscaling methods is that aggregation makes processes appear smoother, so variability decreases with aggregation area.

The statistical upscaling/downscaling approach does not attempt to represent the processes in full detail but rather relies on (lumped) summary descriptions of variability. Similar to other statistical methods, this has the benefit of robustness but at the expense of limited extrapolation potential. Alternative upscaling methods exist that involve equations of the underlying process dynamics in various branches of hydrology including dynamic hydrologic models (*see* **Chapter 11, Upscaling and Downscaling – Dynamic Models, Volume 1**), land–atmosphere interactions (*see* **Chapter 29, Atmospheric Boundary-Layer Climates and Interactions with the Land Surface, Volume 1**), soil water flow (*see* **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2**), and stochastic subsurface hydrology (*see* **Chapter 147, Characterization of Porous and Fractured Media, Volume 4**, **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**).

THE DETERMINISTIC APPROACH – MODEL CONCEPTS AND WHY UPSCALING AND DOWNSCALING IS NEEDED

The alternative to the statistical approach is the deterministic approach, which, likewise, has numerous merits. Deterministic relationships can be formulated in a causal way by making use of the fundamental equations and hence can be used for examining "what happens if" questions in a more reliable way than is typically possible with statistical methods. The downside, however, is that the processes may easily become too complex, so care needs to be taken to limit the models to those processes that are tractable and/or for which sufficient data are available. In terms of their

application, there are two main uses of deterministic models – explanatory models for furthering our understanding of a particular system and predictive models for producing estimates of some future or changed state. In both instances, there exists a range of model types, from lumped to spatially distributed, from low dimensional to high dimensional involving many parameters. The simplest ones are based on input–output relationships of the area of interest, the intermediate ones on some degree of understanding (conceptual models), and the most complex ones are based on the fundamental equations discussed earlier (*see* **Chapter 10, Concepts of Hydrologic Modeling, Volume 1**; **Chapter 11, Upscaling and Downscaling – Dynamic Models, Volume 1**; and **Chapter 134, Downward Approach to Hydrological Model Development, Volume 3**).

Model conceptualization and building usually follows a set number of steps including collecting and examining data and other evidence, assessing which processes may be important for the problem at hand, designing a scheme of the most important process dynamics in the modeler's mind, designing a mathematical model to represent these concepts, calibrating the model by using the data of the region, and testing the model by a separate data set of the same region. If the testing satisfies the modeler's expectations, then the model is ready for use, otherwise one or more of the steps need to be repeated (*see* **Chapter 10, Concepts of Hydrologic Modeling, Volume 1**; **Chapter 122, Rainfall-runoff Modeling: Introduction, Volume 3**; and **Chapter 155, Numerical Models of Groundwater Flow and Transport, Volume 4**). An important component of the model building process and model application is the assessment of the model and data uncertainty to create confidence in the reliability of the model and model predictions (*see* **Chapter 10, Concepts of Hydrologic Modeling, Volume 1**, **Chapter 79, Assessing Uncertainty Propagation Through Physically based Models of Soil Water Flow and Solute Transport, Volume 2**).

In many subdisciplines of hydrology, spatially distributed deterministic models are currently used in a routine way both for addressing practical water resources issues and for more theoretical analyses. The tremendous computing power that is available today facilitates the application of high-resolution models and there exists sophisticated software, particularly for subsurface hydrology and open channel flow. While the usefulness of these models is undisputed, there does remain significant uncertainty with the predictions for several reasons including data limitations and the model formulation (*see* **Chapter 11, Upscaling and Downscaling – Dynamic Models, Volume 1**, **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2**, Grayson *et al.*, 1992). Specifically, the scale issues discussed earlier in the context of fundamental hydrological equations play an important role here, as the empirical flux laws used in these models are indeed point scale equations (Beven, 1989). Awareness of these issues has triggered research into upscaling methods that are able to deal with unknown (small scale) spatial variability in the context of deterministic models. Much of the recent interest started in the 1970s with the early work of A. Freeze and L. Gelhar on aggregating the groundwater flow equation, based on a stochastic approach (*see* **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**), and picked up additional momentum in the 1980s when it was realized that the spatial heterogeneity of the land surface is important for atmospheric models (Gelhar *et al.*, 1977; Eagleson, 1986; Shuttleworth, 1988; **Chapter 32, Models of Global and Regional Climate, Volume 1**, **Chapter 177, The Role of Large-Scale Field Experiments in Water and Energy Balance Studies, Volume 5**). Those branches of hydrology where the basic equations are known with some degree of confidence (e.g. groundwater flow and transport) have had significant progress, but in other areas such as catchment hydrology and hill slope hydrology progress has been slower (Blöschl, 2001). The upscaling methods are either based on volume averaging or ensemble averaging (i.e. averaging all possible realizations on the same location) of the underlying equations. The aggregation methods tend to work very well if (i) the scale of the natural variability to be averaged (such as grains) is small as compared to the scale of the variability to be explicitly represented (such as geologic formations), and (ii) if the small-scale variability is random and does not exhibit organized patterns. Hydrologic variability tends to exhibit organized patterns such as preferential flow and variability tends to occur at all scales, so the upscaling methods have not been used as widely in practice as would be merited by their theoretical underpinnings. The variability within each grid cell of distributed models is hence dealt with in a number of alternative ways including the effective parameter method and statistical schemes for representing this variability (*see* **Chapter 11, Upscaling and Downscaling – Dynamic Models, Volume 1**). The most sophisticated methods of dealing with these scale issues have been developed in subsurface hydrology (*see* **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2**; **Chapter 147, Characterization of Porous and Fractured Media, Volume 4**; and **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**), and to a lesser degree in land–atmosphere interactions (*see* **Chapter 29, Atmospheric Boundary-Layer Climates and Interactions with the Land Surface, Volume 1**), although promising research is underway in catchment hydrology as well (*see* **Chapter 11, Upscaling and Downscaling – Dynamic Models, Volume 1**).

LINKING IT ALL TOGETHER – FEEDBACKS AND ELEMENTS OF A THEORY

Over the past decades there has been a trend in the hydrological sciences for a more comprehensive representation of hydrological processes, moving from an isolated description of one particular component of the hydrologic cycle to integrating hydrology with biogeochemical processes (KNAW, 2005). To a large degree, this is reflected in the many articles of this encyclopedia that deal with process links. This trend has been triggered both by the increase in computing power and a realization that feedbacks in the hydrological cycle may be more important than traditionally acknowledged, particularly for climate impacts. Changes in development paradigms in society seem to have played a major role also **Chapter 203, A Guide to International Hydrologic Science Programs, Volume 5**; Falkenmark, 1991). Feedbacks are manifold and occur at many scales, and they involve a range of other disciplines. In the feedback between the water and energy balances at the land surface, soil moisture plays a crucial role. At longer time scales, there exist feedbacks between hydrology and landscape evolution and feedbacks between hydrology and soil formation (*see* **Chapter 4, Organization and Process, Volume 1**). Feedbacks between hydrological water dynamics and biological processes occur at many scales and in many ways, for example, in subsurface flow and transport through microbial activity (*see* **Chapter 105, Microbial Transport in the Subsurface, Volume 3**), in soil formation (Jenny, 1980), in the vegetation dynamics at the land–atmosphere interface (*see* **Chapter 12, Co-evolution of Climate, Soil and Vegetation, Volume 1**) and in erosion processes (*see* **Chapter 80, Erosion and Sediment Transport by Water on Hillslopes, Volume 2**), and through biofilm and macrophyte dynamics in open channel flow and transport (e.g. Battin and Sengschmitt, 1999; Stephan and Gutknecht, 2002). One avenue to address feedbacks has been to link the various processes by coupled models (Bronstert *et al.*, 2005). The strength of this avenue is that the experience with models for each of the processes to be coupled is usually available, but model complexity may limit the practical applicability. The other avenue has been to make the feedbacks themselves a focus of theoretical, quantitative research and this seems to be an emerging area of hydrology, particularly the interactions of vegetation, land surface hydrology and climate (*see* **Chapter 12, Co-evolution of Climate, Soil and Vegetation, Volume 1**). Through transpiration and photosynthesis, the vegetation links the energy, water, and biogeochemical cycles. A number of strategies have been put forward to explain the functioning of vegetation dynamics such as those based on ecological optimality hypotheses (Eagleson, 1998; **Chapter 12, Co-evolution of Climate, Soil and Vegetation, Volume 1**).

This line of research focusing on feedbacks may assist in addressing a certain tendency of fragmentation of the subdisciplines in hydrology with papers "digging the same hole deeper" prevailing over comprehensive views as pointed out by some analysts (Burges, 1998). Although diversity of approach has great advantages and has probably been one of the strengths of the hydrological sciences, it is also important to stimulate a process of seeing how one picture fits with another. Hydrologists are now actively thinking about what may be the elements of a theory of hydrological sciences (*see* **Chapter 13, Pattern, Process and Function: Elements of a Unified Theory of Hydrology at the Catchment Scale, Volume 1**). Most hydrologists would probably agree that theories for some hydrologic processes exist – a linear theory of the rainfall runoff relationship (Dooge, 1973), a theory of infiltration (e.g. Smith *et al.*, 2002), a theory of stochastic hydrogeology (*see* **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**), but a comprehensive hydrologic theory in its own right is still lacking. It is important that a theory is different from a model in many respects – a theory would have to apply to a variety of circumstances, for example, a range of climates, geological settings, and a range of scales. Similar to a model, one would expect it to be predictive and it must be falsifiable. From a theory one would expect that it has been so thoroughly tested and developed that we know there is indeed some range of phenomena for which they give correct predictions *every time*. With current hydrologic models this does not seem to be the case. These theories would always remain part of our understanding of hydrology, even when new findings take us beyond them in certain ways. The theory would not be invalidated, but rather extended, by new findings. Clearly, the status of a theory is more than that of a model.

There may be still some way until a formulation of this theory becomes viable, but there is value in speculating about elements that may assist in putting it together (*see* **Chapter 13, Pattern, Process and Function: Elements of a Unified Theory of Hydrology at the Catchment Scale, Volume 1**). A new theory may involve an increased focus on interactions and feedbacks between different processes such as those involving vegetation, as this would entail a broadening of the scientific perspectives. To address the generalization issue, a theory may use comparative hydrology (*see* **Chapter 3, Hydrologic Concepts of Variability and Scale, Volume 1**) to develop a common method for assessing and quantifying hydrological similarity through comparisons between catchments in different hydrologic regimes. The theory would have to be valid for all these regimes. Patterns of hydrological response should perhaps be given particular attention to isolate the processes that have led to them, to reconcile the catchment functioning

with the observations, and for testing hypotheses about process interactions and feedbacks. The level of complexity of a theory will clearly be an important consideration. An elegant, parsimonious theory may be favored over a more complex one provided it captures the essential complexity as suggested by the Occam's razor principle (Sivapalan *et al.*, 2003). In this respect, characteristic scales and scaling concepts (Skøien *et al.*, 2003) that focus on the order of magnitudes (similar to fluid dynamics) may assist. In a broader Earth Science context one may wonder where the place is of hydrology in the realms of physics and biology (Sivapalan, 2003). Harte (2002) noted: "Physicists seek simplicity in universal laws. Ecologists revel in complex interdependencies. A sustainable future for our planet will probably require a look at life from both sides". In a similar vein it is likely that hydrology will have to adopt some of the more complex and less universal concepts ecology is rich in, in addition to the traditional quest for physical concepts. For a hydrological theory to become influential, it will likely have to combine elements from both physics and ecology.

Acknowledgments

I would like to thank the many individuals who have shaped my own evolving ideas on hydrology over the years, in particular, Murugesu Sivapalan, Rodger Grayson, and Dieter Gutknecht. I owe much to all of them. I am indebted to Murugesu Sivapalan who contributed to this article through numerous discussions and to Alfred Paul Blaschke, Uwe Haberlandt, Ralf Merz, Dan Moore, Kurt Roth, Jan Szolgay, David Tarboton, Andrew Western, and Ross Woods for offering advice and many constructive criticisms, which have helped to substantially improve the article. Funding from the Austrian Academy of Sciences Project HÖ 18 is gratefully acknowledged.

2: The Hydrologic Cycles and Global Circulation

TAIKAN OKI

International Center for Urban Safety Engineering, Institute of Industrial Science, University of Tokyo, Tokyo, Japan

The role of hydrological cycles in earth system, the amount of water on the Earth's surface and its distribution in various reserves are first introduced together with the water cycles on the Earth. The concept of mean residence time, water stored in various parts over the Earth surface as various phases, such as glacier, soil moisture, water vapor, and water flux among these reserves, such as precipitation, evaporation, transpiration, and runoff, are briefly explained with their role in global climate system, and their quantitative estimates are presented. Detailed annual water balances over land estimated by land surface models are introduced, as well. Water balance requirements over land, atmosphere, and their coupled system are explained with some application of the concept, and the role of rivers in the global hydrological cycle is quantitatively shown. Finally, the impact of increasing magnitude of anthropogenic activities on global water system and its relationships with global changes are briefly discussed.

EARTH SYSTEM AND WATER

The Earth system is unique in that water exists in all three phases, that is, water vapor, liquid water, and solid ice, compared to the situations in other planets. The transport of water vapor is regarded as the energy transport because of its large amount of latent heat exchange during phase change to liquid water (approximately $2.5 \times 10^6\,\mathrm{J\,kg^{-1}}$); therefore, water cycle is closely linked to energy cycle. Even though the energy cycle on the Earth is an "Open System" driven by solar radiation, the amount of water on the Earth does not change on shorter than geological timescales (Oki, 1999), and the water cycle itself is a "Closed System."

On global scale, hydrologic cycles are associated with atmospheric circulation, which is driven by the unequal heating of the earth's surface and atmosphere in latitude (Peixóto and Oort, 1992).

Annual mean absorbed solar energy at the top of the atmosphere is maximum near equator with approximately $300\,\mathrm{W\,m^{-2}}$, decreases suddenly at higher latitudes, and is approximately $60\,\mathrm{W\,m^{-2}}$ at Arctic and Antarctic regions. Emitted terrestrial radiative energy from the Earth at the top of the atmosphere is approximately $250\,\mathrm{W\,m^{-2}}$ for ± 20 degree north and south, gradually decreases at higher latitudes, and is approximately $175\,\mathrm{W\,m^{-2}}$ at Arctic region and $150\,\mathrm{W\,m^{-2}}$ at Antarctic region. As a consequence, the net annual energy balance is positive (absorbing) for tropical and subtropical regions in ± 30 degree north and south, and negative in higher latitudes (Dingman, 2002) (*see* **Chapter 39, Surface Radiation Balance, Volume 1**).

If there is no atmospheric and oceanic circulation on the Earth, temperature difference on the Earth should have been more drastic; temperature in equatorial zone should have been high enough that the outgoing terrestrial radiation balances the absorbed solar energy and temperature in the polar regions, which should have been low enough, as well. In reality, there are atmospheric circulations and oceanic circulations that lessen this expected temperature gradation in the absence of circulations.

Both atmosphere and ocean carry energy from the equatorial region toward both the polar regions. In the case of atmosphere, the energy transport consists of sensible heat and latent heat fluxes (Masuda, 1988). The global water circulation is this latent heat transport itself, and water plays active role in the atmospheric circulation; it is not a passive compound of the atmosphere, but it affects atmospheric circulation by both radiative transfer and latent heat release of phase change.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

WATER RESERVES, FLUXES, AND RESIDENCE TIME (*see* Chapter 173, Global Water Cycle (Fundamental, Theory, Mechanisms), Volume 5)

The total volume of water on the Earth is estimated as approximately 1.4×10^{18} m^3, and it corresponds to a mass of 1.4×10^{21} kg. Compared with the total mass of the Earth (5.974×10^{24} kg), the mass of water constitutes only 0.02% of the planet, but it is critical for the survival of life on the Earth and the Earth is called *Blue Planet* and *Living Planet*.

There are various forms of water on the Earth's surface. Approximately 70% of its surface is covered with salty water, the oceans. Some of the remaining areas (continents) are covered by freshwater (lakes and rivers), solid water (ice and snow), and vegetation (which implies the existence of water). Even though the water content of the atmosphere is comparatively small (approximately 0.3% by mass and 0.5% by volume of the atmosphere), approximately 60% of the Earth is always covered by cloud (Rossow *et al.*, 1993). The Earth is the planet whose surface is dominated by the various phases of water.

Water on the Earth is stored in various reserves, and various water flows transport water from one to another. Water flow (mass or volume) per unit time is also called *water flux*.

The mean residence time in each reserve can be simply estimated from total storage volume in the reserve and the mean flux rate to and from the reserve;

$$T_{\text{mean}} = \frac{\text{Total Storage Volume}}{\text{Mean Flux Rate}} \qquad (1)$$

there is even a distribution of flux rate coming in and going out from the storage (Chapman, 1972). The last column of Table 1 presents some values of the global mean residence time of water. Evidently, the water cycle on the Earth is a "Stiff" differential system with variability on many timescales, from a few weeks through thousands of years.

The mean residence time is also important to consider when water quality deterioration and restoration are discussed, since the mean residence time can be an index of how much water is turned over. Apparently, river water or surface water is more vulnerable than groundwater to be polluted; however, any measure to recover better water quality works faster for river water than groundwater. Since major interests of hydrologists have been the assessment of volume, inflow, outflow, and chemical and isotopic composition of water, the estimation of the mean residence time of certain domain has been one of the major targets of hydrology.

EXISTENCE OF WATER ON THE EARTH (*see* Chapter 4, Organization and Process, Volume 1; Chapter 25, Global Energy and Water Balances, Volume 1)

Table 1 (simplified from a table in Korzun 1978) introduces how much water is stored in which reserves on the Earth:

- The proportion in the *ocean* is large (96.5%). Even though classical hydrology has traditionally excluded ocean processes, the global hydrological cycle is never closed without including them. The ocean circulation carries huge amounts of energy and water. The surface ocean currents are driven by surface wind stress, and the

Table 1 World water reserves. Simplified from Table 9 of "World water balance and water resources of the earth" by UNESCO Korzun, 1978. The last column, mean residence time, is from Table 34 of the report

Form of water	Covering Area (km^2)	Total Volume (km^3)	Mean Depth (m)	Share (%)	Mean Residence Time
World ocean	361 300 000	1 338 000 000	3700	96.539	2500 years
Glaciers and permanent snow cover	16 227 500	24 064 100	1463	1.736	1600 years
Ground water	134 800 000	23 400 000	174	1.688	1400 years
Ground ice in zones of permafrost strata	21 000 000	300 000	14	0.0216	10 000 years
Water in lakes	2 058 700	176 400	85.7	0.0127	17 years
Soil moisture	82 000 000	16 500	0.2	0.0012	1 years
Atmospheric water	510 000 000	12 900	0.025	0.0009	8 days
Marsh water	2 682 600	11 470	4.28	0.0008	5 years
Water in rivers	148 800 000	2120	0.014	0.0002	16 days
Biological water	510 000 000	1120	0.002	0.0001	a few hours
Artificial Reservoirs		8000			72 days
Total water reserves	510 000 000	1 385 984 610	2718	100.00	

atmosphere itself is sensitive to the sea surface temperature. Temperature and salinity determine the density of ocean water, and both factors contribute to the overturning and the deep ocean general circulation (*see* **Chapter 174, Global Water Budgets – Fundamental Theory and Mechanisms, Volume 5**).

- Other major reserves are solid water on the continent (glaciers and permanent snow cover) and groundwater. *Glacier* is accumulation of ice of atmospheric origin generally moving slowly on land over a long period. Glacier forms discriminative U-shaped valley over land, and remains moraine when it retreats. If a glacier "flows" into an ocean, the terminated end of the glacier often forms an iceberg. Glaciers react in comparatively longer timescale against climatic change, and they also induce isostatic responses of continental scale upheavals or subsidence in even longer timescale. Even though it is predicted that the thermal expansion of oceanic water dominates the anticipated sea level rise due to the global warming, glaciers over land are also a major concern as the cause of sea level rise associated with global warming (*see* **Chapter 162, Hydrology of Snowcovered Basins, Volume 4**; **Chapter 164, Role of Glaciers and Ice Sheets in Climate and the Global Water Cycle, Volume 4**).
- *Groundwater* is the subsurface water occupying the saturated zone. It contributes to runoff in its low-flow regime, between floods. Deep groundwater may also reflect the long term climatological situation. Groundwater in Table 1 includes both gravitational and capillary water. Gravitational water is water in the unsaturated zone (vadose zone) which moves under the influence of gravity. Capillary water is water found in the soil above the water table by capillary action, a phenomenon associated with the surface tension of water in soils acting as porous media. Groundwater in Antarctica (roughly estimated as $2 \times 10^6\,\mathrm{km}^3$) is excluded from Table 1 (*see* **Chapter 145, Groundwater as an Element in the Hydrological Cycle, Volume 4**).
- *Soil moisture* is the water being held above groundwater table. It influences the energy balance at the land surface as a lack of available water suppresses evapotranspiration and as it changes surface albedo. Soil moisture also alters the fraction of precipitation partitioned into direct runoff and percolation. The water accounted for in runoff cannot be evaporated from the same place, but the water infiltrated into soil may be uptaken by suction, and evaporated again (*see* **Chapter 72, Measuring Soil Water Content, Volume 2**).
- The atmosphere carries *water vapor*, which influences the heat budget as latent heat. Condensation of water releases latent heat, heats up the atmosphere, and affects the atmospheric general circulation. *Liquid water in the atmosphere* is another result of condensation. *Clouds* significantly change the radiation in the atmosphere and at the Earth's surface. However, as a volume, liquid (and solid) water contained in the atmosphere is quite little, and most of the water in the atmosphere exists as water vapor. *Precipitable water* is the total water vapor in atmospheric column from land surface to the top of the atmosphere. Water vapor is also the major absorber in the atmosphere of both short-wave and long-wave radiation (*see* **Chapter 196, The Role of Water Vapor and Clouds in the Climate System, Volume 5**).
- *Water in rivers* is very tiny as a stored water at each time, however, the recycling speed, which can be estimated as the inverse of the mean residence time, of river water (river discharge) is relatively high, and it is important because most social applications ultimately depend on water as a renewable and sustainable resource.

The amount of water stored transiently in a soil layer, in the atmosphere, and in river channels is relatively minute, and the time spent through these subsystems is short, but, of course, they play dominant roles in the global hydrological cycle.

WATER CYCLE ON THE EARTH (*see* Chapter 4, Organization and Process, Volume 1)

The water cycle plays many important roles in the climate system, and Figure 1 schematically illustrates the various flow path of water (Oki, 1999). Values are taken from Table 1 and also calculated from the precipitation estimates by Xie and Arkin (Xie and Arkin, 1996). Precipitable water, water vapor transport, and its convergence are estimated using ECMWF objective analyses, obtained as four-year mean from 1989 to 1992. The roles of these water fluxes in the global hydrologic system are now briefly introduced (*see* **Chapter 182, The Hydrological Cycle in Atmospheric Reanalysis, Volume 5**):

- *Precipitation* is water flux from atmosphere to land or ocean surface. It drives the hydrological cycle over land surface and changes surface salinity (and temperature) over the ocean and affects its thermohaline circulation. *Rainfall* refers to the liquid phase of precipitation. Part of it is intercepted by canopy over vegetated area, and remaining part reaches the Earth surface as through-fall. Highly variable, intermittent, and concentrated behavior of precipitation in time and space domain compared to other major hydrological fluxes mentioned below makes the observation of this quantity and the aggregation of the process complex and difficult (*see* **Chapter 35, Rainfall Measurement: Gauges, Volume 1**).
- *Snow* has special characteristics compared with rainfall. Snow may be accumulated, the albedo of snow is quite high (as high as clouds), and the surface temperature

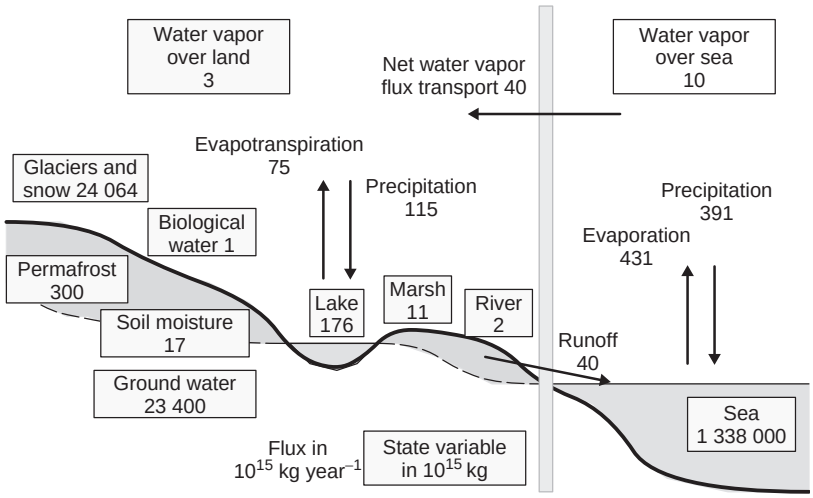

Figure 1 Schematic illustration of the water cycle on the Earth Oki, 1999. Values are taken from Table 1 and calculated from atmospheric water vapor data by European Centre for Medium-Range Weather Forecasts (ECMWF) and precipitation by Xie and Arkin (Xie and Arkin, 1996) for 1989–92

will not rise above 0 °C until the completion of snow melt. Consequently the existence of snow changes the surface energy and water budget enormously. A snow surface typically reduces the aerodynamic roughness, so that it may also have a dynamical effect on the atmospheric circulation and hydrologic cycles (*see* **Chapter 41, Evaporation Modeling: Potential, Volume 1**; **Chapter 43, Evaporation of Intercepted Rainfall, Volume 1**; **Chapter 45, Actual Evaporation, Volume 1**).

- *Evaporation* is the return flow of water from the surface to the atmosphere and gives the latent heat flux from the surface. The amount of evaporation is determined by both atmospheric and hydrological conditions. From the atmospheric point of view, the fraction of incoming solar energy to the surface leading to latent and sensible heat flux is important. Wetness at the surface influences this fraction because the ratio of actual evapotranspiration to the potential evaporation is reduced due to drying stress. The stress is sometimes formulated as a resistance, and such a condition of evaporation is classified as hydrology-driven. If the land surface is wet enough compared to the available energy for evaporation, the condition is classified as atmosphere-driven.
- *Transpiration* is the evaporation of water through stomata of leaves. It has two special characteristics different from evaporation from soil surfaces. One is that the resistance of stomata is related not only to the dryness of soil moisture but also to the physiological conditions of the vegetation through the opening and the closing of stomata. Another is that roots can transfer water from deeper soil than in the case of evaporation from bare soil. Vegetation also modifies the surface energy and water balance by altering the surface albedo and by intercepting precipitation and evaporating this rain water (*see* **Chapter 42, Transpiration, Volume 1**).
- *Runoff* returns water to the ocean which may have been transported in vapor phase by atmospheric advection for inland. The runoff into oceans is also important for the freshwater balance and the salinity of the oceans. Rivers carry not only water mass but also sediment, chemicals, and various nutritional matters from continents to seas. Without rivers, global hydrologic cycles on the earth will never close (*see* **Chapter 80, Erosion and Sediment Transport by Water on Hillslopes, Volume 2**; **Chapter 114, Snowmelt Runoff Generation, Volume 3**; **Chapter 111, Rainfall Excess Overland Flow, Volume 3**; **Chapter 112, Subsurface Stormflow, Volume 3**).

  Runoff at hill-slope scale is nonlinear and a complex process. Surface runoff could be generated when rainfall or snow melt intensity exceeds the infiltration rate of the soil or precipitation falls over saturated land surface. Saturation at land surface can be formed mostly by topographic concentration mechanism along hill-slopes. Infiltrated water in the upper part of the hill-slope flows down the slope and discharges at the bottom of the hill-slope. Because of the highly variable heterogeneity of topography, soil properties such as conductivity and porosity, and precipitation, basic equations, such as Richard's Equation, which can express the runoff process fairly well at a point scale or hill-slope scale, cannot be directly applied for macroscale because of its nonlinearity.

The global water cycle unifies these components consisting of the state variables (precipitable water, soil moisture, etc.) and the fluxes (precipitation, evaporation, etc.).

WATER BALANCE REQUIREMENTS (*see* Chapter 5, Fundamental Hydrologic Equations, Volume 1)

The conservation law of water mass in any arbitrary control volume implies a water balance. In this section, the water balance over land, for atmospheric column, and their combination are presented (Oki, 1999). Some applications are introduced, as well.

Water Balance at Land Surface

In the field of hydrology, river basins have commonly been selected for study, and water balance has been estimated using ground observations, such as precipitation, runoff, and storage in lakes and/or groundwater.

The water balance over land is described as,

$$\frac{\partial S}{\partial t} = P - E - R_o - R_u \tag{2}$$

where S represents the water storage within the area, t is time, $(\partial S/\partial t)$ is the change of total water storage with time, P is precipitation, E is evapotranspiration, R_o is surface runoff, and R_u is the groundwater movement. S includes snow accumulation in addition to soil moisture, groundwater, and surface water storage including retention water within the control volume, defined by the area of concern over land with bottom generally at the impermeable bedrock. These terms are shown in Figure 2(a). Equation (1) means water storage over land increases by precipitation, and decreases by evapotranspiration, surface runoff, and groundwater movement.

If the area of water balance is set within an arbitrary boundary, R_o represents the net outflow of water from the region of consideration (i.e. the outflow minus total inflow from surrounding areas). Generally it is not easy to estimate groundwater movement R_u, and the net flux per unit area within a large area is expected to be comparatively small. If all groundwater movement is considered to be that observed at the gauging point of a river ($R_u = 0$), and equation (2) becomes:

$$\frac{\partial S}{\partial t} = P - E - R_o \tag{3}$$

This assumption is generally valid at the outlet of a catchment. In most cases, surface river runoff R_o becomes river discharge through river channel network, and can be observed at a point unlike other fluxes, such as P and E that should be spatially measured.

Water Balance in the Atmosphere

Atmospheric water vapor flux convergence gives water balance information that can complement the traditional hydrological elements such as precipitation, evapotranspiration, and discharge. The basic concept and an application of using atmospheric data to estimate the terrestrial water balance was presented by Starr and Peixóto (1958).

The atmospheric water balance for a column of atmosphere from the bottom at land surface to the top of the atmosphere is described by the equation,

$$\frac{\partial W}{\partial t} = Q + (E - P) \tag{4}$$

where, W represents precipitable water (*i.e.* column storage of water vapor), Q is the convergence of water vapor flux in the atmosphere. Since the water content in the atmosphere in the solid and liquid phases are generally small, only vapor phase of water is considered in equation (4). The balance is schematically illustrated in Figure 2(b), and describes that the water storage in an atmospheric column is increased by the horizontal convergence of water vapor and evapotranspiration from bottom of the column (land surface), and decreases by precipitation which goes out from the bottom of the atmosphere to land.

Combined Atmosphere–River Basin Water Balance

Equations (3) and (4) can be combined into:

$$-\frac{\partial W}{\partial t} + Q = (P - E) = \frac{\partial S}{\partial t} + R_o \tag{5}$$

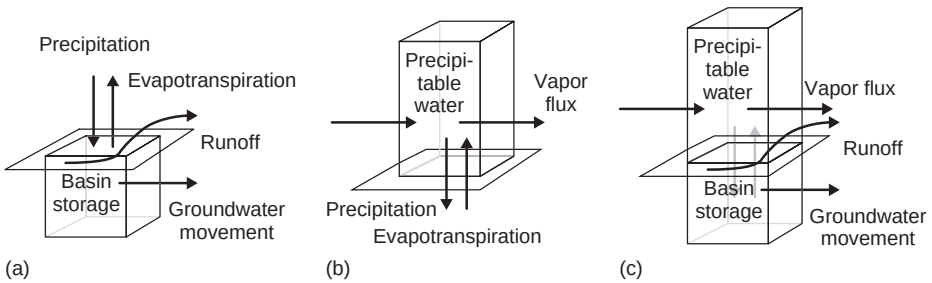

Figure 2 (a) Terrestrial water balance, (b) Atmospheric water balance, and (c) Combined atmosphere-land surface water balance. (a), (b), and (c) correspond to equations (3), (4), and (6), respectively

Figure 2(c) illustrates the balance in this equation, and illustrates that the difference of precipitation and evapotranspiration is equal to the sum of the decrease of atmospheric water vapor storage and horizontal convergence, and also to the sum of the increase of water storage over land and runoff. Theoretically, equation (5) can be applied for any control volume of land area combined with the atmosphere above, even though practical applicability depends on the accuracy and availability of atmospheric and hydrologic information.

The following further assumptions are often employed in annual water balance computations:

- Annual change of atmospheric water vapor storage is negligible ($(\partial W/\partial t) = 0$).
- Annual change of water storage at land is negligible ($(\partial S/\partial t) = 0$).

With these assumptions, equation (5) simplifies to:

$$Q = (P - E) = R_o \tag{6}$$

If a river basin is selected as the water balance region, R_o is simply the discharge from the basin. The simplified equation 6 demands that the water vapor convergence, "precipitation-evaporation", and net runoff should balance over the annual period when the temporal change of storage terms can be neglected.

Estimation of Large-scale Evapotranspiration

The equation

$$E = \frac{\partial W}{\partial t} - Q + P \tag{7}$$

obtained from equation (4) can be applicable over periods shorter than a year, unlike the assumption adopted for equation (6). If atmospheric data with precipitation data are available over short timescales such as months or days, evapotranspiration can be estimated at the corresponding timescales, of course, subject to severe limitations imposed by the accuracy of the data. The region over which the evapotranspiration is estimated is not limited to a river basin but depends only on the scales of the available atmospheric and precipitation data.

Estimation of Total Water Storage in a River Basin

Equations (3) and (4) give

$$\frac{\partial S}{\partial t} = -\frac{\partial W}{\partial t} + Q - R_o \tag{8}$$

which indicates that the change of water storage in the control volume over land can in principle be estimated from atmospheric and runoff data. Although an initial value is required to obtain the absolute value of storage, the atmospheric water balance can be useful in estimating the seasonal change of total water storage in large river basins.

Estimation of Zonally averaged Net Transport of Fresh Water

The meridional (north–south direction) distribution of the zonally averaged annual *energy* transports by the atmosphere and the oceans have been evaluated, even though there are quantitative problems in estimating such values (Trenberth and Solomon, 1994). However, the corresponding distribution of *water* transport has not often been studied although the cycles of energy and water are closely related. Wijffels *et al.*, (1992) used values of Q from Bryan and Oort (1984) and discharge data from Baumgartner and Reichel (1975) to estimate the freshwater transport by oceans and atmosphere, but their results seem to have large uncertainties and they did not present the freshwater transport by rivers.

The annual freshwater transport in the meridional (north–south) direction can be estimated from Q and river discharge with geographical information such as the location of river mouths and basin boundaries (Oki *et al.*, 1995). Results are introduced in the next section.

RIVERS IN GLOBAL HYDROLOGICAL CYCLE

The freshwater supply to the ocean has an important effect on the thermohaline circulation because it changes the salinity and thus the density. The impacts of freshwater supply to ocean are enhanced in the case of large river basins because they concentrate freshwater from large area to their river mouths.

It also controls the formation of sea ice and its temporal and spatial variations. Annual freshwater transport by rivers and the atmosphere to each ocean is summarized in Table 2 based on the atmospheric water balance (Oki, 1999). Some part of the water vapor flux convergence remains in the inland basins. There are a few negative values in Table 2, suggesting that net freshwater transport occurs from the ocean to the continents. This is physically impossible and is caused by errors in the source data. Although a detailed discussion of the values in Table 2 may not be meaningful, it is nevertheless interesting that such an analysis does make at least qualitative sense using the atmospheric water balance method with geographical information on basin boundaries and the location of river mouths. In this analysis, it should be noted that the total amount of freshwater transport into the oceans from the surrounding continents has the same order of magnitude as the freshwater supply that comes directly from the atmosphere, expressed by Q.

The annual freshwater transport in the meridional direction has been also estimated based on atmospheric water

Table 2 Annual freshwater transport from continents to each ocean (10^{15} kg year^{-1}) mean for 1985–88. 'Inner' indicates the runoff to the inner basin within Asia and Africa. $-\nabla_H \cdot \vec{Q}$ indicates the direct freshwater supply from the atmosphere to the ocean. N.P., S.P., N.At., and S.At. represent North Pacific, South Pacific, North Atlantic, and South Atlantic Ocean

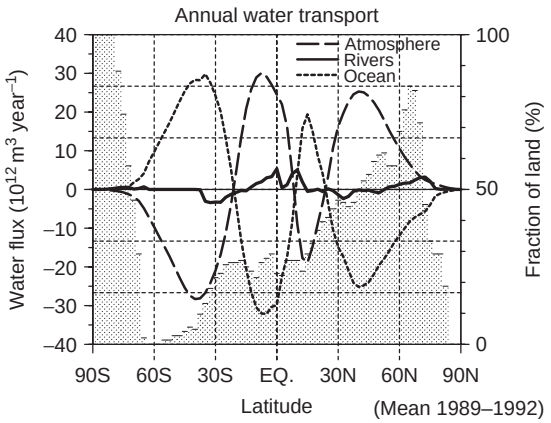

Figure 3 The annual freshwater transport in the meridional (north–south) direction by atmosphere, ocean, and rivers (land) Oki *et al.,* 1995. Water vapor flux transport of 20×10^{12} m^3 year^{-1} corresponds to approximately 1.6×10^{15} W of latent heat transport. Shaded bars behind the lines indicate the fraction of land at each latitudinal belt

balance with results shown in Figure 3. The estimates in Figure 3 are the net transport, that is in the case of oceans, it is the residual of northward and southward freshwater flux by all ocean currents globally, and it cannot be compared directly with individual ocean currents such as the Kuroshio and the Gulf Stream. It should be noted that the directions of river flows are mostly steady unlike ocean or atmospheric circulations, and concentrates the freshwater in one direction through out the year.

Transport by the atmosphere and by the ocean have almost the same absolute values at each latitude but with different signs. The transport by rivers is about 10% of these other fluxes globally (this may be an underestimation because Q tends to be smaller than the river discharge observed at a land surface). The negative (southward) peak by rivers at 30 °S is mainly due to the Parana River in South America, and the peaks at the equator and 10 °N are due to rivers in South America, such as the Magdalena and Orinoco. Large Russian rivers, such as the Ob, Yenisey, and Lena, carry the freshwater towards the north between 50–70 °N.

These results suggest that the hydrological processes over land play nonnegligible roles in the climate system, not only by the exchange of energy and water at the land surface, but also through the transport of freshwater by rivers, which affects the water balance of the oceans and forms a part of the hydrological circulation on the Earth among the atmosphere, continents, and oceans.

GLOBAL WATER BALANCE ESTIMATED BY LAND SURFACE MODELS

The values quoted in Table 1 and Figure 1 are estimated based on various observations with some assumptions in order to obtain global perspectives. These values are sometimes different in other references probably because source of observed data, methodology to estimate, and assumptions are different. In some cases, global water balance are estimated using empirical relationship of evapotranspiration to precipitation in each latitude (Baumgartner and Reichel, 1975).

Recently, under an international research project, land surface models (LSMs) were used to estimate global water and energy balances for 1986 through 1995 in order to obtain global distribution of surface soil moisture, which is not easy to obtain but relevant for understanding the land-atmosphere interactions (IGPO, 2002). The project was called the *Global Soil Wetness Project* (GSWP) and its goal was to produce state-of-the-art global data sets of land surface fluxes, state variables, and related hydrologic quantities (*see* **Chapter 178, Modeling of the Global Water Cycle: Numerical Models (General Circulation Models), Volume 5**; **Chapter 201,**

Land-Atmosphere Models for Water and Energy Cycle Studies, Volume 5).

In the second phase of the project (GSWP-2), Meteorological forcing are hybrid products of National Center for Environmental Prediction (NCEP)/Department of Energy (DOE) reanalysis observational data and satellite data, and provided at 3-hourly time step for a period of thirteen and half years from July 1982 to December 1995. The first three and half years data is used for spin up. The land surface parameters are specified from Earth Resources Observation and Science Data Center (EDC) for land-cover data and International Geosphere–Biosphere Programme Data Information System (IGBP-DIS) for soil data. Both land surface parameters and meteorological forcing are at one degree resolution for all land grids excluding Antarctica.

Figure 4 illustrates the model derived global water balance over global land excluding ice, glacier, and lake. Numerics in the box corresponds to the 10-year mean annual value of 8 LSMs participated to GSWP2 (Oki *et al.*, 2005). The vertical ranges shown above and below the boxes indicate the maximum and minimum values in interannual variation of mean annual value among 8 LSMs. The horizontal ranges shown left and right of the boxes indicate the maximum and minimum values of intermodel variation of 10-year mean value by 8 LSMs. Generally speaking, intermodel variation exceeds the interannual variation, which suggests that the uncertainties associated with the selection of a model or a procedure is larger than the sampling error of estimating global water balance. In the case of rainfall, intermodel variation is small because common precipitation forcing was given to LSMs and the differences among LSM estimates were caused by the different judgment of rain/snow recognition by each modeling group.

The advantage of using models estimating global water balance is the ability to have more detailed insights than observation of only estimates. For example, snow over land excluding ice and glacier area is approximately 10% of total precipitation, and the ratio of surface runoff and subsurface runoff is approximately 2 : 3 in Figure 4. In some LSM, neither surface nor subsurface runoff process is considered and that is the reason why minimum values are zero. Even though now it is impossible to assess the validity of these breakdowns since there is no observational information of either the separated amount of the snow and rain, or the surface and subsurface runoff. However, on the other hand, such estimates will stimulate interest to collect and compile global information on these quantities in the future.

Further, evapotranspiration were estimated separately by bare soil evaporation (Es), evaporation from intercepted water on leaves (Ei), evaporation from open water (Ew), and transpiration from vegetation (Et) as in Figure 5, even though the intermodel variation is quite large partially because some LSM does not consider one or more of these path of evapotranspiration. Even though the values in Figure 5 are not definitive, it is interesting to see that bare soil evaporation and transpiration from vegetation are closely comparative, and interception loss is approximately

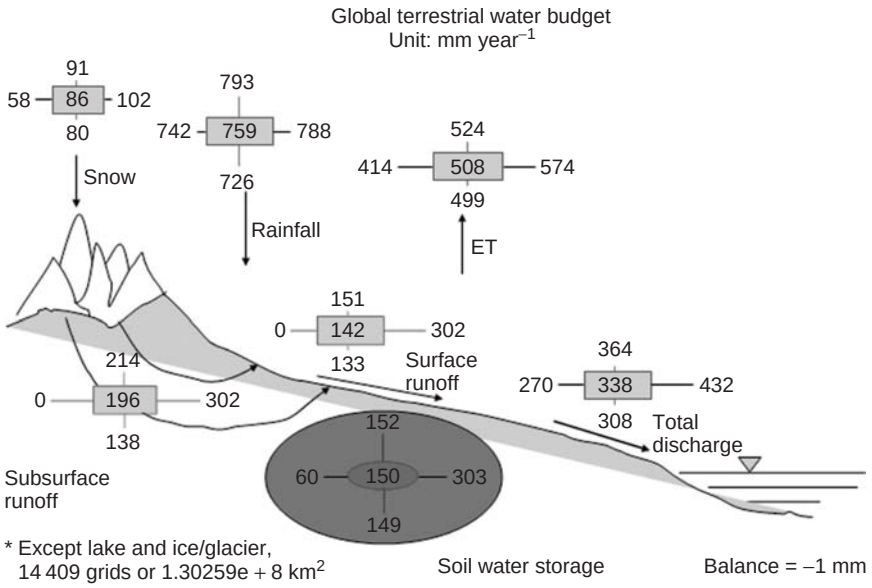

Figure 4 Global terrestrial water balance averaged for 1986–1995 estimated by eight land surface models in boxes. Interannual variation range (vertical) for 1986 through 1995 and intermodel discrepancies (horizontal) among eight models are presented for the annual mean estimates. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

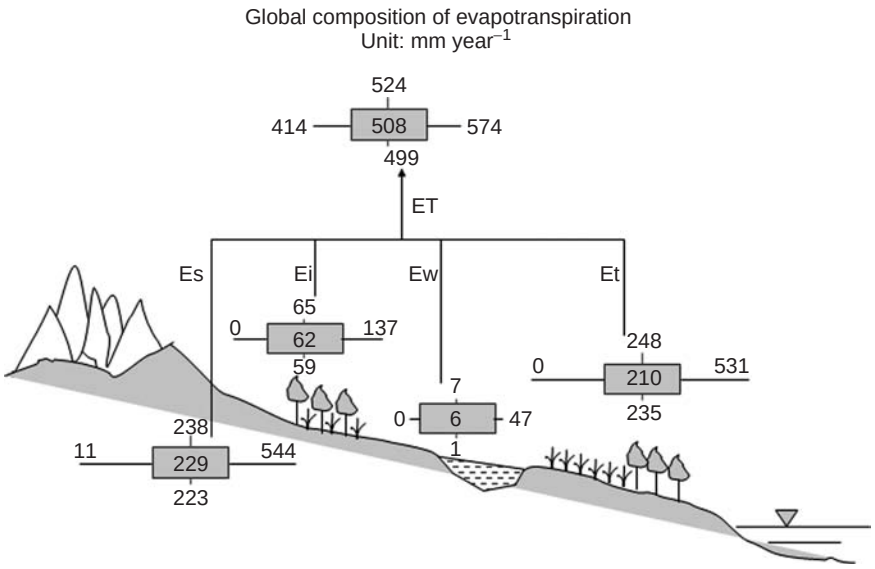

Figure 5 Global composition of evapotranspiration averaged for 1986–1995 estimated by eight land surface models in boxes. Interannual variation range (vertical) for 1986 through 1995 and intermodel descrepancies (horizontal) among eight models are presented for the annual mean estimates. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

10% of the total evapotranspiration. It would be exciting if these estimates are revised and validated by some observational measures, and intermodel discrepancies are reduced.

ANTHROPOGENIC EFFECTS ON THE GLOBAL WATER CYCLE (*see* Chapter 34, Climate Change – Past, Present and Future, Volume 1)

Global water cycles are essential in the Earth System because of flux exchange, mass and heat transport, and control on biogeochemical cycles (*see* **Chapter 189, Land Use and Water Resources Under a Changing Climate, Volume 5**).

According to the paradigm shift of research in natural sciences, after the wide recognition of global environmental problems, it is the era "The Anthropocene" for geosciences to study the real situation of the Earth (Crutzen, 2002) including the various impact of anthropogenic activities. Water cycle is one of the most exposed nature and vulnerable to human impacts. Therefore hydrological science should deal with water cycles on the Earth, its impact on human society, and the anthropogenic impact on water cycles on the Earth (*see* **Chapter 117, Land Use and Land Cover Effects on Runoff Processes: Urban and Suburban Development, Volume 3**; **Chapter 118, Land Use and Land Cover Effects on Runoff Processes: Agricultural Effects, Volume 3**; **Chapter 119, Land Use and Landcover Effects on Runoff Processes: Forest Harvesting and Road Construction, Volume 3**).

Human impacts on hydrologic cycles are various. Land use/land-cover transforms, topographical modification and compression of soil layers, including building cities and cultivation of different species of plants (agricultural activities), have large impacts on water cycles through changing the boundary conditions. Water withdrawals and uptake for irrigation, and municipal and industrial water usages modify water cycle significantly for both quantitative and qualitative aspects (*see* **Chapter 132, Rainfall-runoff Modeling for Assessing Impacts of Climate and Land Use Change, Volume 3**; **Chapter 187, Land Use Impacts on Water Resources – Science, Social and Political Factors, Volume 5**).

These anthropogenic impacts on surface/subsurface water cycles may have indirect effects on atmospheric circulation and regional climate, for example, deforestation may have caused long-term decrease of precipitation in particular months when large-scale circulation (such as Asian Monsoon) is not dominant for precipitation but the local boundary condition matters (Kanae *et al.*, 2001).

Figure 6 schematically illustrates the impacts of increasing population and economic activities associated with consumptive life style on hydrological cycles, water withdrawals, and resulting change in water stress. Water withdrawals are increased directly by the increase in population and water usage per capita, and indirectly through the increase in food production. Food production also changes land use, and land use is changed by industrialization, as well. Increased industrial activities and land use change are increasing the emission of the Green House Gases (GHGs), and changing climate. Any

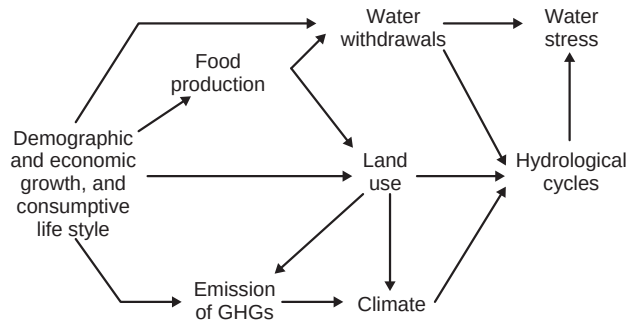

Figure 6 Diagram illustrating major pathways how demographic and economic growth have influence on the changes in hydrological cycles and water withdrawals through changes in land use, water withdrawals, and climate related to food production and the emission of the Green House Gases (GHGs)

change in both supply side (hydrological cycle) and demand side (water withdrawals) will incur adaptation in water resources management, and it will be serious if the climate change will be associated with more intense and intermittent precipitation, which will cause more frequent occurrence of floods (Milly *et al.*, 2002) and droughts (Manabe *et al.*, 2004).

Finally, globalization has increased worldwide trades, and it is associated with true water transport and "virtual water" trade. True water transport is the water transport contained in food, beverage, and other industrial products, and it occurs in local, regional, and international scales. The "virtual water" trade is not the transport of physical water, but it is a concept to consider the external cost of water consumption; namely, the virtual water content of goods is equal to the amount of water required if the transferred goods are produced in the importing/consuming region or country (Allan 1998; Oki *et al.*, 2003). Even though virtual water trade does not correspond to the amount of physical water transport, the concept is useful to assess the real water scarcity in each region, and will be utilized when water resources management issues are concerned. Hydrological sciences are often applied for such issues, and should well cooperate with such socioeconomic concepts of water (Oki *et al.*, 2004).

3: Hydrologic Concepts of Variability and Scale

ROSS WOODS

Catchment Processes and Water Resources Group, National Institute of Water and Atmospheric Research, Christchurch, New Zealand

All hydrological phenomena have significant variations in time and space. Typically, these variations are driven by variations in physiographic factors such as climate, soils, vegetation, topography, geology, as well as by human and animal activities. These externally driven variations then propagate through hydrological systems, leading to an extremely rich variety of hydrological variability apparent at different temporal and spatial scales, in different physical settings. Virtually any quantitative approach to this problem requires the selection of a limited set of spatial and temporal scales within a particular physiographic setting. Any particular choice of time and space scales has a major influence on which aspects of this hydrological variability are perceived. This article surveys hydrological variability in both time and space, across a range of scales.

INTRODUCTION

Variability

Variability is the change in hydrological quantity when comparing one spatial location with another, or one time with another. Variability occurs naturally, and also because of human activity (e.g. land cultivation, urbanization, and forest management). We can see evidence of this variability in measurements of rainfall, air temperature, soil moisture, snow cover, groundwater level, and streamflow, or any other hydrological quantity.

Everyday life already provides us with an intuitive understanding of the many aspects of variability, for example, from the common experience that air temperature is variable with space and time. We know about the time variation of temperature on at least three different scales: first, it is generally cooler at night and warmer during the day; second, daytime temperatures are cooler on cloudy days; and third, it is generally cooler in winter and warmer in summer. These three examples of temporal variability are at different timescales: the first is at the daily timescale, the second has no particular timescale (cloudiness may last for seconds or for days), and the third is at the annual timescale (we will define the concept of scale more carefully in the following text). We also know that air temperature is variable from place to place: it is cooler in the shade of a leafy tree than standing out in the sun, and it is cooler on the mountaintops than in nearby lowlands. We thus have experience of spatial variability for at least two space scales, the plant scale (of the order 1 m) and the landscape scale (perhaps 10 km).

Scale in this article is used to mean a spatial or temporal measure over which a hydrologic variable is being considered. For example, we may think of the amount of water held in the rooting zone of a soil at an instantaneous timescale, or an average value over the timescale of a day or a year or other period. When we choose a scale, this affects how we perceive soil moisture, or whatever other phenomena we care to think of. If we look at the moment-to-moment variability of instantaneously measured soil moisture, we see a particular variation. If we examine daily averaged soil moisture at the same place over the same period, we see something different. This difference is the effect of timescale on variability (e.g. Figure 1). Similarly, we can consider this soil water at the spatial scale of a "point" or a field average, or a catchment average. Again, a change in the scale of observation causes a change in the perceived variability. When one considers measurements or model estimates that are obtained at discrete times and locations, then the concept of scale needs to be expanded: Blöschl and Sivapalan (1995) recognized this need, and defined a "scale triplet" that quantifies the spacing, the extent, and the support of a measurement or model estimate. **Chapter 6, Principles**

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

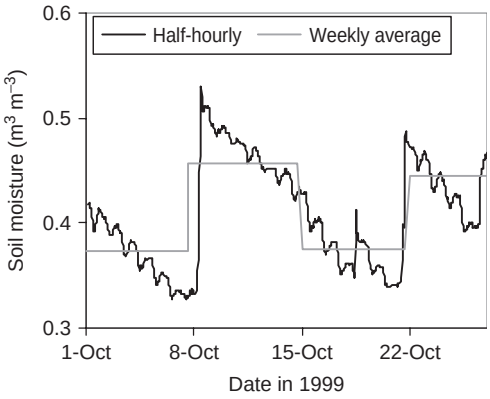

Figure 1 A comparison of half-hourly and weekly average soil moisture in the Mahurangi catchment, northern New Zealand, during October 1999, showing that temporal variability depends on our choice of temporal scale. Storms on the 8th and 21st of October caused soil moisture to rise sharply. Soil moisture also has variability at longer and shorter timescales that are not visible here

of Hydrological Measurements, Volume 1 presents this notion in more detail.

This article discusses concepts that are used to describe hydrological variability, and then examines the forms of variability typically encountered in hydrology, looking at variability in time, in space, and finally simultaneous variability in both time and space. Within each of the sections following, material is generally organized by scale, beginning with phenomena at finer scales. Examples of each type of variability are given, using measurements of hydrological quantities. Since these examples are frequently drawn from New Zealand, they are particular manifestations of a more general concept. It is not practical in this brief article to survey the full gamut of hydrologic variability at every scale across the globe. The purpose of the examples is to simply provide an illustration of each concept. Although this article focuses on the occurrence and movement of water in hydrological systems, many of the same concepts are also used to describe the occurrence and movement of energy and of substances transported by water, such as sediments and nutrients. The focus here is generally qualitative, introducing the nature of hydrological variability and the concepts hydrologists use to deal with variability. **Chapter 7, Methods of Analyzing Variability, Volume 1** presents quantitative methods for analyzing the types of variability introduced in the following text.

Defining the Quantity of Interest

Hydrological variability is much more intricate than our simple air temperature and soil moisture examples would suggest. We have already noted that the variation we observe depends on space scale, time scale, and physiographic setting. In addition, to make meaningful statements about hydrological variability, we need to specify the hydrological quantity we are interested in. For example, we may be interested in a water flux such as precipitation, snowmelt, throughfall, infiltration, evaporation, recharge, or streamflow, or a store of water such as the snowpack, canopy storage, root-zone soil water storage, or water level in an aquifer, river, lake, or wetland. For example, we would expect the temporal variability of groundwater level at a location to be quite different to the temporal variability in rainfall, because of the typically damped response of groundwater to weather. The hydrological cycle for water shown in **Chapter 2, The Hydrologic Cycles and Global Circulation, Volume 1** explains these fluxes and storages, and their relationship to one another. Since each of them possess a different type of variation, we will need to be specific about the flux or store when using a description of variability.

Hydrological Variability at a Range of Scales

Hydrological variability makes the hydrologist's task both interesting and challenging. The same phenomenon has to be treated differently depending on the space and timescales of the problem being considered. At the simplest level, hydrologists treat variability by measuring or estimating the variations at scales that are relevant to the problem at hand (and can be measured), neglecting other variations. This distinction is also referred to as *resolved* and *unresolved* variability. The selection of appropriate time and space scales at which to resolve variability is often a challenging task. Figure 2 provides some guidance by showing the range of time and space scales that are relevant to several hydrological processes. For a comprehensive review of scale issues, see Blöschl and Sivapalan (1995).

The spatial or temporal scale we use has a great effect on the variability we perceive: the scale can act as a filter, which lets us see some aspects of hydrology and masks out others. We can of course make very detailed observations over long time periods or over large regions, encompassing many sources of variability (e.g. hourly rainfall measurements for many years, or satellite imagery at 5 m resolution over thousands of square kilometers). However, humans do not generally comprehend all these scales at once, and typically take steps to reduce or compress the amount of information, perhaps by reducing resolution (e.g. using time series of monthly rainfall), or by reducing the extent of the data set (e.g. using only a day of 15-s rainfall data).

The Nature of Variability: Random and Deterministic

Descriptions of variability can be divided into two main types: random (happening by chance, unexplained, stochastic, probabilistic) and deterministic (caused by preceding events or natural laws, predictable, cyclic, trend, pattern).

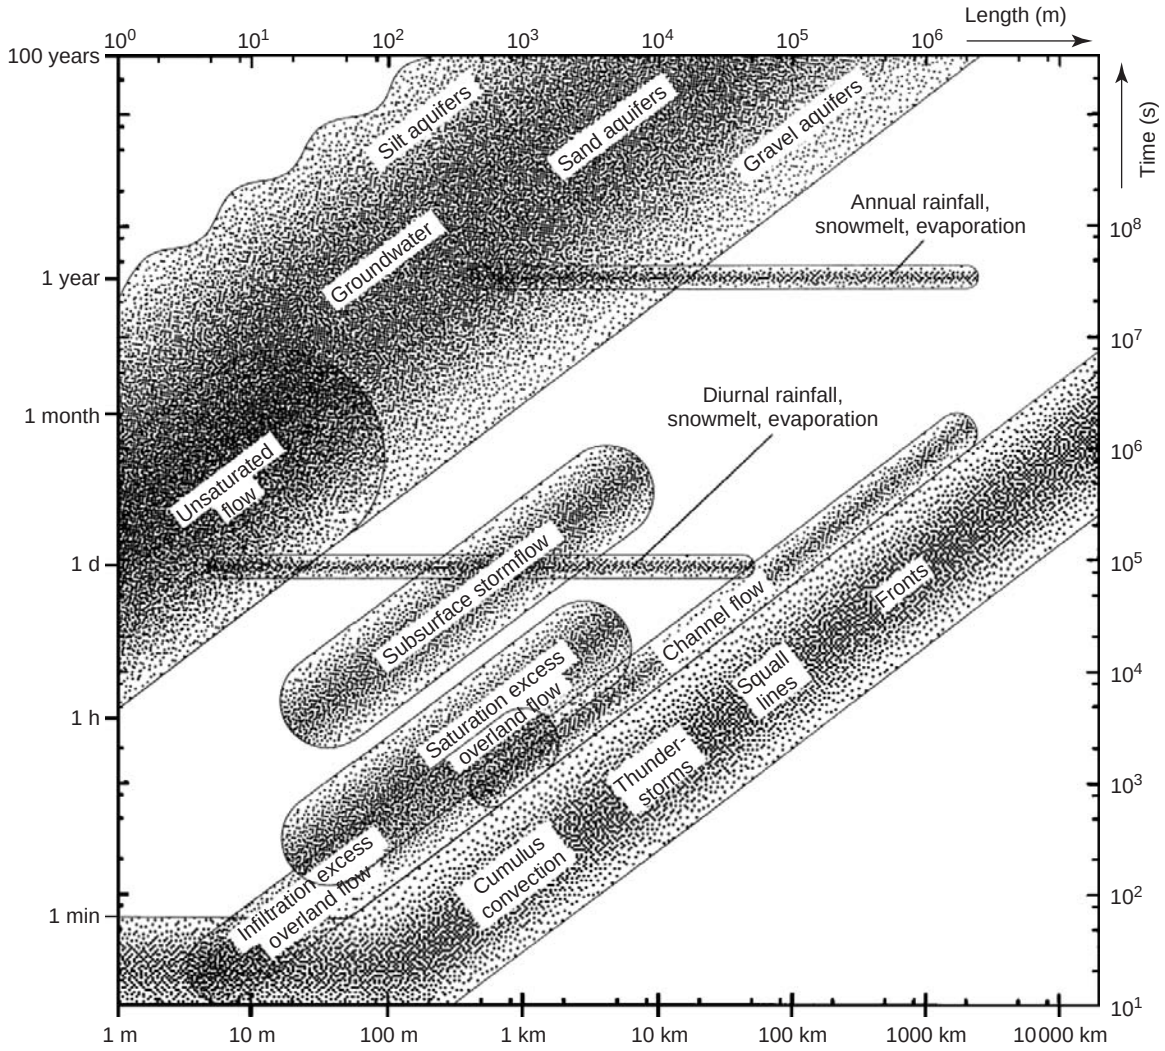

Figure 2 Schematic relationship between spatial and temporal process scales for many hydrological processes (Reproduced from Blöschl and Sivapalan (1995) by permission of John Wiley)

One extreme worldview is that all hydrological variability is deterministic, because every hydrological event has a cause that is knowable at least in principle. However, there are many situations in which the deterministic approach is impractical. There is a long history of treating hydrological quantities as random phenomena, not because they are intrinsically unpredictable, but simply because the random approach is convenient for some tasks. There are also situations in which detailed knowledge of variations and their causes is less helpful than identifying an effective descriptor, such as a statistical parameter or distribution, which captures the essential behavior of the system, without requiring a detailed enumeration of every part of the system. A well-known analogy is the use of thermodynamics to describe the net effect of many interacting molecules, and indeed several attempts have been made to construct hydrological theories using this approach.

The same physical variable can be treated as a random quantity in one context, and as deterministic in another. As an example, consider the rain falling on a small area in a severe storm. For the purpose of understanding a catastrophic flooding event caused by a particular storm, it is appropriate to use detailed measurements of how much rain fell at what time and over which locations to understand the movement of storm runoff and the subsequent flooding. This is a deterministic approach to storm rainfall. However, when designing a structure to withstand severe storms, it is often more useful to consider storm occurrence to be a random phenomena and make a statistical description of storm rainfall, assessing the probability that an event of a certain magnitude might occur. Random and deterministic approaches can also be combined, so that, for example, one might consider the total depth of rain in a storm to be a random variable, but use one or more deterministic patterns

to describe the expected temporal variation of rain intensity during any storm.

Random and Deterministic Temporal Variability

When considering temporal variability, a natural separation between random and deterministic variability is often quite clear. The cyclical movement of the Earth, each day and each year, leads to regular cycles of incoming solar radiation at the top of the Earth's atmosphere. These cycles are conveniently described deterministically, for example, using harmonic functions. These regular cycles of incoming solar radiation are reflected in hydrological variability, to a greater or lesser extent depending on which variables and locations are considered.

The daily cycle is driven by the Earth spinning on its axis, causing the Sun to (apparently) rise and set, so that incoming solar radiation increases and then decreases each day. These regular changes in energy cause daily cycles in evaporation and melting that in turn may cause daily cycles in soil moisture content, snowpack storage, water table position, and streamflow. In some settings, the daily cycle of solar radiation causes thunderstorms or strong winds at particular times of the day, which may then cause other daily cycles in hydrological variables. The two hydrological variables most conveniently described with a deterministic daily cycle are evaporation and snowmelt. At this same timescale, the occurrence and intensity of precipitation is the most obvious example of temporal variability that is conveniently described as random (not withstanding the tendency for afternoon thunderstorms in the tropics).

A similar chain of causes and effects also occurs each year, as the Earth orbits about the Sun. The Earth's axis is tilted at 23.5 degrees to the orbital plane, so in July when the North Pole points towards the Sun, the Northern Hemisphere faces the sun more directly (summer), while the Southern Hemisphere sees the Sun more obliquely (winter). Six months later, when the North Pole points away from the Sun, the seasons are reversed. The consequent seasonal changes of incoming solar radiation cause changes in the hydrological cycle, generally becoming more pronounced as we move away from the equator. There is typically less energy available for evaporation and melting in winter than in summer. During the time of year when evaporation and melt rates are less than precipitation, water may accumulate in storages (e.g. in soil, aquifers, snowpacks, wetlands or lakes) and/or run off as streamflow. As one moves into summer, the energy available for evaporation and melting may increase enough to exceed the precipitation rate so that stored water is evaporated or melted. In very wet or very dry locations where either precipitation or available energy is dominant all year round, this seasonal cycle plays a minor role in the hydrological system.

At some timescales, hydrological variables are understood mainly as random variables. We can illustrate this using both very short and very long timescales, in which our understanding of cause-and-effect is typically the weakest. At the finest space and timescales, highly intermittent turbulent atmospheric processes produce variations in rainfall. As a result, rainfall at those scales appears random.

Figure 3(a) shows 30-s rainfall accumulations that fluctuate strongly in time, with structures at many different timescales. At the other extreme, rainfall at timescales longer than a year typically shows little structure that can be represented deterministically (but see the discussion of the El Nino Southern Oscillation (ENSO) in the following text). In Figure 3(b), the year-to-year variation of annual rainfall at Warkworth in northern New Zealand provides an example of this apparently random phenomena.

Random and Deterministic Spatial Variability

Detailed spatial data for hydrology is much less comprehensive than the corresponding temporal data, mainly because of the difficulties of making spatial measurements covering areas large enough to be hydrologically significant. As a result, hydrologists' current treatment of spatial variability is still maturing. There are very few direct spatial analogues

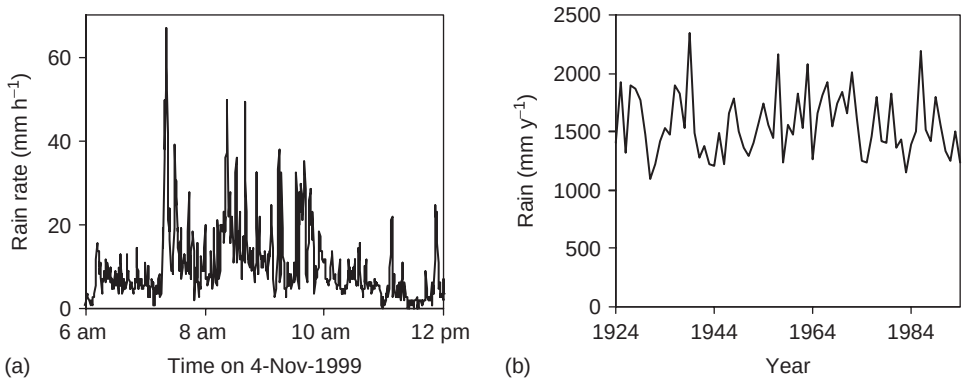

Figure 3 Apparently random variability: (a) Rainfall depths measured every 30 s during a storm over a 6 h duration; (b) annual rainfall depths at one rain gauge over a 70 year duration.

of the regular daily and annual cycles, except perhaps the wave-like landform-vegetation complexes known as *tiger-bush*, where a succession of parallel crests and troughs lead to repeated patterns of moisture content and vegetation growth (e.g. Bromley *et al.*, 1997).

Spatial trends are perhaps more common than spatial cycles – for example, the tendency for precipitation to increase and temperature to decrease, as elevation increases. Figure 4 shows one example of this correspondence in spatial patterns for accumulated rainfall in a small area of northern New Zealand. At the global scale, there is a trend for temperature to decrease as one moves to higher latitudes, as a consequence of the fact that land at high latitudes only faces the Sun obliquely, and thus receives less solar radiation per unit land area.

Much more common than either trends or cycles are irregular formations, sometimes with a repeated spatial structure (e.g. hillslope–floodplain–stream bed) at a variety of spatial scales. An irregular spatial structure is characteristic of almost every hydrological variable. Such systems show a level of organization that is intermediate between deterministic and random – scientifically intriguing, yet elusive. Since the influential work of Mandelbrot (1982), substantial research effort has been directed into recognizing and quantifying patterns in observed hydrology, especially using concepts based on this idea of self-similarity. Although this methodology has been used to describe the scaling of many types of natural variability (e.g. topography, rainfall, river networks), further progress is needed to integrate these patterns into a coherent theory of hydrology. The ideas of self-similarity do allow a concise description of how variability changes from one scale to another, but at present there is little insight into why these relationships exist, or how they might be used to improve our knowledge of the occurrence and movement of water within hydrological systems.

Some spatial patterns in hydrology have a well-understood cause, such as the soil moisture patterns caused by a well-observed storm, or the occurrence of an aquifer that has developed as a result of geological structures that are well mapped. Some current-day patterns are not the result of current conditions at all, but are a legacy of historical climate or tectonic activity. Our knowledge of these causal relationships is frequently valuable in obtaining and interpreting information on spatial variability in complex hydrological settings.

Hydrological Variability Depends on the Physical Setting

It is important to remember when reading this very general introduction, that there are many different manifestations of variability besides those illustrated here. For example, the dominant forms of variability observed in a temperate landscape are very different from those seen in regions of extreme cold or aridity. Global hydrological variability is much more intricate than is commonly presented in textbooks, and although some themes are repeated across the planet, there is a rich diversity between locations. **Chapter 121, Intersite Comparisons of Rainfall-runoff Processes, Volume 3** provides an introduction to intercomparison in the watershed setting.

For further information, the reader is encouraged to consult a reference that takes a comparative approach, such

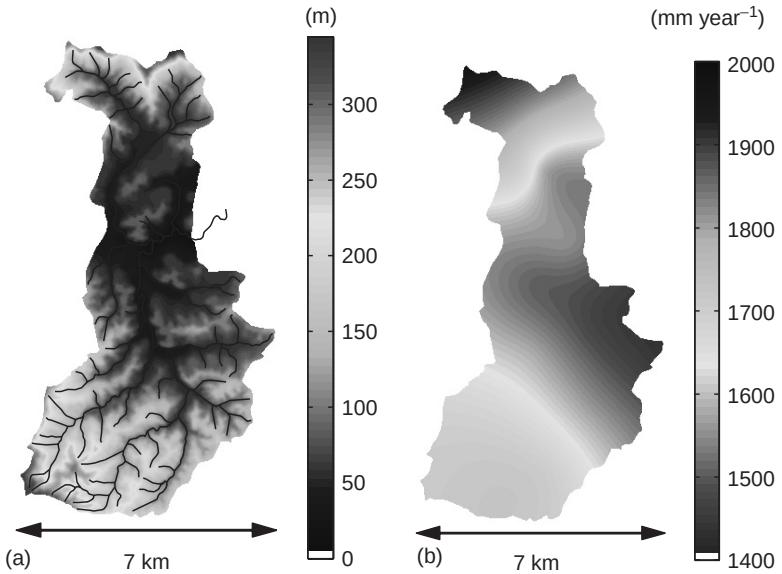

Figure 4 Spatial patterns of elevation (from 20-m elevation contours) and rainfall (interpolated from 19 months of data at 13 rain gauges). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

as Falkenmark and Chapman (1989). There, the authors propose a global hydrological classification, using maps of topography (sloping and flat land), climatic aridity (humid and dry climates), and potential evaporation (cold, temperate, and warm regions). They then provide illustrative examples of the hydrology for each of the classes in the classification system. That approach provides a structured introduction to the astonishing variety of hydrological systems present on our planet, but is beyond the scope of this article.

TEMPORAL VARIABILITY

Weather and climate is the most common direct cause of observed temporal variation in hydrological phenomena such as soil moisture, snow cover, river flow, or groundwater levels. Hydrological systems will modulate the meteorological variations, damping some of them and amplifying others, but the ultimate cause of temporal variability can usually be traced back to meteorological processes that control precipitation and evaporation. The other common source of temporal variability is water or land management by humans. Regardless of the source, we almost always have temporal variability at a wide range of timescales, both the relatively regular diurnal and annual fluctuations, as well as irregular fluctuations.

Diurnal Cycle

Figure 5 shows three examples of diurnal cycles in hydrology. Soil moisture content measured near Warkworth in subtropical northern New Zealand increases during the morning as incoming radiation increases, typically reaching a minimum level shortly after midday each day. The details of the timing at any particular site will depend on the exposure of the site to radiation, and the response characteristics of the soil and vegetation. The groundwater level on the Heretaunga Plains of the temperate eastern North Island of New Zealand reaches its maximum each morning around 7 A.M. local time, and the minimum level occurs about 12 h later. The diurnal fluctuations at this site are typically 0.2 m: the timing and amplitude of the diurnal cycle can vary greatly from one location to another, depending on factors such as how close the groundwater level is to the ground surface and the moisture status of the soil just above the groundwater table. If groundwater is being

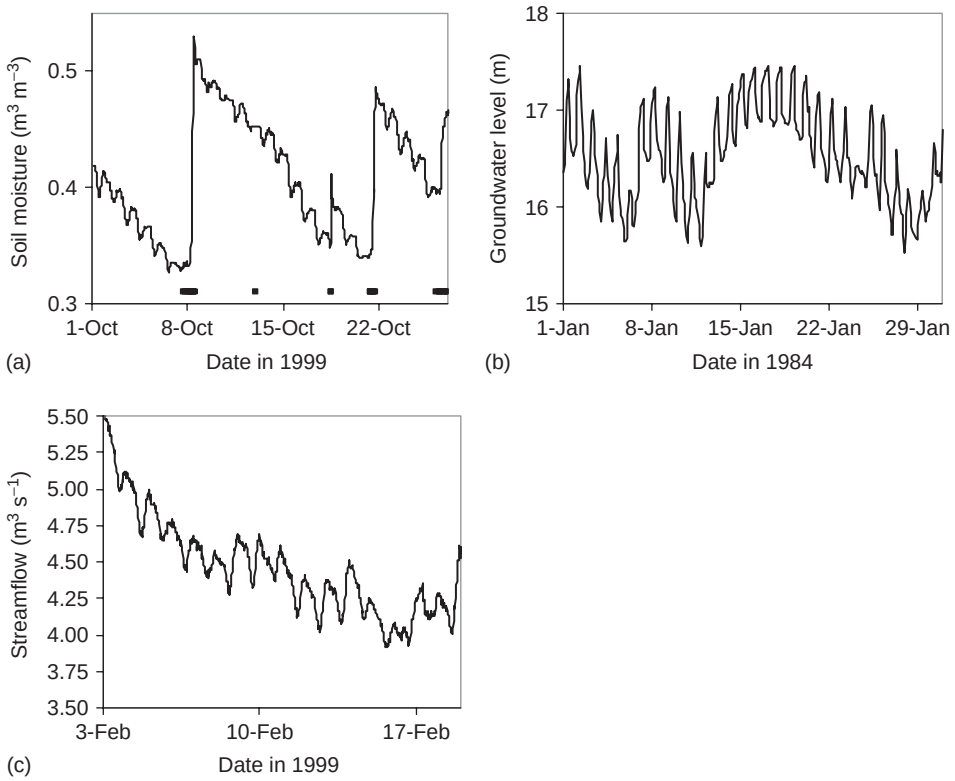

Figure 5 Examples of hydrological systems with strong diurnal cycles: (a) variations in soil moisture near Warkworth, northern New Zealand, caused by diurnal cycle in evaporation (horizontal bars indicate periods of rainfall); (b) variations in shallow groundwater level in Hawke's Bay, eastern North Island of New Zealand, caused by diurnal cycle in evaporation; (c) variations in streamflow on Jollie River at Mt Cook Station, central South Island of New Zealand, caused by diurnal cycle in snowmelt

pumped, then this can change the diurnal cycle significantly. River flow in the Maryburn River in the subalpine central South Island of New Zealand reaches a maximum in mid-afternoon when the peak of the snowmelt from its 52-km^2 catchment reaches the river flow-recording site. The cycle is most pronounced on rainless days in early summer when the seasonal snowpack is melting.

Storm Event

When precipitation falls as a discrete storm, separate from other storms, this is known as an *event*. There are many ways to define storms, so the timescale for events is not precisely defined, but typically ranges from a few minutes to a few days. At even finer timescales of a few seconds, there are significant effects of kinetic energy of raindrops in causing surface erosion. However, although the process might be understood at this timescale, it is treated in practice by estimating a time-averaged input of kinetic energy. The time-varying response of a hydrological system varies tremendously depending on the time pattern of the rainfall, the physical attributes of the land (including its management), the stored water at the beginning of the storm, and the spatial distribution of the rainfall. Figure 6 shows an example from the Mahurangi River at Sheepworld, a 2.6-km^2 catchment near Warkworth, northern New Zealand. For the purposes of this article, the message to be taken from Figure 6 is merely that streamflow responds nonlinearly to rainfall, that is, there is not a direct proportionality between rainfall and streamflow. Thus, temporal variability in rainfall is transformed or filtered by catchments. Understanding the transformation from rainfall to streamflow has occupied thousands of hydrologists for decades, because of its practical engineering significance and its apparent simplicity. Articles **Chapter 111, Rainfall Excess Overland Flow, Volume 3** and **Chapter 134, Downward Approach to Hydrological Model Development, Volume 3** explore this topic in detail.

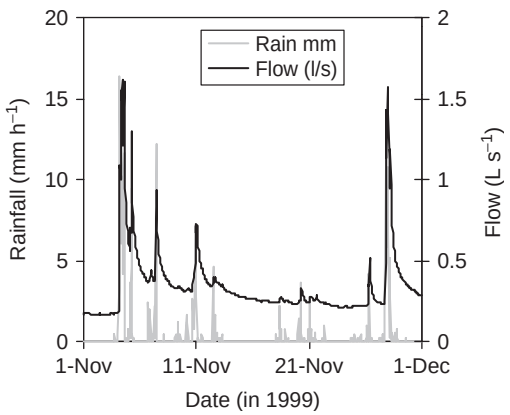

Figure 6 Event-scale variability in hourly rainfall and streamflow from the Mahurangi River at Sheepworld. The response to the small rainfalls over 18–21 November is disproportionately low

Extremes

An important and dramatic practical expression of temporal variability is the occurrence of extreme hydrological events – most obviously floods, severe snowstorms, and very high lake and groundwater levels, and also droughts and very low levels in lakes, rivers, and groundwater. The temporal distribution of floods depends greatly on the physical setting, with some regions having floods that occur at consistent times of the year because of the seasonal weather cycle and its interaction with the landscape and with water resource management, while others can have floods at any time of year, or in fact have years without any significant floods, or even any streamflow at all. The year-to-year variation in flood magnitude is very often treated using statistical techniques to assist in extrapolation from flood records of a few decades' duration up to events that might only be expected once a century, especially as part of the design of engineering structures. **Chapter 125, Rainfall-runoff Modeling for Flood Frequency Estimation, Volume 3** provides a detailed treatment of this subject.

Low river flows typically show less interannual variability than floods, mainly because the distributions of river flows are typically skewed towards lower values, and measured river flows cannot be lower than zero.

In the plots of flow data shown in Figure 7, two rather different examples of interannual variability are shown. The Grey River at Dobson, whose catchment lies in a very high rainfall area, has little year-to-year variation in flood size. In contrast, the much drier Hakataramea River only produces significant floods occasionally. One simple way to quantify interannual variability is to consider the largest or smallest value from every year of record, and then calculate the coefficient of variation (CV, i.e. standard deviation/mean) of this set of observations. Small values of CV (less than one) indicate that the years are similar to one another. The CV values for annual floods are shown in Table 1: for each river, the CV for low flows is less than the CV for floods.

More apparent in Figure 8 is the difference in the range of flows for the two sites. The range of flows in the Grey, from lowest to highest, is less than a factor of 100, whereas the range in the Hakataramea is more than a factor of 1000. Methods for characterizing and comparing the distributions of hydrological variables such as river flows are given in **Chapter 7, Methods of Analyzing Variability, Volume 1**.

Annual Cycle and Seasonality

The seasonal cycle is perhaps the most ubiquitous in hydrology: it is evident in many (but not all) hydrological systems. The causes and effects of seasonal cycles vary considerably

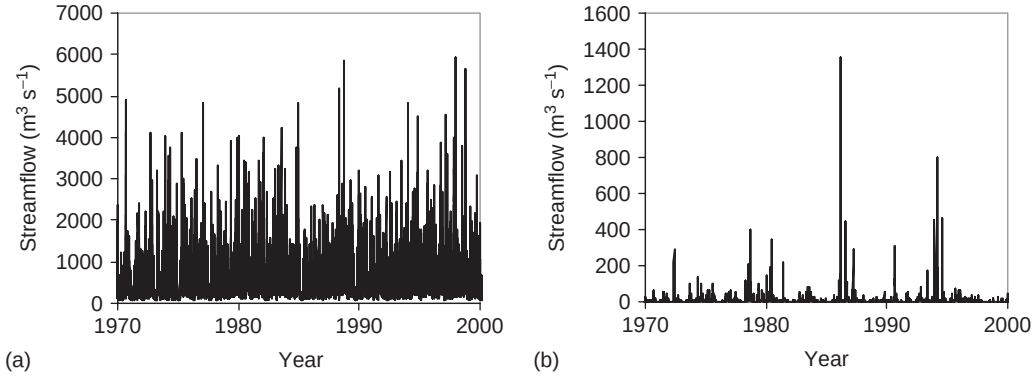

Figure 7 Illustrations of interannual variability in flood peaks: (a) floods vary little from year to year on the Grey River at Dobson (3830 km^2), on the west coast of New Zealand's South Island, where rainfall is frequent and substantial (catchment average annual rainfall exceeds 3500 mm y^{-1}); (b) substantial interannual variability in flood peaks on the Hakataramea River above Main Highway Bridge (899 km^2), on the much drier east coast of New Zealand's South Island (average annual rainfall is ca. 700 mm y^{-1}) (Data from both sites are recorded every 15 min, and the plots show daily maxima)

Table 1 Coefficients of variation for floods and one-day low flows in two contrasting rivers in New Zealand

River measurement site	CV of annual maximum floods	CV of annual minimum one-day flows
Grey River at Dobson	0.24	0.16
Hakataramea River above Main Highway Bridge	1.40	0.48

from region to region, and also across different elements of the hydrological cycle. For example, in regions where temperature is both above and below freezing, seasonal hydrological responses are driven by the accumulation of snow in the cold season and its release as meltwater in the warm season (Figure 9a). In more temperate regions without snow, where rainfall exceeds evaporation in winter, but the reverse is true in summer, water typically accumulates in soils and aquifers over winter (Figure 9b, c), possibly to the extent that water flows into rivers under gravity drainage (Figure 9d). In summer, the water stored in soils and groundwater reduces as plants draw on it to transpire, and gravity drainage gradually exhausts all the pore water it is able to influence. In both these settings, the observed temporal pattern of storage is as much the same (high in winter, low in summer), but the mechanism is different. Of course, there are many regions where neither or both of these descriptions may apply, and it is outside the scope of this article to provide a detailed classification and description of hydrological regimes.

Seasonal hydrological cycles are of tremendous biological, economic, and cultural significance to almost any phenomena that is affected by freshwater, and has response times of months or more. Hydrological seasonality is not only important to hydrologists! To give just a few examples, seasonal changes in soil moisture and rivers affect the growth and viability of almost every kind of terrestrial plant

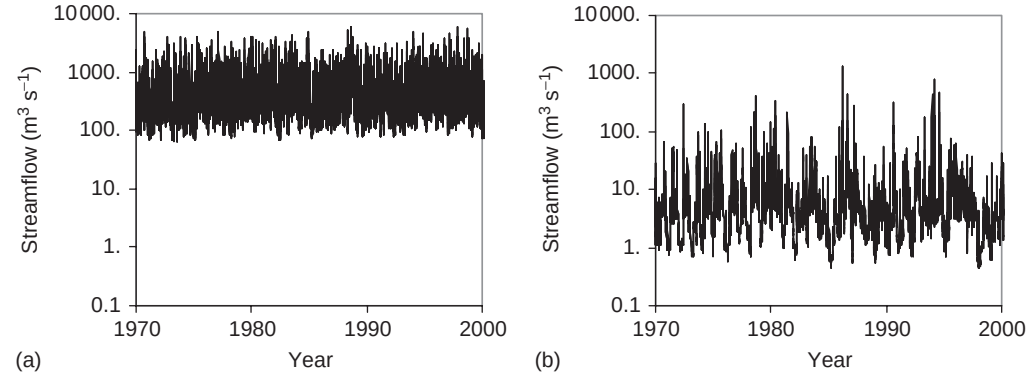

Figure 8 Interannual variability in low flows for the same two rivers shown in Figure 7: these two rivers have rather similar interannual variability in low flows (Data from both sites are recorded every 15 min, and the plots show both daily minima and maxima each day)

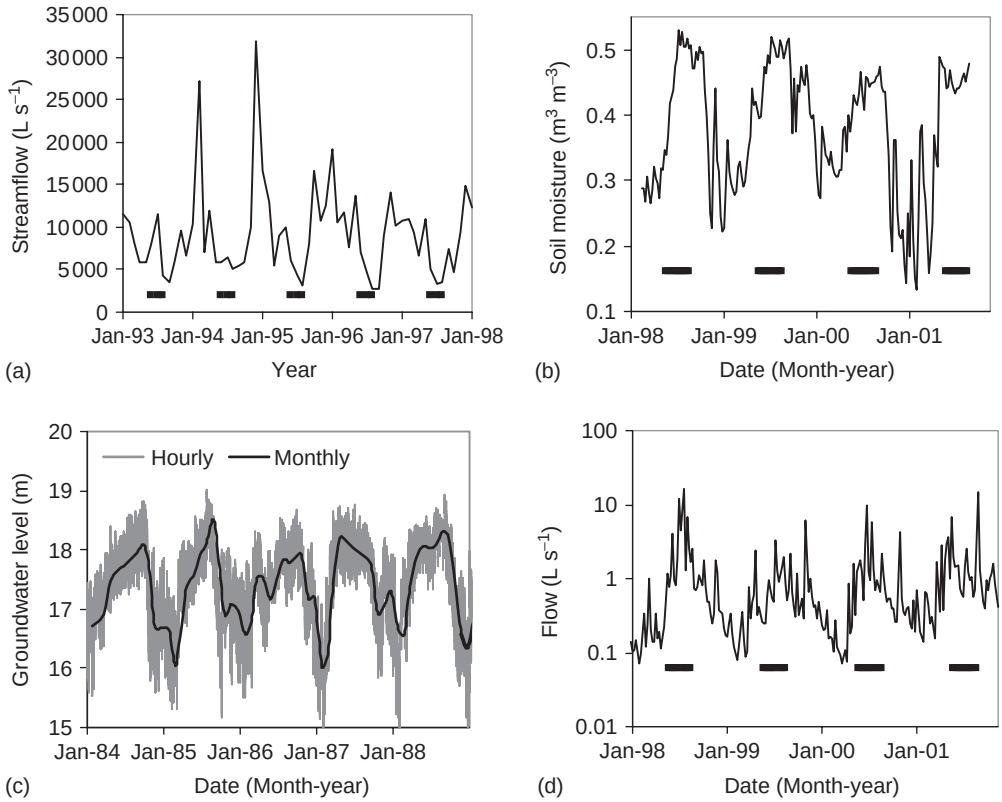

Figure 9 Examples of hydrological systems with annual cycles (horizontal bars indicate winter): (a) streamflow (monthly averages) in the predominantly snow-fed Jollie River, central South Island, New Zealand; (b) soil moisture (weekly averages) near Warkworth; (c) groundwater level (hourly data and monthly averages) on the Heretaunga Plains in Hawke's Bay, eastern North Island, New Zealand; (d) streamflow (weekly averages), for the Mahurangi River at College (46 km^2)

and creature. The availability of water in the warm growing season affects the economic viability of many kinds of terrestrial food production. Finally, many human activities and cultural constructs are centered on the seasons, for example, numerous forms of recreation that use freshwater and snow. It is not hard to see that any changes in the seasonal structure of hydrology would have very far-reaching effects, right across the planet.

Interannual Variability

At timescales longer than a year, detailed understanding of hydrological variability tends to be limited to those systems with long characteristic response times, such as deep groundwater systems and large lakes, which respond relatively gradually to changes in external forcing. In those systems, the impact of a particular event (e.g. a large input of water from a flood) may take years to propagate through the system, and so that system's response may be well understood. In more rapidly responding hydrological systems, our understanding is crucially dependent on understanding the behavior of the external systems such as climate. At timescales longer than a year, atmosphere–ocean phenomena, such as ENSO, PDO (Pacific Decadal Oscillation), and others, are understood to provide significant controls on interannual and interdecadal variations in rainfall, temperature, and solar radiation, all of which can significantly influence hydrology. Statistical analyses have shown that important linkages do exist between these ocean–atmosphere phenomena and local weather (e.g. Salinger and Mullan, 1999).

Finally, at multidecadal and century timescales, climate change can completely alter the hydrological cycle. For example, during previous ice ages, large portions of the earth's surface were permanently covered in ice. Over the last hundred years, a gradual increase in temperatures has occurred, and the most likely scenario is for this temperature increase to continue. This is likely to produce a long-term trend in recorded data for water temperature, snow occurrence, glacier size, and freshwater input to high-latitude oceans. In addition, but with less certainty, forecasts have been made that this global warming will lead to an accelerated hydrological cycle, with more intense rain and more evaporation (Watson *et al.*, 2001).

Hydrological Treatments of Temporal Variability

To summarize, hydrologists have a range of strategies for responding to temporal variability. We frequently resolve the variability down to days, hours, minutes, or even seconds using high-resolution recording instruments or explicit time steps in detailed simulation models. If this approach is impractical or inappropriate, we may select particular time periods of interest, and confine our study to those periods – the study of particular floods or droughts in hydrological systems is an example of this. Finally, where interest is predominantly in providing answers at longer timescales, but short timescale effects are known to be relevant, we may statistically summarize the short timescale variation and use mathematical techniques (e.g. Eagleson, 1978; Milly, 1994) to integrate over this variability.

SPATIAL VARIABILITY

Spatial phenomena in hydrology are mainly driven externally by spatial patterns in climate, soils, vegetation, topography, and geology. However at very long timescales, complex spatial organization develops which is created by the internal dynamics of the hydrological system. In surface hydrology, this self-organization appears to manifest itself in (i) consistent upslope-to-downslope structure of soils and hillslope geomorphology (e.g. Chappell and Ternan, 1992); (ii) regularities in channel network geomorphology (e.g. Rodriguez-Iturbe *et al.*, 1992, but see also Kirchner, 1993); and (iii) braided river networks (Sapozhnikov and Foufoula-Georgiou, 1997). However, our knowledge of how and why such regularities emerge remains very limited, and as a result, they (and other emergent features) have yet to find a place in a coherent theory of hydrology.

Geological variation is a dominant source of spatial variability in groundwater-dominated systems, and several distinctive approaches have been developed to conceptualize and quantify subsurface variability in hydrology (e.g. Anderson, 1997). A distinction between deterministic and random approaches is once again useful. The random (or stochastic) approach has been used to quantify a continuous model of heterogeneity, while more deterministic methods have typically been used when a discrete model of geological facies is employed.

For both surface and subsurface hydrology, the extremely complex nature of the problem and the difficulties in making comprehensive measurements have limited the amount of progress made, although in both cases very sophisticated approaches have been developed. Frequently, the level of sophistication in the concepts has outstripped our ability to collect data that might allow us to choose amongst the competing ideas.

In the light of the more complex, less well-understood situation with spatial variability, here some characteristic spatial patterns in a number of the driving variables known to influence spatial variability in hydrology are outlined. However, since it is not clear how these factors combine, we are unable to provide a clear synthesis at this stage. We conclude this section by summarizing a number of approaches currently taken by hydrologists to address the resulting challenges.

Climate

Climate and weather variability in space occurs in all three spatial dimensions, right down to the scale of a raindrop. Vertical variability is a relatively well-understood matter for meteorologists, but is generally neglected in hydrology, where the emphasis is generally on exchanges of water and energy at the ground surface. At the very fine scale of a raindrop, instantaneous rainfall is patchy and evaporative forcing is turbulent. However, if one considers average fluxes over timescales of minutes or more, then the corresponding spatial scales are correspondingly larger.

Within a rainstorm, there are numerous nested evolving structures, typically within any characteristic scale between the smallest turbulent eddy and the extent of the entire storm. Figure 10 shows several snapshots of a rainstorm at scales from hundreds of kilometers down to a few hundred meters. Structure and complexity is visible at every scale. This intricate system is generally either conceptualized as a continuous hierarchy of scales, linked by some form of self-similarity, or as a discrete hierarchy of macro-, meso-, and microscales.

In locations where the vertical relief provided by hills and mountains is significant, an additional feature is typically found – rainfall tends to be greater at higher elevations. More specifically, rain is typically greater on the upwind side of mountain ranges, where orographic uplift causes rapid cooling of the air. Such cooled air has less capacity to hold moisture, and excess water is precipitated as rain or snow. On the downwind side of the range, the air is able to warm again, and rainfall may be lower, because of the increased moisture capacity of the air. In cases of extremely steep mountains, the downwind rainfall may also be lower if much of the moisture in the air column is rained out on the upwind side.

At the very largest spatial scales, one finds a climate regime – that is, a region with a characteristic set of seasonal weather patterns. Thus, one has, for example, a Mediterranean climate, with cool wet winters and warm dry summers, in contrast to the humid tropical climates found near the equator. The Köppen climate classification (Trewartha and Horn, 1980) provides a formal list of climate types with operational definitions that have been mapped for the globe.

The pragmatic response of hydrology to within-storm spatial variability is to make a very limited attempt to resolve the within-storm spatial patterns. Only recently

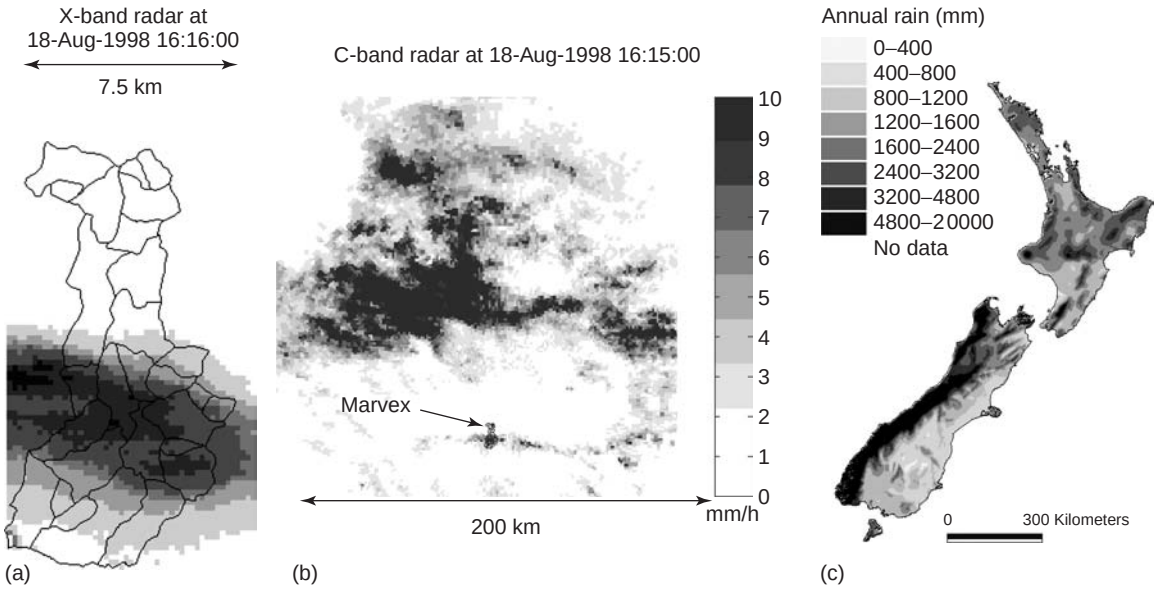

Figure 10 Spatial rainfall patterns for three space-time combinations (a) hourly rain over a 15-km radius near Warkworth, northern New Zealand; (b) hourly rain over a 200-km radius near Auckland, New Zealand; (c) estimated average annual rainfall over New Zealand

have weather radar and numerical modeling technology begun to show promise of reliable quantitative estimates of rainfall. The lack of spatial knowledge has greatly restricted progress in understanding surface hydrology. However, it has had little effect on groundwater hydrology, which is relatively unresponsive at the timescale of a storm. Spatial patterns driven by orographic effects are better understood, but spatial gradients are substantial and often poorly measured. Climate regions are generally well resolved in space and time – over small study areas, the existence of a single region is generally taken for granted.

Soils

Soils develop as a result of interactions between geology, climate, topography, vegetation, and biological processes; this happens over periods that are long in comparison to many hydrological timescales. In geologically young landscapes, the evolution of soils is actively linked to the hydrological cycle. As a result of the numerous factors affecting soil formation and development, soils show complex spatial patterns.

The soil pedon, at a scale from a millimeter up to no bigger than a fist, provides discrete three-dimensional objects around which water may flow preferentially; such flow is a significant cause of complex water and solute movement. The study of macropore flow is an active area of research; suitable research concepts are beginning to emerge, but much remains to be done in order to provide a quantitative assessment of the effect of macropore flow. Water flow within a pedon, known as *matrix flow*, is a well-advanced topic of soil physics, with a relatively mature understanding of the dominant processes. However, the application of this knowledge at larger scales is problematic, because pure matrix flow usually occurs only over short spatial scales.

As one moves downward from the ground surface, soils typically show sharp vertical contrasts in their physical properties, including porosity and permeability. These layers of soil are known as *horizons*, and they play a major role in surface water hydrology, through their ability to limit vertical flow of water and redirect it downslope. Once we descend more than a few meters below the surface, horizons tend to be thicker, but the material is now geological, not soil. We discuss geology in the next section.

In the presence of sloping land, soils typically show a topographically related structure, with shallower, lighter soils on the upper slopes of hills, and deeper, heavier soils at the base of the slope, where soils are generally wetter. This spatial arrangement is known as a *soil catena*. The direct observation of soil properties using core or point-based measurements is rarely practical as a method of obtaining highly resolved spatial soils data. Within limited spatial extents, the above spatial associations between soil and topographic position provide a potential method for mapping spatial patterns of soils. Remote sensing techniques, for example, microwave, ground-penetrating radar, and electromagnetic induction or resistivity, do provide alternative methods for obtaining spatial soils information, though not always in traditional formats.

Except in experimental settings, hydrologists tend to use rather generalized soil maps developed by soil scientists. Soil maps typically define a type of soil within a defined

region. However, since the hydrologist is typically concerned with water (and solute) storage and movement, recourse is needed to a table of physical properties for each type of soil, known as a *pedo-transfer function*. This rather generalized approach has tended to limit progress.

Geology

Geology has all the complexity of soils, but over a much deeper and less accessible region, well below the earth's surface. Anderson (1997) has recently reviewed the geological heterogeneity of sedimentary systems and provides two complementary views of heterogeneity: continuous and discrete. In the continuous view, statistical descriptions are used to describe random fields of hydrogeological properties such as permeability and porosity. The discrete view, on the other hand, emphasizes recognizable structures, known as *facies*, which are effectively homogeneous. In either case, the essential feature is that some regions permit more rapid flow and transport than others, and that the relative locations and extents of these regions are important. *See* **Chapter 9, Statistical Upscaling and Downscaling in Hydrology, Volume 1** for more details on this topic.

Mathematically sophisticated models of flow and transport have been developed on the basis of statistical models of geology. These models enable predictions of heterogeneous flow fields. However, the challenges of obtaining enough geological data to parameterize these models still make the task a challenging one.

Vegetation

Vegetation interacts strongly with the hydrologic cycle, both in influencing water movement and being affected by water availability. In this respect, it is rather like soil. However, the timescales for vegetation are much shorter in some cases, given that the lifetime of a plant may be as short as a few weeks. On the other hand, plant communities can continue at the same location for centuries, if suitable conditions persist.

At the finest scale of an individual plant, the spatial pattern of plant roots (and water uptake) or the presence or absence of a plant's canopy over the ground surface (controlling throughfall) can cause spatial patterns of moisture content at scales of centimeters, below and in between plants. At scales of tens of meters in landscapes with sloping land, one may find the same arrangement as found in a soil catena, with different types and amounts of vegetation at the base of the slope, because of the relative abundance of soil moisture at the bottom of the slope. In addition, differences in the topographic aspect of a hillside may cause differences in solar radiation, and thus in evaporation.

At scales from a few meters to many kilometers, plants may form communities with particular mixtures of species that form a community. The plant canopy will typically show some vertical structure, with one or more upper stories and an understory. At larger scales than this, plants tend to reflect the climate and physiography of the region, and community composition may change in response to long-term changes in climate.

Topography

The rich structure of topographic variability interacts with hydrology at scales ranging from microtopography (1–1000 mm wide depressions and rills) to hillslopes (10–1000 m long) and stream environments (0.1–1000m wide), up to channel networks (1–10 000 km long). Each environment hosts distinctive hydrological processes and spatial complexity.

Microtopographic features are generally sufficiently numerous and variable, in relation to most field studies and practical applications, that they are treated using either a representative uniform value per unit area or by statistical approaches. For example, depressions in the land surface that may provide storage of water can be approximated as an equivalent storage capacity per unit land area, while rills could be assumed to occur at regularly spaced intervals across a hillside.

Hillslopes and streams are large enough in relation to some hydrological studies that their spatial structure may be resolved in two or three dimensions down to the meter or submeter scale (e.g. from topographic survey), in order that the spatial structure of water movement along or within them is explicitly investigated. For studies at larger scales, more generalized approaches are often taken, where, for instance, a hillslope may be represented using a sloping plane or another suitable geometric model. Similarly, a generalized stream geometry may be used to represent the broadscale details, using perhaps a trapezoidal cross section and planar long section.

Similarly, the tremendously rich three-dimensional geometric detail of channel networks extending over thousands of kilometers can be represented either explicitly (albeit only down to the resolution of the available data) or in summary form, or as a statistical summary of the distances (or travel times) which water moving along the channels must cover in order to traverse the network.

Figure 11 shows the predominantly hilly topography of New Zealand at a range of spatial scales, from a few hectares to thousands of square kilometers. Since surface topography is readily accessible to many measurement techniques, enormously rich data is now available in some locations. As a result, topography is a common source of spatially detailed data in hydrological studies, often without equivalent detail in other hydrologically relevant fields, for example, precipitation, whose spatial patterns are often very important but difficult to measure.

Catchments and Aquifers

Catchments and aquifers are the dominant human-scale hydrological systems in which all the factors listed above can interact. With so many different sources of spatial variability all influencing water storage and movement, each with multiple spatial scales, it is perhaps no surprise that spatial variability in hydrology is only dimly understood at present.

What do we know about spatial variability in hydrological responses such as soil moisture, evaporation, groundwater, and streamflow? We know that almost all these patterns are difficult to observe in detail, and in the common situation when the observational data is limited, the patterns are difficult to interpret. Putting aside these very serious limitations for one moment, we can say that large differences from place to place in precipitation (e.g. a factor of two or more) generally lead to pronounced differences in hydrology. In fact, such strong spatial gradients of precipitation are generally sufficient to overwhelm almost any other differences, say in soils, vegetation, geology, or topography. However, in places where the spatial precipitation gradients are subtler, all the other factors are potentially of great importance, and it is not yet possible to make general statements about the detailed interactions of all these factors.

Instead, we may make some statements about the effects of patterns in each of these factors, assuming no variability in any of the others. Other things being equal, one may generally find that forested areas have more evaporation, drier soils, and lower streamflows, when compared to areas with short vegetation. Similarly, areas with a high proportion of clay soils can only infiltrate water slowly; if the rain falls mainly as intense, infrequent storms, then soil moisture is only occasionally replenished. The flow of streams in these areas will fall quickly as summer comes. Steeper terrain causes water to flow towards flatter locations, where water tends to accumulate and move more slowly. Along the same lines, geological structures with thicker layers or larger pores can store more water and will respond more slowly to temporal changes in inflows. Most of these generalizations are based in interpretations of rather limited spatial data sets, often in the presence of confounding effects from other variables. For detailed examinations of spatial patterns in hydrology, see the collection of studies by Grayson and Blöschl (2000).

In response to these difficulties, a number of strategies have been evolved. The first step to managing the complexity is usually to limit the spatial extent of the study area as much as possible, and to assume simple boundary conditions so that flow enters and leaves the study area in as few ways as possible. Thus, catchment boundaries and impervious strata are both commonly used no-flow boundaries. The second step is to assume that at most only one or two of the above sources of variability are significant. Thus, one might build a groundwater model with detailed geological heterogeneity, but assuming that rainfall and recharge are effectively spatially uniform. Or, one might model a catchment using a detailed spatial representation of precipitation, but assuming that soil and vegetation characteristics are effectively uniform.

More sophisticated treatments of spatial patterns may seek to identify a characteristic spatial scale over which spatially averaged quantities are calculated. The assumption here is that the details of finer-scale heterogeneity may be neglected without losing important information. The representative elementary volume (REV) idea (Hubbert, 1956; Blöschl *et al.*, 1995) provides a clear example of this approach, with the REV being defined in order to average over the pores and grains in a porous medium, and an equivalent continuum representation for flow being assumed to apply at the scale of the REV. This concept forms the conceptual basis for much of groundwater hydrology. However, it relies on the assumption that variability at scales larger than the REV will be resolved – in practice, this is not always simple because of the difficulty of collecting sufficient data. However, the continuum approach remains a generally accepted paradigm for groundwater.

Inspired by the REV, an entirely analogous concept, the representative elementary area (REA), has been suggested for catchment hydrology (Wood *et al.*, 1988). It was suggested that the REA might provide an averaging scale suitable for a continuum representation of hydrology, and this idea has been further extended by Reggiani *et al.* (1998), to a representative elementary watershed. However, considerable challenges still remain in (i) identifying an area that is truly representative, rather than simply being an arbitrary averaging area and (ii) finding physically meaningful ways to parameterize the effects of subarea heterogeneity: this latter task will remain extremely challenging until characteristic forms are determined for the heterogeneity.

Following several reviews of REA ideas, some attempts to generalize from the REA concept have included the Dominant Length Scales idea of Seyfried and Wilcox (1995), the Dominant Processes Concept of Grayson and Blöschl (2000), and dominant sources of space-time variability by Woods and Sivapalan (1999). However, at this stage, it is fair to say that our concepts of spatial pattern in surface hydrology remain incomplete, being either too qualitative or too limited in applicability to form the basis of a widely adopted approach.

SPACE-TIME VARIABILITY

The ultimate challenge in the context of this article is to combine temporal and spatial variability at a wide range of scales. If a hydrological system is highly damped, then it may be reasonable to view the system as a succession of steady states. However, in most cases, space variability is intimately linked with temporal evolution. At this early stage of understanding, most of our knowledge on space-time variability in hydrology is preliminary based on a small number of hydrological datasets and on simulation models that are not validated in detail. The concepts are perhaps easiest to grasp if one thinks of a time sequence of images, each showing a bird's-eye view of a catchment or aquifer at a moment in time. What is the nature of the movie formed from these images? What do the images look like? How does this change if we look closely at part of the image? What controls the way the images change over time? Do they change smoothly or abruptly in time?

Aquifers are generally dissipative systems, using their storage capacity to filter out high-frequency variability in both space and time. However, heterogeneity, such as localized areas of fracturing or high transmissivity, will cause localized changes in flow, distorting the smoothness that might otherwise predominate.

Similar concepts apply for catchments as well, but across a wider range of timescales. At the very short timescales of storms in river catchments, the complex time-space patterns of weather are concentrated in space by catchments (via downslope flow in hillsides towards valley bottoms and via flow along river networks towards larger streams), and also filtered in time (temporal oscillations are typically damped by the variety of travel times present in a catchment) (Sivapalan *et al.*, 2001). To take a specific example, imagine a catchment with travel times in the river network that range from 3 h for the most remote parts of the catchment, down to zero for places at the catchment outlet. Water that is in the river at the catchment outlet at 3 P.M. is then a mixture of rain that fell at the outlet at 3 P.M., and rain that fell at noon in the upper reaches of the network (and every space-time combination in between). The spatial extent of the catchment, combined with the travel times through it, provides this space-time filtering. Water from different places and times are mixed together by the catchment, damping out both the spatial and temporal variability.

To understand these complex systems, we need to understand both the space-time features of the driving forces and the processes by which they are transformed into hydrological responses. At present, it is common to think of rainfall and radiation as providing the space-time drivers, while soils, vegetation, topography, and geology are viewed

as static, and provide only spatial variability. Of course at longer timescales, even these "static" environmental variables do change significantly over time, for example, through land use changes, soil development, and landscape evolution. The interactions among all these fields lead to space-time fields of hydrological variables such as evaporation, snowpack, soil moisture, streamflow, and groundwater.

Rainfall

As a space-time phenomenon, rainfall is astonishingly variable. As well as the fundamental differences between storm types that cause rain (e.g. thunderstorm vs. stratiform rainfall), rainfall has complex space and time structures right down to the raindrop. The dominant paradigm is that of a complex spatial structure that both moves in space and evolves over time. The spatial element plays the dominant role in the description and time acts as a modifying agent over which spatial patterns change. Somewhat analogous to the treatment of geological heterogeneity as either continuous or discrete, there are two conceptual approaches to the spatial aspect of rainfall models. Fractal and multifractal models (e.g. Seed *et al.*, 1999) use a cascade of nested structures: a simple relationship explains the connections between spatial scales purely as a function of the ratio of those two scales. In this model, the same essential spatial structure is repeated over and over again at a continuum of spatial scales. Discrete conceptual models are still nested spatial models, but these instead use just a few discrete concepts, such as storm, large mesoscale area, small mesoscale area, and storm cell (e.g. Sivapalan and Wood, 1987).

In general, such models typically have parameters that must be estimated from observed rainfall, rather than directly evaluated from knowledge of atmospheric physics. This has limited the transferability of such models to regions without space-time rainfall data, and they remain an active area of research.

Streamflow

Observations of the detailed space-time response of streamflow, or indeed the entire hydrological cycle, are extremely rare, and as a result, our understanding of such fields is limited. Several theoretical constructs have been suggested (e.g. Woods and Sivapalan, 1999), but all such theories await comprehensive data suitable for validation. Most attempts to construct these theories concentrate on a limited range of timescales (e.g. flood only) and are relevant to a limited range of hydrological settings. Much theoretical work remains to be done in this area, but little progress can be expected without more comprehensive data. An attempt to measure multiple sources of hydrological variability at multiple scales is described in Woods *et al.* (2001), but no conclusive results have emerged at this stage. Figure 12 shows the time-evolution of spatial patterns in both rainfall and streamflow, showing some indication of the spatial damping role played by catchments, and also some unexplained variability.

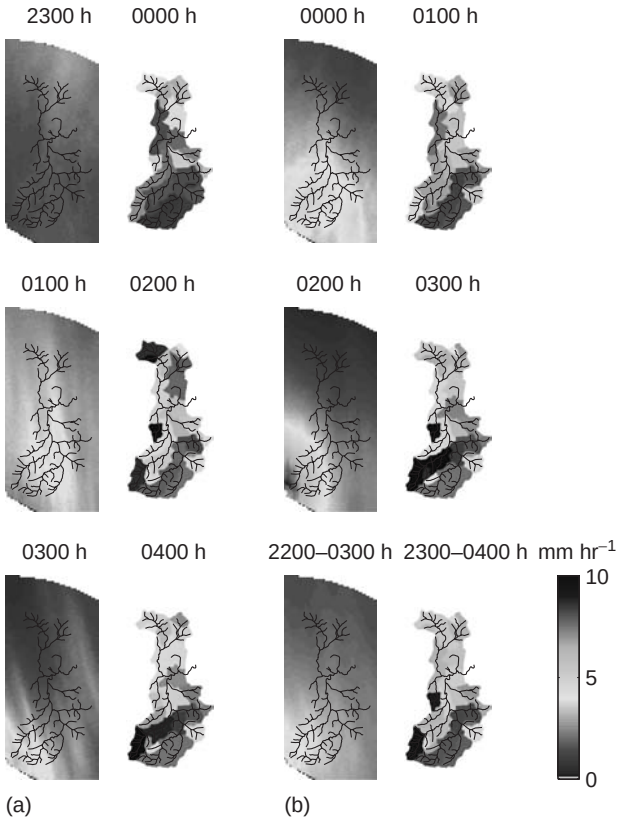

Figure 12 A time sequence of spatial patterns of rainfall and streamflow in the Mahurangi catchment in northern New Zealand. Rainfall (a) and flow (b) are shown in pairs, with rainfall for the previous hour associated with each hour of flow, since the catchments have a response time of the order one hour. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Soil Moisture

Detailed and spatially extensive space-time observations of soil moisture have permitted significant progress in understanding its variability. Grayson and Western (1998) have identified a consistent spatial structure over time in small experimental areas, and proposed the observational concept of catchment average soil moisture monitoring (CASSM). The idea is that some locations in the landscape are consistently good indicator sites to represent spatially averaged soil moisture. Such an approach provides spatial information through the assumption that the site is representative, and provides the temporal information by monitoring continuously at just the CASSM site. Additional observations have suggested that spatial patterns themselves may show a

switching behavior over time in some settings, from a predominantly topographically controlled pattern when soils are relatively wet to a predominantly soil-controlled pattern during drier periods (Grayson *et al.*, 1997).

Recently, a relatively comprehensive theoretical framework has been proposed for space-time variability of soil moisture (Albertson and Montaldo, 2003), and this may go some way to interpreting the time-evolution of statistical spatial variability in soil moisture.

SUMMARY

Variability is fundamental to hydrology. Without it, we would have solved most of our great challenges decades ago. To make useful quantitative statements about variability, we need to quantify and summarize these place-to-place or time-to-time changes. Table 2 provides some examples of the approaches taken to conceptualize and quantify hydrological variability in space and time.

Early efforts to interpret variability have been confounded by the changes in variability that occur as scale changes. The recognition of spatial scale as a controller on the expression of variability has at least allowed us to understand why spatial hydrology seems so complex, but much remains to be done both in terms of measurement and theoretical constructs. There are numerous options for making progress on hydrological variability, depending on the nature of the variability.

At the coarsest level, we lack a fundamental context in which to place our knowledge of variability. For example, suppose you are somehow able to unravel the intricacies of time and space variability of some aquifer or catchment. How do we decide whether your hard-won knowledge can be applied elsewhere? Surely some of your conclusions will carry over to other similar systems elsewhere, but how do we define "similar"? The scientific hydrology community has no globally agreed way of assessing similarity, and this is a considerable impediment to the transfer of information and the assembly of meaningful international data sets for comparative studies (McDonnell and Woods, 2004). Securing agreement on this ought not to be onerous or time-consuming if we set realistic expectations for a relatively general, but widely accepted, system for determining broad similarity. Once the basic elements of such a classification method is that in place, they can be refined to suit local or specialist needs as required.

At the technical level, much is still to be gained from improving our measurement technology, in order to observe variability in hydrology (e.g. evaporation, soil moisture, mountain catchments) and in the key drivers (e.g. precipitation, geological structure). Recent advances in measurement have stimulated new conceptual approaches, and we must remain optimistic that this will remain a fruitful source of inspiration. Most difficult, but potentially rewarding, would be improvements in subsurface measurement techniques, for there we are often working almost "blind", generally with at best a peephole view of the hydrology.

It seems that many of the questions about temporal variability are well understood, at least for timescales from seconds up to years. This is in part due to the relative ease with which we can measure at high temporal resolution for years at a time, and in part due to the small number of dominant sources of temporal variability (mainly climate). At timescales of decades and longer, we are at more of a disadvantage simply because we do not have good quality observational data over sufficient time with which to investigate the questions. This problem seems unlikely to be fully resolved for several decades, unless longer historical records of hydrological response can be reconstructed.

Every step forward in understanding variability at various spatial and temporal scales is crucial to advancing the theoretical underpinnings of hydrology. We strongly suspect that some of our concepts are inappropriate or incomplete, and frequently this is because our treatment of variability is suspect. For example, the effect of macropores on hillslope water flow remains poorly developed, and as a result, our detailed models of water movement do not usually include macropores. It is possible that much of this difficulty occurs because we do not know how to represent the spatial occurrence and connectivity of these pathways. If that problem

Table 2 Examples of deterministic and random views of hydrological variability

	Deterministic	Random/statistical
Temporal	• Time series (for many variables) • Constant value (e.g. temperature of deep groundwater) • Diurnal cycle (e.g. solar radiation, evaporation, snowmelt) • Annual cycle (e.g. soil moisture, snowmelt, streamflow)	• Rain bursts • Occurrence and magnitude of storm events • Occurrence and magnitude of floods and droughts • Interannual variability in climate
Spatial	• Map (where possible, e.g. vegetation type, topographic elevation) • Constant value • Transect along hillslope catena • Transect across mountain range (orographic uplift and rain shadow)	• Climate statistics • Soil • Geology • Microtopography

were solved, it is possible that familiar dynamical equations could then be solved in some as-yet unquantified geometry. Then again, a completely new approach may be needed. In a more general sense, there is still a considerable legacy of thought that the idea of an equivalent homogeneous medium exists, which has essentially the same hydrological characteristics as the spatially heterogeneous medium of the real world. This concept has pervaded both surface and subsurface hydrology for many decades, but now seems certain to be superseded by approaches that acknowledge the crucial role of spatial heterogeneity. There are many hydrological questions, especially those connected with the transport of solutes and particulates, for which a typical medium is not especially helpful. Often, the key attribute of such a transport system is in fact not the typical path but the fastest or most effective transport path.

Given the very limited current observational capabilities for spatial hydrology, it seems almost certain that the next major advances ought to come in this area. Some of this progress seems likely to emerge from the fusion of simulation models of the hydrological cycle with remotely sensed data. Hydrologists will need to continue to actively engage with the remote sensing design process in order to ensure that the data collected not only has desirable space-timescales but is also as sensitive as possible to both water and energy.

As hydrologists gradually solve the problem of characterizing spatial and temporal variability at a wide range of scales, across a variety of hydrological settings, we will be ready to focus our attention on the dynamics. Hydrological dynamics went through a tremendous period of growth and innovation in the 1960s and 1970s, to some extent because temporal variations were sufficiently well observed and conceptualized that the time was ripe to explore the dynamics. Let us hope that we will soon be in the same position with regard to space-time variability!

Acknowledgments

I wish to thank the many organizations that provided data used in this article, including New Zealand's National Institute of Water and Atmospheric Research (NIWA), the University of Auckland, Auckland Regional Council, Hawke's Bay Regional Council, University of Melbourne, and Meridian Energy Limited. I also wish to acknowledge the advice and patience of my editors, Günter Blöschl and Murugesu Sivapalan.

4: Organization and Process

MIKE KIRKBY

School of Geography, University of Leeds, Leeds, UK

Water, its movement, changes of state, and chemistry, is fundamental to the nature of planet Earth. It is involved in the most important processes near the surface and supports life as we know it. Hydrological sciences potentially address all aspects of water movement and transformation, although with major divisions between hydrology, which is essentially focused on the principle of conservation of mass; hydraulics, based on conservation of momentum (Newton's laws of motion); and meteorology, based on the laws of thermodynamics. This review of processes takes a primarily hydrological viewpoint, concerned with where water is, its pathways, and impacts on other aspects of the environment. A good understanding of these processes is an essential prerequisite to modeling and forecasting the behavior of water, and much of the history of hydrological science reflects changes in our conceptual understanding of how and where water moves. The main theme of this article is the way in which the landscape influences the flow of water, particularly surface hydrology, and how the hydrology in turn influences the form of the landscape.

Introduction – The Hydrological Cycle

Water has a number of properties that give it an overwhelming influence on the environment and life of planet Earth. The equilibrium temperature of the Earth's surface at about 15 °C is a balance between incoming solar radiation and outgoing long-wave radiation at the ambient temperature, with important secondary corrections for atmospheric and albedo effects (*see* **Chapter 25, Global Energy and Water Balances, Volume 1**). Water is able to change in state between solid, liquid, and vapor at a range of temperatures that are close to this equilibrium, and so plays a large part in providing a global thermostat, with substantial areas of ice, open water, and atmospheric vapor that interact to control regional temperatures and energy flows between low and high latitudes.

On geological timescales, water is exchanged with the earth's crust, principally through burial in sediment, subduction along tectonic plate boundaries, and release in volcanic eruptions, leading to the large volumes of water in the oceans today. In the global circulation of water (Figure 1) over shorter time spans, a few large reservoirs dominate the storage of water and, through their slow turnover, act to moderate the circulation processes and the weather (UNESCO, 2000). The smaller stores, and those most intimately associated with surface water hydrology, are the atmosphere, rivers, and soil moisture. With high fluxes and short residence times, these stores are characterized by high variability in time and space, giving surface hydrology its dynamic character and large regional contrasts.

Catchments have residence times that increase with their catchment areas. For small catchments, residence time is limited by the response time for soil moisture that stores and releases precipitation, whereas the response time for larger catchments ($>>100\,\mathrm{km}^2$) is determined more by travel time through the channel network. Because of their longer residence times, larger catchments respond more strongly to storms that both cover greater areas and have longer durations, whereas small catchments typically respond most strongly to localized intense storms.

The atmosphere ultimately draws its water from the greater evaporative potential of the oceans, and can only maintain its moisture supply over the continents by exchanging water and thermal energy with the land and vegetation through rainfall and evapotranspiration. The global distribution of hydrological regimes can be characterized by the interaction of precipitation and evapotranspiration, which is strongly related to temperature. The seasonal patterns of these variables immediately give a strong indication of the overall pattern of hydrological responses (Figure 2).

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

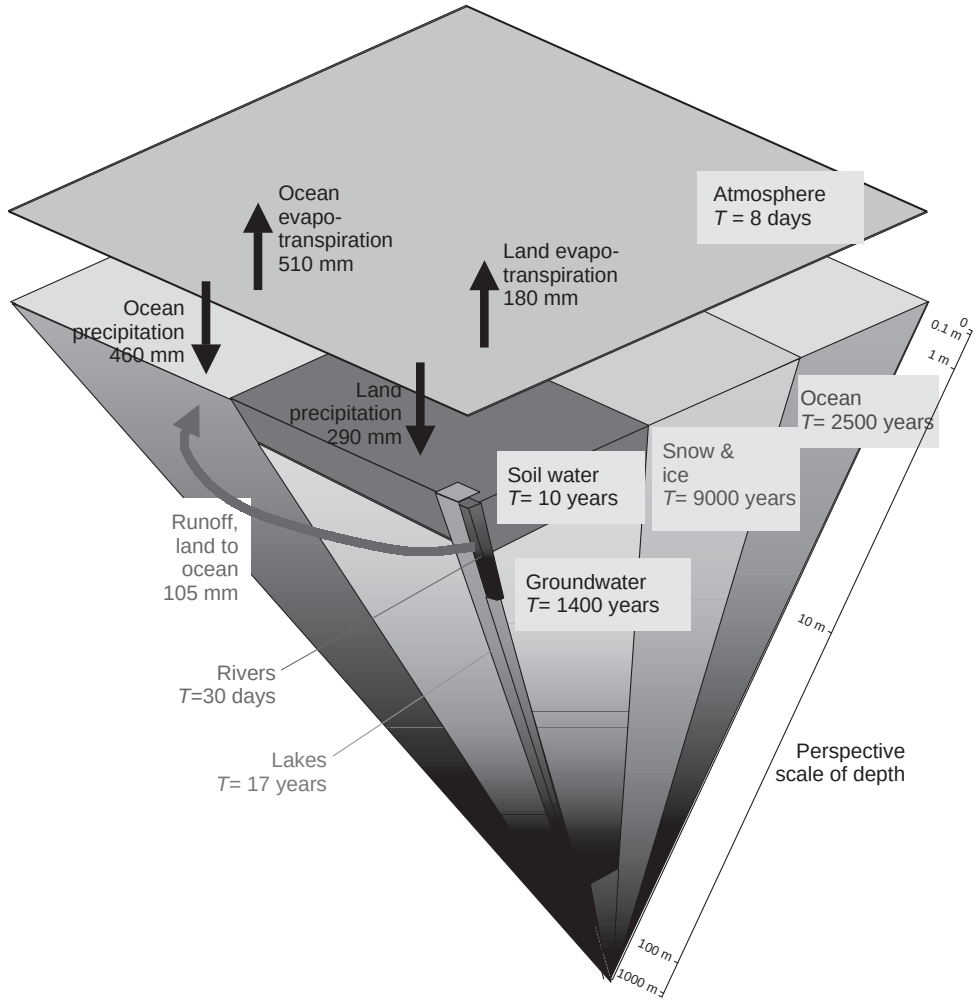

Figure 1 The global hydrological cycle on an annual scale. The area of each block indicates its areal extent, and the depth, on a perspective scale and its mean depth over its area. *T* indicates residence time in each store, and arrows show major transfers between the principal stores. Geological and other long-term exchanges are not included. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Where potential evapotranspiration exceeds precipitation, there is little soil moisture and most runoff is associated with infiltration of excess overland flow. Where potential evapotranspiration is less than precipitation, runoff is associated mainly with saturated conditions. In between these extremes, the role of groundwater is potentially greatest, with significant recharge that can then act as a dominant supplier of runoff where bedrock lithology and structure allow significant transmission of water. Finally, cold conditions lead to precipitation as snow and frozen soil, giving regimes where seasonal melting becomes the dominant hydrological process. Many areas show a significant seasonality so that the dominant processes may change throughout the year, as indicated for some of the example areas sketched in the figure. These issues are pursued in greater detail below, with their implications for and dependencies on the landscape form.

HYDROLOGICAL PATHWAYS

All of the various hydrological processes and pathways discussed here are examined completely elsewhere in the Encyclopedia. The focus here is on the interactions with geomorphological and other processes that help to determine the importance of each pathway. With only few and generally minor exceptions, the surface skin of the landscape acts as a one-way system that transports water, sediment, and solutes downhill and downstream, ultimately towards the sea. Gravity drives this one-way system and water is usually its direct or indirect agent. Its gravitational potential is constantly being renewed by the solar energy that drives evapotranspiration, and about 0.1% of this energy is used to erode the land. Only very small amounts of material are recycled in precipitation, and the continual downward movement of earth materials would

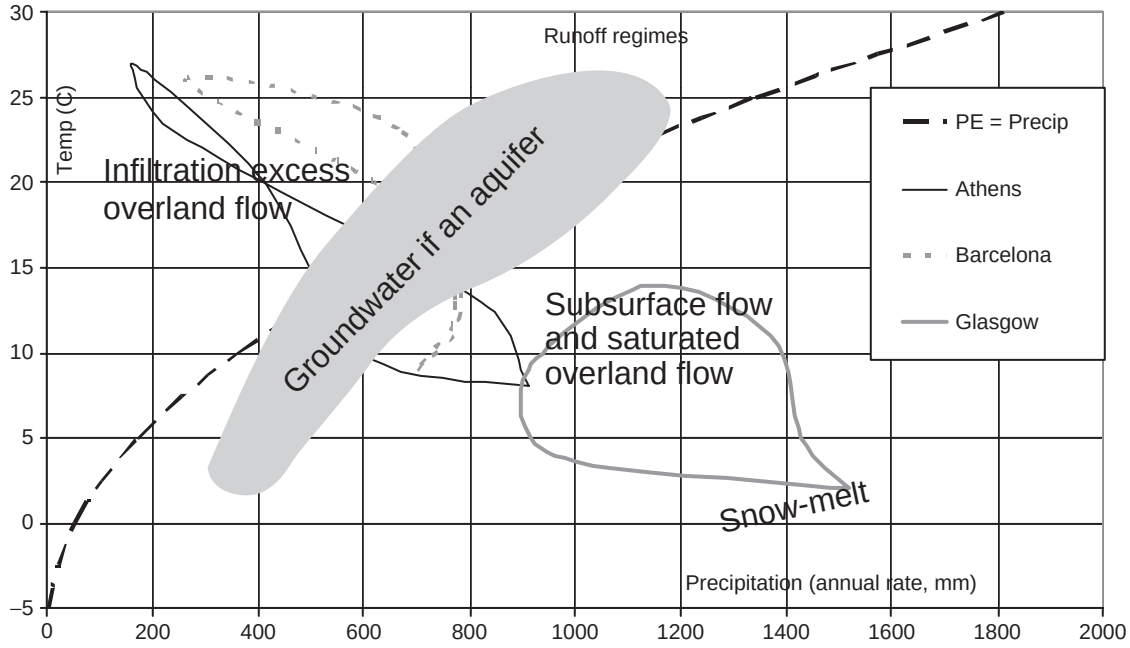

Figure 2 Hydrological regimes in terms of seasonal variations in temperature and precipitation. For the three example areas, monthly values for precipitation (P) and evapotranspiration (E), associated with temperature show the overall hydrological regime over the year. Arid conditions occur where P >> E, humid conditions where P <= E, and cold-dominated regimes where the temperature is below freezing. Groundwater is most important, in the presence of an aquifer, where P and E are similar, because there is substantial infiltration without dominance by shallow subsurface flow

therefore reduce the continents to a low-lying plain over 10–100 million years if they were not periodically uplifted through tectonic activity.

During the denudation of the land, geomorphological processes bring about a structural organization of the land surface that is broadly related to the hydrological regimes shown in Figure 2. The style of the landscape is a response to the mechanisms and potential to export water and earth materials to the oceans. In permanently cold regions, at high latitudes and at high elevations, landscapes are dominated by glaciers and ice caps that convey water as ice, both across broad ice shelves and in relatively narrow ice streams and glaciers focused on topographic depressions that convey most of the ice and the eroded sediment. In humid regions, landscapes are organized into a strong hierarchy of branching river networks, with the 12 largest rivers draining half of the land area. For both ice streams and rivers, the organization into dominant paths indicates a nonlinearity in the driving processes. This nonlinearity is much more marked for sediment transport than for rivers, and the valleys in which they flow are necessarily produced as eroded depressions in the land so that structural organization may be primarily a response to sediment flow rather than hydrology on its own (Kirkby, 1993).

Only the most arid areas show a lack of organization, with internal drainage and sediment accumulation where all precipitation can evaporate without draining to the sea, and wind (that does not respect the gradient of the land) may be the most important agent of sediment transport. Even arid areas, however, eventually develop drainage networks, partly as sediment fills depressions and creates continuously sloping pathways to the sea, and partly as a relic of previous, more humid climates, as global climates have changed and tectonic plates have moved. On the boundary between humid and arid regimes, limestone regions may mimic aridity by allowing water to percolate downwards, so that drainage need not rely on a surface channel network, although many limestone areas have both surface and subsurface drainage routes, reflecting their evolutionary history.

Here we focus on areas that are dominated by river flow, where there are generally connected dendritic channel networks that periodically or continuously carry flows of water, solute, and sediment. Although the same hydrological principles apply everywhere within this system, the balance between processes differs enough to alter the dominant processes and behaviors in different parts of the system and under different climatic regimes. Hillslopes are dominated by processes of runoff generation and the potential for areas to be connected or isolated from drainage channels. Channelways are dominated by the routing of flow, by relationships between channel and floodplain, and by issues of

sediment transport. Groundwater is also dominated by the transmission system and its evolution.

Hillslopes

Hillslopes are distinguished from channelways by the lack of continuous drainage lines, but it will be seen that this separation is somewhat arbitrary, because channel heads change in position over time during storms and over longer periods, and because there may be subsurface drainage lines that have no surface expression. A more functional definition may be in terms of surface morphology, defining hillslopes as the upstream areas without continuous surface channels, and channels by the existence of eroded banks to give a morphological feature. This definition remains difficult to apply in practice, particularly where channels are delimited without field survey, from maps, Digital Elevation Models (DEMs), or remotely sensed images. However, the functional definition can be linked to the stability of the landscape form, in the sense of linearity for sediment transport processes, and will be used here.

Figure 3 shows the main pathways for water on the hillslope (*see* **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2**). Precipitation falls on the vegetation and the soil surface. Some water is intercepted on foliage and some held in puddles on the surface as depression storage. These stores, together with soil moisture, are available for evaporation, and plants also draw water up from the soil through their roots and transpire it through their leaves, transporting nutrients, supporting photosynthesis, and maintaining the rigidity of soft tissue. Water penetrates the soil surface as infiltration, both across a saturated interface in wet depressions and through the direct entry

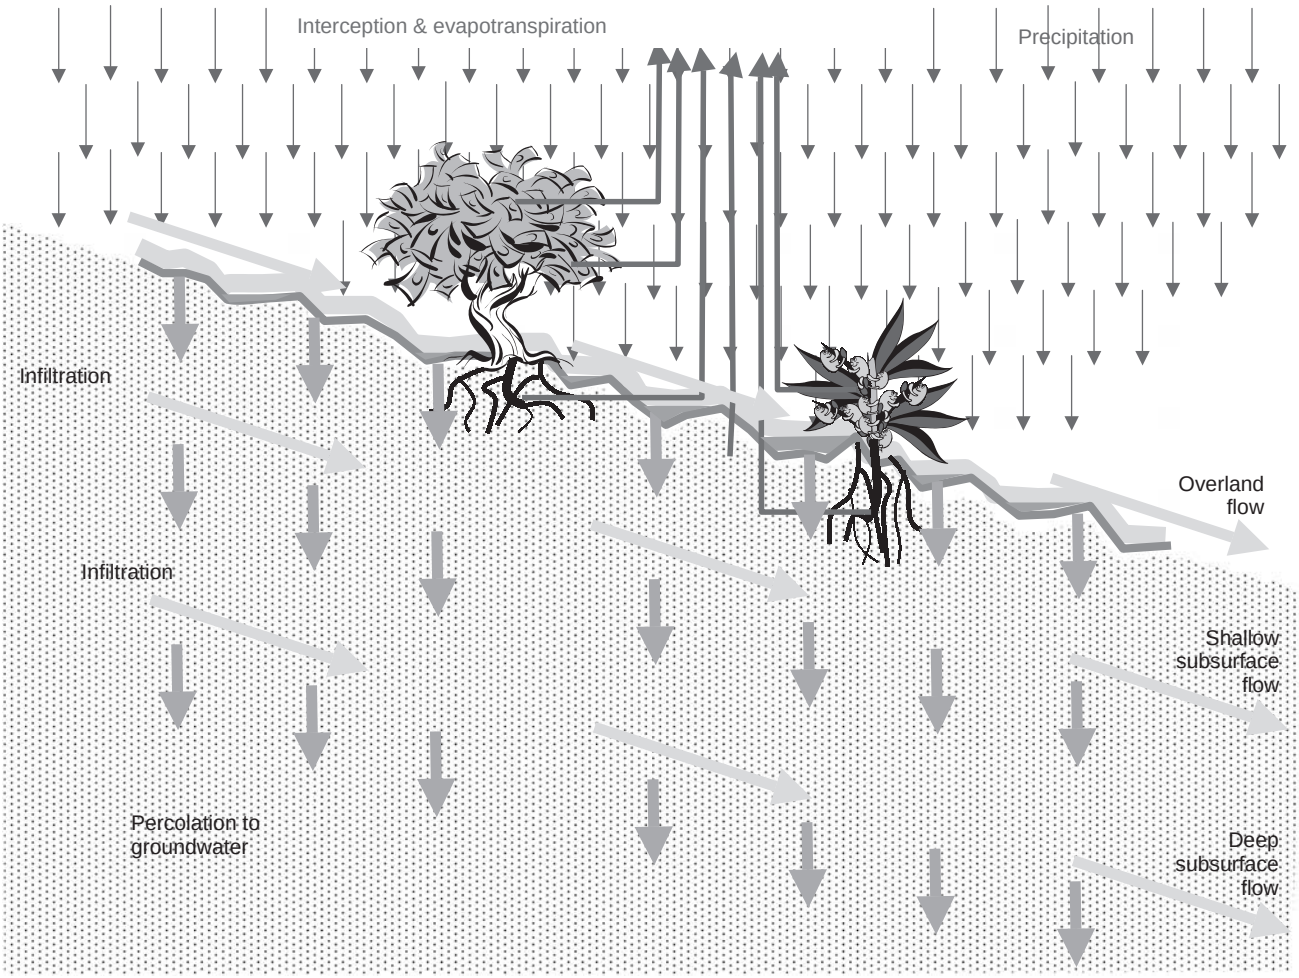

Figure 3 The principal pathways for precipitation on the hillslope. Water is most strongly diverted downslope at levels where the infiltration capacity is decreasing with depth, often associated with soil horizons, and may be extracted by evapotranspiration over the full depth of plant roots. Subsurface flow can take place both through the soil matrix and along discrete macropores. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

of raindrops in unsaturated areas. Percolation continues down into the soil, which generally becomes less permeable with depth, although with important exceptions to this rule. Where permeability is maintained into the bedrock, there is scope for recharging groundwater within the rock.

At the soil surface, and progressively through the soil profile during the infiltration process, flow may be diverted laterally to increment downslope discharge and may also be lost to evaporation and root uptake. At the surface, any water diverted becomes overland flow, which has the greatest impact on storm hydrograph response because of its relatively high flow velocity. Overland flow rarely exceeds half of the rainfall and is generally less than 10%. At the surface and at all levels in the soil, water is diverted when the soil beneath becomes saturated, and this may occur either because of decreasing vertical infiltration rates or because of saturation by laterally flowing water from upslope. The balance between these processes varies significantly with soil types, but more strongly with climate, which has a consistent influence on the spatial and temporal patterns of hillslope hydrology, and its interaction with geomorphology.

Humid Areas

Humid areas are those in which precipitation exceeds potential evapotranspiration over the year as a whole so that there is generally a reservoir of soil moisture. If there is a dry season, there may be some alternation between humid and semiarid behavior through the year. The excess of rainfall over evapotranspiration generally leads to substantial infiltration. The infiltrated water may percolate down to groundwater where the parent material acts as a good aquifer, but elsewhere must contribute to lateral subsurface flow at some depth within the soil profile.

Where there is an aquifer, percolating water can flow down through open fissures, as for example, in most karstic limestones, or more slowly through matrix pores as in many sandstones, so that the time delay between rainfall and the corresponding rise in groundwater piezometric levels varies substantially with rock lithology and joint structures, from a few days to many years. In addition, alternating and/or spatially varying lithological sequences, dipping strata, and disconformities between aquifers and impermeable layers can greatly complicate the relationships in any area. Fissures in karstic limestones are enlarged by solution of the limestone along preferential flow lines, initially very slowly and then more rapidly as they grow in size, and may generate flow connections that have little relation to surface topography. Thus, although recharge rates can be estimated, detailed local studies are needed to understand the relationships between groundwater recharge and discharge sites. However, in a uniform aquifer, the uniform recharge is eventually returned to streams under low flow conditions, and the piezometric surface therefore drains towards the channels, with a form that broadly mirrors surface topography, but with much reduced relief.

Where there is no aquifer, then the soil and rock at depth is, in principle, saturated, but transmits a negligible amount of water. Thus, the subsurface moisture profile shows saturation at depth, and, on average a general decrease in the proportion of saturation upward towards the surface. However, there may be consistent differences in this profile, for example, with more frequent saturation above a relatively impermeable iron pan horizon and less frequent saturation below it. There are also differences over time, for example, when intense rainfall wets the surface, driving a wetting front down into unsaturated soil below.

Movement of water in the soil is driven by gravity and by the gradient in hydraulic potential, generally drawn from wetter to drier zones by capillary forces. A simple theory assumes that a soil has a uniform hydraulic conductivity at any moisture content, and that water advances into drier areas along a uniform front. However, soils generally have two or more populations of pores that can be distinguished as matrix and macropores. For a soil consisting of randomly arranged aggregates, the interior of each aggregate acts as a matrix, while the spaces between the aggregates behave as macropores. For a cracking soil, such as heavy clay, the mass of clay may behave as the matrix, while shrinkage cracks between them providing macropores that vary in size with the shrink-swell history. Other macropores can be initiated as animal burrows, surface channels reroofed by bank collapse, or through internal erosion (hydraulic piping) by water, and these processes may reinforce one another.

Flow in the soil matrix approximately follows the simple theory, but flow in macropores bypasses matrix flow so that the overall wetting front below a saturated surface generally consists of a shallow uniform wetting front with spikes of much greater penetration in a thin film of water following the walls of macropores, along which secondary wetting fronts spread into parts of the matrix adjacent to each macropore. In some cases, the overall flux is largely dominated either by matrix infiltration or by macropore flow, but there are many cases where both are important (Beven and Germann, 1982; Brammer and McDonnell, 1996);

Where the soil is unsaturated, the total potential gradient (gravitational plus hydraulic) is much greater in the vertical than lateral directions and flow is predominantly vertical, but where water reaches the saturated level, the potential gradient becomes greatest in a downslope direction and flow becomes predominantly lateral. This most commonly occurs close to the surface, but in some cases may give rise to more than one such perched water table within the regolith.

In a humid area with low permeability bedrock, every point down a slope profile contributes additional water

to the shallow subsurface discharge. For a uniform soil, this subsurface runoff contribution, j, will be more or less constant downslope so that the total subsurface discharge at unit area a from the divide is given by:

$$q = ja \tag{1}$$

where the unit area a is defined as the area drained per unit contour width and is the same as distance from the divide where contours are parallel.

If the saturated subsurface discharge is considered to take place in a layer with fixed hydraulic conductivity K, and the gradient of the flowing layer is s (that will be approximately the same as the surface gradient in many cases), then the depth h of flowing water over the impermeable bedrock is obtained by equating the two expressions for subsurface discharge:

$$q = ja = Khs \tag{2}$$

And the depth of subsurface flow is:

$$h = \frac{j}{K}.\frac{a}{s} \tag{3}$$

It can be seen from this expression that the depth of flow tends to increase with the "topographic index", a/s. If soil depths are more or less uniform downslope, then the degree of saturation is positively linked to the flow depth, h. It follows that the degree of saturation is generally more or less constant on the upper part of the slope profile, which is usually convex, so that s increases with a, and the degree of saturation increases sharply towards the base of the slope, where a tends to increase because of the plan convergence towards stream heads and s tends to decrease because of profile concavity.

Levels of saturation vary over time depending on the sequence of previous rainfalls. Under wet conditions, flow velocities near the surface are high enough to respond during the course of a storm, and under dry conditions, velocities deeper in the soil are slow enough to maintain low flows for several months after the last rainfall. Once the soil becomes saturated by this wedge of subsurface flow, additional rainfall cannot infiltrate however low its intensity, and flow is diverted laterally as "saturation excess" overland flow. Clearly this condition is met most frequently near the base of the slope, leading to time-varying areas of saturation excess overland flow and the concept of the dynamic "saturated contributing area" (Beven and Kirkby, 1979).

Semiarid Areas

In contrast, semiarid areas are characterized by an excess of potential evapotranspiration over precipitation. Thus, much of the rainfall that infiltrates into the soil is used by plants for transpiration, and, even where surface crown cover is sparse, the broader root network is able to utilize soil water efficiently. Under these conditions, the main movement of soil moisture is vertical, with little or no lateral subsurface flow. The conditions for saturation excess overland flow therefore rarely or never occur, and overland flow occurs only when and where rainfall intensity exceeds the infiltration capacity of the soil, which decreases as the wetting front penetrates into the soil. This is called *infiltration excess overland flow* or *Hortonian overland flow* after Horton (1933), who made this concept widely known.

Where the soil surface is directly exposed to raindrop impact, without protection by overhanging vegetation or stones, the surface layer of aggregates can be broken into their constituent particles that are then packed into the surface, creating an almost impermeable crust and sealing macropores. Crusts can also form in depressions where fine particles are washed in and below the surface where the fines are concentrated below a layer of sand or stable aggregates (Valentin and Bresson, 1992). In all cases, they greatly reduce infiltration rates and therefore increase infiltration excess overland flow (*see* **Chapter 111, Rainfall Excess Overland Flow, Volume 3**). Over time, crusts may be broken by, for example, plant shoots, ploughing, and wetting/drying cycles, so that their development and survival are highly dynamic in relation to weather and crop or natural plant growth.

Although semiarid areas are dominated by infiltration excess overland flow and vertical exchanges of soil water, there is a transition between the typical "humid" and "arid" responses. Infrequent storms and high intensities favor this Hortonian behavior, whereas frequent, low intensity storms favor subsurface flow and saturation excess behavior (Figure 4). Some areas show regular seasonal transitions between these modes, and exceptional periods of weather can lead to nontypical behavior for any area (Beven, 2002). Thus, summer thunderstorms can give infiltration excess overland flow in Britain and winter periods with persistent rainfall can generate subsurface flow in southern Spain.

With the dominance of vertical soil moisture exchanges in semiarid areas, the effect of topography is less important than for humid areas, and differences in overland flow response are more focused on areal differences in land use and soil properties.

In storms, most water infiltrates into the soil, even though local runoff coefficients may be high. As storm size is increased, more water infiltrates and penetrates deeper into the soil and some will be out of the reach of plant roots and evapotranspiration. This very small fraction of the rainfall is then available to percolate to depth, eventually recharging groundwater. Hillslope recharge is significant only in areas of well-developed karst, where surface water can reenter the soil through enlarged joints. Thus, in principle there is always a saturated zone at depth, but this interacts minimally with surface hydrology except in karstic areas.

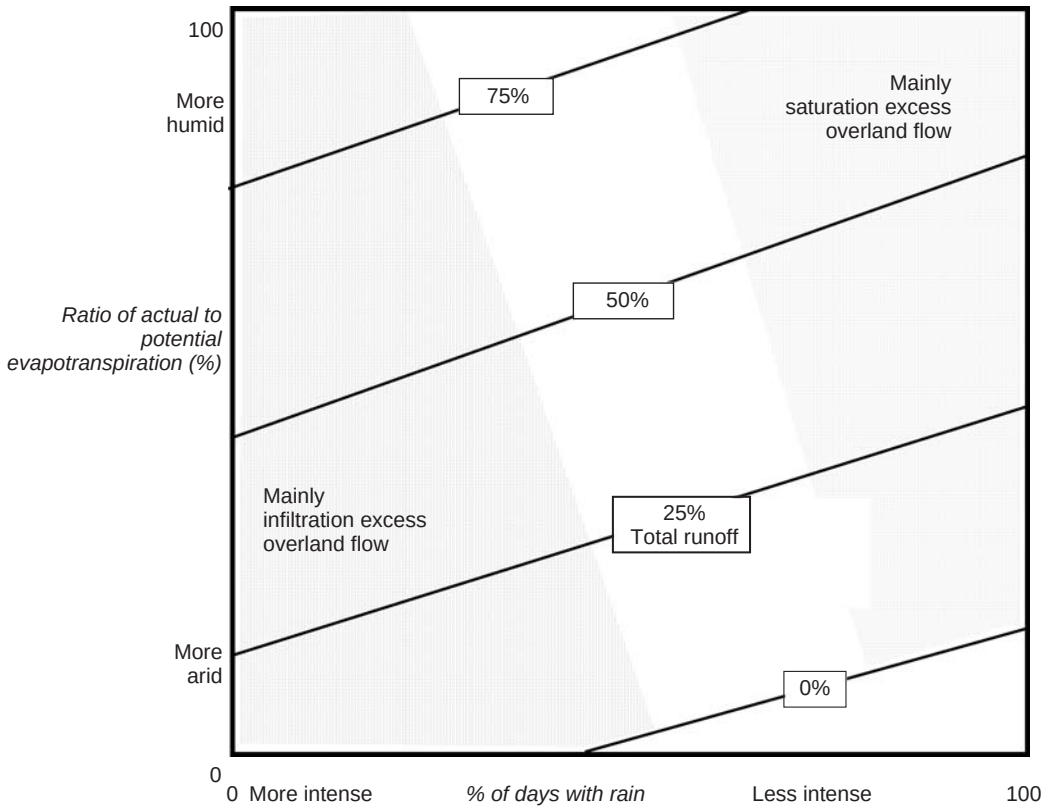

Figure 4 Generalized dependence of runoff coefficient and style of overland flow on degree of aridity and on storm rainfall intensities. Saturation excess overland flow is more common in humid areas, with a high ratio of rainfall to potential evapotranspiration, and under low rainfall intensities, indicated by low values of mean rain per rain day. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Connectivity

Overland flow is generated locally by infiltration and saturation excess mechanisms according to the climatic regime and local surface properties. However, not all of this flow necessarily reaches a stream channel, but may reinfiltrate on the way. This applies to overland flow generated from seminatural areas and uniform cropland, and also from artificial features, particularly roadways and cultivation artifacts such as wheel-tracks and headlands in ploughed fields.

The concept of connectivity considers whether a flux from a point A reaches a down-flow point B. The flux may be of any quantity, but in the present context refers to water flow. At any moment connection is either on or off but, over a period, there is a frequency distribution that varies from point to point, and connection may be expressed in terms of other hydrological state variables, usually with some uncertainty.

In humid conditions, there is generally good subsurface connectivity that determines the dynamics of saturated areas. Normally, the topographic index, a/s (from equation 3) increases steadily downslope along a flow path, but this is not necessarily the case. Where the topographic index shows a continuous increase and soils are more or less uniform, then saturation at a point can only occur when all points down-flow are already saturated, guaranteeing complete connectivity between every point and the catchment outlet. Where, however, differences in soil properties or intervening topography give a reduction in saturation along the flow path, then connectivity of surface flow only occurs if every point along the path is saturated. Figure 5 shows an example of the forecast pattern for an area in the Yorkshire Dales, UK, based on a 2 m DEM, where anomalous down-flow decreases in the topographic index occur at the margins of a summit plateau and between incised side slope gullies.

In general, humid areas generate runoff only in the narrow and variable saturated area close to the streams. In any storm overland flow, discharge is initially zero or very low and rises more or less linearly across the saturated area. Summed across the frequency distribution of storms, discharge can begin to grow far upslope in the most extreme storms, but only closer and closer to the stream in smaller and more frequent storms. The general form of increase

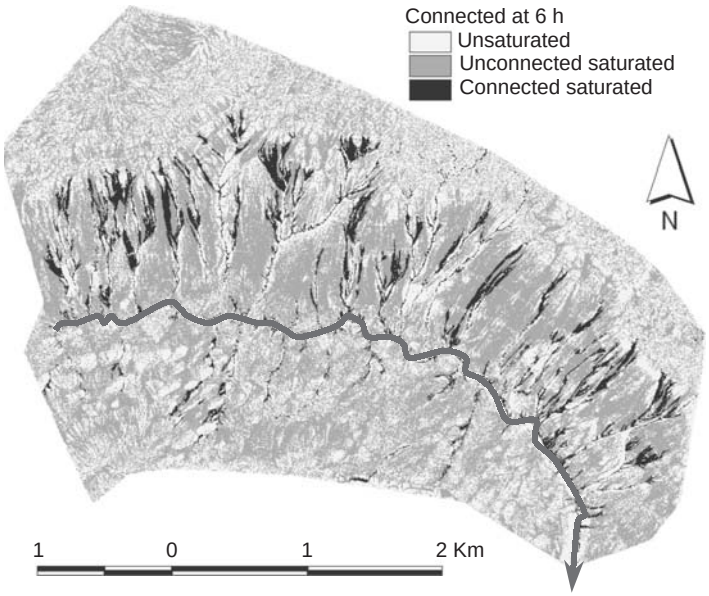

Figure 5 Example of partially connected overland flow, Wharfedale, UK (Reproduced from Lane *et al.*, 2004, by permission of John Wiley & Sons Ltd)). In many areas, saturated areas at any moment may not be connected to the catchment outlet by a continuously saturated pathway. Such disconnected areas are not contributing strongly to peak flows, although flow from them helps to saturate other areas downslope. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

in runoff production downslope may be expressed in a relationship such as

$$j = j_0 \exp\left(\frac{-x_0}{x}\right) \tag{4}$$

where j is the local rate of runoff production at distance x downslope, x_0 is a scale distance that decreases as storm size increases, and the discharge is obtained by summing this expression downslope.

In semiarid conditions, without the unity provided by subsurface flow, connectivity is generally much less complete. The two main reasons are thought to be spatial variability at various scales and the structure of rainstorms. In uncultivated areas, vegetation cover is generally incomplete in semiarid areas with bare patches between perennial plants. Bare patches may be crusted and have less of the organic litter and faunal activity that is concentrated under the vegetation, and therefore have lower infiltration and higher runoff. Bare patches may be joined to form a connected drainage path, but frequently drain into a vegetated area so that their runoff is lost and they do not connect with the streams. At a larger scale, fields may form a tapestry of different runoff generation rates so that high runoff areas may not connect with streams.

Storms in many semiarid areas consist of brief showers of intense rain with longer periods of lower intensity between them. Runoff may be generated widely during a shower and flow can begin to move downslope, but when the intensity drops this flow may reinfiltrate, with connected flow only reaching the stream from a narrow band along its banks. Average overland flow velocities are commonly only $1-2\,\mathrm{cm\,s^{-1}}$ so that flow travels only 18–36 m during a 30 min shower.

Both patchiness (i.e. spatial variability in runoff generation) and the short duration of intense showers limit the connectivity of overland flow, so that discharge increases less than linearly with increasing drainage area downslope. Instead, discharge in a storm initially increases downslope and finally reaches an asymptotic upper limit. The effective connection distance is generally greater in larger storms and discharge increases to a higher asymptotic value. Taking a weighted average across all storms, there is therefore a continuous increase of average discharge downslope, but at an ever decreasing rate, perhaps corresponding to a downslope increase in runoff production j and discharge q, of the form:

$$j = \frac{j_1}{(1 + x/x_1)}$$
$$q = j_1 x_1 \ln\left(1 + \frac{x}{x_1}\right) \tag{5}$$

Thus the downslope buildup of overland flow discharge in humid and arid regions takes the strongly contrasting forms sketched in Figure 6, both giving partial area contribution but generated through different mechanisms. In humid areas, saturation excess mechanisms concentrate runoff generation at the base of the slope. In semiarid areas,

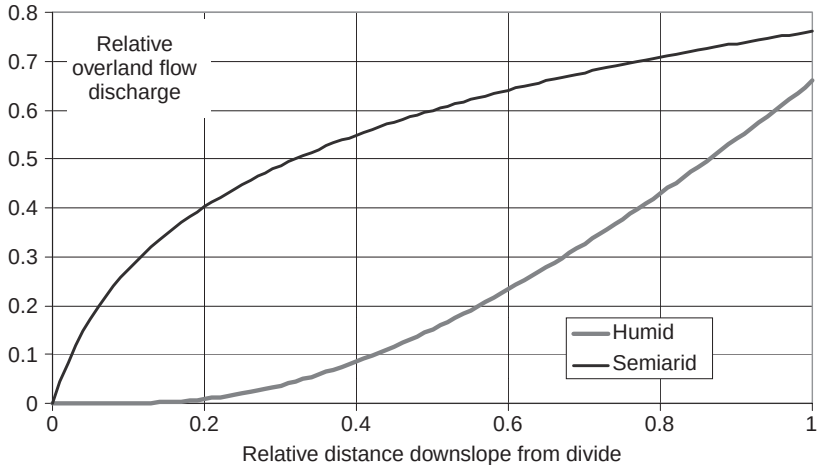

Figure 6 Sketch showing buildup of overland flow downslope in humid and semiarid climates. In humid areas, with saturation excess overland flow, local runoff generation generally increases downslope so that overland flow discharge increases more than linearly with hillside catchment area. In semiarid areas, although overland flow may be generated widely, flow from areas far upslope commonly reinfiltrates before reaching the stream, as storm intensity decreases. Overland flow discharge therefore increases less than linearly with hillside catchment area. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

with infiltration excess overland flow, runoff is generated everywhere but reinfiltrates because of the short connection distances (Kirkby *et al.*, 2002).

Roads and similar linear features tend to generate high volumes of local runoff, with an impermeable surface and local intersection of subsurface flow paths in cuttings. Like natural streams they provide efficient conduits to channel flow that collects in them, and in some areas they can significantly increase the effective drainage density and connectivity, particularly in forest areas (Croke and Mockler, 2001).

The form of the hillslope hydrograph is generally highly nonlinear, and typically shows a lower threshold for storm runoff, as well as increasing fraction of runoff as storm size increases. In humid regions, this is associated with an increase in the saturated area, and in semiarid areas with reductions in infiltration over time and the short duration of intense rainfall pulses, as sketched in Figure 7, although with wide variations according to the intensity structure of the storm. In the most extreme storms, all hillslopes would theoretically give 100% runoff irrespective of soil and climate, but the largest observed storms generally fall far short of this extreme, so that hillslope hydrographs generally show much greater and earlier response to rainfall as storm size increases, in strong contrast to the more linear response of stream channels.

Because of the different flow velocities along different primary pathways, the response time and peak flow generated along different pathways also varies greatly. Figure 8 illustrates the differences in observed peak flows for infiltration and saturation excess overland flow, and for shallow subsurface flow. It can be seen that they differ by more than an order of magnitude. Delays to peak show corresponding strong contrasts. In humid areas, both saturation excess overland flow and subsurface flow contribute to flood hydrographs. In some cases, the two pathways can generate double peaked hydrographs but, more commonly, subsurface flow supports the tail of the overland flow peak, giving a highly skewed hydrograph form, in which shallow subsurface flow is able to maintain low flows for many weeks after rainfall and provides sufficient water in some headwater areas to supply regional stream base flows. For arid areas, there is no subsurface contribution, and runoff commonly reinfiltrates as rainfall intensity decreases so that hydrographs not only show a rapid rise with a burst of intense rainfall, but also an abrupt decline as rainfall ceases. A hydrograph form is therefore more symmetrical for a pulse of rainfall and more generally shows a pattern of rise and fall, which closely mirrors the storm profile. Although there are wide variations, hillslope hydrographs in humid areas commonly peak in about 1 h and fall again over 24 h or more; whereas arid hillslope hydrographs peak within 15 min and fall again within 30 min.

Channelways

In their upper reaches, channels generally provide good transmission of the water flow delivered to them by hillslope hydrological pathways (*see* **Chapter 143, Mountain Streams, Volume 4**). This is because they are eroded forms, with thin or absent regolith cover, so that there is little opportunity for reinfiltration except over aquifers.

Natural and artificial channels typically intersect overland and shallow subsurface flow, and their effect on hydrological response results from the partially opposing effects of

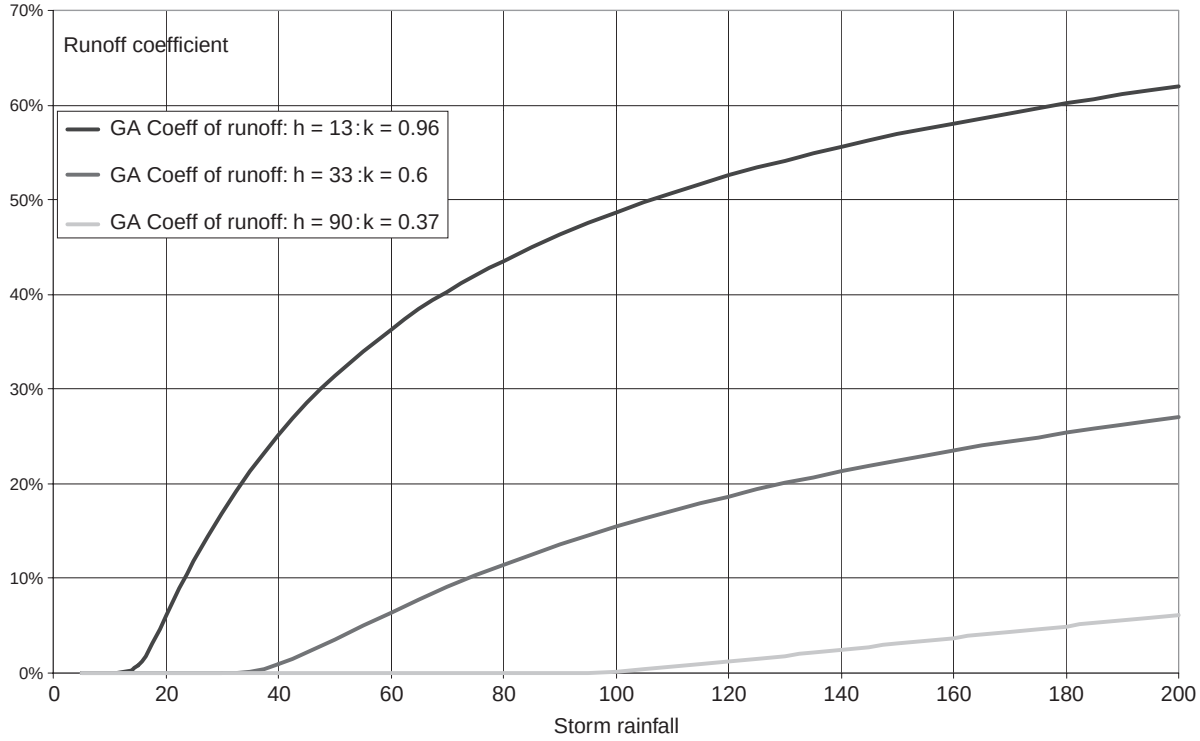

Figure 7 Generalized runoff coefficients for infiltration excess overland flow, for soils with different infiltration characteristics. Comparing sites with different infiltration rates, total storm runoff increases as infiltration rates fall. For comparable conditions, plots of accumulated runoff against accumulated rainfall show a family of nonoverlapping curves as infiltration rates are changed. Such behavior is described empirically by the SCS curve method (xx), as well as by applying infiltration equations (here Green and Ampt, 1911). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

the surface and subsurface regimes. Firstly, direct channel precipitation provides an important component of rapid response to storms. Secondly, overland flow will be transmitted with lower reinfiltration losses within a channel. Thirdly, a high water table will be depressed locally by a channel cutting through it so that the initial response to rainfall may be a recharge of the water table, with only a slow release of the added water: this effect is strongest where the water table depression extends across the whole interchannel area (Holden *et al.*, 2004). Thus, an increase in channel density is likely to increase storm runoff in semiarid areas through the first two effects, but can reduce peak flows in humid areas with a high water table through the dominance of the third effect. Nevertheless, in wet climates, shallow water tables in the riparian zone may be very dynamic during events and contribute to subsurface stormflow (Sklash and Farvolden, 1979).

Farther downstream, channelways are increasingly associated with floodplain deposits that may absorb and carry part of the flow below the surface in endorheic flow and that allow high flows to spread over a much broader area. Where the sediment load is high relative to the transporting capacity of the channelway, channels are mobile, with frequent lateral shifting and often with multiple threads of flow in braided floodplains and deltas.

Permanent Flow

Channel flow is an almost linear process and the hydrology of large basins corresponds fairly closely to the assumptions of the Instantaneous Unit Hydrograph (IUH, **Chapter 122, Rainfall-runoff Modeling: Introduction, Volume 3**), or Geomorphological Unit Hydrograph (GUH), in which hillslope input hydrographs are linearly related to downstream output hydrographs, using the network width function (Surkan, 1968; Kirkby, 1976; Valdes *et al.*, 1979) to transform input to output within an area of uniform inputs. The assumption of linearity is physically based on a constant downstream routing velocity that is equivalent to a straight line relationship between discharge Q and cross-sectional area A:

$$Q = c(A - A_0) \tag{6}$$

where c is the routing velocity (Beven, 1979). This relationship empirically compares favorably for many rivers with the power law expression ($Q \propto A^{1.6}$) more commonly used.

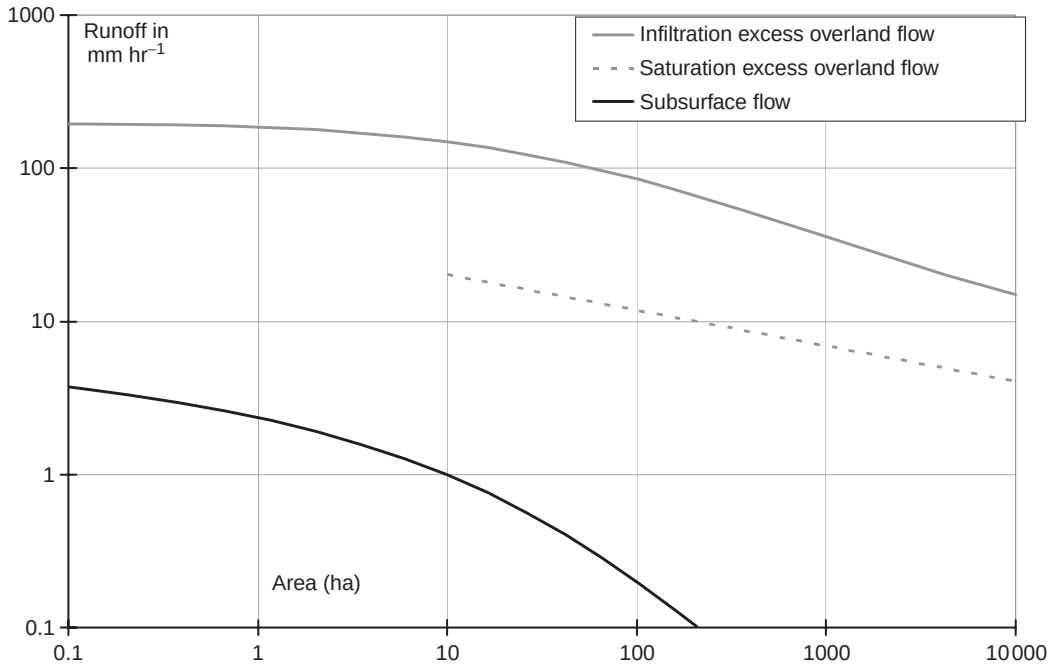

Figure 8 Peak hillslope responses from different runoff generation mechanisms (data from Dunne, 1978). The curves summarize empirical data that shows that the three runoff generation mechanisms, infiltration excess overland flow, saturation excess overland flow, and subsurface flow respectively generate lesser peak flows from a given area. Data also shows that runoff from these mechanisms generates respectively longer delays to peak flow

Clearly, equation (6) does not fully express the physical relationship between channel morphology and discharge, and, to that extent the linear assumption breaks down, and therefore does not provide the best available routing model. However, it does clearly demonstrate and explain the close relationship between channel network morphology and hydrograph response. Provided that attention is paid to the spatial and temporal patterns of rainfall, then catchments draining more than about 100 km^2 show a strong relationship between network morphology and flood hydrograph form, while smaller catchments show less of a link. The critical crossover catchment area varies somewhat with conditions, and is essentially the area above which the response time due to channel flow becomes greater than the response time of the hillslope hydrograph. For areas below this crossover, the nonlinearity of hillslope response then plays an increasing role in determining the form of the outlet hydrograph.

Where storms move across a catchment, then the movement of the storm cell, or the generation of new cells also has a strong impact on flood magnitudes. Where the storm moves downstream at a rate comparable to the celerity of the flood wave, there is very strong reinforcement of the flood peak, since storm rainfall from all parts of the catchment arrives at the outlet more or less simultaneously. If, however, the storm moves upstream, then the flood peak is attenuated and its duration extended.

Ephemeral Flow

In areas where streams are dry for part of the year, because of aridity or in karst areas, flow only occurs above a threshold determined by the subsurface flow capacity, in either deep karstic aquifers or in fluvial sediments within the channelway. Where storms are local, then flow may also be local, building up within the storm area and declining again through bed transmission losses downstream. In these environments, the simple near-linear behavior of humid streams is suppressed.

In extremely arid areas, or along channels with extensive gravels or karst sinkholes, floods may only occur with storms, and many events produce a flow in only part of the catchment. Other areas show a transitional behavior, with connected flow for part of the year and dry beds, sometimes with moisture persisting in bed gravels.

Since bursts of intense rain may produce a flood of only short duration and local extent, the movement of storm cells, and their sequence over time, becomes even more critical for the generation of floods over a catchment of more than a few km^2. Clearly, larger storms have more bursts of intense rain, and each burst may be larger, so that the potential for reinforcement increases with overall storm size, adding to the nonlinearity of arid catchment response.

Although recharge is generally small in semiarid areas, it is greatest along the stream channels because flow persists longest there. In many cases, this recharge supports

moisture within a local aquifer formed by sediment along the channelway. Where there is a uniform regional aquifer, however, recharge occurs primarily along the channels so that the piezometric surface is highest along the stream network, with a general form that is a low-gradient inversion of the surface relief.

IMPACTS ON THE LANDSCAPE

It has been shown above that the hydrological response of the landscape is strongly structured by the climatic regime, as well as by the form of the landscape. Turning to the impacts of the hydrology on the landscape, it will be seen below that the hydrology organizes and structures both the vegetation cover and the landscape morphology, although changes in morphology are only slowly implemented through the action of erosion and sediment transport, generally over periods of tens to hundreds of thousand years. Since climate is changing continuously, and on more rapid timescales, it is geologically normal to see an imbalance between the landscape forms and the contemporary hydrology, with landscapes rarely if ever in phase with climate and hydrology.

The flow of water is, as explained above, strongly influenced by the form of the landscape, expressed in hillslope plan and profile form, and in the density and morphology of the channel network. It is also strongly influenced by the climatic regime, expressed most relevantly by the balance between precipitation and potential evapotranspiration. The climatic link is significantly mediated by the vegetation cover that interacts strongly and dynamically with the hydrology, both influencing the response of the surface to rainfall and growing in response to available water.

Water flow is also, directly or indirectly, the main driver of sediment and solute transport, and the distribution and flow of water is therefore responsible for the erosion of the landscape, creating a second important impact and feedback. However, significant erosion of the landscape generally takes thousands to hundreds of thousand years so that the current landscape is not molded by current hydrology, but has been molded by a set of previous climates that commonly differ appreciably from the present. It is therefore important to consider the response times of different elements of the landscape and the implications of better or worse coupling between present hydrology and the present landscapes.

Vegetation Growth

Plant crown cover protects the soil surface, and its extent determines the proportion of the surface exposed to raindrop impact. Large drops fall at a terminal velocity of up to $10\,m\,s^{-1}$, and their momentum is largely absorbed where they fall on living or dead vegetation, or on surface litter or mulch on the soil surface. Drops that fall from the leaves may approach terminal velocities from high forest canopies ($>10\,m$), but their impact is generally much reduced below multistorey canopies or lower vegetation.

The vegetation, in turn, grows at a rate that is closely related to the transpiration stream, although there are variations according to the type of metabolic pathways (C3 or C4 plants), the level of atmospheric and soil CO_2, and the availability of nutrients, particularly nitrogen and phosphorus. Thus, many of the differences between humid and semiarid hydrological responses are directly related to natural vegetation growth, and artificial management of vegetation cover can create similar contrasts (*see* **Chapter 117, Land Use and Land Cover Effects on Runoff Processes: Urban and Suburban Development, Volume 3**–**Chapter 120, Land Use and Land Cover Effects on Runoff Processes: Fire, Volume 3**). This is most relevant in the context of human land management. Cropland is kept artificially clear of cover through tillage and harvesting for part of the year. Rangeland is grazed, keeping vegetation cover artificially low and is cleared periodically by fire to promote fresh growth in many regions. Widespread farming practices thus commonly allow seasonal crusting of the soil surface and infiltration excess overland flow in areas that would naturally be dominated by saturation excess runoff year round.

In semiarid areas, natural vegetation cover is generally incomplete, except for a carpet of annuals following rain. Perennials tend to be denser in areas of greater moisture, and therefore concentrated particularly along channelways, where flow lasts longest and moisture persists in the bed sediments.

Sediment and Solute Transport

Hillslope hydrology is vital to most sediment transport. Although hillslopes are not generally the most active part of the landscape, they provide almost all of the material that eventually leaves a river catchment through the more active channelways (*see* **Chapter 80, Erosion and Sediment Transport by Water on Hillslopes, Volume 2**). The processes by which material is weathered and transported to the streams are therefore vital to an understanding of how the catchment works. The regolith is also the raw material from which soils are developed. Geomorphological processes form an essential part of this crustal recycling that continually renews the surface, and is itself ultimately driven by the hydrological cycle (Holden, 2004; Kirkby *et al.*, 2002).

Water helps to break up the rocks into soil in the processes of weathering and drives the sediment transport processes that carry soil materials down to the ocean, progressively eroding the land. The balance between the rates of the various sediment transport processes has a very strong influence on the form of both the landscape and its soils, and plays a large part in the distinctive appearance of

landscapes in different climatic regions. Hillslope erosion also provides the raw material that rivers transport through their valleys to the oceans. Changes in hillslope erosion rate may not immediately be matched by similar changes in river sediment transport, resulting in either floodplain aggradation and widening, or valley incision.

Material transport processes are of two very broad types, (i) weathering and (ii) transport of the regolith. Within each of these types, there are a number of separate processes that may be classified by their particular mechanisms into three main groups. Most slope processes are greatly assisted by the presence of water that helps chemical reactions, makes masses slide more easily, carries debris as it flows, and supports the growth of plants and animals. For both weathering and transport, the processes can conveniently be distinguished as chemical, physical, and biological.

Weathering Processes

Weathering is the in-place transformation of parent materials into regolith and the further transformation of regolith materials. Chemical transformations change the chemical composition of the minerals in the regolith. The net effect of these changes is to remove the more soluble constituents of the rock minerals and change them into a series of new minerals, which become more and more like clay-forming minerals. Rock composition can be simplified as a combination of bases, silica, and sesquioxides (Carson and Kirkby, 1972). Bases are the most soluble so that weathering removes them first. Silica, although at least 10 times less soluble than bases, is itself at least 10 times more soluble than the sesquioxides. The changes due to chemical weathering can be shown on a triangular diagram (Figure 9),

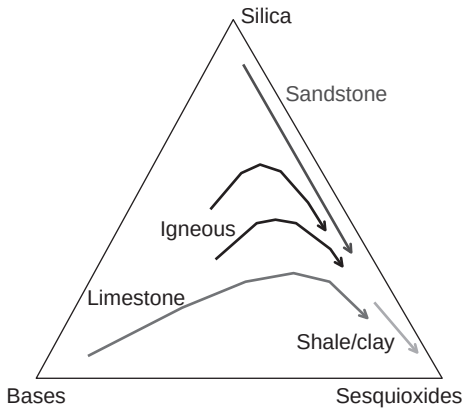

Figure 9 Schematic weathering of rocks, represented as a mixture of bases, silica ($Si0_2$), and sesquioxides (Al_2O_3, Fe_2O_3). The arrows illustrate courses of weathering for typical rock types and their lengths indicate relative rates of change. Thus, in the general course of weathering, bases are lost first, followed by sesquioxides, and long continued weathering leads to clay and eventually lateritic residual soils. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

which shows the proportional composition in terms of these three components. Weathering first reduces the proportion of bases and then the proportion of silica so that all parent materials eventually end up in the sesquioxide corner, essentially as clays, which are the end products in equilibrium with the pressures and temperatures in the regolith. In general, minerals that are formed close to the surface, such as the clays, are less liable to change in this way, and so undergo less chemical weathering than, for example, igneous rock minerals that were formed at high temperatures. Chemical weathering usually produces new minerals that are physically weaker than before, and so makes the material more easily transported by physical processes.

Physical weathering transforms rock and regolith materials by mechanically breaking them into smaller fragments. In some cases, chemical and biological processes help this mechanical breakdown. The most important processes of physical weathering are freeze–thaw and salt weathering. Biological processes are also effective through a combination of biochemical and mechanical methods, mainly through root action and faunal digestion (e.g. worms and termites).

Transport Processes

Where there is a plentiful supply of material, and the process which moves it can only move a limited amount for a short distance, then the rate of transport is limited by the *Transporting Capacity* of the process, which is defined as the maximum amount of material that the process can carry (Kirkby, 1971). Other processes are limited, not by their capacity to transport but by the supply of suitable material to transport, and are described as *Supply Limited*. Although there is not always a completely rigid line between Transport Limited and Supply Limited processes, it is an important distinction, and has a substantial impact on the way in which landscapes evolve. Landscapes that are dominated by transport limited removal are generally covered by a good layer of soil and vegetation, and slope gradients tend to decline through time. Landscapes where removal of material is mainly supply limited, on the other hand, tend to have sparse vegetation, thin soils, and steep slopes which tend to remain steep throughout their evolution. There is a general tendency for humid landscapes to be dominated by transport limited removal and semiarid landscapes by weathering limited removal.

Solute and Nutrient Transport The process of solution is closely linked to chemical weathering. As material is altered in place by weathering, the lost material is removed in solution. Rocks that weather rapidly therefore also lose material in solution rapidly. Rain falls on the soil, where it picks up solutes from the regolith, at a concentration roughly proportional to the amount of each constituent in the regolith, and its solubility. Some water is lost to evapotranspiration, and this carries little or no

solutes so that the remaining overland flow and subsurface flow runoff has an increased concentration of solutes. This distillation effect becomes marked in relatively arid climates, where the evapotranspiration is high. In extreme cases, some of the soluble material reaches its maximum saturated concentration, and any further evapotranspiration leads to redeposition of the dissolved material near the surface, most commonly for calcium, which is often found to form crusts of calcrete near the surface in arid and semiarid areas. The concentration of solutes is therefore generally highest in dry climates, but the total amounts removed in solution are less than for humid areas.

Where a flow of water contains dissolved material, the rate at which the solutes are removed is determined by their concentration in the runoff water. This leaching is generally the most important process in carrying solutes down the slope and into the rivers. Once material is leached out, it generally travels far downstream and its rate is *supply limited.*

When material is physically transported down a hillslope, it may travel as a mass or as independent particles. In a mass movement, a block of rock or soil moves as a single unit, although there may be limited relative movement within the block. The movement of the block is mainly determined by the forces on the block as a whole, and the individual rock or soil fragments within the block are in close contact so that they are moved selectively according to their size, shape, or density. The alternative to a mass movement is a particle movement, in which grains move one, or a few, at a time, and do not significantly interact with one another as they move. For a particle movement, forces act on each particle separately, and they move selectively, mainly depending on their sizes and also on other factors such as shape and density. Both mass movements and particle movements can occur at a range of rates. In general, however, movements that are driven by large flows of water tend to be more rapid than drier movements and tend to be supply limited, whereas drier and slower movements tend to be transport limited.

Mass Movements Mass movement of material is decided by a balance of forces, some of which promote movement and some of which resist movement. For mass movements, the forces act on the block of material that is about to move, and for particle movement on each individual particle. The main forces promoting movement are those of gravity and water detachment. On a slope, there is always a component of the weight of the material that tends to pull it downslope, and this applies equally to particle and mass movements. Friction and cohesion provide resistance to movement.

There are many names for different types of rapid and slow mass movements. In rapid mass movements, the crucial distinction is between *slides*, in which the moving mass essentially moves as a block over a failure surface, and *flows* in which different parts of the mass move over each other with differential movement or *shear*. It is usually found that flows occur in masses with more water mixed into the moving mass, in proportion to the amount of regolith or rock material. In a slide, water is often very important in reducing the frictional resistance, and allowing movement to begin, but there is little water within the moving mass. In a flow, there is usually almost at least as much water as solids, and sometimes many times more. Water and regolith materials can be mixed together in almost any proportions if they are moving fast enough, although coarse materials (sand, gravel, and boulders) can only remain suspended in the mixture in the fastest or most viscous flows.

Initiation of rapid mass movements occurs when gravity forces overcome frictional resistance and cohesion, either in a narrow zone or throughout the depth of the mass. Initial movement dilates the failure zone, separating the moving solids and reducing frictional resistance so that movement initially accelerates. Comparing mass movements with increasing proportions of water in the mass, the intergranular resistance during movement decreases progressively as grain to grain contacts become less frequent. Flow continues until either the driving forces decrease, generally by running out onto a lower gradient, or the frictional forces increase because of drainage of the water.

The essential contrast with slow mass movement (seasonal soil creep) is that it does not involve movement bounded by a discrete slip surface. Failures occur between individual soil aggregates and not over the whole of an area. Movements are usually driven either by "heaves" of expansion or contraction, or by apparently random movements between aggregates. Heaves are usually caused by freezing and thawing of soil water, or by wetting and drying of the soil. Random movements are usually caused by biological activity that mixes the soil in all directions. In all cases, these movements would not cause any net downhill movement on level ground but, on a slope, the steady action of gravity causes more downhill than uphill movement, and there is a gradual downhill transport of regolith material, at a rate which increases with slope gradient. These three main drivers for soil creep, wetting–drying, freeze–thaw, and biological mixing, can all be of similar magnitudes, although one or other dominates in any particular site. Tillage erosion is an additional form of slow mass movement, driven by ploughing and other cultivation that turns and dilates the topsoil at rates 100–1000 times more rapidly than in soil creep, moving material downslope without the direct agency of water.

Particle Movements Where there are cliffs, rockfall from bedrock slopes and its incorporation into talus slopes provides one important category of particle movement. The debris builds up screes of coarse debris that eventually weathers into finer material and may be removed.

Water is directly responsible for the other main process of particle movement, in the group of wash or soil erosion processes. In these processes, material may be detached by the two processes of raindrop impact and flow traction, and transported either by jumping through the air or in a flow of water. Combinations of these detachment and transport processes give rise to the three different processes, rainsplash, rainwash, and rillwash.

Raindrops detach material through the impact of drops on the surface. Drops can be as large as 6 mm in diameter and fall through the air at a terminal velocity that is related to their size. For the largest drops, the terminal velocity is $10\,m\,s^{-1}$, but they only attain this after falling through the air for about 10 m. If their fall is interrupted by hitting the vegetation, drops hit the ground at a much lower speed and have much less effect on impact. As drops hit the surface, their impact creates a shock wave that dislodges grains of soil or small aggregates and projects them into the air in all directions. Grains that are as large or larger than the raindrop which moved them may be detached, so that grains of up to 10 mm can be detached by raindrop impact. The total rate of detachment increases rapidly with the energy or momentum of the raindrops, and therefore with the rainfall intensity. As a working rule, the rate of detachment is roughly proportional to the square of the rainfall intensity. Where the raindrops fall into a layer of surface water that is deeper than the raindrop diameter (6 mm), the impact of the drop on the soil surface is largely lost. Impact through thinner films can still detach aggregates into the water, and other grains jump into flowing water films that can then transport grains which they do not have the power to detach. These forces are also responsible for breaking up the surface aggregates and packing them into the soil surface to form a crust, as described above, which severely limits subsequent infiltration and increases infiltration excess overland flow runoff.

Transportation through the air, in a series of hops, is able to move material both up- and downslope, but there is a very strong downslope bias on slopes of more than about 5°. As a rough guide, the net rate of transportation (downhill minus uphill) increases more or less linearly with slope gradient and inversely with the grain size transported. The gross rates of material transport, for rainsplash, are generally similar to those for soil creep. Rainsplash, however, is strongly particle size selective and operates only on the surface, whereas soil creep operates over a significant depth of soil and carries material together as a coherent mass. Protection from raindrop impact, either by vegetation or by stones, strongly suppresses rainsplash and crusting by reducing the impact velocity of raindrops. Microtopography, including tillage features are gradually smoothed out as rainsplash redistributes material, eroding high points, and filling depressions.

Once there is overland flow over the soil, material can be carried in the flow, and some material can move much farther than through the air in rainsplash. The presence of overland flow provides a thin layer of water on the soil surface, generally distributed rather unevenly following the microtopography that may attenuate the impact of raindrops. In shallow flows, the combination of detachment by raindrop impact and transport by the flowing water is the most effective transport mechanism and is known as *rainflow*. This process is active in inter-rill areas, and provides a significant fraction of the material carried into and along rills and larger channels.

If flow is deeper (i.e. more than 6 mm), raindrop detachment becomes ineffective, and detachment is related to the tractive stress of the flowing water. Sediment is detached when the downslope component of gravity and the fluid entrainment forces overcome frictional and any cohesive resistance in the soil, that is, when the safety factor falls below its critical value. It can be seen that detachment increases with discharge and gradient, and decreases with grain size except where cohesion is significant. Flows that are powerful enough to detach material generally suppress raindrop detachment, and detached material is also carried by the flow. This combination of processes is called *rillwash*, and is responsible for most of the erosion by running water in major storms. Much of the material exported from an eroding field is the direct product of channel enlargement during the storm, and almost all of the material detached by raindrop impact must also eventually leave the area through these channels.

Combining the effects of these three wash processes that are active during storms under a sparse vegetation cover, much of the area is subject only to rainsplash that feeds into areas, some spatially disconnected, with thin films of water where rainflow is dominant. These areas in turn provide sediment to the eroding channels where rillwash is actively detaching material and enlarging the channels. In larger storms, the areas of rillwash and rainflow increase and become better connected to the channels. The runoff generated per unit area and the area contributing runoff to the outlet therefore both increase, giving a more than linear response of runoff to increased storm rainfall. Because sediment transport also increases more than linearly with discharge, the nonlinearity of the sediment load dependence on rainfall is much stronger than for the water flow.

Selective transportation removes fine material from the soil, leaving a lag of coarse material that armors the surface. As the surface is lowered by erosion, the armor layer consists of the coarsest fraction in the layer of soil that has been eroded, and so develops more and more over time. The coarse armor progressively begins to protect the soil by reducing detachment rates, increasing infiltration by preventing soil crusting and providing an increased resistance to flow, and all of these effects reduce the rate

of erosion until some equilibrium is approached. In this equilibrium, local differences in sediment transport rate balance differences in armor grain size. This effect is most commonly seen in a relationship between surface grain size and gradient, with coarser material on steeper slopes.

The effects of selective transportation are only evident where the regolith contains some coarse material. This usually consists of weathered bedrock, but may consist of fragments of calcrete or other indurated soil horizons. Thus, the erosion of deep loess deposits or deeply weathered tropical soils, for example, that contain little or no coarse material, is not affected by the development of armoring, and may continue unchecked to great depths, often allowing the formation of extensive gully systems. On shallow, stony soils weathering from bedrock on the other hand, the effect of armoring is increased because, as the surface erodes, lower layers of the regolith contain less and less fines, and the end point of erosion may be a rocky desert. Some rocks, for example, coarse sandstones and granites, produce a discontinuous distribution of grain sizes in their weathering products, dominated by joint-block boulders of weathered rock and the sand grains that are produced as the boulders breakdown. On these rocks, desert slopes often show a sharp break in slope at the base of steep hillsides, between straight slopes close to the angle of rest and the basal concavity. If grain size is plotted against gradient for these slopes, the sharp break in slope represents missing gradients that correspond to the gap in the grain size distribution.

It would be hard to overemphasize the extreme importance of land cover and agriculture for wash processes. Through the actions of vegetation in preventing crusting and improving soil texture though the addition of organic matter, there is a very strong casual link from vegetation cover to increased infiltration capacity and reduced runoff and erosion. As forests have been cleared for agriculture, erosion rates have greatly increased, removing the most fertile topsoil or stripping mountains to bare rock and causing sedimentation along rivers. In the Middle East, Northern Europe, North America, and Brazil, this process of severe erosion and eventual partial recovery is evident at various stages. Today, land management for food production and amenity remains an important issue, requiring sensitive choices to limit erosion while maintaining productivity. Furthermore, through crusting, armoring, and the promotion of infiltration excess overland flow, wash processes have a powerful impact on hydrological response.

Channel Cutting and Infilling

Many sparsely vegetated areas develop rills and ephemeral gullies that are defined as temporary channels, formed during storms and destroyed by infilling between storms. In cultivated fields, infilling is generally through tillage, sometimes deliberately after each storm and otherwise following the annual cultivation calendar. In uncultivated areas, natural processes of wetting and drying, or freezing and thawing, create a loose surface layer that accumulates downslope along the depressed rill lines and gradually obliterates them. Rills are small channels, generally 5–10 cm deep that are formed on a smooth hillside and are not associated with a depression. Over a series of storms, the rills reform in different locations and gradually lower the whole hillside more or less evenly. Ephemeral gullies form along shallow depressions, and therefore reform along the same line in each storm, gradually enlarging and deepening the depression, while the infilling processes bring material from the sides and widen the depression.

In a particularly large storm, channels may form, which are too large to be refilled before the next event. These channels then collect runoff in subsequent events, leading to further enlargement, and may become permanent additions to the channel network. Where the soil is stronger close to the surface than in the horizons beneath, either due to the presence of a tough vegetation root-mat or due to the exposure of an indurated soil layer, then gullies that breach the surface layer may incise rapidly into the weaker horizons beneath. As material is exported, undercutting of the surface layer can lead to further rapid growth of a linear or branching gully system that disrupts agriculture and roads and may be very difficult to heal. These features can also intercept groundwater and may enlarge through subsurface piping, particularly in sodic soils.

Hillside erosion, either by wash erosion or mass movements, may deliver more sediment to the main channels than they are able to carry. In the short term, high erosion rates initiated by reductions in vegetation cover generally increase downstream transporting capacity less than the increase in load, so that channelways aggrade, giving broad valley floors, often with braided channels. Contrariwise, reductions in hillslope erosion, for example, by converting agricultural land back to forest, may cause downstream incision. In the long-term, channel systems adapt to carry changed sediment loads, but historical changes have shown that this adjustment may take hundreds of years (*see* **Chapter 84, Floodplain Sedimentation – Methods, Patterns, and Processes: A Review with Examples from the Lower Rhine, the Netherlands, Volume 2**).

Sediment transport in rivers is highly episodic, and sediment concentrations increase more than linearly with discharge so that sediment flux is strongly concentrated on the largest flood events, and more than half of the annual sediment load is carried in 5% of the time. In a flood event, layers of sediment are entrained roughly in the proportions in which they lie on the stream bed (equal mobility), where fine material is released when the flow entrains the coarser material that shelters it. However, material is deposited selectively according to grain size. The coarsest material typically travels short distances, as bed load, and its movement is usually transport limited.

Finer material is carried progressively farther in each flood event, and for the finest material is effectively supply limited, with transport limited by the lack of available material. Thus, silt and clay wash load and solute transport are largely controlled by the hillslope source areas for these materials. The progressive reduction in stream travel distance with increasing grain size is responsible for the much coarser grain size distributions found on stream beds than in hillslope soils, as similar volumes of material pass through every part of the system, from weathered bedrock to soils to channel deposits and down to the sea.

FEEDBACKS

The landscape form shapes the hydrological response to precipitation, both on the hillslopes and through the channel network, particularly in flood events. The form of flood hydrographs has a strong impact on the sediment transport throughout the catchment and, in the long-term, erodes and shapes the catchment. This nonlinear feedback loop reinforces some components of the hydrological response and some landscape features to give the familiar characteristics of fluvial landscapes, and the differences between landscapes that are often characteristic of particular lithologies, climates, and tectonic settings.

Landscapes evolve over time in response to the internal redistribution of sediment, usually with some net removal of material to rivers or the ocean. The way in which channel networks and hillslopes evolve depends on their initial form, the slope processes operating, and the boundary conditions that determine where and how much sediment is removed.

The assemblages of sediment and solute processes tend to fall into two groups (Figure 10), corresponding to the dominance of infiltration excess overland flow or subsurface flow.

In humid areas, where subsurface flow is dominant, wash processes are less important than large and small mass movements for transporting sediment. Subsurface flow carries dissolved material, often removing more material in solution than is lost as particulate sediment. This leads to good soil development, dominance of transport limited removal, and a strong hydrological reinforcement of hollows (plan concavities). Hollows preferentially generate subsurface flow so that solution is greatest there, leading to enlargement of the hollows, and this is particularly striking in areas with soluble rocks. These hollows then generate saturation excess overland flow, enlarging them by some surface erosion. Mass movement processes give rise to convex (creep) or rectilinear (landslides) profiles so that the characteristic slope profile consists of a broad convexity and a narrow concavity that is often also concave in plan, forming a hollow around stream heads.

In contrast, semiarid areas are dominated by infiltration excess overland flow; surface wash processes are the most

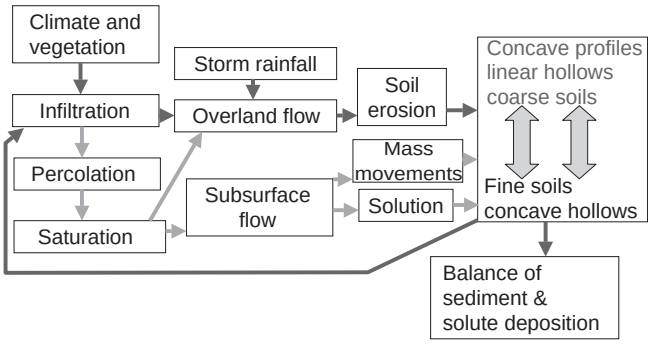

Figure 10 Overland and subsurface flow pathways and their geomorphic consequences. In semiarid conditions, hillslope development is dominated by overland flow and soil erosion, with relatively low chemical weather, and slopes are typically concave in profile, with coarse-textured soils. In humid areas, subsurface flow dominates, promoting weathering and mass movements, and tending to produce fine grained soils on mainly convex slope profiles, often with strong plan convergence around stream heads. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

important and solution less rapid. Soils are less weathered, thinner, and with lower clay content, and removal is commonly supply limited. The dominance of wash processes gives rise to concave slope profiles with only a narrow convexity around divides and, with none of the reinforcement processes to emphasize hollow development, landscapes tend to be more rectilinear in plan form.

Climate and hydrology also influence the density of stream channels within a landscape. Channels may be considered as a balance between hillslope processes that tend to fill them with sediment and channel processes that tend to clear them out. Both sets of processes are episodic so that stream heads may be filled with mass movement deposits for thousands of years before they are evacuated in a major flood. Thus, there are elements of chance in the position of observed stream heads due to the incidence of prior major flood events. The observed position may therefore fluctuate over time, but the persistence of a major valley represents some kind of time average of the balance between processes.

Theoretically (Smith and Bretherton, 1972), this balance is related to the balance between processes that increase less than linearly with drainage area (creep and rainsplash), for a given gradient, and those that increase more than linearly (certainly rillwash and perhaps landslides), that is, between processes that are not driven directly by water flow and those that are. For an unchanneled hillslope, it can be shown that there is a strong correspondence between the development of profile concavity and the dominance of water-driven processes.

As with hillslope forms, it is the balance between processes that determines the observed drainage density.

Two generalizations can be made, although the determining factors are still not fully understood. The first observation is that drainage density is generally higher in semiarid than in humid areas (e.g. Melton, 1957), and this seems to be a natural corollary of the narrower convexities in semiarid areas. The second observation is that drainage density is higher where gradient around the stream head is steeper. This result seems to indicate that the rate of water-driven processes increases more rapidly with gradient than for creep and rainsplash. The first of these effects is the stronger and creates regional contrasts, resulting in drainage densities of $>100\,\mathrm{km\,km^{-2}}$ in some semiarid areas, and down to $1-5\,\mathrm{km\,km^{-2}}$ in many humid areas. The gradient effect is generally weaker with about a 10 times range in the area needed to support a stream head, and is observed within as well as between areas following local topography.

CONCLUSION

In following the influences on catchment hydrology, it is clear that the form of the landscape is vitally important in affecting the response of the landscape to a storm event. The form of the landscape, however, is already a product of the hydrology over a long period, determining the soil, vegetation, hillslope forms, and channel network morphology. The climate has never remained constant, and is now changing, perhaps more rapidly than ever before. In understanding the structure of hydrological processes and their dynamic organization with respect to vegetation and landscape morphology, it is necessary to understand which parts of the physical system are truly constant, and which are dynamically changing in response to differences in both land use and climate.

5: Fundamental Hydrologic Equations

ROGER BECKIE

Department of Earth and Ocean Sciences, University of British Columbia, Vancouver, BC, Canada

In this article our goal is to present an overview of the fundamental principles that are the basis of most models used in hydrology. We develop the fundamental principles of mass, momentum, and energy conservation and express them in mathematical form. We first outline the general approach that can be used to develop a mathematical statement of a conservation law, using a so-called Eulerian framework, where we consider volumes fixed in time and space through which material may flow. We then derive the general conservation equations for mass, momentum, and energy for the case of flowing fluids. We next provide examples from hydrology that illustrate the application of the general conservation principles. We begin with relatively straightforward applications of the conservation equations and progress to more complex and less direct applications. Our first and simplest example is the advection–dispersion equation, which is a relatively transparent application of the conservation of mass principle, augmented with a so-called gradient-flux model, Fick's law, which describes the dispersion and diffusion of solute mass within the bulk flowing fluid. Next we present the Navier–Stokes equations, which are the conservation of momentum equations for a Newtonian fluid. The next suite of examples involves flow in porous media, which is described by more than one conservation principle applied simultaneously. Our last example is from engineering hydraulics, the Saint Venant equations, which are gross but practical simplifications of the general conservation statements.

INTRODUCTION

The principles of mass, momentum, and energy conservation are fundamental to quantitative hydrology. Most physically based models in hydrology respect these principles, and those models that violate them are viewed with great suspicion. These fundamental conservation principles are applied in the form of mathematical expressions so that they can be communicated precisely and succinctly and used for quantitative analysis. One may view mathematics as a "grammar" and "language" to communicate the "literature" of physical principles. In this article, we shall therefore focus mostly upon the mathematical development of the conservation principles and their manifestation in hydrology. In this way, we hope that our development will give physical meaning to the mathematical expressions. We will assume that the reader has an elementary understanding of multivariate calculus and differential equations.

We first state the fundamental principles and then outline the general ways in which mathematical expressions for these principles are formulated. We then develop general mathematical equations for each principle for the specific case of a flowing fluid, which in hydrology is usually water. These general equations are then typically used as the basis for expressions used in hydrology. We therefore conclude the article with a sequence of examples from hydrology to show how the principles are manifested in expressions that describe hydrologic processes.

FUNDAMENTAL CONSERVATION PRINCIPLES

The three fundamental principles are:

1. Conservation of mass: Mass is neither created nor destroyed.
2. Conservation of momentum: The momentum of a body is conserved unless it is acted upon by a force, in which case the rate of change of momentum equals the net force on the body.
3. Conservation of energy: Energy is neither created nor destroyed.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

There are two general ways in which these fundamental principles are applied in hydrologic analysis. In one way, the principles are used to establish an accounting or bookkeeping scheme to keep track of the mass, momentum, or energy moving into and out of a finite-sized closed region called a *control volume*. When applied to control volumes, the resulting conservation laws typically lead to algebraic expressions that quantify the gross behavior of the entire control volume. In the second general usage, conservation statements are written that apply at every mathematical point in a continuous medium. The conservation statements are then written in the form of differential equations, which when solved, yield detailed, point-wise information about the system. These continuous conservation statements can be understood and developed as limiting cases of finite-sized control volume statements. Generally, the control-volume approach is simpler to apply, but leads to coarser, bulk results. The second approach, using differential equations, has the potential to provide much more detailed information at the cost of a more difficult computation. Indeed, for many problems, analytical solutions do not exist for the differential equations and analytical simplifications or numerical approximations are required.

All the three conservation principles follow the same essential theme. When applied to a control volume, the conservation principles imply that *the amount of the conserved quantity (mass, momentum, or energy) entering a control volume during a specified time period, less the amount leaving during that time period, must equal the net change in conserved quantity stored in the control volume during that time period.*

For example, consider the control volume shown in Figure 1, which contains a catchment. The dotted line represents the surface of the control volume. If we let P be the precipitation rate, and ET be the rate at which water evaporates or transpires from plants out of the catchment, and G_{in} and G_{out} be the rates at which groundwater enters and leaves the catchment, and Q_{in} and Q_{out} be the rates at which surface water enters and leaves the catchment, then we can write the following statement for the conservation of mass (water) for an arbitrary time period Δt:

$$(P - ET + G_{\text{in}} - G_{\text{out}} + Q_{\text{in}} - Q_{\text{out}})\Delta t = \Delta S \qquad (1)$$

where ΔS is the change in mass stored over the time period Δt and where each term in the brackets has dimension of mass per unit time $[M/T]$. This algebraic expression of mass conservation is called a *water balance*. The terms in the water balance may depend upon other variables, leading to a more complex expression.

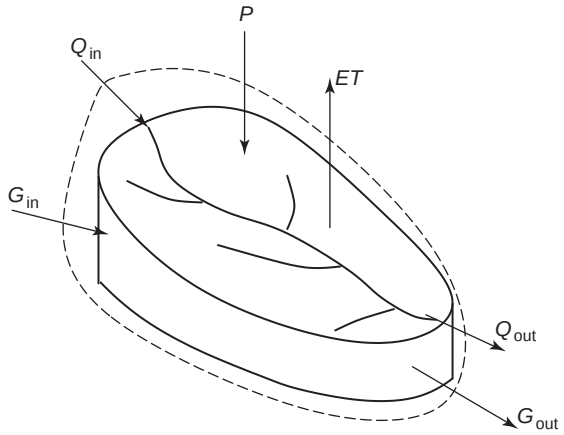

Figure 1 A control volume is any closed region where fluxes across the volume boundaries and changes in internal storage of mass, momentum, or energy are accounted for over specified time intervals. The catchment above can be considered a finite-sized control volume. P is precipitation flux, ET is the evapotranspiration flux, Q_{in} and Q_{out} are surface water flow into and out of the catchment, and G_{in} and G_{out} are subsurface fluxes into and out of the catchment

DIFFERENTIAL FORM OF CONSERVATION EXPRESSIONS

Differential representations of the fundamental conservation principles for flowing fluids are typically developed in one of two ways. In the first way, one refers to a control volume and then considers how a physical quantity, such as the mass contained in the control volume, changes with time. In this case, the control volume is usually fixed in space and time while fluid moves through it. This type of description is called an *Eulerian description*. In the second approach, a system under examination is considered to be composed of so-called material particles, which are small elements of constant mass. One then describes how properties such as the energy content, momentum, and geometry of each particle change in time. This type of description is known as a *material* or *Lagrangian description* of the system. In a sense, one tags along with an element of fluid mass and describes how it moves and its geometry, momentum, and energy change. The two different descriptions lead to different mathematical representations for the same conservation concepts. Convenience dictates the preference, although the Eulerian approach appears to be most common in hydraulics and hydrology. We shall develop Eulerian expressions here.

The derivations for the differential form of the mass, momentum, and energy conservation expressions all follow the same basic pattern. We consider a finite-sized control volume, fixed in space with fluid moving through it, and a time interval from t to $t + \Delta t$. We then write expressions

for: (i) $\{Stored\}_t$ and $\{Stored\}_{t+\Delta t}$, the amounts of the conserved quantity stored in the control volume at times t and $t + \Delta t$; (ii) $\{Net\ flux\}_{t \to t+\Delta t}$, the net amount of the conserved quantity carried into or out of the control volume by the flowing fluid during the time interval t to $t + \Delta t$; and (iii) $\{Sources\}_{t \to t+\Delta t}$, the net amount of the conserved quantity added to or removed from the control volume by other processes during the time from t to $t + \Delta t$. Processes that can add or remove a conserved quantity to or from the control volume are typically specific to a conserved quantity. For example, the process of heat conduction can transport energy into and out of the control volume. With the expressions described above, the conservation principle for the control volume is written:

$$\{Net\ flux\}_{t \to t+\Delta t} + \{Sources\}_{t \to t+\Delta t} = \{Stored\}_{t+\Delta t} - \{Stored\}_t \quad (2)$$

If we then divide this expression by the volume of the control volume and the time interval Δt, and shrink the volume and time interval to a point in space and time, then a differential conservation expression results.

The differential conservation equations are idealizations that apply at the mathematical point and instant in timescale, whereas the finite-volume conservation equations, such as the catchment-scale water balance (equation 1), apply to finite volumes for discrete intervals of time. Accordingly, if the differential conservation equation holds at each point in a region of space over a continuous time interval, then a finite-volume conservation expression can also be developed for any closed finite subvolume and time interval in that region.

The general conservation equations that we develop are valid for any continuous media such as solids, gases, and liquids. In the case of hydrology, the most common medium will be water. The only critical assumption is that the media be continuous, meaning that its physical properties change smoothly in time and space, such that derivatives of these properties exist at all points. We shall see later in the examples where we develop equations for flow in porous media that we have to first define a continuum to apply these principles. We next derive the differential mass, momentum, and energy conservation equations.

Conservation Of Mass

The mass conservation principle states that mass is neither created nor destroyed. Einstein showed that this is not exactly true, since mass and energy are equivalent. However, for almost all processes of interest to hydrology, energy levels are not high enough for a measurable exchange between mass and energy. Consequently, mass is essentially conserved in hydrologic systems.

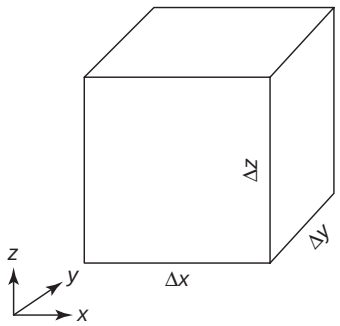

Figure 2 A control volume that is used to develop differential forms of the conservation principles. We conceptually shrink this finite-sized control volume to a mathematical point to develop differential forms of the conservation principles

To develop a differential expression, we examine mass conservation over an interval of time from t to $t + \Delta t$ for a rectangular control volume of size $\Delta x \Delta y \Delta z$ fixed in space at a point (x, y, z) (Figure 2). To avoid confusing subtleties, we first assume that the control volume is always fully saturated with water. Later we will consider more than one fluid phase when we develop expressions describing the unsaturated zone in soils. We also assume that we can define mathematically continuous parameters such as density ρ and dependent variables such as velocity with components (v_x, v_y, v_z). To derive the mass conservation expression, we must compute the net mass flux into the control volume and equate it with the change in mass storage over the time interval Δt.

Consider the two faces of the control volume that are perpendicular to the x coordinate direction, one located at x and one at $x + \Delta x$ (Figure 3). Over the time interval, Δt the mass carried into the control volume by the flowing fluid on the x face is $\rho v_x|_x \Delta y \Delta z \Delta t$, and the mass carried out of the $x + \Delta x$ face is $\rho v_x|_{x+\Delta x} \Delta y \Delta z \Delta y$ (the notation $\rho v_x|_{x+\Delta x}$ is to be read "ρv_x evaluated at the

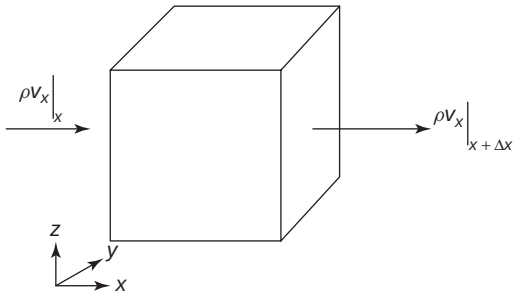

Figure 3 The control volume used to develop the conservation of mass equation. Here, ρ is the fluid density and v_x is the x-component of the fluid flow velocity. Accordingly, ρv_x is the x-component of the mass flux vector

Table 1 Conservation of mass flux terms

Face	Inlet mass flux	Outlet mass flux
x	$\rho v_x\|_x \Delta y \Delta z \Delta t$	$\rho v_x\|_{x+\Delta x} \Delta y \Delta z \Delta t$
Y	$\rho v_y\|_y \Delta x \Delta z \Delta t$	$\rho v_y\|_{y+\Delta y} \Delta x \Delta z \Delta t$
z	$\rho v_z\|_z \Delta x \Delta y \Delta t$	$\rho v_z\|_{z+\Delta z} \Delta x \Delta y \Delta t$

point located at $x + \Delta x$"). In the same fashion, we can express the mass flux across the faces in the y- and z-direction. The fluxes across each face are summarized in Table 1.

The mass contained in the volume at time t and time $t + \Delta t$ is simply the density times the volume at those times, or $\rho \Delta x \Delta y \Delta z|_t$ and $\rho \Delta x \Delta y \Delta z|_{t+\Delta t}$. Referring to the general conservation principle in equation (2), where we assume that there are no sources of mass inside the volume, we can write the finite-volume mass conservation expression

$$\begin{aligned}(\rho v_x|_x - \rho v_x|_{x+\Delta x})\Delta y \Delta z \Delta t \\ + (\rho v_y|_y - \rho v_y|_{y+\Delta y})\Delta x \Delta z \Delta t \\ + (\rho v_x|_z - \rho v_z|_{z+\Delta z})\Delta x \Delta y \Delta t \\ = (\rho|_{t+\Delta t} - \rho|_t)\Delta x \Delta y \Delta z \end{aligned} \quad (3)$$

Dividing by the volume $\Delta x \Delta y \Delta z$ and the time interval Δt we have

$$\begin{aligned}\frac{(\rho v_x|_x - \rho v_x|_{x+\Delta x})}{\Delta x} + \frac{(\rho v_y|_y - \rho v_y|_{y+\Delta y})}{\Delta y} \\ + \frac{(\rho v_z|_z - \rho v_z|_{z+\Delta z})}{\Delta z} = \frac{(\rho|_{t+\Delta t} - \rho|_t)}{\Delta t} \end{aligned} \quad (4)$$

Last, recognize that as the dimensions of the volume and the length of the time interval shrink, we can interpret terms as derivatives $(\rho v_x|_x - \rho v_x|_{x+\Delta x})/\Delta x \rightarrow -\partial(\rho v_x)/\partial x$, where $\partial(\rho v_x)/\partial x$ is the partial derivative of ρv_x with respect to x, and can be thought of as the rate at which the value of ρv_x changes in the x-direction. The result is the mass conservation equation for a flowing fluid,

$$-\frac{\partial(\rho v_x)}{\partial x} - \frac{\partial(\rho v_y)}{\partial y} - \frac{\partial(\rho v_z)}{\partial z} = \frac{\partial \rho}{\partial t} \quad (5)$$

This equation is also known as the *continuity equation*. The continuity equation is written using the so-called vector notation as

$$-\nabla \cdot (\rho \overline{v}) = \frac{\partial \rho}{\partial t} \quad (6)$$

where $\overline{v}$ is the notation for the water velocity vector, and the divergence operator $\nabla.()$ is defined for Cartesian coordinates as $\nabla \cdot (\rho \overline{v}) = \partial(\rho v_x)/\partial x + \partial(\rho v y)/\partial y + \partial(\rho v_z)/\partial z$.

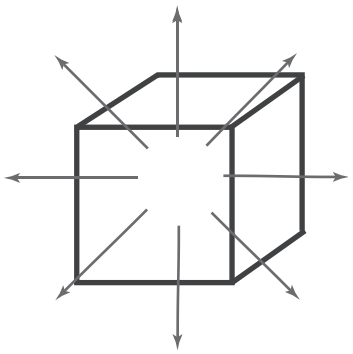

Figure 4 Divergence of a quantity is positive at a point when the flux of the quantity is diverging from a point. In the absence of sources of the quantity at that point, the amount of the quantity at that point must be decreasing

A conservation expression is often betrayed by the divergence operator, in vector form $\nabla \cdot (\overline{f})$, where $\overline{f}$ is the flux rate of a conserved quantity into a point by some transport process (e.g. in the conservation of mass, equations (5) or (6), the mass flux rate is $\rho \overline{v}$ and the transport process is the flow of water). As shown in Figure 4, a positive divergence at a point indicates that the flux of the conserved quantity is *diverging* or flowing away from the point. Accordingly, the amount of the conserved quantity at that point must be decreasing with time. Mathematically, if for example, the divergence of the mass flux is positive at a point, $\nabla \cdot (\rho \overline{v}) > 0$, then by equation (6), $\partial \rho / \partial t < 0$ and the mass at that point must be decreasing. The divergence is easy to recognize when written in vector form such as in equation (6).

Essentially, the differential continuity equation is a balance between the net mass flux rate into a mathematical point (the three terms on the left-hand side of equation 5) and the rate at which the mass stored in the point changes in time (the term on the right-hand side). However, because the equation is derived from a finite-sized control volume, it is sometimes easier to interpret the differential conservation equations with a small control volume in mind. We will show in examples to follow that a conservation principle is concealed in many of the common expressions used in hydrology.

An important, special case of the continuity equation is that for an *incompressible fluid*. If the fluid is incompressible, $\partial \rho / \partial t = 0$ and so $\nabla \cdot (\rho \overline{v}) = 0$, and since $\nabla \rho = 0$ also holds for an incompressible fluid, the continuity equation (6) becomes

$$\nabla \cdot \overline{v} = 0 \quad (7)$$

Conversely, at any moment when the divergence of the fluid velocity is not zero, $\nabla \cdot \overline{v} \neq 0$, then the fluid must be compressing or expanding. Indeed, we state without proof

that $\nabla \cdot \overline{v}$ equals the volumetric rate of deformation of a fluid element (Panton, 1984).

Conservation Of Momentum

The relationship between momentum and force is given by Newton's second law, which states that a force $\overline{F}$ (a vector) on an isolated body equals the mass of the body times the acceleration. Acceleration is defined as rate of change of the velocity vector $\mathrm{d}\overline{v}/\mathrm{d}t$ so

$$\overline{F} = m\frac{\mathrm{d}\overline{v}}{\mathrm{d}t} = \frac{\mathrm{d}(m\overline{v})}{\mathrm{d}t} \tag{8}$$

where the momentum is $m\overline{v}$. The conservation of momentum principle states that *the momentum of a body is constant unless it is acted upon by a force, in which case the rate of change of momentum equals the net force* (equation 8). The conservation of momentum equations can be developed for a flowing fluid in much the same fashion as the continuity equation. There are actually three equations, since momentum is a vector quantity, unlike mass, which is scalar.

To develop the momentum balance, we must consider all forces acting on the fluid, since forces are a source of momentum. It is sometimes difficult to determine what forces are relevant to a problem, especially when the reference frame (coordinate system) that is used for the problem is accelerating. Such a coordinate system is called a *non-inertial reference frame*. For large-scale problems in geophysical fluid dynamics, in the order of tens of kilometers and more, the acceleration of the earth's surface, relative to the fixed stars, means that a coordinate system fixed to the earth will be non-inertial. For smaller-scale problems, the effect of the earth's rotation is negligible and can be ignored.

We derive the differential form of the conservation of momentum for a flowing fluid in an inertial (nonaccelerating) reference frame. For simplicity, we will only present the development for the x-component of momentum in detail. We follow the same procedure that we used to develop the mass conservation equation: we consider a small control volume of size $\Delta x \Delta y \Delta z$ fixed in space at a point (x, y, z) and compute the momentum flux by fluid flow into the volume over a time period from t to $t + \Delta t$, plus any momentum-generating forces acting on the fluid, and equate these with the change in momentum stored in the volume.

The x-momentum contained in the volume at time t and time $t + \Delta t$ is the fluid density times the velocity in the x-direction (i.e. the x-component of momentum) times the volume, or $\rho v_x \Delta x \Delta y \Delta z|_t$ and $\rho v_x \Delta x \Delta y \Delta z|_{t+\Delta t}$. Following the argument for the conservation of mass, the $x-$component momentum fluxes carried into and out of the volume by the flow are summarized in Table 2.

Table 2 Conservation of momentum flux terms

Face	Inlet x-momentum flux	Outlet x-momentum flux
x	$\rho v_x v_x\|_x \Delta y \Delta z \Delta t$	$\rho v_x v_x\|_{x+\Delta x} \Delta y \Delta z \Delta t$
y	$\rho v_x v_y\|_y \Delta x \Delta z \Delta t$	$\rho v_x v_y\|_{y+\Delta y} \Delta x \Delta z \Delta t$
z	$\rho v_x v_z\|_z \Delta x \Delta y \Delta t$	$\rho v_x v_z\|_{z+\Delta z} \Delta x \Delta y \Delta t$

Two other similar tables could be listed for the y- and z-component fluxes. Each term in this table is actually an impulse, that is, a force through time, which according to equation (8), is an increment of momentum, that is, $\overline{F} \times \mathrm{d}t = \mathrm{d}(m\overline{v})$.

The terms in Table 2 quantify the flux of momentum into the control volume by the flow of the fluid. To complete conservation law, we must account for remaining sources of momentum, namely, the forces acting on the fluid.

The forces acting on the fluid include gravity, pressure gradients, and friction (viscous stresses). Here it is best to conceptualize the conservation equations with a control volume in mind (a point-scale volume for the differential equations). In that context, forces acting on a fluid are often conceptualized as body forces, acting on the bulk material or as surface forces, typically pressure and viscous drag effects acting on the boundaries of the control volume. We next compute the impulses contributed by these forces on the fluids.

The x-component of impulse contributed to the fluid in the control volume by gravity is simply the mass of fluid times gravity (the gravity force) times the time interval, $\rho g_x \Delta x \Delta y \Delta z \Delta t$ where g_x is the x-component of the acceleration of gravity.

To show how pressure leads to a net force, we must consider the small control volume again (Figure 5). Pressure over an area is a force, so there is an inward directed force on each face of the control volume. If the pressure

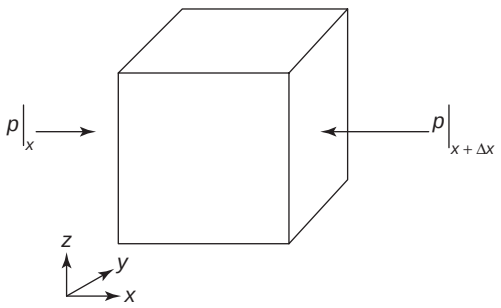

Figure 5 Pressure on a face creates a force that is directed toward the center of the volume. If pressures on opposite sides of the volume are the same, then each generates the same force and the net force is zero. Pressure forces therefore result from pressure differences, which are quantified by the pressure gradient

is the same everywhere, then there will be no net force on the volume. A net force results when there is a difference in pressure force in a given direction. Accordingly, the net x-component impulse contributed by fluid pressure is $(p|_x - p|_{x+\Delta x})\Delta y \Delta z \Delta t$. As we show next, a stress imbalance across the control volume also leads to a net force.

Internal shearing and viscosity lead to stresses that are felt on each face of the control volume. Consider the control volume in Figure 6. On the x face at $x + \Delta x$ is shown three components of the viscous stress τ. For example, on the face perpendicular to the x-direction, there is a normal viscous stress τ_{xx} and two shear components, one pointing in the z-direction, τ_{zx} and one in the y-direction, τ_{yx}. The viscous stress state in the fluid can be described by a 3×3 *viscous stress tensor* that is given in Cartesian components as

$$\overline{\overline{\tau}} = \begin{bmatrix} \tau_{xx} & \tau_{yx} & \tau_{zx} \\ \tau_{xy} & \tau_{yy} & \tau_{zy} \\ \tau_{xz} & \tau_{yz} & \tau_{zz} \end{bmatrix}$$

A tensor is a generalization of the concept of a vector, and has magnitude and directional properties (Bird *et al.*, 1960). For our purposes, each component of the stress tensor can be thought of as a force per unit area such that a net force on a surface from a stress component is the stress component times the area over which it acts. Following the example for pressure from above, (see Figure 5) the net impulse from the viscous stress force in the x-direction results from the differences in normal stress components at x and $x + \Delta x$, $(-\tau_{xx}|_x + \tau_{xx}|_{x+\Delta x})\Delta y \Delta z \Delta t$, plus the x-component of the net shear stress forces contributed by differences in shear forces at the faces perpendicular to y-direction, $(-\tau_{yx}|_y + \tau_{yx}|_{y+\Delta y})\Delta x \Delta z \Delta t$ and the z-direction, $(-\tau_{zx}|_z + \tau_{zx}|_{z+\Delta z})\Delta x \Delta y \Delta t$. Note that stress here is positive for tension, in contrast to pressure, which is positive for compression; in some developments stress is positive for compression however.

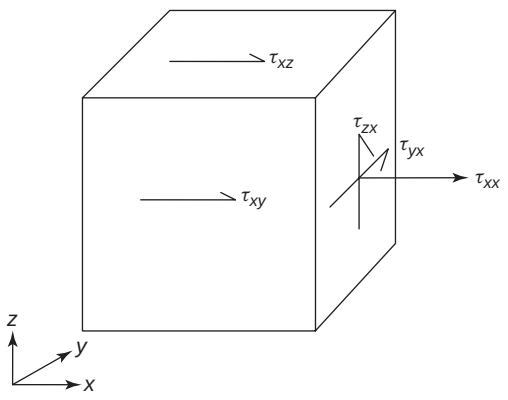

Figure 6 Stress over an area is a force. The net x-component force is a sum of the force caused by the normal stress on the face normal to the x-direction, τ_{xx} plus the shear stresses on the other faces, such as τ_{xy} and τ_{xz}

We now collect the expressions for the flux of momentum through the boundary of the control volume, the sources of momentum from surface and body forces, and equate the sum to the change in the momentum stored in the control volume at times t and Δt to give

$$\begin{aligned}
&(\rho v_x v_x|_x - \rho v_x v_x|_{x+\Delta x})\Delta y \Delta z \Delta t \\
&\quad + (\rho v_x v_y|_y - \rho v_x v_y|_{y+\Delta y})\Delta x \Delta z \Delta t \\
&\quad + (\rho v_x v_z|_z - \rho v_x v_z|_{z+\Delta z})\Delta x \Delta y \Delta t \\
&\quad + \rho g_x \Delta x \Delta y \Delta z \Delta t + (p|_x - p|_{x+\Delta x})\Delta y \Delta z \Delta t \\
&\quad + (-\tau_{xx}|_x + \tau_{xx}|_{x+\Delta x})\Delta y \Delta z \Delta t \\
&\quad + (-\tau_{yx}|_y + \tau_{yx}|_{y+\Delta y})\Delta x \Delta z \Delta t \\
&\quad + (-\tau_{zx}|_z + \tau_{zx}|_{z+\Delta z})\Delta x \Delta y \Delta t \\
&\quad = (\rho v_x|_{t+\Delta t} - \rho v_x|_t)\Delta z \Delta y \Delta z
\end{aligned} \tag{9}$$

Dividing by the volume and time interval, and shrinking the control volume and time interval as we did in equations (3) to (5), we arrive at the following conservation of the x-component of momentum equation

$$-\frac{\partial(\rho v_x v_x)}{\partial x} - \frac{\partial(\rho v_y v_x)}{\partial y} - \frac{\partial(\rho v_z v_x)}{\partial z} - \frac{\partial p}{\partial x} + \left(\frac{\partial \tau_{xx}}{\partial x} + \frac{\partial \tau_{xy}}{\partial y} + \frac{\partial \tau_{xz}}{\partial z}\right) + \rho g_x = \frac{\partial(\rho v_x)}{\partial t} \tag{10}$$

Similarly, there are two more equations for the y- and z-components of the momentum vector

$$-\frac{\partial(\rho v_x v_y)}{\partial x} - \frac{\partial(\rho v_y v_y)}{\partial y} - \frac{\partial(\rho v_z v_y)}{\partial z} - \frac{\partial p}{\partial y} + \left(\frac{\partial \tau_{yx}}{\partial x} + \frac{\partial \tau_{yy}}{\partial y} + \frac{\partial \tau_{yz}}{\partial z}\right) + \rho g_y = \frac{\partial(\rho v_y)}{\partial t} \tag{11}$$

$$-\frac{\partial(\rho v_x v_z)}{\partial x} - \frac{\partial(\rho v_y v_z)}{\partial y} - \frac{\partial(\rho v_z v_z)}{\partial z} - \frac{\partial p}{\partial z} + \left(\frac{\partial \tau_{zx}}{\partial x} + \frac{\partial \tau_{zy}}{\partial y} + \frac{\partial \tau_{zz}}{\partial z}\right) + \rho g_z = \frac{\partial(\rho v_z)}{\partial t} \tag{12}$$

All three equations can be written in a compact vector form as

$$-\nabla\cdot(\rho \overline{v}\overline{v}) - \nabla p + \nabla\cdot\overline{\overline{\tau}} + \rho \overline{g} = \frac{\partial(\rho \overline{v})}{\partial t} \tag{13}$$

The terms in equation (13) can be read from left to right as: (i) the net flux of momentum into the point by the flow of the fluid (note the divergence operator here); (ii) the source or sink of momentum per unit volume by the pressure gradient (a net force caused by a force imbalance);

(iii) the source or sink of momentum per unit volume due to viscous stress gradients (again a force imbalance); (iv) the source of momentum due to the gravitational force, all summed and balanced by; (v) the time rate of change of momentum at the point.

Equation (13) is sometimes more specifically called the *conservation of linear momentum* to distinguish it from the conservation of angular momentum equation. We will not discuss angular momentum here. The three equations contained in (13), one for each coordinate direction, are often the *equations of motion* and can be thought of as statements of Newton's second law.

Conservation of Energy

The conservation of energy principle states that energy is neither created nor destroyed. For a control volume, this implies that *the net rate at which energy is transferred into or out of the control volume by heat or work must balance the net rate of change of energy stored in the control volume*. Energy can be stored in three forms: (i) internal energy u, which is the energy stored by molecular motions and vibrations of the material in the control volume; (ii) kinetic energy, given by $mv^2/2$ for a body and by $v^2/2$ on a per unit mass basis, where v^2 is the magnitude of the velocity vector of the bulk fluid squared; and (iii) potential energy. Gravity can be treated in terms of potential energy or as work against a force. Potential energy is "stored" by work against a potential field ϕ, where the potential field is related to the acceleration of gravity by $\nabla\phi = \overline{g}$. Therefore, for the situation where z is pointed up and the acceleration of gravity is uniform and directed down, the gravitational potential is $\phi = gz$, where g is the magnitude of the gravity vector and z is measured from a specified plane in a direction opposite to the gravitational field. Instead of following the potential approach, we will develop the fundamental conservation of energy equation where we treat gravity in terms of work.

We again consider a fixed control volume $\Delta x\Delta y\Delta z$. The internal and kinetic energy inside the control volume at time t and $t+\Delta t$ is $\rho\left(u+1/2v^2\right)\big|_t \Delta x\Delta y\Delta z$ and $\rho\left(u+1/2v^2\right)\big|_{t+\Delta t} \Delta x\Delta y\Delta z$. Energy is transported into the control volume by the bulk fluid flow. Over the time interval Δt, the energy transport by the bulk fluid is given by the terms in the Table 3.

Next we determine the energy transfers by heat and work. Here we let the vector $\overline{q}_h$ be the heat-flux vector with units of energy per unit area per unit time. The net heat conduction into the control volume over the time interval Δt is then given by

$$(q_{hx}|_x - q_{hx}|_{x+\Delta x})\Delta y\Delta z\Delta t + (q_{hy}|_y - q_{hy}|_{y+\Delta y})\Delta x\Delta z\Delta t + (q_{hz}|_z - q_{hz}|_{z+\Delta z})\Delta x\Delta y\Delta t \quad (14)$$

We consider work by the bulk fluid by body forces such as gravity, and work done by the fluid at the surface of the control volume by pressure and viscous stress. Work by definition is a force through a distance in the direction of the force. Work *by* the fluid on the surroundings is negative (energy loss) and work *on* the fluid is positive (energy gain). The work by the x-component of gravity is the gravity force (which is the acceleration of gravity in the x-direction, g_x, times the mass of fluid $\rho\Delta x\Delta y\Delta z$) multiplied by the distance moved in the direction of the force ($v_x\Delta t$). Summing the work by all components gives:

$$\rho(v_x g_x + v_y g_y + v_z g_z)\Delta x\Delta y\Delta z\Delta t \quad (15)$$

The fluid gains energy (work on the fluid) when the velocity vector and gravity vectors are oriented in the same direction.

The energy added by pressure forces can be described in simple terms as a force multiplied by the velocity at the surface of the control volume. The force is the pressure times the area. Summing from all sides, the energy entering over the time interval Δt from pressure work is

$$\{(pv_x)|_{x+\Delta x} - (pv_x)|_x\}\Delta y\Delta z\Delta t + \{(pv_y)|_{y+\Delta y} - (pv_y)|_y\}\Delta x\Delta z\Delta t + \{(pv_z)|_{z+\Delta z} - (pv_z)|_z\}\Delta x\Delta y\Delta t \quad (16)$$

We will examine the meaning of the pressure work term in more detail later.

Viscous-stress work takes the form of a force (difference in stress × area) times distance in the force direction (velocity × time interval). For example, the net work from normal stresses on the x faces is ($[\tau_{xx}|_{x+\Delta x} -$

Table 3 Conservation of energy flux terms

Face	Inlet energy flux	Outlet energy flux
x	$\rho v_x\left(u+\frac{1}{2}v^2\right)\Big\|_x \Delta y\Delta z\Delta t$	$\rho v_x\left(u+\frac{1}{2}v^2\right)\Big\|_{x+\Delta x} \Delta y\Delta z\Delta t$
y	$\rho v_y\left(u+\frac{1}{2}v^2\right)\Big\|_y \Delta x\Delta z\Delta t$	$\rho v_y\left(u+\frac{1}{2}v^2\right)\Big\|_{y+\Delta y} \Delta x\Delta z\Delta t$
z	$\rho v_z\left(u+\frac{1}{2}v^2\right)\Big\|_z \Delta x\Delta y\Delta t$	$\rho v_z\left(u+\frac{1}{2}v^2\right)\Big\|_{z+\Delta z} \Delta x\Delta y\Delta t$

$\tau_{xx}|_x]\Delta y\Delta z)(v_x\Delta t)$. We must account for both normal and shear stress components. Summing the stress-related work on all faces, and rearranging, we have

$$\begin{aligned}
&\{(\tau_{xx}v_x + \tau_{xy}v_y + \tau_{xz}v_z)|_{x+\Delta x} \\
&\quad - (\tau_{xx}v_x + \tau_{xy}v_y + \tau_{xz}v_z)|_x\}\Delta y\Delta z\Delta t \\
&\quad + \{(\tau_{yx}v_x + \tau_{yy}v_y + \tau_{yz}v_z)|_{y+\Delta y} \\
&\quad - (\tau_{yx}v_x + \tau_{yy}v_y + \tau_{yz}v_z)|_y\}\Delta x\Delta z\Delta t \\
&\quad + \{(\tau_{zx}v_x + \tau_{zy}v_y + \tau_{zz}v_z)|_{z+\Delta z} \\
&\quad - (\tau_{zx}v_x + \tau_{zy}v_y + \tau_{zz}v_z)|_z\}\Delta x\Delta y\Delta t \qquad (17)
\end{aligned}$$

The physics of energy transfer by radiation is complex. We represent it by R, the radiation flux density per unit volume. The net energy lost by radiation over the time interval Δt is then

$$R\Delta x\Delta y\Delta z\Delta t \qquad (18)$$

The conservation of the energy equation is now obtained by summing the terms for the flux of internal energy across the boundaries of the control volume, the net transfer of energy by conduction, pressure and viscous work, and radiation and equating that with the difference in energy stored at times t and $t + \Delta t$. Following the familiar procedure, we divide by the volume and time interval to arrive at the conservation of energy equation with $e_t = u + 1/2v^2$,

$$\begin{aligned}
&-\frac{\partial(\rho v_x e_t)}{\partial x} - \frac{\partial(\rho v_y e_t)}{\partial y} - \frac{\partial(\rho v_z e_t)}{\partial z} \\
&+ \rho(v_x g_x + v_y g_y + v_z g_z) - \frac{\partial q_{hx}}{\partial x} - \frac{\partial q_{hy}}{\partial y} - \frac{\partial q_{hz}}{\partial z} \\
&- \frac{\partial(pv_x)}{\partial x} - \frac{\partial(pv_y)}{\partial y} - \frac{\partial(pv_z)}{\partial z} \\
&+ \frac{\partial}{\partial x}(\tau_{xx}v_x + \tau_{xy}v_y + \tau_{xz}v_z) \\
&+ \frac{\partial}{\partial y}(\tau_{yx}v_x + \tau_{yy}v_y + \tau_{yz}v_z) \\
&+ \frac{\partial}{\partial z}(\tau_{zx}v_x + \tau_{zy}v_y + \tau_{zz}v_z) - R = \frac{\partial(\rho e_t)}{\partial t} \qquad (19)
\end{aligned}$$

In vector notation,

$$\begin{aligned}
&-\nabla\cdot(\rho\overline{v}e_t) + \rho(\overline{v}\cdot\overline{g}) - \nabla\cdot\overline{q}_h - \nabla\cdot(p\overline{v}) + \nabla\cdot(\overline{\overline{\tau}}\cdot\overline{v}) - R \\
&\qquad = \frac{\partial(\rho e_t)}{\partial t} \qquad (20)
\end{aligned}$$

Although the equation appears impenetrable, it has a simple interpretation. Reading each term in the vector-notation equation (20) starting at the left: (i) the net rate of energy input by transport with flowing fluid; (ii) the rate of work done on the fluid per unit volume by gravitational forces; (iii) the rate of energy input per unit volume by heat conduction; (iv) the rate of work done on the fluid per unit volume by pressure forces; (v) the rate of work done on the fluid by viscous forces; (vi) the rate of energy received per unit volume by radiation; and (vii) the right-hand side which equals the net rate of energy gain per unit volume.

To better appreciate the pressure work term $\nabla\cdot(p\overline{v})$, we chain out the derivative to give

$$p(\nabla\cdot\overline{v}) + \overline{v}\cdot\nabla p \qquad (21)$$

The first term can be interpreted as a contribution to internal or thermal energy. Because $(\nabla\cdot\overline{v})$ is equal to the volumetric rate of deformation of a fluid, $p(\nabla\cdot\overline{v})$ can be interpreted as a force (pressure) times a deformation. The term thus represents the heating or cooling of the fluid because of compression or expansion. In the second term $\overline{v}\cdot\nabla p$, the pressure gradient can be interpreted as a force imbalance across a fluid element that is multiplied component-wise with the velocity, and thus is a contribution to the kinetic energy.

The conservation of energy is often further divided into a conservation of a mechanical energy equation and a conservation of a thermal energy equation. The mechanical energy equation is given by

$$-\nabla\cdot\left(\rho\overline{v}\frac{v^2}{2}\right) + \rho\overline{v}\cdot\overline{g} - \overline{v}\cdot\nabla p + \overline{v}\cdot(\nabla\cdot\overline{\overline{\tau}}) = \frac{\partial}{\partial t}\left(\rho\frac{v^2}{2}\right) \qquad (22)$$

The terms of the mechanical energy equation (22) represent: (i) the transport of kinetic energy into the volume by the bulk fluid flow; (ii) the work on the fluid by the gravitational force; (iii) a velocity times a force gradient, or pressure work; (iv) a velocity time a stress (force) gradient; equals (v) the rate of change of kinetic energy at the point.

The conservation of thermal energy is then given by subtracting the mechanical energy equation from the total energy equation to give

$$-\nabla\cdot(\rho\overline{v}u) - \nabla\cdot\overline{q}_h - p\nabla\cdot\overline{v} + \overline{\overline{\tau}} : \nabla\overline{v} - R = \frac{\partial(\rho u)}{\partial t} \qquad (23)$$

where $\overline{\overline{\tau}} : \nabla\overline{v}$ is notation for the complex expression

$$\begin{aligned}
\overline{\overline{\tau}} : \nabla\overline{v} = {} & \tau_{xx}\frac{\partial v_x}{\partial x} + \tau_{yx}\frac{\partial v_y}{\partial x} + \tau_{zx}\frac{\partial v_z}{\partial x} \\
& + \tau_{xy}\frac{\partial v_x}{\partial y} + \tau_{yy}\frac{\partial v_y}{\partial y} + \tau_{zy}\frac{\partial v_z}{\partial y} \\
& + \tau_{xz}\frac{\partial v_x}{\partial z} + \tau_{yz}\frac{\partial v_y}{\partial z} + \tau_{zz}\frac{\partial v_z}{\partial z}
\end{aligned}$$

The terms in the thermal energy equation (23) represent: (i) the transport of thermal energy into the control volume by the bulk fluid flow; (ii) the flux of heat into the volume by conduction; (iii) the heating or cooling of the fluid by volume expansion; (iv) the heating (always) of the fluid by viscous dissipation because of fluid–fluid friction; (v) the net transport of energy into the volume by radiation equals (vi) the rate of change of internal energy within the volume.

Summary of Conservation Equations

1. Conservation of Mass:

$$-\nabla\cdot(\rho\overline{v}) = \frac{\partial\rho}{\partial t} \tag{24}$$

2. Conservation of Linear Momentum (three equations):

$$-\nabla\cdot(\rho\overline{v}\overline{v}) - \nabla p + \nabla\cdot\overline{\overline{\tau}} + \rho\overline{g} = \frac{\partial(\rho\overline{v})}{\partial t} \tag{25}$$

3. Conservation of Total Energy:

$$-\nabla\cdot(\rho\overline{v}e_t) + \rho(\overline{v}\cdot\overline{g}) - \nabla\cdot\overline{q}_h - \nabla\cdot(p\overline{v}) + \nabla\cdot(\overline{\overline{\tau}}\cdot\overline{v}) - R = \frac{\partial(\rho e_t)}{\partial t} \tag{26}$$

   (a) Conservation of Mechanical Energy:

$$-\nabla\cdot\left(\rho\overline{v}\frac{v^2}{2}\right) + \overline{v}\cdot(\nabla\cdot\overline{\overline{\tau}}) - \overline{v}\cdot\nabla p + \rho\overline{v}\cdot\overline{g} = \frac{\partial}{\partial t}\left(\rho\frac{v^2}{2}\right) \tag{27}$$

   (b) Conservation of Thermal Energy:

$$-\nabla\cdot(\rho\overline{v}u) - p\nabla\cdot\overline{v} + \overline{\overline{\tau}} : \nabla\overline{v} - \nabla\cdot\overline{q}_h - (\varepsilon - \alpha) = \frac{\partial(\rho u)}{\partial t} \tag{28}$$

HYDROLOGY EXAMPLES

We conclude this article with several examples of these general conservation principles from hydrology. Most of the models used in hydrology are based upon one or more of the fundamental equations above, typically augmented by semiempirical expressions that describe specific processes. Here we focus upon the equations and their relationship to the fundamental conservation statements. We refer the reader to the other articles in this volume for a comprehensive development of the physical principles behind these hydrology examples. In the examples that follow, we begin with relatively straightforward applications of the conservations and progress to more complex and less direct applications.

Our first and simplest example is the advection–dispersion equation, which is a relatively transparent application of the conservation of mass principle, augmented with a so-called gradient-flux model, Fick's law, that describes the dispersion and diffusion of solute mass within the bulk flowing fluid. Our second example is the Navier–Stokes equations, which are mathematically complex and challenging, but are essentially just the conservation of momentum equations augmented with a model that describes the dissipation of momentum to heat caused by internal friction (viscosity) within the fluid.

The next suite of examples involves flow in porous media, which is described by more than one conservation principle applied simultaneously. First we develop the groundwater flow equation, which results when the conservation of momentum equations are substituted into the mass conservation equation. The conservation of momentum equations appears in the form of Darcy's law, which was only recognized as a conservation of momentum equation after its original formulation. We then consider the simultaneous flow of more than one fluid in porous media, which can be described with a coupled system of equations, sometimes called *the multiphase flow equations*. Often, in the air-water systems found in unsaturated porous media (e.g. soils), the multiphase flow equations can be simplified, flow of air ignored, and a single equation called *Richard's equation* can be used to describe the flow of water.

Our last example is from engineering hydraulics, the Saint Venant equations which are perhaps the most difficult to directly connect to the fundamental equations as developed above. The Saint Venant equations are gross simplifications of the general conservation statements, but prove to be quite practical and are widely used in application to flood routing and open-channel flow.

Advection–Dispersion Equation

An equation that arises frequently in hydrology is the advection–dispersion equation, which describes the transport of solutes such as a salt or dissolved species in a flowing fluid. It is applied in open fluids, such as streams, lakes, and rivers, as well as in porous media (*see* **Chapter 69, Solute Transport in Soil at the Core and Field Scale, Volume 2** and **Chapter 152, Modeling Solute Transport Phenomena, Volume 4**).

To develop the advection–dispersion equation, we first define the solute concentration c as the mass of the solute per volume of solution. The mass of solute in a control volume (assuming that the solution fills the entire control volume) is then the concentration multiplied by the volume of the control volume, $c\Delta x\Delta y\Delta z$. The corresponding

expression from the earlier conservation of fluid mass development is $\rho\Delta x\Delta y\Delta z$ (cf. equation 3).

Solute is transported by the flow of the bulk fluid and by a combination of diffusion and dispersion relative to the bulk flow. The mass of solute transported by the bulk flow of water that moves at mean velocity v_x across the face perpendicular to the x-direction in time period Δt is $v_x c\Delta y\Delta z\Delta t$. Recall that the corresponding expression from the conservation of fluid mass development is $v_x\rho\Delta y\Delta z\Delta t$ (Table 1).

Mass transport relative to the bulk flow by diffusion and dispersion is often modeled using Fick's law, which for one-dimensional transport in the x-direction is given by $-D\partial c/\partial x$, with dimensions of $[M/L^2T]$ or mass crossing unit area in unit time, where D is the diffusion/dispersion coefficient with dimensions of $[L^2/T]$. The negative sign indicates that solute mass moves in the direction from high concentrations to low concentrations. In three dimensions, Fick's law is written using the diffusion/dispersion coefficient tensor $\overline{\overline{D}}$ and the solute concentration gradient vector ∇c as

$$-\overline{\overline{D}}\cdot\nabla c \tag{29}$$

The mass flux across the control volume face normal to the x-direction over time period Δt by diffusion and dispersion is then $-\left(D_{xx}\partial c/\partial x + D_{xy}\partial c/\partial y + D_{xz}\partial c/\partial z\right)\Delta y\Delta z\Delta t$, which simplifies for the case of a diagonal diffusion/dispersion coefficient tensor to $-D_{xx}\partial c/\partial x\Delta y\Delta z\Delta t$.

The net flux of mass across the control volume face perpendicular to the x-direction is then $\left(v_x c - D_{xx}\partial c/\partial x - D_{xy}\partial c/\partial y - D_{xz}\partial c/\partial z\right)\Delta y\Delta z\Delta t$. The conservation of solute mass is therefore written (cf. equation 24)

$$\nabla\cdot(\overline{v}c - \overline{\overline{D}}\cdot\nabla c) = \frac{\partial c}{\partial t} \tag{30}$$

This is called the *advection–dispersion equation*. This equation is often simplified for the case of incompressible fluid, where $\nabla\cdot\overline{v} = 0$. Using this fact, after we apply the chain rule to the first term in equation (30), we get $\nabla\cdot(\overline{v}c) = (\nabla\cdot\overline{v})c + \overline{v}\cdot\nabla c = \overline{v}\cdot\nabla c$ and the advection–dispersion equation becomes

$$\overline{v}\nabla c - \nabla\cdot(\overline{\overline{D}}\cdot\nabla c) = \frac{\partial c}{\partial t} \tag{31}$$

We can also modify this equation to take into account other sources of solute. For example, if a solute is dissolving from a solid mineral into the solution at a rate W, which has dimensions of mass of solute entering the solution, per volume of solution per unit time $[M/L^3T]$, then the advection–dispersion equation becomes

$$\overline{v}\nabla c - \nabla\cdot(\overline{\overline{D}}\cdot\nabla c) + W = \frac{\partial c}{\partial t} \tag{32}$$

If W is positive, then solute is dissolving into solution.

Navier–Stokes Equations

The Navier–Stokes equations describe the motions of a class of fluids that have the same mechanical behavior (response to stress). The Navier–Stokes equations are fundamentally the conservation of momentum equations (equations 25). To describe the motions of a fluid with the conservation of momentum equations (25), we must first provide a theory for the viscous behavior of the fluid. That is, we need to provide a model for $(\nabla\cdot\overline{\overline{\tau}})$ in terms of primary dependent variables and perhaps additional parameters. Such a theory is called a *constitutive theory* or a *closure theory* and the model for these terms is called a *constitutive model* or *constitutive equation*. In the case of fluids, one of the most common models for viscous behavior is that of a *Newtonian fluid*. When the Newtonian model for viscous stress is used in the conservation of momentum equations, the resulting equations are called *the Navier–Stokes equations*.

According to the Newtonian model of viscosity, the viscous stress is linearly proportional to the strain rate. Specifically, in Cartesian coordinates,

$$\tau_{xx} = 2\mu\frac{\partial v_x}{\partial x} - \frac{2}{3}\mu(\nabla\cdot\overline{v}) \tag{33}$$

$$\tau_{yy} = 2\mu\frac{\partial v_y}{\partial y} - \frac{2}{3}\mu(\nabla\cdot\overline{v}) \tag{34}$$

$$\tau_{zz} = 2\mu\frac{\partial v_z}{\partial z} - \frac{2}{3}\mu(\nabla\cdot\overline{v}) \tag{35}$$

$$\tau_{xy} = \tau_{yx} = \mu\left(\frac{\partial v_x}{\partial y} + \frac{\partial v_y}{\partial x}\right) \tag{36}$$

$$\tau_{xz} = \tau_{zx} = \mu\left(\frac{\partial v_x}{\partial z} + \frac{\partial v_z}{\partial x}\right) \tag{37}$$

$$\tau_{zy} = \tau_{yz} = \mu\left(\frac{\partial v_z}{\partial y} + \frac{\partial v_y}{\partial z}\right) \tag{38}$$

where μ is the *viscosity* of the fluid. The terms for the strain rate can be understood intuitively. For example, if $\partial v_x/\partial x$ is not zero, then the fluid is stretching or compressing in the x-direction. Terms such as $\partial v_x/\partial y$ describe shearing motion. For example, if $\partial v_x/\partial y$ is greater than zero, then the x-component of velocity increases as the y coordinate value increases. The difference in x velocity of fluid at two points separated from each other in the y-direction leads to shearing, and this shearing motion is the principal source of internal friction in fluids.

To derive the Navier–Stokes equation in their traditional form, the conservation of momentum equations are first rearranged. Consider the x-component of equation (10). Using the continuity equation (5), the x-component of the

conservation of momentum equation may be written

$$-\rho\left(v_x\frac{\partial v_x}{\partial x}+v_y\frac{\partial v_x}{\partial y}+v_z\frac{\partial v_x}{\partial z}\right)-\frac{\partial p}{\partial x}+\left(\frac{\partial \tau_{xx}}{\partial x}+\frac{\partial \tau_{xy}}{\partial y}+\frac{\partial \tau_{xz}}{\partial z}\right)+\rho g_x=\rho\frac{\partial v_x}{\partial t} \quad (39)$$

Now, we substitute in the Newtonian model, equations (33)–(38) for the viscous stress tensor $\overline{\overline{\tau}}$ to get, (for the x-component)

$$-\rho\left(v_x\frac{\partial v_x}{\partial x}+v_y\frac{\partial v_x}{\partial y}+v_z\frac{\partial v_x}{\partial z}\right)-\frac{\partial p}{\partial x}+\mu\left(\frac{\partial}{\partial x}\left(2\frac{\partial v_x}{\partial x}-\frac{2}{3}(\nabla\cdot\overline{v})\right)+\frac{\partial}{\partial y}\left(\frac{\partial v_x}{\partial y}+\frac{\partial v_y}{\partial x}\right)+\frac{\partial}{\partial z}\left(\frac{\partial v_x}{\partial z}+\frac{\partial v_z}{\partial x}\right)\right)+\rho g_x=\rho\frac{\partial v_x}{\partial t} \quad (40)$$

Similarly, for the y and z coordinate directions,

$$-\rho\left(v_x\frac{\partial v_y}{\partial x}+v_y\frac{\partial v_y}{\partial y}+v_z\frac{\partial v_y}{\partial z}\right)-\frac{\partial p}{\partial y}+\mu\left(\frac{\partial}{\partial x}\left(\frac{\partial v_x}{\partial y}+\frac{\partial v_y}{\partial x}\right)+\frac{\partial}{\partial y}\left(2\frac{\partial v_y}{\partial y}-\frac{2}{3}(\nabla\cdot\overline{v})\right)+\frac{\partial}{\partial z}\left(\frac{\partial v_y}{\partial z}+\frac{\partial v_z}{\partial y}\right)\right)+\rho g_y=\rho\frac{\partial v_y}{\partial t} \quad (41)$$

$$-\rho\left(v_x\frac{\partial v_z}{\partial x}+v_y\frac{\partial v_z}{\partial y}+v_z\frac{\partial v_z}{\partial z}\right)-\frac{\partial p}{\partial z}+\mu\left(\frac{\partial}{\partial x}\left(\frac{\partial v_x}{\partial z}+\frac{\partial v_z}{\partial x}\right)+\frac{\partial}{\partial y}\left(\frac{\partial v_z}{\partial y}+\frac{\partial v_y}{\partial z}\right)+\frac{\partial}{\partial z}\left(2\frac{\partial v_z}{\partial z}-\frac{2}{3}(\nabla\cdot\overline{v})\right)\right)+\rho g_z=\rho\frac{\partial v_z}{\partial t} \quad (42)$$

There are four primary unknowns in these equations: the three velocity components and the fluid pressure. A closed system of equations is formed with the three Navier–Stokes equations (40), (41), and (42), the continuity equation (6), and the relationships between pressure and density and viscosity and density. These equations are extremely challenging to solve, even numerically, and are rarely tackled in the form given above. Typically, a simplified set of equations is used.

If the fluid can be assumed to be incompressible, and viscosity does not change, then the continuity equation (7) applies and the more common form of the Navier–Stokes equations results, here in vector form,

$$-\rho\overline{v}\cdot\nabla\overline{v}-\nabla p+\mu\nabla^2\overline{v}+\rho\overline{g}=\rho\frac{\partial\overline{v}}{\partial t} \quad (43)$$

The Navier–Stokes equations are thus the conservation of momentum equations for the case of a Newtonian fluid. The Navier–Stokes equations make a surreptitious appearance in our next suite of examples, which involve flow in porous media.

Flow In Porous Media

Flow in porous media that is fully saturated with water is described by the groundwater flow equation. In this section, we derive the groundwater flow equation by combining the conservation of mass equation with Darcy's law. Darcy's law is an empirical law that relates the flux of water to the forces that drive water. We then develop the equations that describe the flow of both air and water in porous media (the multiphase flow equations), and finally simplify these equations to arrive at what is called *Richards equation*, a model of the flow of water in partially saturated porous media (see Part 6: Soils and Part 13: Groundwater).

Groundwater Flow Equation

To write equations describing flow in porous media in differential form requires that we first define continuous porous media properties, such as porosity, that are valid at a mathematical point and vary smoothly in space. Because pores and solid grains in aquifers can be rather large (compared to molecules in a fluid), it is not clear how to define the porosity or other porous media properties at a mathematical point. This issue has received much attention in the literature (see Baveye and Sposito, 1984) so we will only outline the basic steps involved.

Continuous porous media properties are defined in terms of volume averages centered at a specific point. See Figure 7 for a cartoon of the idea. Consider V, a finite-sized spherical averaging volume that contains porous media and is centered at point (x, y, z). The volume contains solids of volume V_s and voids of volume V_v, where $V = V_s + V_v$. The porosity n at the point (x, y, z) is defined as the ratio of the volume of voids in the volume, to the total volume,

$$n(x, y, z) = \frac{V_v}{V} \quad (44)$$

If the center of the averaging volume is moved infinitesimally to a nearby point $(x + \Delta x, y, z)$, then we can define the porosity at the new point in the same way. Moving the averaging volume throughout the domain allows us to define the porosity at all points in the area under investigation. Because it is defined using a finite-sized averaging volume, porosity is a scale-dependent quantity, which means that the numerical value of the porosity in most natural materials depends upon the averaging volume size. Note that we never shrink the averaging volume to a point – it must be finite in size to produce continuous properties.

To develop the groundwater flow equation, we first write the conservation of mass equation for porous media.

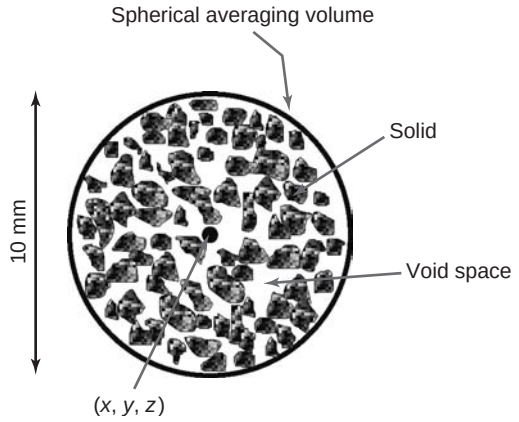

Figure 7 Most variables that describe porous media properties are defined with respect to a finite-sized averaging volume. For example, the value of the porosity at a point (x, y, z) is defined as the ratio of the volume of voids in the averaging volume to the total volume of the averaging volume. When properties are defined in this way, they are continuous at the mathematical point scale, such that derivatives of them are well defined. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Consider the same control volume that we used to develop the conservation of mass equation (Figure 2). In our earlier development, the volume was filled with fluid only; now it is filled with both solids and fluid. Here we are concerned with the conservation of fluid mass in the volume. If the porous media is fully saturated with water, then the volume of water in the control volume is equal to the volume of voids, $V_w = V_v = n\Delta x\Delta y\Delta z$ and the mass of water in the sample is $\rho n\Delta x\Delta y\Delta z$.

In porous media, water flow is quantified by the specific discharge vector $\overline{q}$. Consider an averaging volume in Figure 8, and the cross-sectional area A_x perpendicular to the x-direction. If the volume of water that crosses the area A_x in a time interval Δt is Q_x, then we define the x-component of the specific discharge vector, q_x as

$$q_x = \frac{Q_x}{A_x \Delta t} \tag{45}$$

that has dimensions of $[L/T]$. The other components of the specific discharge vector are defined in a similar manner. Although the specific discharge has the same dimensions as flow velocity, it is a volumetric flux. The mass flux into a control volume across the face perpendicular to the x-direction is then $\rho q_x \Delta y \Delta z$. Accordingly, the conservation of mass equation in porous media becomes (cf. equation 5)

$$-\frac{\partial(\rho q_x)}{\partial x} - \frac{\partial(\rho q_y)}{\partial y} - \frac{\partial(\rho q_z)}{\partial z} = \frac{\partial(\rho n)}{\partial t} \tag{46}$$

The specific discharge is modeled in porous media with Darcy's law. Darcy proposed his famous law in 1856 on the basis of an experiment consisting of a sand packed column with two water reservoirs on either end maintained at a constant elevation, shown schematically in Figure 9. Darcy found that the specific discharge through the column depended inversely upon the length of the column and linearly upon the difference in vertical elevation between the water levels in the two reservoirs, with water flowing from the reservoir with higher water elevation to that with lower, or $q_x \propto -\mathrm{d}h/\mathrm{d}x$ for x aligned with the axis of the column, where the minus sign indicates that the

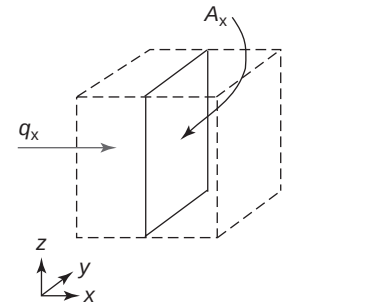

Figure 8 Each component of the specific discharge vector $\overline{q}$ is defined using a finite-sized averaging area oriented perpendicular to the component to be defined as the ratio of the volume of water crossing the area in a time interval divided by the size of the averaging area and the length of the time interval. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

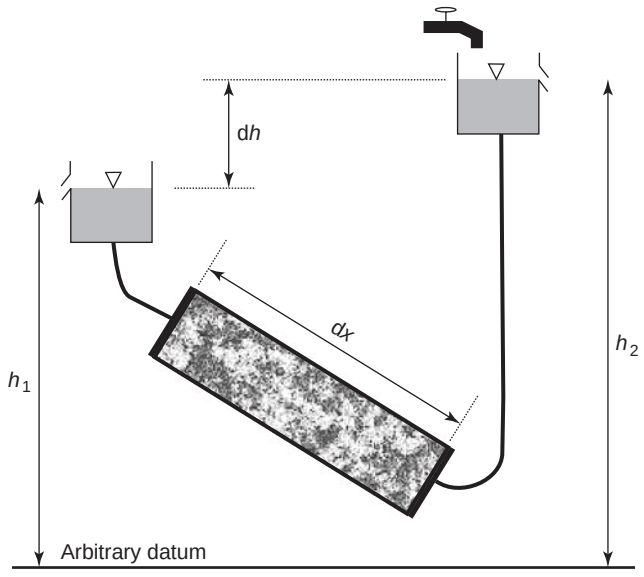

Figure 9 A cartoon of Darcy's column experiment. The column is filled with porous media and connected to two reservoirs in which the water levels are maintained at a constant elevation. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

direction of flow is opposite to the direction in which h is increasing. The quantity h is called *the hydraulic head*, and $\mathrm{d}h/\mathrm{d}x$ is the x-component of the hydraulic head gradient. Hydraulic head is a measure of the mechanical energy of the fluid and is only properly defined for irrotational flows, which in practice means, for fluids with constant density or with density that is a function of fluid pressure alone. The value of the constant of proportionality in the relation between flux and the head gradient depends upon the porous media (high for sand, low for silt) and the fluid (low for a relatively viscous fluid, high for a relatively inviscid fluid). In one dimension, for the flow of water, $q_x = -K\,\mathrm{d}h/\mathrm{d}x$ where K is the hydraulic conductivity. In natural porous media, stratification of sediments can result in a directionally dependent hydraulic conductivity. Darcy's law is then written in terms of the hydraulic conductivity tensor as

$$\begin{Bmatrix} q_x \\ q_y \\ q_z \end{Bmatrix} = -\begin{bmatrix} K_{xx} & K_{xy} & K_{xz} \\ K_{yx} & K_{yy} & K_{yz} \\ K_{zx} & K_{zy} & K_{zz} \end{bmatrix} \begin{Bmatrix} \frac{\partial h}{\partial x} \\ \frac{\partial h}{\partial y} \\ \frac{\partial h}{\partial z} \end{Bmatrix} \tag{47}$$

or in vector notation, $\overline{q} = -\overline{\overline{K}}\cdot\nabla h$, where

$$\overline{\overline{K}} = \begin{bmatrix} K_{xx} & K_{xy} & K_{xz} \\ K_{yx} & K_{yy} & K_{yz} \\ K_{zx} & K_{zy} & K_{zz} \end{bmatrix}$$

is the hydraulic conductivity tensor. Darcy's law works well for most situations encountered in the field, although it loses accuracy whenever inertial forces become important, for example, when head gradients or pore sizes are very large (Bear, 1972). A more general Darcy's law expression applies to fluids other than water and to situations where hydraulic head is not properly defined,

$$\overline{q} = -\frac{\overline{\overline{k}}}{\mu}\cdot(\nabla p - \rho\overline{g}) \tag{48}$$

where $\overline{\overline{k}}$ is the permeability tensor with dimensions $[L^2]$, and μ is the dynamic fluid viscosity, with dimensions $[M/LT]$. The permeability is related to the hydraulic conductivity by $K = k\rho g/\mu$.

Darcy's law can be conceived of as a form of the conservation of momentum equations. Consider equation (48), rewritten as follows

$$\overline{\overline{k}}^{-1}\,\mu\overline{q} = -(\nabla p - \rho\overline{g}) \tag{49}$$

where $\overline{\overline{k}}^{-1}$ is the inverse of the permeability tensor. The term on the left side of equation (49) quantifies the loss of momentum through friction with the pore walls, whereas the terms on the right are forces that drive the fluid. Although it was originally proposed on the basis of empirical observation, Darcy's law has subsequently been justified from the Navier–Stokes equations by considering slow flow (called *creeping flow*) in pores (Bear, 1972).

To develop the equation describing the flow of water in saturated porous media, we begin with the conservation of mass equation (equation 46) and substitute for the specific discharge with Darcy's law (equation 47),

$$\nabla\cdot(\rho\overline{\overline{K}}\cdot\nabla h) = \frac{\partial(\rho n)}{\partial t} \tag{50}$$

We state without derivation that when the porous media is fully saturated with water, and a hydraulic head formulation is valid, the storage term $\partial(\rho n)/\partial t$ can be written in terms of hydraulic head as $\partial(\rho n)/\partial t = \rho S_s \partial h/\partial t$ (Freeze and Cherry, 1979), where S_s is the specific storage coefficient, which characterizes how the aquifer and pore fluids compress in response to changes in stress. If spatial gradients in density are assumed sufficiently small (a good assumption in fresh waters), then $\nabla\cdot(\rho\overline{\overline{K}}\cdot\nabla h) = \rho\nabla\cdot(\overline{\overline{K}}\cdot\nabla h)$, and the groundwater flow equation results,

$$\nabla\cdot(\overline{\overline{K}}\cdot\nabla h) = S_s\frac{\partial h}{\partial t} \tag{51}$$

Because we have factored out density, this equation can be viewed as a conservation of volume equation, combined with the conservation of momentum equations in the form of Darcy's law. The term on the left is the volume of water entering or leaving a point, per unit volume of porous media per unit time (flux divergence), and the term on the right side is the change in the volume of water at a point per unit volume of porous media per unit time. With the appropriate boundary conditions, this equation can be solved in a problem domain to determine the hydraulic head at every point.

Multiphase Flow And Richards Equation

If more than one fluid is present in the porous media, we can generalize the single flow equation to the multiphase flow equations. The approach is conceptually straight forward: we write distinct mass conservation and Darcy's law statements for each fluid, as well as a statement that says the total fluid volume cannot exceed the porosity. The end result is a coupled system of equations that describe the flow of each fluid. We develop the equations for a two-phase system consisting of air and water. We show how the coupled system of equations from the multiphase formulation can be simplified into Richards equation if we assume that the air phase is infinitely mobile.

We note at this point that there are many possible ways to formulate the multiphase flow equations and Richards equation. Our presentation here should not be considered a comprehensive development of the theory, but as an example of the application of the fundamental equations.

In multiphase flow, each individual fluid is a distinct phase, meaning that it has unique physical properties and is separated from other phases by an interface. A pressure difference caused by interfacial tension exists across the interface between each pair of fluids (e.g. air and water) and is called a *capillary pressure* p_c,

$$p_c = p_a - p_w \tag{52}$$

where p_a, p_w are the air and water fluid pressures. For a single interface as in an individual pore, the capillary pressure is given by $p_c = 2\sigma_{aw}/r$ where σ_{aw} is the interfacial tension between these fluids and r is the radius of curvature of the interface between the fluids (Bear, 1972).

Following equation (46), the conservation of mass equations for air and water are

$$-\frac{\partial}{\partial x}(\rho_a q_{ax}) - \frac{\partial}{\partial y}(\rho_a q_{ay}) - \frac{\partial}{\partial z}(\rho_a q_{az}) = \frac{\partial(\rho_a \theta_a)}{\partial t} \tag{53}$$

$$-\frac{\partial}{\partial x}(\rho_w q_{wx}) - \frac{\partial}{\partial y}(\rho_w q_{wy}) - \frac{\partial}{\partial z}(\rho_w q_{wz}) = \frac{\partial(\rho_w \theta_w)}{\partial t} \tag{54}$$

where the subscripts a, w refer to the air and water phases, and θ_a and θ_w are fluid contents, analogous to porosity and defined for an averaging volume V as (e.g. for the air phase),

$$\theta_a = \frac{V_a}{V} \tag{55}$$

where V_a is the volume of air in the averaging volume. Each fluid phase thus requires an independent conservation of mass equation. The sum of all the fluid contents must sum to the porosity,

$$n = \theta_a + \theta_w \tag{56}$$

The fluid content is related to the capillary pressure by a nonunique and hysteretic (history-dependent) pressure-saturation characteristic relationship (Bear, 1972),

$$\theta_\alpha = \theta_\alpha(p_c),\ \alpha = a, w \tag{57}$$

This relationship also implies that the capillary pressure is a function of the fluid contents.

Each fluid phase is described by a distinct Darcy's law with its own permeability that depends upon fluid content $\overline{\overline{k}}(\theta_\alpha)$, $\alpha = a, w$ (Bear, 1972). Typically, the permeability felt by a fluid phase drops to essentially zero when the phase no longer fills a connected pathway through the pores. For multiphase flow, Darcy's law is written for each phase as,

$$\overline{q}_\alpha = -\frac{\overline{\overline{k}}(\theta_\alpha)}{\mu_\alpha}\cdot(\nabla p_\alpha - \rho_\alpha \overline{g}),\ \alpha = a, w \tag{58}$$

Substituting Darcy's law into the conservation of mass equations gives the following two equations for air and water (for the case where the off diagonal components of the permeability tensor are zero)

$$\begin{aligned}&\frac{\partial}{\partial x}\left[\rho_\alpha \frac{k_{xx}(\theta_\alpha)}{\mu_\alpha}\left(\frac{\partial p_\alpha}{\partial x} - \rho_\alpha g_x\right)\right] \\ &\quad + \frac{\partial}{\partial y}\left[\rho_\alpha \frac{k_{yy}(\theta_\alpha)}{\mu_\alpha}\left(\frac{\partial p_\alpha}{\partial y} - \rho_\alpha g_y\right)\right] \\ &\quad + \frac{\partial}{\partial z}\left[\rho_\alpha \frac{k_{zz}(\theta_\alpha)}{\mu_\alpha}\left(\frac{\partial p_\alpha}{\partial z} - \rho_\alpha g_z\right)\right] \\ &\quad = \frac{\partial(\rho_\alpha \theta_\alpha)}{\partial t},\ \alpha = a, w\end{aligned} \tag{59}$$

or, in vector notation,

$$\nabla\cdot\left(\rho_\alpha \frac{\overline{\overline{k}}(\theta_\alpha)}{\mu_\alpha}\cdot(\nabla p_\alpha - \rho_\alpha \overline{g})\right) = \frac{\partial(\rho_\alpha \theta_\alpha)}{\partial t},\ \alpha = a, w \tag{60}$$

For the case of two fluids, there are four unknowns: p_a, p_w, θ_a, θ_w. These can be determined by solving the four independent equations: (i) the two fluid flow equations (equations 60); (ii) the capillary pressure relationship (equation 52); and (iii) the constraint on the pore volume (equation 56). In addition, the permeability-fluid content relationships $\overline{\overline{k}}(\theta_\alpha)$ must be known *a priori*. These coupled equations are very challenging to solve because they are strongly nonlinear.

Richards equation results when we simplify the air–water multiphase flow equations. Richards equation is typically used to describe water flow in the unsaturated zone, the zone where water and air are present in the subsurface. First, we assume that air is infinitely mobile. Consequently, no pressure gradients develop in the air phase and the pressure in the air phase is a constant everywhere p_a. Under this assumption, the capillary pressure is essentially equivalent to the water pressure: $-p_w = p_c - p_a$ and the capillary pressure–fluid-content relationship (equation 57) simplifies to a single relationship that is a function of water pressure alone: $\theta_w = \theta_w(p_w)$.

Richards equation is conventionally written in terms of hydraulic head, which is related to the water pressure through

$$h = z + \psi \tag{61}$$

where z is the elevation of the point of measurement and $\psi = p_w/\rho_w g$ is the pressure head. Darcy's law for water in the unsaturated zone can be written using hydraulic head as

$$\overline{q}_w = -K(\theta_w)\cdot\nabla h \tag{62}$$

where $K(\theta_w)$ is the water-content dependent hydraulic conductivity. Substituting this into the conservation of mass equation for water, and assuming that the fluid density is constant, yields the so-called mixed form of Richards equation,

$$\nabla\cdot(\overline{\overline{K}}(\theta_w)\cdot\nabla h) = \frac{\partial\theta_w}{\partial t} \tag{63}$$

There are two unknowns in this equation: the hydraulic head h and the water content θ_w. These unknowns can be determined by solving Richards equation with a specified water-content pressure relationship $\theta_w = \theta_w(p_w)$ or, as a function of pressure head, $\theta_w = \theta_w(\psi)$.

Richards equation can also be written in terms of hydraulic head. To do this, we eliminate the water content θ_w from the mixed form, equation (63), by substituting the water-content pressure relationship $\theta_w(\psi)$ and then express water pressure in terms of pressure head to give

$$\nabla\cdot(\overline{\overline{K}}(\psi)\cdot\nabla h) = C(\psi)\frac{\partial\psi}{\partial t} \tag{64}$$

where $\partial\theta_w/\partial t = \mathrm{d}\theta_w/\,\mathrm{d}\psi\,\partial\psi/\partial t = C(\psi)\partial\psi/\partial t$ and $C(\psi) = \mathrm{d}\theta_w\,\mathrm{d}\psi$ is the specific moisture capacity. The specific moisture capacity plays the same role in the unsaturated zone as the specific storage coefficient does in the saturated zone and characterizes the incremental change in water content with an incremental change in pressure head. Richards equation is also nonlinear: to solve the equation one must know the value of the hydraulic conductivity and specific moisture capacity at each point, but these cannot be specified without knowing the pressure head.

Saint Venant Equations For Open-channel Flow

Open-channel flow is often modeled using a one-dimensional form of the conservation of mass and conservation of momentum (*see also* **Chapter 135, Open Channel Flow – Introduction, Volume 4**). For this application, the equations are called the *Saint Venant equations*. The Saint Venant equations are simplified versions of the conservation of mass and momentum, where the following assumptions are made (Chow *et al.*, 1988):

1. Flow is one-dimensional, depth and velocity vary only in the longitudinal direction of the channel.
2. Flow is gradually varying along the channel so that hydrostatic conditions exist and vertical flow is negligible.
3. The longitudinal axis of the channel is approximated by a straight line.
4. The bottom slope of the channel is small. The channel bed is fixed.
5. Resistance coefficients for steady, uniform turbulent flow are applicable.
6. The fluid is incompressible and density is constant.

The Saint Venant equations are developed for a control volume positioned across the channel, which has cross-sectional area A and width along the channel $\mathrm{d}x$ (Figure 10). The volume of the control is then $A\,\mathrm{d}x$. For such a control volume, the conservation of mass is written for the time increment from t to $t + \Delta t$:

$$\rho(Q|_x - Q|_{x+\Delta x})\Delta t + \rho q\ \ \mathrm{d}x\Delta t = \rho A\ \ \mathrm{d}x|_{t+\Delta t} - \rho A\,\mathrm{d}x|_t \tag{65}$$

where $Q[L^3/T]$ is the flow in the channel such that $V = QA$ and $q[L^3/LT]$ is the lateral inflow with units of flow per unit length of the channel. Dividing by the length of the control volume ($\mathrm{d}x$) and time increment Δt and density ρ, we arrive at a one-dimensional conservation of mass equation:

$$-\frac{\partial Q}{\partial x} + q = \frac{\partial A}{\partial t} \tag{66}$$

To describe the flow in the channel, we must also provide a conservation of momentum equation. To develop this equation, we must sum the forces on the control volume, account for the flux of momentum into the control volume by the flow of the fluid, and then equate these with the change in momentum in the control volume. The forces considered in the Saint Venant equations are: (i) gravity; (ii) friction along the bottom and sides of the channel; (iii) expansion forces produced by changes in the channel cross section; (iv) wind shear force; and (v) pressure forces. We present the mathematical expressions for these forces without derivation (see Chow *et al.*, 1988). The gravity force on the control volume is given by $\rho g A S_0 \mathrm{d}x$, where S_0 is the slope of the channel bottom. The friction force

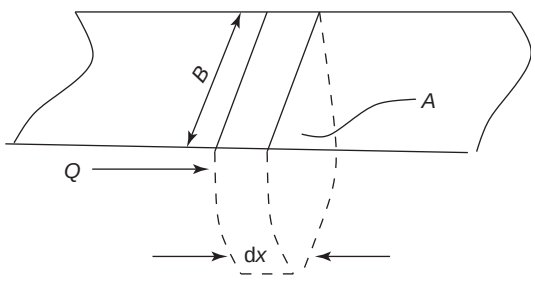

Figure 10 A schematic of the channel used to develop the Saint Venant equations

on the control volume is $-\rho g A S_f \mathrm{d}x$, where S_f is the so-called friction slope. The expansion/contraction forces are incurred when the channel contracts or expands suddenly. It is given by $-\rho g A S_e \mathrm{d}x$, where S_e is called *the eddy loss slope*. Wind shear on the free surface is given by $-\rho W_f B \mathrm{d}x$, where W_f is the wind shear factor and B is the width water surface perpendicular to the flow direction. The pressure force is given by $-\rho g A \partial y/\partial x \, \mathrm{d}x$, where y is the depth of water in the channel.

An impulse of momentum enters the control volume from upstream as $\rho\beta V Q \mathrm{d}t|_x$, where $\beta = 1/V^2 A \int\int v^2 \, \mathrm{d}A$ is the Boussinesq coefficient that accounts for nonuniform velocity at a cross section and v is the velocity through a small element $\mathrm{d}A$ of the cross section. Momentum also enters from lateral inflow into the channel with velocity v_x as $+\rho\beta v_x q \mathrm{d}x \mathrm{d}t$. The momentum outflow at the downstream boundary is $\rho\beta V Q \mathrm{d}t|_{x+\Delta x}$. The conservation of momentum for the control volume can thus be written as

$$\begin{aligned} &\rho[\beta V Q|_x - \beta V Q|_{x+\Delta x}] \, \mathrm{d}t + \rho\beta v_x q \, \mathrm{d}x \, \mathrm{d}t \\ &\quad + \rho g A S_0 \, \mathrm{d}x \, \mathrm{d}t - \rho g A S_f \, \mathrm{d}x \, \mathrm{d}t - \rho g A S_e \, \mathrm{d}x \, \mathrm{d}t \\ &\quad - \rho W_f B \, \mathrm{d}x \, \mathrm{d}t - \rho g A \frac{\partial y}{\partial x} \mathrm{d}x \, \mathrm{d}t \\ &= \rho V A \, \mathrm{d}x|_{t+\Delta t} - \rho V A \, \mathrm{d}x|_t \end{aligned} \tag{67}$$

Dividing by the length of the control volume $\mathrm{d}x$ and the time interval gives the Saint Venant conservation of momentum equation,

$$\begin{aligned} &-\frac{\partial(\rho\beta V Q)}{\partial x} + \rho\beta v_x q + \rho g A S_0 - \rho g A S_f \\ &- \rho g A S_e - \rho W_f B - \rho g A \frac{\partial y}{\partial x} = \frac{\partial(\rho Q)}{\partial t} \end{aligned} \tag{68}$$

6: Principles of Hydrological Measurements

ANDREW W WESTERN, RODGER B GRAYSON AND JUSTIN F COSTELLOE

CRC for Catchment Hydrology and Department of Civil and Environmental Engineering, The University of Melbourne, Victoria, Australia

This article highlights several key considerations in a successful measurement programme. These are:

- *The need to have a clear set of objectives or hypotheses to be tested*
- *An understanding of the temporal and spatial variability of the phenomena of interest.*
- *An understanding of the characteristics of the instruments available for measurement, including errors.*
- *Matching of the temporal and spatial characteristics of the measurement with those of the processes of interest.*
- *Considering the trade-offs inherent in sampling including the number of measurements and accuracy.*
- *Considering a range of practical issues related to setup in the field and the need to check and manage the data as it is collected.*

Successful monitoring programs are well designed, well resourced, and analysis will occur during the monitoring program. Timely analysis allows an ongoing review of performance and appropriate modification, which is critical to success.

New and emerging sensor technologies, as well as the ever-increasing availability of remote sensing information, bode well for the future of hydrological measurement. The synthesis of "smart measurements" with theoretical developments and modeling will yield the greatest advances in the coming years.

INTRODUCTION

There are at least three main reasons why we might want to undertake measurements of hydrological phenomena:

- improving the understanding of processes (e.g. a plot or small catchment study) involving hypothesis testing
- quantifying a resource (e.g. stream gauging)
- compliance (e.g. regular water quality measurement).

In all cases we are seeking data to provide some insight into the "truth" about a hydrological phenomenon, but the detail of information we wish to obtain from the data is quite different. In Case 1, we might want to characterize a particular process, determine the pathways of water to a stream, or define the heterogeneity of an aquifer. This information may be used to develop predictive models, test theories, or even develop new theories. Case 1 generally places the most rigor on the associated sampling design since it is likely that a number of measurements of different fluxes or states will be involved, each with different spatial and temporal characteristics. Similar considerations may be involved in Case 2, albeit simpler. Case 3 is often a prescriptive type of measurement where the basic measurement, frequency of sampling, and possibly the sample size are specified as part of the compliance requirement. Nevertheless, an understanding of the principles of measurement, sampling, and statistical analysis is required for proper design of sampling strategies for compliance monitoring. In this article, we focus on fundamental principles underlying measurements, with examples most relevant to Cases 1 and 2.

The most important question to answer before any measurements program can be designed is "What are the objectives of this data collection – that is what are the hypotheses that are being tested"? This sounds like a simple question but it is all too often ignored, or answered in only a cursory manner. A detailed answer will provide the basics

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

needed to design a sampling strategy including:

- phenomena to be measured
- key spatial and temporal scales of interest
- required accuracy and
- available resources.

This article is based on the assumption that a clear answer to the question has been provided, but such "*trite assumptions*" should *never* be made in a real sample design! Indeed, the objectives should be returned to many times, since, as discussed below, sampling design is an iterative process. Hydrological measurement is also generally an expensive activity involving a significant capital cost of equipment, personnel for design, construction and maintenance, and travel and infrastructure costs. Hence, there are strong incentives for the design of measurement systems to be well targeted to the questions at hand.

The article is presented in four main sections. In the first section, we summarize some common hydrological instruments and logging equipment and discuss recent advances. We then present some fundamental issues related to scale, followed by a discussion of considerations in planning a measurement system. Finally, we address key practical matters to be considered in the measurement of hydrological variables.

This article focuses on fundamental principles, providing examples to assist the explanation; but it is not a comprehensive review of measurement instruments or data logging equipment. There are a number of reference texts that provide excellent discussions of hydrological measurements and details on particular measurement methods and sampling protocols. A selection of these texts is included in the "References" section. In addition, the Internet provides access to information from the major manufacturers of instrumentation, most of whom can provide technical assistance and guidance for using their equipment.

INSTRUMENTS AND DATA LOGGING SYSTEMS

Instruments

A compilation of the most common hydrological measurement techniques is provided in Table 1. This list is by no means exhaustive but covers the techniques in general used for measurement of the most commonly required data related to the wide range of activities that are part of hydrological monitoring. The measurements have been divided into four broad categories; meteorological, surface water, porous media, and physico-chemical techniques.

The Table is organized so that the phenomenon being measured is identified in the first column, with the actual parameter that represents the phenomenon in the second column. The technique(s) used for each parameter are then identified in the third column and the typical time-step and resolution of the technique/instrument are noted, as well as its typical error margin. These error margins are generally manufacturer specified and typically represent performance under ideal conditions. Actual performance in the field often depends on installation, calibration, site characteristics, and maintenance. Finally, a brief comment is made about each technique. Where possible, a suitable reference that provides greater detail about the technique is noted.

The techniques range from time-honored methods that have been in use for decades to those that take advantage of the latest scientific advances in monitoring and recording of data. All are point measurements collected *in situ* unless otherwise stated. Techniques with extensive calibration and increased complexity are also identified.

Many of the techniques and sensors listed in Table 1 can be interfaced to a data logging system. Data loggers vary in the number of channels available, the input signal formats that can be measured, measurement precision and accuracy, measurement rates, storage (memory) capacities, memory volatility, robustness, programming language, and power requirements. The choice of a data logger is dictated in part by the number, variety, and characteristics of the sensor outputs to be used and by the conditions in which the logger is to be deployed. Some sensors have requirements for high sensitivity, such as net radiometers, which typically produce voltage output in the μV range and thus require analogue input channels with sufficient sensitivity and accuracy in this range. These are typically not available on the cheaper loggers. Counter channels on data loggers typically have lower and upper limits on input frequencies. Systems such as eddy correlation systems also typically require higher end loggers with relatively high measurement rates and processing speeds. Many data loggers can be interfaced with modems and telemetry systems. There is also an emerging suite of microsensors and processors with inbuilt low-power radio systems that can develop self-configured networks (sensor webs). Applications of such systems to hydrological monitoring are likely to develop over the next decade.

The measurement techniques described in Table 1 are mostly ground-based, physical measures. The burgeoning use of satellite-based remote sensing and chemical (especially isotopic) measurement techniques form a relatively new and exciting frontier for measuring hydrological processes (see Section "Advances in techniques"). For the sake of brevity, they have been omitted from Table 1. Remote sensing measurement techniques are more discussed in detail in Part 5 (**Chapter 46, Principles of Radiative Transfer, Volume 2** to **Chapter 61, Estimation of River Discharge, Volume 2**) and chemical/isotopic techniques

Table 1 Common hydrological measurement techniques and their characteristics

Measurement	Parameter	Instrument	Time-step	Typical resolution	Instrument accuracy	Comment
Meteorological						
Precipitation	Rainfall depth (mm) and intensity ($mm\,h^{-1}$)	Rain gauge	Minutes to daily	Sub mm to mm	5–15% error	Range from manually read daily totals, tipping-bucket mechanisms that measure intensity and universal gauges that measure both weight and outflow of precipitation (including frozen precipitation) from a pan. Errors occur due to wind field, siting characteristics, precipitation type, temperature. Heated tipping-bucket gauges can be used for measuring frozen precipitation but have problems with high-power requirements and evaporation and deflection of precipitation. Dingman (2002), Maidment (1992).
	Rain drop size, total precip. depth and intensity	Disdrometer, optical, and Doppler radar precipitation gauges	Continuous to minutes	Sub mm	1–5%	Disdrometers convert mechanical momentum of raindrop to an electrical impulse with amplitude proportional to rain drop diameter. Optical and Doppler radar gauges measure variations in scintillations of infrared beam or Doppler frequency shifts caused by precipitation and this is converted to rainfall intensity. Can differentiate between rain, snow, and mixed precipitation. Also can provide raindrop-size analysis (with 5% accuracy of diameter) and requires a drop size >0.5 mm for accurate measurement. Dingman (2002).
	Reflectivity	Radar	Sub min to min	Sub mm	2–3 $mm\,hr^{-1}$ or a factor of 2	Requires extensive calibration using a raingauge network to convert reflectivity to precipitation intensity. Error figures here are for hourly rainfall of moderate intensity with storm-by-storm calibration against a good raingauge network. Accuracy depends on rainfall type and intensity. A remote technique measuring a field and the only technique to provide two-dimensional coverage of rainfall events. Meischner (2004).
Frozen precipitation on ground	Pressure, depth, and water equivalent	Pressure and acoustic sensors, snow tube	Single to minutes	mm	4–10% or 2.5 mm for pressure sensors	The water equivalent pressure of snow (or other frozen precipitation) is measured using snow pillows and other pressure sensors. Acoustic, optical, and radioactive sensors can be used to measure depth of snow to ground surface or as a flux rate of snowfall (Lehning *et al.*, 2002). Manual method determines depth and weight of snow using aluminium tubes of known volume. Measured in sections as snow courses and requires estimation of snow density to convert to water equivalent depth. Dingman (2002).

(continued overleaf)

Table 1 *(continued)*

Measurement	Parameter	Instrument	Time-step	Typical resolution	Instrument accuracy	Comment
Mean wind sensors	Wind velocity and direction	Anemometers and Doppler sonars and lasers	Continuous	0.1–0.5 m s^{-1} over range of 0.3–75 m s^{-1} 1° direction	Vel <3% Dir: 1°	Anemometers can use rotating cup or propellers, differential pressure or thermoelectric (hot wire) and acoustic/sonic devices to measure wind velocity and direction. Anemometers with rotating cups/propellers or using differential pressure need to be in plane of wind for most accurate measurement and error increases in wind gusts or low velocity winds. Acoustic/sonic/Doppler sonar anemometers can measure three-dimensional wind movement. Kaimal & Finnigan (1994).
Mean air temperature	Degrees Celsius	Thermometer (electrical)	Continuous	<0.1 °C	0.05–0.5 °C	Platinum resistance, thermocouple, thermistor, and quartz thermometers use variations in resistance, voltage, or frequency with temperature. Quartz thermometers provide the highest accuracy but are mostly used in laboratory applications. Kaimal & Finnigan (1994).
		Infrared thermometer	Continuous	<1 °C	<0.1 °C	Remotely senses temperature using infrared emissivity.
Humidity	Absolute and relative humidity	Hygrometer, psychrometer, capacitance, radiation absorption	Continuous	<0.1 °C	<0.5 °C (hygrometer) 0.5–1.0 °C (others)	Absolute humidity is measured by dew-point hydrometers while relative humidity is measured by wet and dry bulb (psychrometric) temperature sensors or capacitance sensors. Humidity fluctuations can also be measured using ultraviolet or infrared radiation absorption sensors. Most methods require periodic cleaning and checks on calibration. Kaimal & Finnigan (1994).
Air pressure	Atmospheric air pressure (hPa)	Barometer	Continuous	0.1–1 hPa	0.3–1 hPa	Aneroid, mercury, and piezoresistive sensor barometers measure changes in air pressure. The piezoresistive barometer records and logs data digitally and is small, mobile, and relatively rugged relative to traditional and accurate aneroid and mercury barometers. The aneroid barometer can be attached to analogue recorders for logging.
Heat flux	Solar radiation and net radiation flux density	Net radiometer, Pyranometers, Pyrgeometer	>30 s Daily	10–35 W m^{-2}	10% daily total	Thermopile or solar cells measure incoming shortwave or long wave (infrared) radiation (solar radiation) or incoming and outgoing radiation (net radiation flux density). Measured radiation decreased by wind. Sensors can measure direct (tracking movement of sun), diffuse or total radiation. Kaimal & Finnigan (1994).

	Sensible heat flux	Soil heat flux plates	>4 min	50 μV W^{-1} m^{-2}		Thermopile measures temperature difference between two metal plates separated by material with known conductivity. Large errors (up to 50%) can occur in drying soils where soil evaporation is occurring beneath the soil surface. Kaimal & Finnigan (1994).
	Latent heat flux	Lysimeter	Continuous	1–100 g	10–100 g	Measures changes in weight of a block of soil and collects runoff and percolation. Can range in size from 1 m^2 to >10 m^2.
Cloudiness and sunshine hours	Amount of cloud	Visual or spectral radiometers, Campbell-Stokes recorder	Single or Continuous	10%	>10%	Cloudiness is commonly visually estimated but can be quantitatively estimated using radiometers (comparing difference between clear sky and cloudy skies) or analyzing digital photographs. Sunshine hours can be measured using a Campbell-Stokes glass dome that burns a trace on a card.
Actual evapo-transpiration.	Bowen ratio	Wet and dry bulb or dew-point sensors at two heights	>30 min averages		<30 Wm^{-2} mean daily latent heat flux	Temperature and vapor pressure are measured at two heights to by wet and dry bulb (psychrometric) or by temperature and dew-point (hygrometric) sensors to determine the vertical energy transport defined by the ratio of sensible heat flux over the latent heat flux (the ''Bowen ratio''). Requires relatively large fetch of surface being measured. Drexler *et al.* (2004), Kaimal & Finnigan (1994).
	Eddy covariance	Triaxial sonic anemometer, humidity-temperature sensors	10–30 min periods		Generally within 10% of Bowen ratio method	Sonic anemometers measure turbulent eddy flux. The covariance between the vertical wind velocity component and the measured temperature and humidity is used to estimate the sensible and latent heat flux. Drexler *et al.* (2004), Kaimal & Finnigan (1994).
	Surface renewal	High-frequency temperature sensors, sonic anemometer (for calibration)	Continuous		30–50 Wm^{-2}	High-frequency temperature sensors measure the duration and amplitude of temperature ramplike variations. This is used to estimate the sensible heat flux and the latent heat flux is estimated as the residual of the heat balance equation. This method needs to be calibrated against a sonic anemometer to allow for unequal heating of air below the sensor height. Drexler *et al.* (2004).
	Water vapor mixing ratio	Raman LIDAR	Continuous	1.5 m spatial resolution	4%	A LIDAR system measures the backscattered radiation from a laser beam. The wavelength of the radiation and the amount of backscattering at that wavelength provides estimates of temperature, concentrations of atmospheric constituents (e.g. water vapor) and wind. The water vapor mixing profiles are used to estimate heat fluxes. Drexler *et al.* (2004).

(continued overleaf)

Table 1 *(continued)*

Measurement	Parameter	Instrument	Time-step	Typical resolution	Instrument accuracy	Comment
Potential evapo-transpiration.		Evaporation pans. Manual or water level logger	Daily	<1 mm	1 mm	Traditional method of measuring evaporation loss from large open pans. A "pan factor" needs to be applied to the measurements to convert to a potential evapotranspiration applicable to larger areas (including larger water bodies). Water loss can be measured manually or using a water level logger. Various models or formulae (e.g. Penman, Penman Monteith, Priestly-Taylor) can be used to estimate potential evapotranspiration from meteorological data.
Surface water						
Water level	Stage (m)	Mechanical, electronic, acoustic, pressure gauges	Subhourly	<1 mm	0.2–3.0 mm	Mechanical devices use a float in a stilling well that is attached by cables to a rotational encoder that records changes in water level. Commonly used in permanent gauging stations. Water level variations result in changes in capacitance along a sealed cable for electronic gauges or pressure variations in a pressure transducer, bubble gauges use changes of pressure induced in a mercury reservoir and acoustic/laser sounders measure changes in stage above a stable section and pressure. Herschy (1995), Boiten (2000).
Channel shape	Two-dimensional position (m)	Dumpy level or total station	Single	mm	mm	Dumpy level used in conjunction with tapes or chains to measure positions relative to a datum (horizontal) level. Total station is able to rotate theodolite in vertical plane when measuring positions relative to station location.
Discharge	Average velocity (m/s)	Current meter	Single	Depth >0.15 m Velocity >0.1 m s^{-1}	5–10% (25% in turbulent streams)	Velocities measured as a series of profiles in a cross section across channel. Gordon *et al.* (1992), Herschy (1995).
		Acoustic Doppler velocimeter	Single or Continuous	0.01–2.5 m s^{-1}	1% of measured range	Measures velocity and direction from Doppler shift of acoustic signals backscattered from particles in flow. Measured as a cross-section across channel or as a 3-D field around objects when measuring turbulent flow. Herschy (1995), McLelland & Nicholas (2000).
	Tracers	Dilution gauging	Single			A tracer (chemical, radioactive, fluorescent) is added at an upstream point and its diluted concentration is measured at a downstream point assuming full mixing. Used in turbulent mountain streams. Tracer can be added as a slug or at a constant rate. Gordon *et al.* (1992), Herschy (1995).

Porous media						
Bulk density and total porosity	Dry mass/volume (Mg/m^3)	Oven drying samples	Single	<mg	mg	A ''wet'' weight of the soil sample (core or solid clumps) is taken and then the sample is oven dried and a dry weight taken. The volume of the sample is taken by measurement (core) or by a water displacement method. Porosity is measured by dividing the bulk density by the particle density, the latter usually taken from the literature. McKenzie *et al.* (2002).
Soil water characteristic		Suction plates	Single			Relationship between volumetric water content (%) and matric potential (-m) of sample. Mostly measured in the laboratory using suction plates to determine points on curve for given matric potentials. McKenzie *et al.* (2002).
Matric potential		Heat dissipation or electrical resistance sensors	Single			Heat dissipation or electrical resistance of a porous matrix in equilibrium with the soil is measured and related to matric potential by previous calibrations. Allows matric potential to be measured in the field. Scanlon *et al.* (2002).
Saturated and unsaturated hydraulic conductivity (K_s)	K (mm/hr)	Twin ring and tension infiltrometer, well permeameter	Single	$<1\,mm\,hr^{-1}$	Coefficient of variation <0.5 with 20 readings	The steady-state rate of infiltration from water filled rings or discs (twin ring and tension infiltrometers) are used to measure soil hydraulic conductivity while a well permeameter uses maintains a constant head of water in an auger hole and the rate of outflow is measured from the steady-state inflow from the well permeameter and used to calculate K_s. Useful for measuring K_s at depths from 0.15–2.0 m below ground surface. Infiltrometers can also be used to measure the hydraulic conductivity of soil cores in the laboratory. McKenzie *et al.* (2002).
Hydraulic conductivity	K (mm/hr)	Rainfall simulator	Single	$<1\,mm\,hr^{-1}$		Rainfall simulator applies ''rain'' at a constant rate to a sealed, *in situ* plot. Runoff is measured by a calibrated container or tipping bucket and these measurements allow the calculation of hydraulic conductivity. Advantages of being applied to larger areas than other techniques and integrates soil heterogeneities.
	K (mm/hr)	Rising and falling head slug tests	Single	$mm\,hr^{-1}$		A slug test removes (rising head) or adds (falling head) a volume of water from the piezometer and monitors the time taken for the water level to recover to its predisturbance level to determine saturated hydraulic conductivity.

(continued overleaf)

Table 1 *(continued)*

Measurement	Parameter	Instrument	Time-step	Typical resolution	Instrument accuracy	Comment
	K (mm/hr)	Cone permeameters	Single	$mm\,hr^{-1}$		Cone permeameters inject water radially into the borehole at a constant rate and the pressure gradient away from the injection site is measured and used to estimate the permeability and hydraulic conductivity at that point. Allows measurements at a number of points within a borehole.
Piezometer	Hydrostatic groundwater level (m)	Manual or logger – see surface water	Single or sub hourly	<1 mm −10 mm	<1–10 mm	Depth to groundwater from a datum level is manually measured using tape or water level loggers (see surface water section) can be installed.
Soil moisture	% volumetric water content	Time domain (TDR) and Frequency-domain (FDR) reflectometers	Continuous	1%	3%	TDR measures the dielectric permittivity of soil by measuring the time it takes for an electromagnetic wave to propagate through the soil, while FDR does this by determining the resonant frequency with greatest amplitude. The volumetric water content is determined through calibration with the dielectric permittivity.
	% volumetric water content	Neutron probes	Single and logged			A decaying source emits fast neutrons into the soil. The neutrons are backscattered and slowed by the presence of water. A detector in the probe measures the amount of slowed neutrons and via calibration this provides a measure of the soil water content.
physico-chemical						
Conductivity	Siemens/cm	Resistance and induction conductivity probes	Continuous	0.1 μS	0.5%	Resistance between two electrodes or induced current and resulting magnetic field measured by a coil is used as a measure of water conductivity. Temperature usually measured in conjunction with conductivity. Induction probes have the advantage of not having exposed electrodes.
pH	pH scale	Potentiometric (electrode) pH meter	Continuous	0.01 unit	0.02–0.1 unit	Potentiometric electrodes monitor changes in voltage caused by changes in the activity of hydrogen ions in a solution to determine the pH of the solution.

Dissolved oxygen (DO)	Mg/L or % saturation	Polarographic DO meter	Continuous	0.01 mg L^{-1}	0.3 mg L^{-1} or 2%	Dissolved oxygen diffuses through a membrane and is then measured by a sensor cell. Membrane requires regular maintenance.
Turbidity	nephelometric turbidity units (NTU)	Photoelectric turbidimeters	Continuous	0.01–0.2 NTU		Light is emitted from the sensor and the amount of backscattered radiation is converted to a measure of turbidity in nephelometric turbidity units.
Water Clarity	Depth (cm)	Secchi disc	Single	0.5 cm	0.5 cm	A disc is lowered into the water and the depth that it disappears from sight
Water samplers	Suspended sediments, water quality	Sediment sampler – depth or point integrated, rising stage sampler	Single			Samples collected from a point in the stream section or lowered through the water column to collect a velocity-weighted sample through the section. Sample bottles can also be used with siphons or one-way valves to collect samples during the rising stage. Gordon *et al.* (1992).
Bed load	Bed load sediments	Pits and baskets, pressure-difference sampler	Single			Various pits and baskets installed into the stream bed are used to collect bed load samples. Pressure-difference samplers use a pressure drop at the exit ensuring that the entrance velocity is the same as the stream and that separation of bed load material occurs at the exit and is collected in a mesh bag.
Erosion and deposition		Pins and chains	Single			Pins and chains can be inserted into the bank and channel bed and rates of scour and fill can be quantitatively monitored by surveying changes in bed-bank position relative to the pins or chains.
		Pressure meters	Continuous – daily	Mg	mg	Pressure plates placed onto the stream bed or embedded into the sediments can measures changes in overlying pressure to estimate changes in sediment coverage.

Note: DO, dissolved oxygen; TDR, time domain reflectometers; FDR, Frequency domain reflectometers; NTU, nephelometric turbidity units.

are discussed in Part 10 (**Chapter 116, Isotope Hydrograph Separation of Runoff Sources, Volume 3**).

Advances in Techniques

In recent times, there have been some major advances in measurement techniques, and this continues to be an area of active development. The number of satellite-based remote sensing platforms has increased dramatically and they are more focused on environmental applications (*see* **Chapter 47, Sensor Principles and Remote Sensing Techniques, Volume 2** and Part 5 generally). Important components of the water balance such as soil moisture (e.g. via Time Domain Reflectometry-based devices) and evapotranspiration (e.g. via eddy covariance equipment) are now much cheaper and simpler to measure. Logging equipment is getting cheaper and smaller, and the cost of telemetry has dramatically reduced, particularly where cellular phone coverage is available or distances permit low-power radio-based communication networks. This has led to the development of "sensor webs" where large numbers of compact sensor/logger/telemetry units can be deployed with an automatic feed of information to Internet-connected computers, making real-time data available at relatively low cost. In some cases, sensors are considered "disposable" such as those dropped ahead of fire fronts to provide real-time information to fire fighters. This sort of technology is rapidly developing and is certain to find hydrological applications, where the limitation of a relatively small number of point measurements has constrained our ability to observe spatial patterns. Similarly, the ground truthing of satellite observations will be enhanced by more spatially dense sensor networks.

Streamflow measurement remained almost unchanged for 100 years with discharge measured using a propeller meter at points across a cross section. But this has been revolutionized with the advent of Acoustic Doppler Current meters and profilers, providing fast, accurate information on velocity fields over a wide range of depths. Sensors measuring important water quality parameters *in situ* are also developing to include nutrients and other measures of ecological significance, although the costs of these devices are still high.

Techniques involving tracers to assist in defining pathways and residence times of water, sediment, and other constituents in the environment have been available for many years but are gaining more widespread use in hydrology (e.g. Kendall and McDonnell, 1998). These methods are particularly useful because they provide *complementary* information to that obtained from more traditional methods. For example, a study into hill slope processes of water movement would commonly include wells and soil moisture equipment to measure time series of responses in the saturated and unsaturated zone, but also knowing how long water had been in the soil, or perhaps what pathway it had taken is likely to add a great deal to understanding of the hill slope behavior. In addition, the combined use of time series of discharge data and conservative tracers, such as chloride, can substantially decrease parameter value uncertainty during the calibration of catchment models (Kuczera and Mroczkowski, 1998). There are other examples of complementary measurements such as remote sensing and *in situ* sensors collecting time series. The former provides detailed spatial information but only a snapshot in time, whereas the latter is "dense" in time but only at a point. Together they can help build some detail in both time and space.

Many of the developments in measurement are aimed at providing more data at lower cost and this is generally achieved by making a "surrogate" measure that is related to the phenomena of interest and is quick to make. Calibration between the surrogate and the actual phenomena is therefore of critical importance with many of these new sensor technologies. Our experience is that "factory calibrations" should always be checked under the conditions in which the device is to be used, and rechecked at regular intervals to correct for any drift (see also later discussion).

We look forward to more developments in measurement technology. Hydrology would greatly benefit from nonintrusive measurements of shallow subsurface flow, preferred pathways, and hydraulic properties of soils that can be applied over large areas. Other methods to indicate the pathways of water such as isotopic and other tracers will increase in use as they provide new information of particular importance to environmental issues. Remote sensing will continue to improve, and the synthesis of different data sources into integrated products will produce information in which we will have much improved confidence. The development of new instrumentation enabling higher density of measurements in space and time or the ability to cover large areas will also continue. But to exploit all this new capability fully, and avoid getting "lost in a sea of data" we will still require a careful design of measurement programs based on some fundamental concepts.

FUNDAMENTAL ISSUES OF SCALE

Designing an efficient program for measurement of hydrological variables involves a conundrum. We make measurements to inform us about a process or resource, but to make those measurements efficiently, we need to know about that process or resource. Designing measurement programs is therefore an iterative activity and one that often draws on past experience from other places. We use measurements to tell us about the phenomena and as we learn more, we can use this knowledge to design a better sampling program. Similarly, we can set up a hypothesis, test it with some data, and then refine the hypothesis and measurement

program. We can often add modeling to this iterative loop to further enhance the information that we glean from the data collected. For example, if we know that a particular water quality parameter varies rapidly during a runoff event but only slowly during baseflow conditions, we can use this knowledge (a "model" if you like) to design a structured sampling approach that provides more information than the same number of samples obtained with a naive random or uniform sample spacing in time. Such a design can be statistically sound, thereby maximizing the value of the data. A variety of sophisticated random approaches exist that can incorporate existing knowledge as well as information on sampling costs to maximize the efficiency of a sampling effort.

Sampling theory is a well-developed field in itself and texts such as Thompson (2002) provide a range of useful sampling schemes. The following is based on Thompson (2002). They key advantages of a statistically sound sampling scheme are that:

- it allows statistical inference of the population characteristics with known confidence;
- it minimizes the likelihood of the inadvertent biasing of measurements associated with subjectively choosing "representative" sites;
- it provides a representative data set derived from sites that are objectively chosen; and
- well-designed sampling schemes can incorporate existing knowledge to maximize the efficiency (i.e. minimize uncertainty), minimize costs, and to be robust to errors in the existing knowledge.

Fundamentally, a sampling design consists of assigning probabilities of selection into the sample for all members of a population, then randomly selecting from the population. Simple random sampling assigns an equal probability of selection to every member of a population (say every point in a spatial field). More sophisticated approaches assign unequal probabilities based on existing information about a phenomena and/or about the cost of sampling in such a way as to maximize the value of the information gained from the measurements. In this case some points are more likely than others to be selected, for example, it might be worth allocating a higher probability of selection to high flows when sampling water quality for load estimation or using randomly selected transects for spatial sampling to minimize costs of moving between measurement points. The interpretation of the measurements then takes into account the probability of selection when inferences about the population characteristics (say the mean) are made.

Some useful sampling designs include stratified random sampling, cluster sampling, a variety of model-based sampling schemes including designs that utilize existing or more densely sampled auxiliary data (say topographic information in a regression), sampling in the presence of spatial (or temporal) correlation, and adaptive sampling, among others. Stratified random sampling allows a population to be stratified, say on the basis of geology, soil type, or elevation, and then samples are taken randomly within each stratum (group). Adaptive sampling uses information already collected during the measurement process to aid in selecting the next points in the sample. An example might be a sampling design that samples more intensively around a point when specific (usually rare) conditions are encountered, say a preferential recharge area of coarse sediment on a floodplain otherwise dominated by fine sediments. It is useful where clusters of rare events occur. This allows the sampling process to focus on a particular interest while still obtaining useful information about the population.

It is important to note that structured sampling approaches are always based on some form of model or understanding of a variable's behavior, and that if this turns out to be wrong then poor results can be obtained if such approaches are applied naively; however, there are designs that are robust to model errors. Of course, this is clearly also the case with choosing "representative" sites using some subjective approach. Another issue relating to sample selection that can arise is related to systematic sampling in the presence of a periodic process. If the sampling interval closely matches the period (or an integer multiple thereof), then biases in estimates of both mean properties and variability are likely to result. This is an issue with sun-synchronous remote sensing platforms, as they always observe at the same point in the diurnal cycle.

A prerequisite for useful hydrological measurements is that the temporal and spatial scales of the measurement appropriately match those of the phenomena of interest. For example, if we are interested in the total annual runoff from a small arid-zone ephemeral stream, a sensor that takes an instantaneous water level every week will not provide useful information. The sampling frequency (a week) is too large compared to the timescale of the process (probably minutes to hours in this example), whereas a week may be quite sufficient for measuring a slow-changing groundwater level. There is some basic theory that provides a framework for these scale considerations. The spatial (and temporal) dimensions of measurements can be characterized by three scales as depicted in Figure 1. These scales are the spacing, the extent, and the support, and have been termed the *scale triplet* by Blöschl and Sivapalan (1995).

The *spacing* refers to the distance (or time) between samples, the *extent* refers to the overall coverage of the data (in time or space), and the *support* refers to the averaging volume or area (or time) of the samples. All three components of the scale triplet are needed to uniquely specify the space and the time dimensions of measurements. For example, for TDR soil moisture samples in a research catchment, the scale triplet in space may have typical values of, say, 10 m spacing (between the samples), 200 m extent

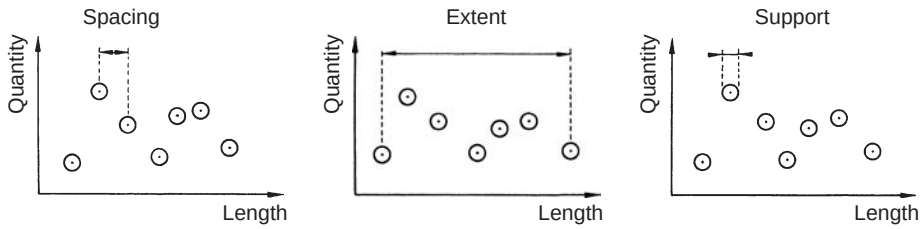

Figure 1 Definition of the scale triplet (spacing, extent, and support). After Blöschl and Sivapalan (1995)

(i.e. the length of the plot sampled), and 10 cm support (the diameter of the region of influence of a single TDR measurement). Similarly, for a remotely sensed image, the scale triplet in space may have typical values of, say, 30 m spacing (i.e. the pixel size), 10 km extent (i.e. the overall size of the image), and 40 m support (i.e. the "footprint" of the sensor). The footprint of the sensor is the area over which it integrates the information to record one pixel value. It is usually on the order of the pixel size but not identical to it. There are more complex cases such as measurements of evapotranspiration using eddy covariance equipment where the support is difficult to define and may vary in time due, for example, to different wind conditions. Similarly, the support for a groundwater measurement well may not be clearly defined. While the terms spacing, extent, and support are commonly used in spatial analysis, the analogous terms in time series analyses are sampling interval, length of record, and smoothing or averaging interval (e.g. Blackman and Tukey, 1958).

Ideally, measurements should be taken at a scale that is able to resolve all the variability (in both space and time) that influences the hydrological features in which we are interested. In general, because of logistical constraints, this will not be the case and so the measurements will not reflect the full natural variability. For example, if the *spacing* of the data is too large, the small-scale variability will not be captured and the measurements will appear "noisy" or discontinuous. If the *extent* of the data is too small, the large-scale variability will not be captured and will translate into a trend in the data. If the *support* is too large, most of the variability will be smoothed out. These examples are depicted schematically in Figures 2 and 3. Figure 2 is for the temporal domain, where the sine wave relates to the natural variability of some hydrological variable and the wavelength is related to the scale of the true hydrological features. The points in Figure 2(a) relate to the scale triplet of the measurements. Similar concepts apply to the spatial domain (Figure 3). We are often particularly limited with capturing spatial variability since many of our techniques are essentially point measurements. Measurements of soil hydraulic conductivity are good examples where the measurement support is limited – just a few cm^3 for laboratory measurements of soil cores to perhaps a few m^3 for small-scale permeameter tests to perhaps 10 000 m^3 or more for large-scale well pumping tests in sandy aquifers. A large number of tests would be required to fully characterize a particular location. Often in such instances, a statistical approach is taken where sampling is designed to define the statistical properties of the phenomena and the data are used in a stochastic rather than a deterministic manner.

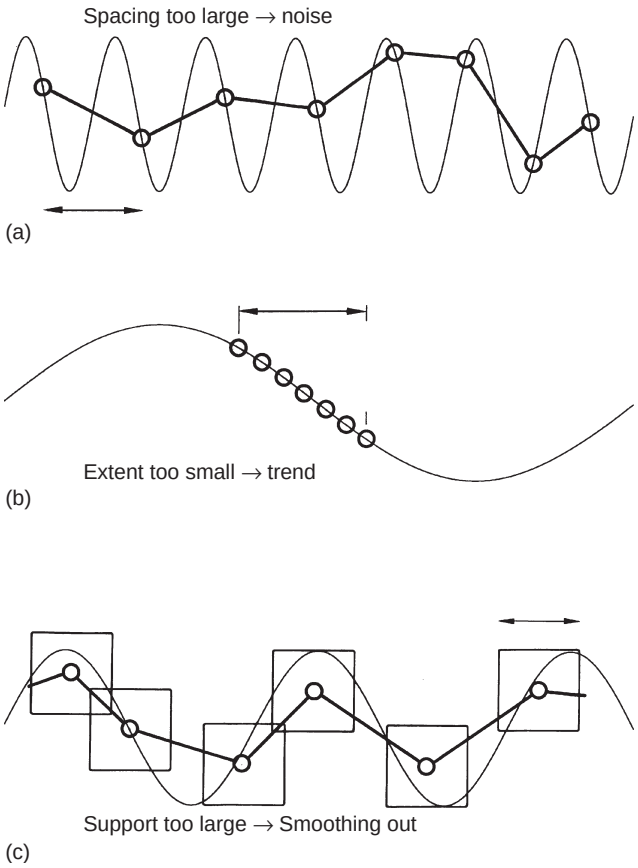

Figure 2 Pattern of a generic temporal phenomena showing the effects of too large a spacing (a); too small an extent (b) and too large a support (c). After Blöschl and Sivapalan (1995)

It is clear that measurement is a sort of filtering, that is, the true spatial and temporal patterns are filtered by the properties of the measurement, which are then reflected in

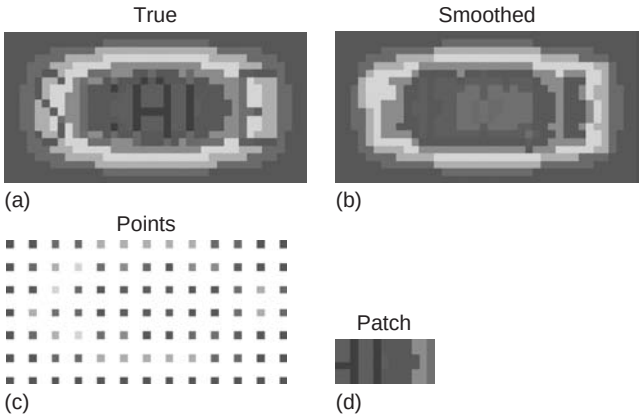

Figure 3 (a) shows the pattern of generic spatial phenomena; (b) shows sampling over the whole extent but with a large *support* thereby smoothing the small-scale variability; (c) shows sampling over the whole extent with a small *support* and medium *spacing* that captures the basics of the pattern but not the detail; and (d) shows sampling with too small an *extent* where we see a trend and some detail of a small section of the pattern. Redrawn from Western *et al.* (2002). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

the data. The effect of this filtering is to introduce errors into the observed variability if the scale of the measurement does not match the scale of the process. There is a substantial body of literature that deals with methods for defining and predicting the way in which variability is captured (or not captured) by the measurement characteristics (e.g. Wiener, 1949; Krige, 1951; Matheron, 1965, 1973; Blackman and Tukey, 1958; Federico and Neuman, 1997). An important practical outcome of that work is the development of methods to (i) assess how many measurements are needed to capture (to a certain accuracy and under particular assumptions) a natural pattern and (ii) to quantify the bias in variability introduced by filtering (e.g. Journel and Huijbregts, 1978; Vanmarcke, 1983; *see* **Chapter 9, Statistical Upscaling and Downscaling in Hydrology, Volume 1**).

PLANNING A MEASUREMENT SYSTEM

The hypotheses being tested, or objectives of the sampling exercise will define the processes (or states and fluxes) that need to be measured. But do the instruments available have the characteristics to measure what you really need and how do you match the type of measurement to the process of interest?

Matching of Measurement to Process

While often a quantitative treatment will not be needed, a qualitative consideration of the scale of the natural variability and that of the measurements is important to assess at least the magnitude of information on variability not resolved by the sampling. In Figure 4, the spatial spacing and extent of several different types of measurement devices are plotted versus their typical temporal spacing and extent. The shaded area refers to the domain between spacing and extent of the measurements. For daily rain gauges, the domain covers ranges, in time, from 1 day to, say, 100 years, and in space, from 10 km (average spacing of the gauges) to 2000 km (size of the region). Figure 4 also shows the typical scales of TDR measurements of soil moisture in research catchments as well as a number of space-borne sensors relevant to hydrology.

Figure 5 is a similar plot of spatial and temporal scales related to key hydrological processes (after Blöschl and Sivapalan, 1995). Figure 4 can be compared with Figure 5 and the parts of the space-time domain that overlap are those where we have measurement techniques that are appropriate for describing the process of interest, whereas areas that do not overlap are not described well. In other words, from a particular measurement one can only "see" processes within a limited window (determined by the scale triplet), and processes at larger and smaller scales will not be reflected in the data. For example, daily rain gauges cannot capture atmospheric dynamics at the 10-km scale as the temporal spacing is too large, but on the other hand the Meteosat satellite sensor is commensurate with atmospheric processes from thunderstorms to fronts and one would expect it to capture these processes with little bias as a result of scale incompatibility. The comparison also indicates that TDR measurements can potentially capture runoff generation processes in a small research catchment setting. Figures 4 and 5 are used here just as examples, but the concept of matching measurements with processes in space and time is critical to efficient measurement design.

Accuracy and Error

The preceding discussion highlighted that poor sampling design can introduce considerable error or uncertainty but that these can be minimized by considering the spatial and temporal characteristics of the phenomena of interest to ensure that measurements are representative of the variability. Once the preferred temporal and spatial characteristics of a measurement are defined, consideration must be given to the accuracy of the measurement itself. Measurements can be a direct measure of a hydrological variable (such as the stage of a stream, rainfall depth, or snow water equivalent measured by weighing a snow core), or they can be indirect measures where some feature that is closely related to the variable of interest is recorded. In either case, the measurement accuracy can be defined via knowledge of the sensor response and quality of calibration.

If the measurement error is large relative to the overall magnitude of the signal, the spatial or temporal patterns apparent in the data will be a poor representation of the

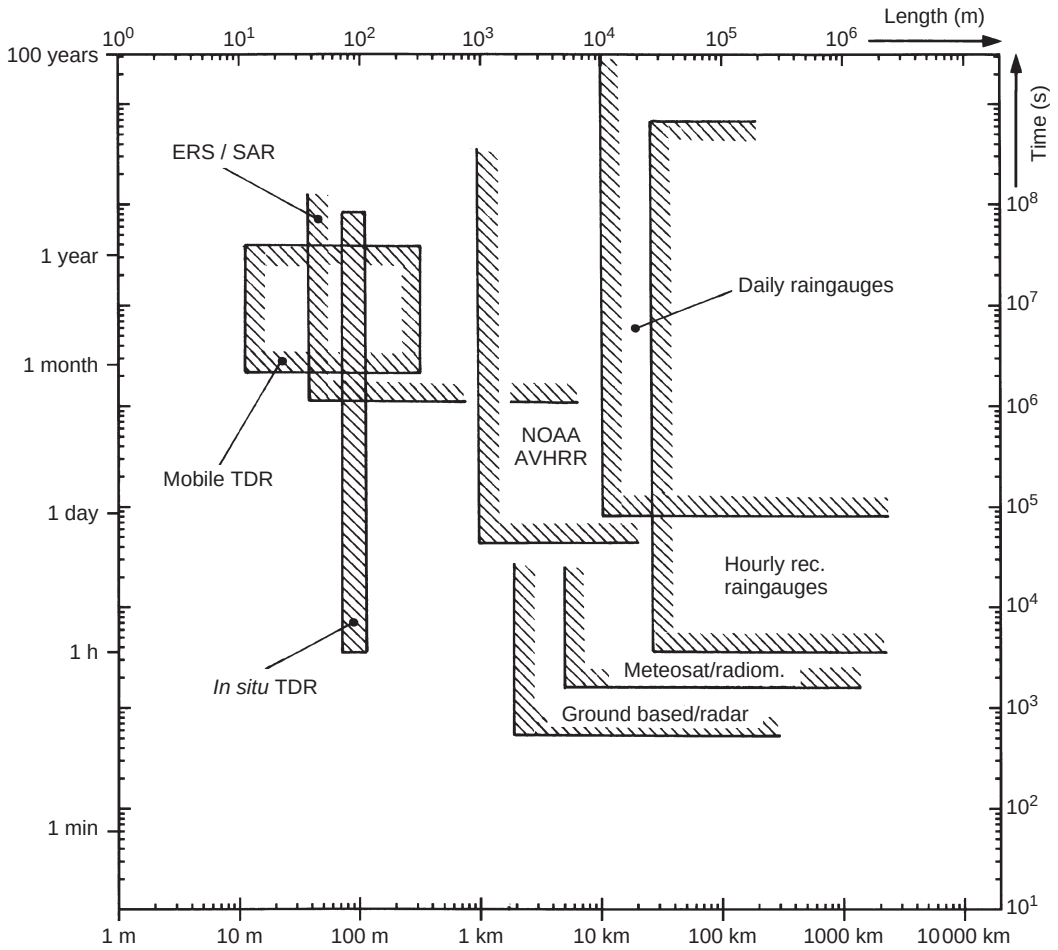

Figure 4 Space and timescales of rainfall and soil moisture variability that can be captured by different instruments represented as the domain between spacing and extent of the measurements. After Blöschl and Grayson (2000)

true underlying pattern. For example, random errors in TDR measurement of soil moisture are typically 2% v/v for field applications. In a temperate environment, soil moisture may vary by over 30% v/v so the relative error is low, but in dry times when soil moisture is close to wilting point, the range may be only 5% v/v and the measurement error is significant. Measurement of water level in a stream can be quite accurate (within a few mm), but there may be considerable error in the rating curve that converts depth to discharge because of, for example, extrapolation of the curve above the highest gauged water level.

There are two types of measurement errors, systematic and random. A systematic measurement error may be introduced either by an improper measurement setup (such as the catch deficit of rain gauges caused by wind exposure) or by improper rating functions (e.g. incorrect TDR calibration curves). Systematic errors can also be introduced by systematic sampling. For example, sun-synchronous satellite orbits lead to sampling at a consistent time during the diurnal cycle, thereby potentially introducing a bias in the observed variables. In many cases, it will be possible to correct for such systematic errors, provided additional (more accurate) data are available for comparison. A random measurement error is inherent in the stochastic processes of nuclear decay and neutron scattering, which underlie the operation of neutron soil moisture meters or it may be introduced by inaccurate readings of an observer who reads off the stage of a stream gauge. While for random errors it is not possible to apply a correction, taking multiple measurements of the same variable significantly reduces random errors and allows the statistical uncertainty to be assessed. For example, if there is a measurement error variance of 3 $(\%V/V)^2$ attached to a single TDR measurement, 10 such measurements at the same location and time pooled together only have a measurement error of 0.3 $(\%V/V)^2$, provided the errors of these 10 measurements are statistically independent. More generally speaking, the measurement error variance decreases with the inverse of the number of samples that are aggregated (see any basic statistics text e.g. Kottegoda and Rosso, 1996).

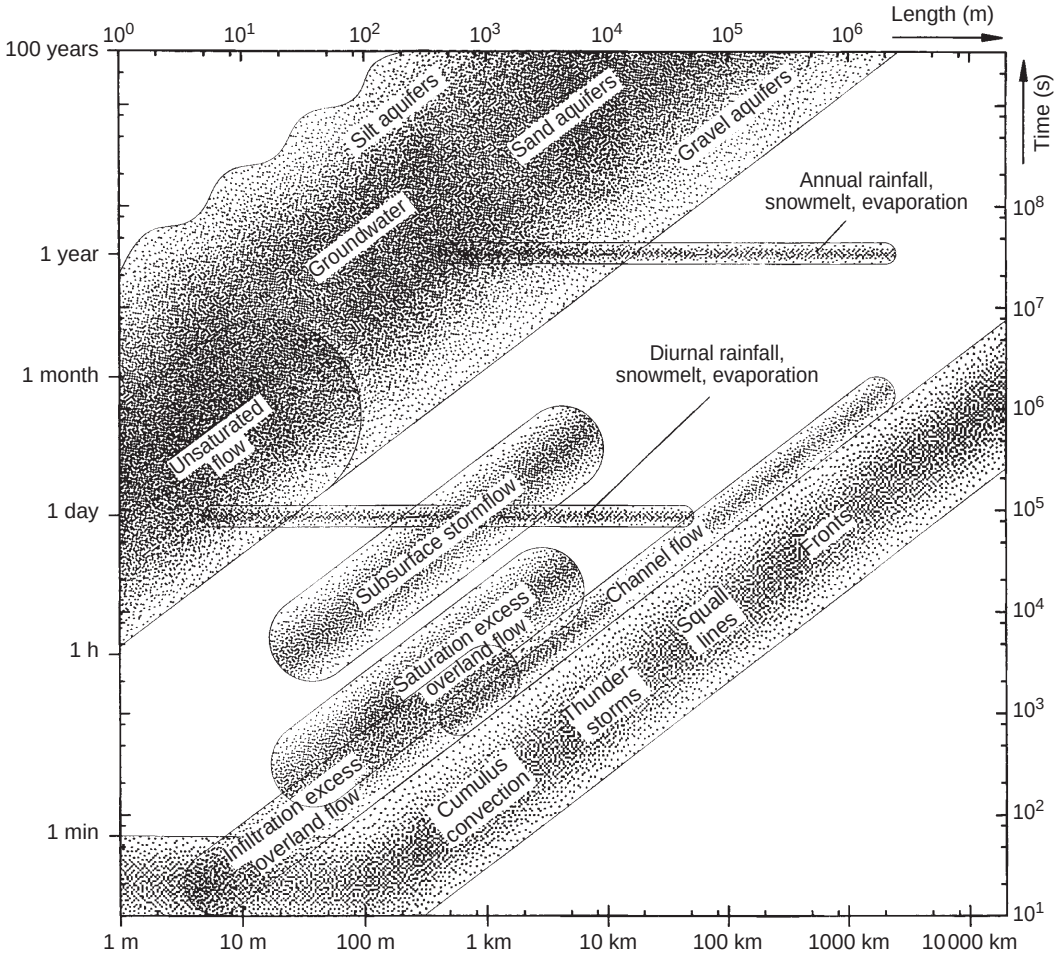

Figure 5 Schematic relationship between spatial and temporal process scales for a number of hydrological processes (after Blöschl and Sivapalan, 1995)

Trade-offs in Measurement

There is often a trade-off between great accuracy and few points (and hence a poor resolution/coverage), and poorer accuracy and lots of points. An important example in hydrology is the use of remote sensing data. For example, weather radar does not measure rainfall, but radar reflectivity, which is correlated with rainfall intensity, also depends on other factors (such as drop-size distribution and the presence of snow), only some of which are known. As a consequence, there is often a substantial error introduced when converting reflectivity to rainfall and good measurement systems integrate rain gauge and radar data. Other examples in remote sensing include soil moisture as estimated from SAR sensors where a huge number of points (pixels) in space are available but correlations between the SAR backscatter and soil moisture tend to be poor. The same is true with some ground data. For example, in an Alpine environment, it typically takes of the order of 3 min to measure snow depth but it may take 30 min or more to collect a sample of snow water equivalent. Similarly, total suspended solids (TSS) in a stream is best measured by collecting a sample, filtering a known volume in the laboratory, and weighing the dried solids, but stream turbidity, which can be measured continuously using attenuation of light, is often related to TSS concentration, albeit with some error. The optimum sampling strategy will often therefore involve some combination of a few measurements of high accuracy (to test surrogate relationships and calibrations) and many measurements of lower accuracy (to provide the spatial and temporal spacing required to capture the processes of interest).

Trialling and Pilot Studies

The preceding sections provide some basic concepts to assist in designing a measurement system, but there is nothing like a trial to see how those ideas translate to reality. There are two basic forms of pilot studies, small-scale field applications and synthetic studies.

Field trials are designed to test the real-world performance of sensors or monitoring networks to see if they do indeed perform as expected. Is the information sufficient to meet the objectives or test the hypotheses? Are the errors greater than was thought? Is the real-world variability greater or smaller than expected? Essentially, this is part of the iterative process referred to earlier where the field-pilot study is the opportunity to learn more about the phenomena of interest and refine the sampling before fully committing to an expensive program.

Synthetic studies can also be useful, particularly in the early planning phases of a measurement program. The idea is to use either similar data from elsewhere or simulated data with the characteristics of data expected from the instruments in the field to test how well the objectives of a sampling program are likely to be met. For example, if we are interested in estimating the total annual load of suspended solids from a river, we might use data from a similar river with high-resolution flow and TSS measurement to trial a range of different sampling strategies. This is done by "subsampling" from the TSS and flow data to see how the annual load estimates vary depending on how many samples are taken at what time. Is regular sampling the best or is it better to separate base flow from high flow? What is the minimum number of samples needed during high flow to estimate storm loads within the accuracy that is needed? Synthetic studies can also be used to assess the impact of error on the usefulness of the data. This is common in remote sensing applications where a "perfect pattern" is generated and then noise is added to see whether the resulting data are still useful for the intended applications.

Network Design and Site Selection

Network design and site selection are critical to quality monitoring outcomes. Network design covers aspects of site density and distribution and has been discussed earlier from a theoretical perspective, to maximize the likelihood of the data meeting the measurement objectives. In practice, accessibility, availability of power, coverage by cellular phone for telemetry, and agreement by landholders should also be considered.

Site selection is associated with the specific characteristics a site should have, which vary between measurement types, and must be determined from an understanding of the characteristics of the measurement systems. Examples of key requirements include fetch requirements for eddy correlation measurements and the desirability of locating a stream gauge at a hydraulic control. Often a site is chosen to be "representative" of a broader area. A highly accurate measurement at a point can introduce considerable error to a survey if it is extrapolated to a larger area of which that point is not representative. For example, piezometers sited along fault structures are likely to be unrepresentative of groundwater conditions in the same geological unit away from fault structures. It may be necessary to undertake a broader survey or use other data to quantify this "representativeness". Soils, geology, vegetation, and topographic mapping can be used to define the distributions of these characteristics in a study catchment compared to a broader area. In addition, remotely sensed data (both satellite and airborne geophysical data) may be required to define representative sites, particularly for subsurface studies. Similarly, the shape of a flow-duration curve indicates important features of streamflow response that can be used to compare catchments.

PRACTICAL ISSUES

To achieve trouble-free operation and high-quality data, a number of important practical issues must be addressed. These include:

- power
- time and date
- telemetry
- quality assurance
- calibration
- data archiving and documentation
- security and protection
- occupational health, safety, and site access
- capital/operation cost trade-offs.

It is difficult to give prescriptive answers on how these issues should be addressed, partly because technologies are changing rapidly and partly because they are often very situation-dependent. Thus, the following discussion aims to identify common issues rather than providing detailed solutions.

Power requirements of modern electronics are usually low and it is possible to run monitoring systems off batteries that can be periodically replaced. However, for extended operation, where telemetry is required, or for some higher power consumption sensors, such a solution is not sufficient. In these cases, solar panels offer a reasonably cheap and reliable power source for many environments. Solar panel charging circuits should include appropriate voltage regulation. It is valuable to monitor battery voltages to detect problems early, especially in telemetered systems, and to use loggers with nonvolatile data storage so that loss of data due to power problems is limited. It is still the case that a large proportion of reliability problems with instrumentation are related to power supply reliability, so attention to detail is important here as in other aspects.

Time and date: the golden rules are to make sure that they are set properly, that different data loggers (and computers used to access and reset data loggers) are synchronized, and that "summer" time issues are dealt with. Our preference is to always use the local standard time or UTZ. It is useful if

the clock in a data logger continues to run during a power outage because solar charging systems would allow loggers to restart measurements. This requires a backup power source (usually an internal logger battery) to maintain the core logger operation.

A variety of *telemetry* options are available and this is an area of rapid change with developments such as novel uses of modern cellular phone systems including text messaging, and innovations like sensor webs becoming available. The options at present include landlines, cellular phones, various satellite uplink options, and radio networks. Each of these options has advantages and disadvantages in terms of data rates, capital and operating costs, coverage (an issue in remote areas), and reliability. The key general advantages of telemetry are near real-time data access and archiving, early identification of instrument problems, and a reduced cost of station maintenance due to reduced site visit requirements.

Quality assurance is a critical part of any measurement campaign and it has pre-, co-, and post-measurement aspects. Many factors go to ensuring high-quality data. Elements that need to be considered here are sensor quality, sensor and logger calibration, sensor installation (poor installation = poor measurements), sensor and site maintenance, data checking, data documentation, and data archiving.

Calibration involves both ensuring that the data logging system measures and records the sensor response correctly, as well as relating the sensor response to the variable being measured. The golden rule is "do not rely on factory calibrations supplied with an instrument", especially where the environmental characteristics affect the sensor response (e.g. soil type effects on soil moisture sensor response). Calibration is an ongoing process because for most sensors, relationships drift over time. The frequency of recalibration required for different types of sensors varies greatly as a result of different instrument stabilities. Where multiple measurements of the same variable are being made, instrument cross-calibration and intercomparison are important for maximizing our ability to compare measurements. In some cases, there can be a dependence of the sensor response on the installation, as is often the case with soil moisture sensors. In such cases, field calibration is preferred. It is also important to ensure appropriate site maintenance occurs, particularly where some site exclusion causes vegetation conditions to be markedly different to maintenance of the surrounding area. Appropriate maintenance for sensors (e.g. cleaning) and loggers (e.g. battery changes) also needs to be considered.

Data checking and archiving are also important components of quality assurance, but is something that is often not done well. Gross data checking can be undertaken automatically by comparing measurements to expected ranges, by checking rates of change over time, and by comparisons to appropriate climatologies. This should be done as soon as possible after data collection and ideally in real time. It is no use realizing a year later that there was an instrument problem that could have been fixed immediately. Other important aspects of data checking include plotting data, comparing data to models, and intercomparisons between sites and sensors. Once data are checked they need to be stored (usually in digital format) in well-documented formats, with meta data about the measurement and quality assurance procedures and site characteristics, including geographic coordinates (with information stating the map coordinate system used). This is time consuming but critical to the long-term utility of your data. To ensure long-term database integrity, appropriate backup, archiving to stable media, and planned media migration are necessary. Again this is an area that is often not done well, particularly in the research environment. It is salutary to consider how much data has been generated during PhD and other research studies around the world, but is for all intents and purposes lost. The cost of digital storage is constantly reducing and the Internet provides an ideal avenue for making data widely available. Hopefully, this will encourage better archiving of data over time.

Physical security of instrumentation from interference by people, animals, and the physical environment is important. Prevention of interference by people and animals is dependent on using adequate enclosures, housings, and cable protection systems (e.g. cable conduits). Animals can be curious and can cause damage to equipment, especially cables, or disturb the site, which can be problematic if it influences the variable being measured (Figure 6). An example is destruction of vegetation cover under a net radiometer. Insects such as ants can cause problems by colonizing instrument housings. Issues to consider related to the physical environment include flooding during extreme events, adequate water proofing, anchoring of sensors (and cables) in streams, wind loads on masts and tripods, lightening protection, and control of operating temperature for some instruments.

A variety of *occupational health and safety* issues exist with any field activity. These range from issues such as traffic accident risks, being stuck in remote areas due to vehicle breakdown, exposure to the environment (heat and cold), and exposure to risks associated with local fauna and flora (e.g. snake bites) to issues specifically associated with setting up and maintaining measurement stations. This latter group can include elevated working platforms, excavations, machinery, and plant related risks (e.g. drilling rigs), and risks associated with stream gaugings by wading, from boats and from aerial cableways, among others. Modern occupational health and safety procedures generally require risk assessment of work activities, appropriate risk mitigation approaches, and appropriate training of personnel. It is always useful, while in the warm security of your office, to think through all of the possible problems

Figure 6 Before and after – curious animals around a reflector for aircraft overpass of a microwave sensor. Photos Rodger Young. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

you may encounter in the field and plan a solution to each, being sure you pack the necessary materials or equipment to carry out your plan.

Given many of the practical issues discussed above, it is clear that there can often be significant trade-offs between capital and operating costs. For example, telemetry systems generally reduce time requirements and travel cost for infield logger maintenance. Good quality installations with robust enclosures and housings also generally require a lesser basic maintenance of equipment. Therefore when planning a measurement system, this trade-off needs to be considered early in the process as it affects site design and equipment purchasing.

Back in the Office

A critical element to successful measurement programs is checking and using the data as soon as possible after it is collected. Part of the planning for a measurement program is designing what will be done with the data to actually test the hypothesis. Analysis methods may have even been tested as part of synthetic or pilot field studies. Early use of the "real" data will quickly expose instrument errors or flaws in the measurement program that may prevent your objectives being met. It is difficult to overstate the importance of this step. When in the middle of major field programs, it is very easy to be overwhelmed by the immediate practical matters of the measurement network and put off initial analysis of the data. High-quality measurement programs are regularly reviewed by reconsidering the objectives, analyzing whether the data are best meeting those objectives, ensuring that the data quality and archiving processes are sound, and so on.

SUMMARY

This article highlights several key considerations in a successful measurement programme. These are:

- The need to have a clear set of objectives or hypotheses to be tested.
- An understanding of the temporal and spatial variability of the phenomena of interest.
- An understanding of the characteristics of the instruments available for measurement, including errors.
- Matching of the temporal and spatial characteristics of the measurement with those of the processes of interest.
- Considering the trade-offs inherent in sampling, including the number of measurements and accuracy.
- Considering a range of practical issues related to setup in the field and the need to check and manage the data as it is collected.

These steps are summarized in the boxed section below.

Successful monitoring programs have a number of common features that contribute to the success. They are well designed and well resourced financially and in terms of expertise both in the initial stages and for the full measurement period. Good monitoring programs tend to be comprehensive in terms of measuring a number of complementary responses. Analysis will occur during the monitoring program and will look at the interrelationships between measurements to take advantage of complementarity and to test against the theoretical framework underlying the experimental design. However, it is important that the analysis is not blinkered by the assumed theoretical framework as this may disguise important results. For instance, the analysis of chemical (conservative ion and isotopic) techniques in conjunction traditional streamflow data is challenging previous conceptions of rainfall-runoff processes in a number of humid catchments (see discussion by McDonnell, 2003). Timely analysis allows an ongoing review of performance and appropriate modification, which is critical to success.

There are a number of new and emerging sensor technologies, as well as the ever-increasing availability of remote sensing information that bodes well for the future of hydrological measurement. But as has always been the case,

Box Basic questions for the design of a measurement program

A) What are the processes we are trying to capture (or hypotheses we are testing) with the measurement programme?

- What is the variability in time and space of the feature of the process that we will be measuring?
- Which variables should we measure and how representative are they of the process?
- What is the typical length scale of the feature of interest?
- How quickly does the feature change and are there particularly important timescales (e.g. diurnal, seasonal etc.)?
- What are the minimum and maximum values that are expected to be measured?
- Do we have *predictive methods* (e.g. relationships to auxiliary data) for defining the variation of the feature and how accurate are these?

B) How will the actual measurement be made?

- What measurement device (or devices) could be used?
- What is the accuracy of the chosen devices?
- What is the sampling support (time and space) of the device?
- Over what extent (time and space) do we need to make measurements?
- What level of calibration is needed for the device (initial and ongoing)?
- What are the practical constraints related to time, cost, and the logistics of the measurements to be made? Will telemetry be used? (Answers will indicate the possible number of samples or sites and enable the network to be planned.)
- Are there alternative variables to be measured that perhaps are less representative of the process or less accurate, but can be more easily collected?

C) We then need to try and match the needs of the measurement exercise with the variability in the feature being measured and the characteristics of the measurement device. In this step we need to recall that:

- if the spacing is too big compared to the feature of interest, we will not characterize small-scale variability (it will become ''noise'');
- if the extent is too small, we will miss out on the big scale pattern and instead measure a trend;
- if the support is too large, small-scale variability is smoothed out;
- if the sampling error is large compared to the variance of the feature, we will not detect the pattern.

Compromises will always be needed and, because of lack of knowledge, there will be some guesswork. Pilot trials in the field or using synthetic data can assist in this step. There will ultimately be constraints imposed by equipment, finances, and so on, and hence the final measurement system will not be ''ideal.'' A realistic assessment is needed of whether the original objectives will still be met given these pragmatic limitations, or whether the objectives themselves need to be revised.

D) Implementation of the measurement network

- how will the power be supplied?
- what amount of data storage or telemetry speed is needed?
- what physical protection is required?
- what are the capital and operating costs of various options?
- what procedures are in place for data checking and archiving?

The next step then is to look at the data set as it becomes available and ask how well did the measurement programme meet the objectives or enable the hypotheses to be tested? Are revisions to the program required? And so the process begins again as we understand more about both the underlying processes and the practical performance of our design.

it is the synthesis of "smart measurements" with theoretical developments and modeling that will yield the greatest advances in the coming years.

7: Methods of Analyzing Variability

LARS GOTTSCHALK

Department of Geosciences, University of Oslo, Oslo, Norway

In an introductory part basic concepts from probability theory, and specifically from the theory of random processes, are introduced as a basis for the characterization of variability of hydrological time series, space processes and time-space processes. A partial characterization of the random process under study is adopted in accordance with three different schemes:

1. *Characterization by distribution function (one dimensional),*
2. *Second moment characterization, and*
3. *Karhunen–Loève expansion, that is, a series representation in terms of random variables and deterministic functions of a random process.*

The article follows the same division into three major sections. In the first one, distribution functions of frequent use in hydrology are shortly described as well as the flow duration curve. The treatment of second-order moments includes covariance/correlation functions, spectral functions and semivariograms. They allow establishing the structure of the data in space and time and its scale of variability. They also give the possibility of testing basic hypothesis of homogeneity and stationarity. By means of normalization and standardization, data can be transformed into new data sets owing these properties.

The section on Karhunen–Loève expansion includes harmonic analysis, analysis by wavelets, principal component analysis, and empirical orthogonal functions. The characterization by series representation in its turn assumes homogeneity with respect to the variance–covariance function. It is as such a tool for analyzing spatial-temporal variability relative to the first- and second-order moments in terms of new sets of common orthogonal random functions.

INTRODUCTION

Observations from studies of hydrological systems at an appropriate scale are characterized by complex variation patterns in time and space and reflect regularity in a statistical sense. It is commonly reasonable to apply concepts from statistics and probability theory to be able to properly describe these observations and model the system. The theory of random processes is of particular interest.

The basic ideas of probability theory and random processes are well known. Experiments are basic elements of probability theory and statistics and are defined as actions aimed at investigating some unknown phenomenon or effect. The result is, as a rule, a set of values in a region in space and/or an interval in time. An experiment in a laboratory can be repeated and different realizations can be obtained under the same conditions (*experimental data*). In hydrology, it is the nature that performs experiments and therefore it is not possible to control the conditions (*historical data*). The historical data at hand are considered as *samples* (or *realizations*) from some very large or even infinite *parent population*. In the following small letters, say x, will denote the sample while capital letters, X, will denote the corresponding theoretical population. The structure of the available data guides the method to be used for analyzing variability. It is possible to distinguish between three different situations:

1. An observation point in space is fixed and only the development in time is observed at this point, as

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

illustrated in Figure 1, where the annual streamflow for the Göta River for the period 1807–1938 is shown. This is referred to as a *time series* $x_k = x(t_k),\ k = 1, \ldots, N$, where t_k denotes the (regular) observation points in time (here years) and N is the number of observations (in the example, $N = 131$). The process is characterized by an active and inherent dynamic uncertainty, the properties in different points change with time in a random manner. In the general case, the order in which time series is sampled is of outmost importance as the temporal fluctuations show *persistence*, that is, adjacent observations show dependence. The opposite situation when data are independent and can be reshuffled without loss of information is an important special case.

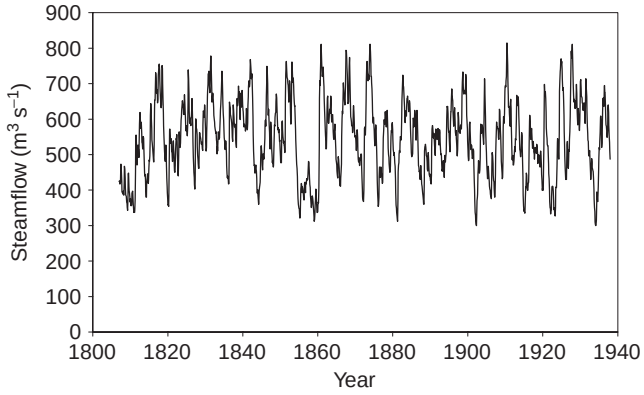

Figure 1 Time series: Streamflow of the Göta River at Sjötorp, Sweden 1807–1938

2. The second situation – a *space process* $x_i = x(\mathbf{u}_i),\ i = 1, \ldots, M$- is illustrated by georadar measurements reflecting the geological structure of the top layer of the Gardermoen delta deposit at Moreppen (Norway) along transects of some 10th of meters. $\mathbf{u}_i$ denotes the position in space of the i-th measurement, of totally M (Figure 2). In the example, observations are made at a regular grid in space. More common is the case of spatial measurements from an irregular observation network. It may be assumed in this case that the changes over time of the system are small (at a human timescale). The uncertainty in the description

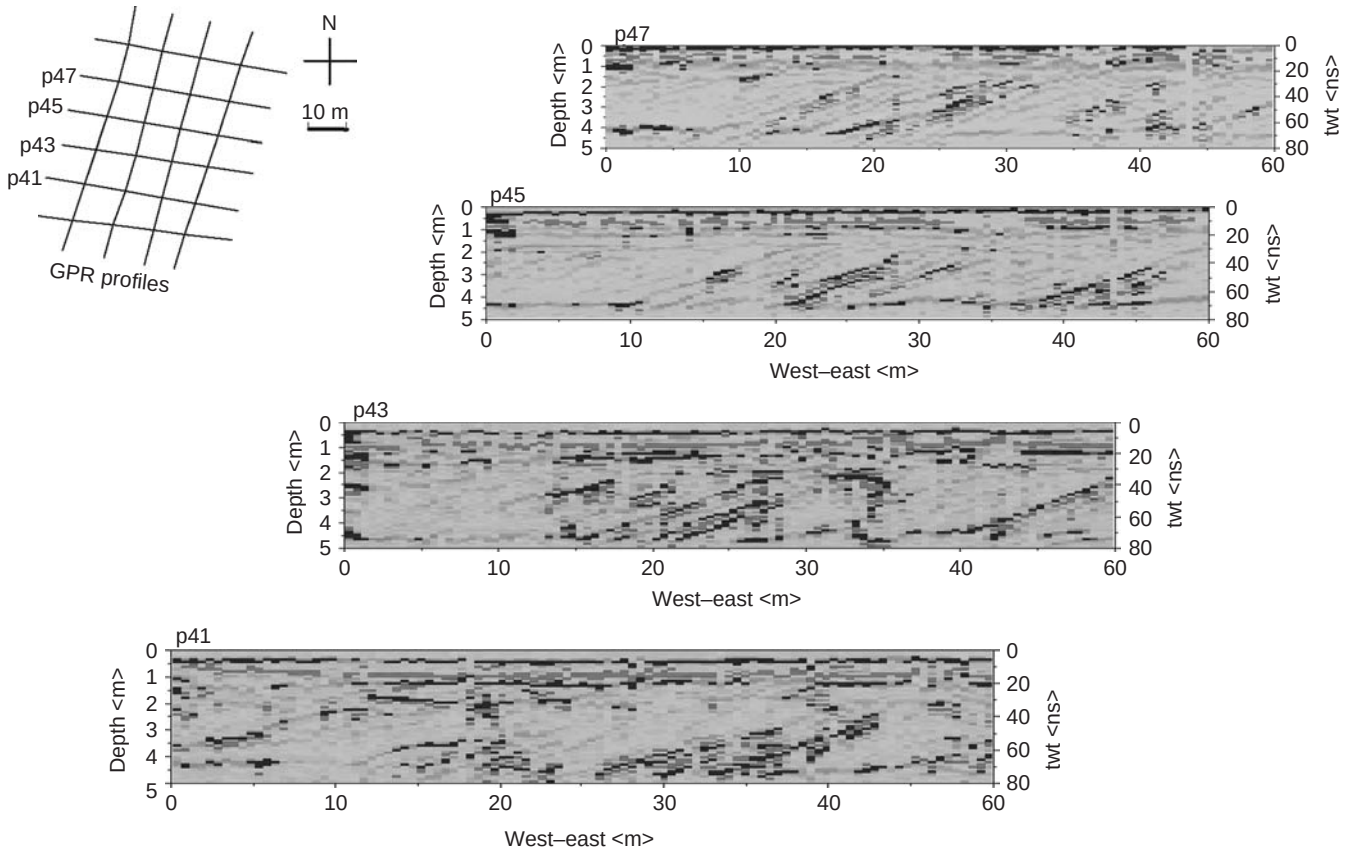

Figure 2 Space process: The geological structure of the top layer of the Gardermoen delta deposit at Moreppen (Norway), as reflected by georadar measurements (ground penetrating radar (GPR) signals for four profiles. The strong reflectors in the dipping forest unit are from silty layers with high soil moisture content. Yellow and green colors reflect drier sand. of the properties of a disordered system, for which the development in time does not matter, is of passive nature. Though the changes in time of a characteristic at a given position might be negligible, its value is unknown until it is measured. Measurements in all possible points are, as a rule, neither feasible nor economic, and the information value is lowered by the measurement errors as well. Persistence in data is also of relevance for spatial data, that is, the order in which they are sampled in the two-dimensional space is of vital importance.

3. Figure 3 offers an attempt to illustrate of the most general case showing the space-time development of streamflow (monthly values) along the different branches of the Rhône River (French part). In reality, observations of such a *time-space process* $x_{ik} = x(\mathbf{u}_i, t_k),\ i = 1, \ldots, M; k = 1, \ldots, N$ represent measurements in discrete irregular points along the river network at discrete regular times (and not as the fully reconstructed space-time development as in Figure 3), that is, a vector of data where columns represent different points in space and rows time. These observations are used to get an idea about the pattern of variation of the whole system by means of reconstructing the past development in time and space and/or forecasting the future.

The scale problem is fundamental in all description and modeling of time-space processes. A phenomenon that seems to contain mainly deterministic elements in a micro scale might at a larger scale demonstrate characteristics that vary much and demand a probabilistic approach for their description. At a still larger scale (macro scale), the same structure can appear to be a part of an object that can be described by its mean value or by classes. Variation of precipitation intensity at annual and daily timescales seems to behave totally at random, while, at a finer timescale, (minutes) this variation assumes a dynamically varying pattern (Figure 4). At the monthly scale, a seasonal variation might be present. In other words, there is, as a rule, the lower and the upper boundary for the variation range (distance or time) within which a model for characterization of the patterns of variations has a practical value. This is the point of departure for the application of classical theory of random processes in hydrology, which has been mainly applied to study stationary (time independent) random processes like annual or submonthly quantities (upper three graphs, and lower graph in Figure 4). Possible large-scale elements like "trends" and "periods" were looked upon as "deterministic", and, as such, identified and subtracted from the original data (e.g. Hansen, 1971; Yevjevich, 1972). This perspective contrasts with the current view accepting "... irregularly changes, for unknown reasons on all timescales" (National Research Council, 1991). Random process models need to be changed accordingly. The scale problem is of course not only limited to processes in time. Referring to the geological structure in Figure 2, the patterns of variability and its character will change drastically both when going down in scale as when going up. The topic of scale is further developed in **Chapter 6, Principles of Hydrological Measurements, Volume 1** and **Chapter 9, Statistical Upscaling and Downscaling in Hydrology, Volume 1**).

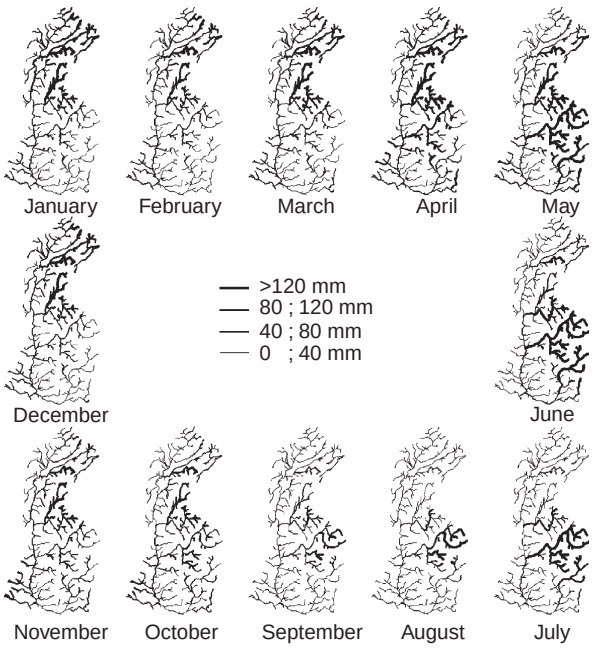

Figure 3 Time-space process: Estimated streamflow of the Rhône River for 12 months of the year (Reproduced from Sauquet and Leblois, 2001, by permission of Societe Hydrotechnique de France)

Let us turn back to probability theory terminology and continue formalizing the description of the outcome of an experiment. In the elementary case, the population is described in terms of a random variable and, in more complex situations, as a random process (random field). Figure 3 may be used to illustrate our basic model, where each point in the sample space $\mathbf{u} \in \Omega$ (points along rivers) maps into a time function $X(\mathbf{u},t)$. A point $\mathbf{u}_k$ in space can be specified, which results in a random process in time, a time series, $X(t) = X_k(t)$, like the one shown in Figure 1. If the data of the series fulfill the condition of having an independent identical distribution (i.i.d.), they can be treated as a sample of a random variable X. Only in this latter case, the one-dimensional probability distribution $F_X(x)$ will give a complete characterization of X. The time $t = t_i$ can be frozen, which leads to a random process in space only $X(\mathbf{u}) = X_i(\mathbf{u})$, illustrated in Figure 2. Also, in this case, a one-dimensional distribution describes variations across space. The i.i.d. condition should, of course, be fulfilled to give a complete description.

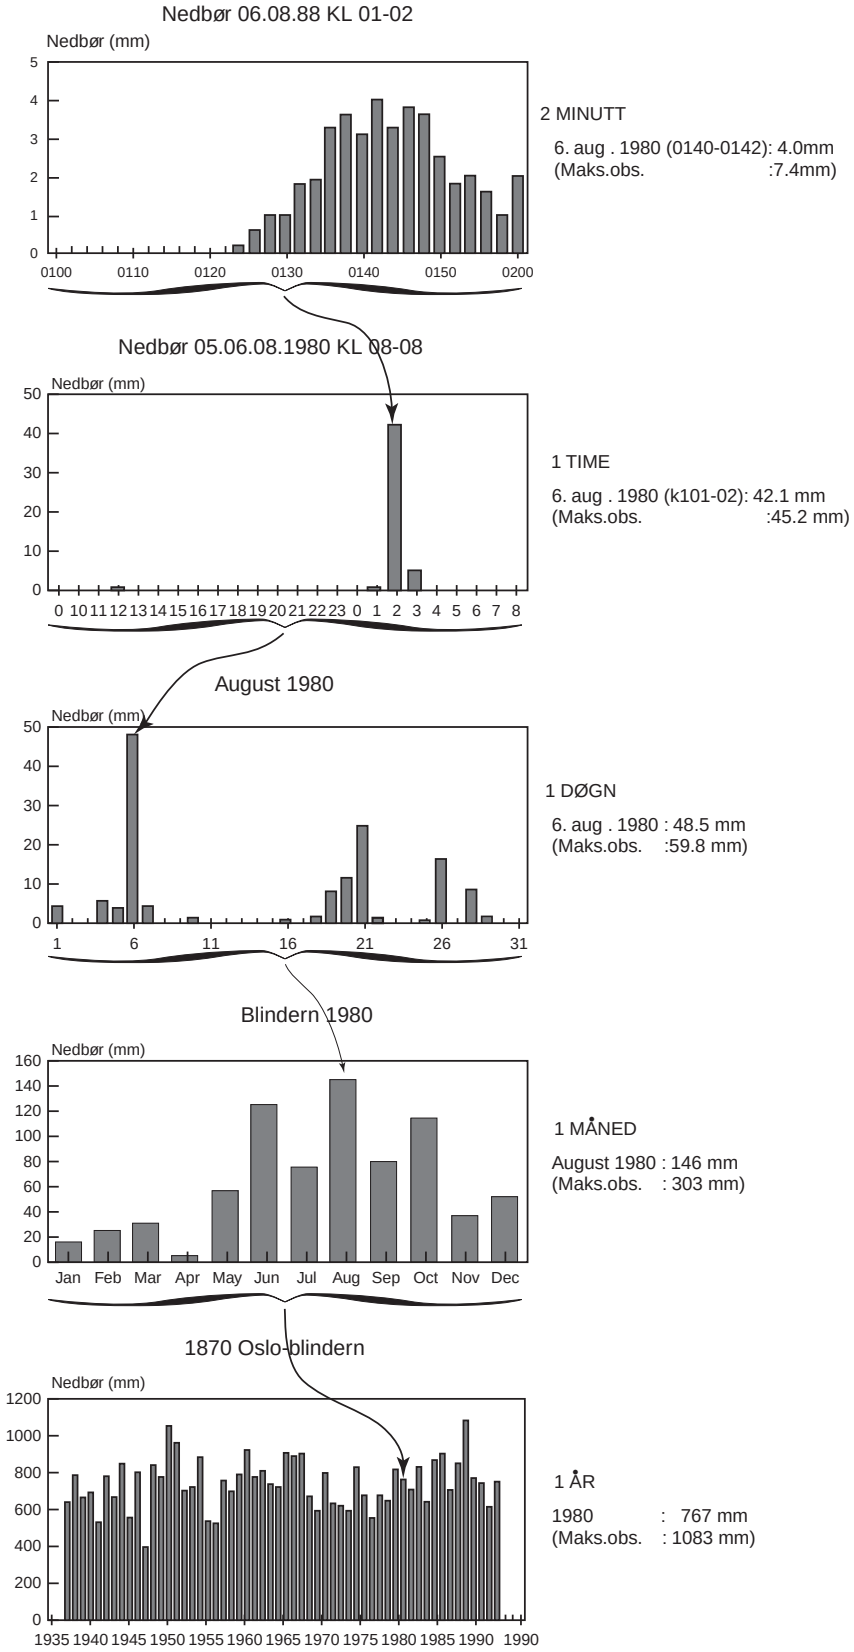

Figure 4 Observed precipitation at Blindern (Oslo) with 5 different time resolutions 2 min, 1 h, 1 day, 1 month, and 1 year

Many important characteristics of random processes viz. *homogeneity* (*stationarity*), *isotropy*, and *ergodicity*, permit a more effective use of the limited data amount available for estimation of important properties of the process. The strict definitions of these characteristics can be formulated with the help of the multivariate (M-dimensional) distribution function $F_M(\mathbf{x})$ (abbreviated df). A random process is called *homogeneous* if all multivariate distributions do not change with the movement in the parameter space (translation, not rotation). This implies that all probabilities depend on relative and not absolute positions of points in the parameter space. The term "*stationary*" instead of homogeneous is usually used for one-dimensional random processes (time series), that is, the df does not change with time. A process is called *isotropic* if the multivariate distribution function remains the same even when the constellation of points is rotated in the parameter space. A random process is *ergodic* if all information about this multivariate distribution (and its parameters) is contained in a single realization of the random field. It is important to note that this property is also related to the characteristic scale of variability of the process. If the process is observed over a time interval (or region in space), which in its extension is of the same order of magnitude as the characteristic scale (or smaller), the estimate of the variability of the process will by necessity be negatively biased. The process will not be able to show its whole range of patterns of variability. A rule of thumb has been to say that a process needs to be observed for a period of time that is at least 10 times the characteristic scale of the process, in order to eliminate the negative bias in the variance. In times when environmental and climate change are in focus and accepting that the process shows variability on a range of scales, the dilemma related to the ergodicity problem is obvious. Do the observed data reveal the real variability of the natural processes under study? In **Chapter 9, Statistical Upscaling and Downscaling in Hydrology, Volume 1**, this topic is brought further and the process scale related to the natural variability is confronted with the measurement scale, defined in terms of *extent* (coverage), *spacing* (resolution), and *support* (integration volume (time) of a data set).

The parameter space of a random process $X(\mathbf{u},t)$ in the general case includes an unlimited and infinite number of points. Characterization by means of distributions functions is therefore only of a theoretical value. When complex variation patterns are concerned, a possibility of a direct estimation of the underlying multivariate distribution function is not tractable. The conventional way of handling this difficulty is to accept a *partial characterization*. The two most widely used are as follows:

1. Characterization by distribution function (one dimensional).
2. Second-moment characterization.

In a characterization by the distribution function, only the first-order probability density is specified. In a characterization by distribution function in the general case, a multivariate distribution would be needed for a complete characterization. The one-dimensional distribution constitutes in this case the *marginal distribution* of the data. The *flow duration curve* (fdc) widely used in hydrology is a good example. In a second-moment characterization, only the first and second moments of the process are specified, that is, mean values, variances, and covariances. Random processes, which are postulated to be homogeneous (stationary), in practice satisfy this condition only in a weak sense and not strongly, which means that they possess this property only with respect the to the first- and second-order moments (*weak homogeneity, weak stationarity*). A further possibility is to apply

3. Karhunen–Loève expansion, that is, a series representation in terms of random variables and deterministic functions of a random process.

The deterministic functions can either be postulated as for harmonic analysis and analysis by wavelets or they can be determined from the data themselves by analysis in terms of empirical orthogonal functions (eof) or principal components (pca).

In this article, these three ways for representation of a random process will be followed, thus defining three methods for describing variability of hydrologic variables. The development of relations between variability and scale is treated in **Chapter 9, Statistical Upscaling and Downscaling in Hydrology, Volume 1**, although some aspects of the problem are touched upon here as well. Before going into a detailed statistical analysis the importance of "looking" at data should be stressed. A visual inspection of graphical plots of the observed data like those shown in Figures 1, 2, and 4 is a natural point of departure when analyzing variability. In our age of nearly unlimited computing power, this visual graphical data exploration is becoming increasingly important. A further step is an exploratory data analysis, where different hypotheses concerning the structure of the data are tested (Tukey, 1977).

CHARACTERIZATION BY DISTRIBUTION FUNCTION

Restricting ourselves to the one-dimensional case, the basic problem is the following: find a distribution function (df) $F_X(x)$ (probability density function $f_X(x)$, pdf), which is a good model for the parent data $x_1, x_2, \ldots, x_N$. From probability theory, it is well known that this distribution only gives a full description of phenomena in case data can fulfill the condition of being independent identically distributed (i.i.d.). In many applications in hydrology, the

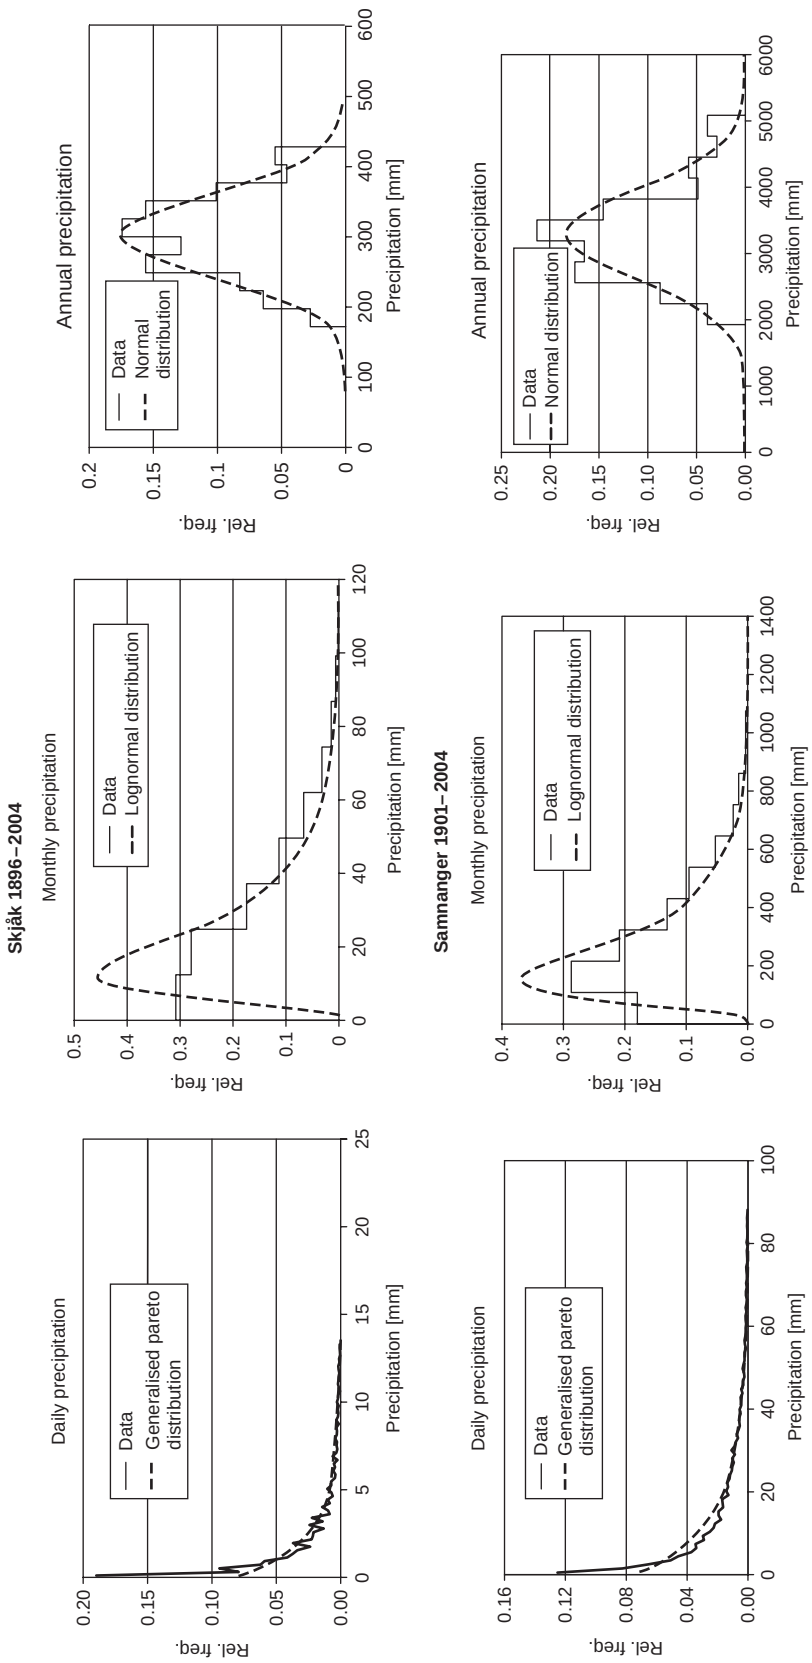

Figure 5 The distribution (pdf) of rainfall at two Norwegian rainfall stations (Skjåk and Samnanger) for three different durations 1 day, 1 month, and 1 year

i.i.d. assumption is rather postulated than really tested and the one-dimensional distribution is to be interpreted as a partial characterization (the marginal distribution function of a multivariate one). Anyhow, this marginal distribution might be a proper tool to study the data. The application of the normal distribution for frequency analysis of runoff data by Hazen (1914) symbolizes the start of the fitting a theoretical distribution to observed data in hydrology. Somewhat later, it became obvious that the river runoff distribution is not symmetrical and also the gamma distribution was introduced in hydrological analysis (Foster, 1924; Sokolovskij, 1930). Important benchmarks in the utilization of probability theory and statistical methods in hydrology were the developments by Kritskij and Menkel (1946), who suggested a transformation of the gamma distribution and Chow (1954), who introduced the lognormal distribution. Figure 5 illustrates the change in the distribution (pdf) of precipitation with changing time step for data from to two stations in Norway, starting from a highly skewed distribution for daily data, to a lognormal shape for monthly data and ending with a symmetric normal distribution for annual data. This example provides an illustration of the central limit theorem in statistics that states that the distribution of a sum of random variables converges to normal distribution as the number of elements in the sum approaches infinity. How quickly the sum converges (and also if it converges) depends on how well certain assumptions are fulfilled. Still, it is important to note that data follow statistical laws and that knowledge of these laws helps when analyzing and interpreting results as well as in choosing an appropriate model. The list of theoretical distributions applied to hydrological data since Hazen can be made very long. A remark might be that the advantage of using a more complex distribution with many parameters instead of the classical ones (the normal, the gamma, the lognormal) is usually minor in relation to the small data samples commonly available and thereby related uncertainty.

The flow duration curve (fdc) represents the relationship between the magnitude and frequency of daily, weekly, monthly (or some other time interval) of streamflow for a particular river basin, providing an estimate of the percentage of time a given streamflow was equaled or exceeded over a historical period (Vogel and Fennessey, 1994). The fdc has a long tradition of application for applied problems in hydrology. The first paper on this topic, in accordance with Foster (1933), is the one published by Herschel in 1878. The interpretation of fdc by Foster is "(Frequency and) duration curves may be considered as forms of probability curves, showing the probability of occurrence of items of any given magnitude of the data". In this respect, an fdc is a plot of the empirical quantile function X_p, that is, the p-th quantile or percentile of streamflow for a certain duration versus exceedance probability p, where p is defined by

$$p = 1 - P\{X \leq x\} = 1 - F_X(x) \tag{1}$$

Foster sees two distinct uses of the fdc: (i) if treated as a probability curve, it may be used to determine the probability of occurrence of future events; and (ii) it can be used merely as a conventional tool for studying of the data. Mosley and McKerchar (1992) look at the problem from a different point of view: "It (a flow duration curve) is not a probability curve, because discharge is correlated between successive time intervals, and discharge characteristics are dependent on season of the year. Hence the probability that discharge on a particular day exceeds a specific value depends on the discharge on proceeding days and on the time of the year". Indeed, the fdc gives a static and incomplete description of a dynamic phenomenon in terms of cumulative frequency of discharge. To have a complete description, it is necessary to turn over to a multivariate distribution, which defines the parent distribution of the data. Anyhow, the marginal distribution of this parent distribution is the fdc. It is a natural point of departure when analyzing streamflow data, which is evident from its wide practical application (Foster, 1933; Vogel and Fennessey, 1995; Holmes *et al.*, 2002).

Foster, in his original paper, compared daily, monthly, and annual fdcs and recognized the fact that the differences between the curves for different durations (timescale) changed with the type of river basins. Searcy (1959) performed a similar comparison. With present computer technology, it is usually taken for granted that the fdc is founded on daily data records (Fennessey and Vogel, 1990; Yu and Yang, 1996; Holmes *et al.*, 2002), although exceptions exist where monthly and 10-day period data are applied to determine the fdc (Mimikou and Kaemaki, 1985; Singh *et al.*, 2001).

SECOND-MOMENT CHARACTERIZATION

The characterization of a random process by means of moments is an alternative to the characterization by means of distribution function. When analyzing hydrologic data as realizations of random processes, it is as a rule neither tractable nor of interest to formulate models in terms of distribution functions. The most common situation is the one when only one realization of the random process is at hand. In order to be able to solve problems of identification, interpolation, and extrapolation, it is usually assumed that the following conditions are satisfied, namely that the random process studied is ergodic, homogeneous, and isotropic. Usually, the second-order homogeneity is a sufficient condition, which is also called weak homogeneity (weak stationarity), as explained earlier. The classical methods for the second-order analyses of stationary stochastic

processes are based on the works by Wiener (1930, 1949) and Khinchin (1934, 1949), where similarity and relationship between autocorrelation function (acf) and spectral function (sf) have been explained. Correlation and persistence (memory, inertia) described by means of acf and sf, which are statistical moments of the second order, belong to the most important characteristics of random processes. If a random process has a normal distribution, then the information of the first (mean value) and second order (acf, sf) are sufficient for an application to multidimensional problems, that is, in this case, weak stationarity implies strict stationarity.

As stated earlier, the point of departure for our study is a space-time random process. Depending on the way data are sampled from this general process, the observations may be looked upon as a random variable, a time series, a random vector, and a dynamically coupled time-space process, respectively.

Random Variable

It is a common situation in hydrology that observed data are treated as a sample from a random variable, as already mentioned in the previous section. The typical situation is data sampled over time with regular intervals at a fixed site in space – $x_1, x_2, \ldots, x_N$. The situation of data sampled on a regular or irregular network in space at a fixed time is also of interest, for example, snow or soil moisture surveys.

If X is a random variable with cumulative distribution function $F_X(x)$, the first moment is the *mean value* or expected value of X:

$$m = m_X = E[X] \tag{2}$$

The second-moment $E[X^2]$ is the mean square of X. Central moments are obtained as the expected values of the function $g(X) = (X - m)^n$. The first central moment is zero. The second central moment is by definition the *variance* of X:

$$\sigma^2 = \sigma_X^2 = \mathrm{Var}[X] = E[(X - m)^2] = E[X^2] - m^2 \tag{3}$$

The square root of the variance σ_X^2 is the *standard deviation* σ_X of X. If $m = 0$, the standard deviation is equal to the root of the mean square. When $m \neq 0$, the variation of X is usually described by means of the *coefficient of variation*:

$$V = V_X = \frac{\sigma_X}{m_X} \tag{4}$$

The *skewness coefficient* γ_1 is defined from the third-order central moment

$$\gamma_1 = \frac{E[(X - m_X)^3]}{\sigma_X^3} = \frac{E[X^3] - 3m_X E[X^2] + 2m_X^3}{\sigma_X^3} \tag{5}$$

Moments are used to describe the random variable and its distribution. The mean value is a measure of central tendency, that is, it shows around which value the distribution is concentrated. Other alternative measures are (i) the *median, Me*, the value of which for X corresponds to $F(x) = 0.5$ (i.e. the middle value in the distribution) and (ii) the *mode*, M, which corresponds to the value of x when the pdf is at maximum (i.e. the most frequent value). The variance, alternatively the standard deviation, describe how concentrated is the distribution around its center of gravity, the mean. The skewness describes how symmetrical the distribution is. If $\gamma_1 = 0$ the distribution is totally symmetrical, while if $\gamma_1 > 0$, it has a "tail" to the right (towards large x values) and if $\gamma_1 < 0$, it has a "tail" to the left (towards small values of x). The parameters m_X, σ_X, and γ_1 offer an acceptable approximation of the (marginal) distribution function $F_X(x)$ of the variable X for most applications in hydrology. In the applied case, m_X, σ_X, and γ_1 are substituted by the corresponding *sample moments* $\overline{x}$, s, g_1, respectively:

$$\overline{x} = \frac{1}{N}\sum_{k=1}^{N} x(t_k) \tag{6}$$

$$s_X{}^2 = \frac{1}{N}\sum_{k=1}^{N} x(t_k)^2 - \overline{x}^2 \tag{7}$$

$$g_1 = \frac{\left(\frac{1}{N}\sum_{k=1}^{N} x(t_k)^3 - 3\overline{x}\frac{1}{N}\sum_{k=1}^{N} x(t_k)^2 + 2\overline{x}\right)}{s^3} \tag{8}$$

The moments of the sample are accompanied with *sampling errors* (*standard errors*) and biases. The well-known formula for the standard error of the mean is

$$\sigma_{\overline{x}} = \frac{\sigma_X}{\sqrt{N}} \tag{9}$$

or as estimated from the sample

$$s_{\overline{x}} = \frac{s_X}{\sqrt{N}} \tag{10}$$

The standard error of the mean is not dependent on the distribution of the population. Standard errors of higher-order moments are related to the theoretical distribution (Kendall *et al.*, 1987). The moments developed here are obviously of the same importance whether or not the necessary i.i.d. conditions are satisfied. On the other hand, it is important to clearly state whether the moments of the one-dimensional distribution of a random variable are considered or the moments of the marginal distribution of a random process. In the latter case, the standard errors and the bias of the moments are related to the

structure (covariance function) of the data (*see* "Time Series" below). The classical methods for statistical tests for random variables are thus not directly applicable in this latter case.

Time Series

A time series is a sequence of data that are sampled over time with regular intervals at a fixed site in space or data that are sampled along a line in space at regular intervals at a fixed time – $x(t_1), x(t_2), \ldots, x(t_N)$ like in Figure 1. The difference, compared to the previous section, is that the order in which data are sampled in the parameter space $t_1, t_2, \ldots, t_N$ is of vital importance here. The two first-order moments m_X and σ_X determine the marginal distribution function $F_X(x)$ of the random process $X(t)$, like in the case of a random variable. However, for a random process, a descriptor of the random structure of this process needs to be added and the autocovariance function (acf) (the second-order mixed moment) determines this structure as an acceptable approximation. The covariance $B(t, t')$ of the state of a random process between two different points in time $X(t)$ and $X(t')$ defines this *autocovariance* function (of t and t'):

$$\begin{aligned} B(t, t') &= B_X(t, t') = \mathrm{Cov}[X(t), X(t')] \\ &= E[X(t), X(t')] - m(t)m(t') \end{aligned} \tag{11}$$

Similarly, the *autocorrelation* function is defined by

$$\rho(t, t') = \rho_X(t, t') = \frac{B(t, t')}{\sigma(t)\sigma(t')} \tag{12}$$

which is the correlation coefficient between $X(t)$ and $X(t')$. A weakly stationary random process has the following properties:

$$\begin{aligned} &E[X(t)] = m(t) = m, \\ &\mathrm{Var}[X(t)] \text{ exists for all } t, (\mathrm{Var}[X(t)] < \infty), \\ \text{and} \quad &B(t, t') = B(|t - t'|) = B(\tau) \end{aligned} \tag{13}$$

$\tau = |t - t'|$ describes the relative distance between the two points in time. The autocovariance function, as well as the autocorrelation function, depend therefore only on relative positions in time, and not absolute ones. A simple measure of the scale of variability can be defined as the integral under the autocorrelation for $\tau > 0$, the integral scale θ_X of a stationary process, that is,

$$\theta_X = \int_0^\infty \rho(\tau)\, \mathrm{d}\tau \tag{14}$$

For stationary processes, a characterization using the *spectral function* (sf) $S_X(f)$, where f is the frequency, is equivalent to the covariance function characterization:

$$S_X(f) = \int_{-\infty}^{\infty} B_X(\tau)\, \mathrm{e}^{i2\pi\ f\tau}\, \mathrm{d}\tau \tag{15}$$

and

$$B_X(f) = \int_{-\infty}^{\infty} S_X(f)\, \mathrm{e}^{-i2\pi\ f\tau}\, \mathrm{d}f \tag{16}$$

These two equations are usually referred to as the Wiener–Khinchin relations.

The stationarity assumption equation (13), which also is the theoretical background for the derivation of the Wiener–Khinchin equations, demands finite variance. The existence of a process with variation at many scales might violate this assumption theoretically. The demand of a weak stationarity is then too strong. An alternative is then to put the demand of stationarity on the differences $[X(t_i) - X(t_j)]$, that is, that its mean value is constant and variance is finite and independent on absolute position. This means mathematically:

$$E[X(t_i) - X(t_j)] = 0, \tag{17}$$

$$\begin{aligned} \text{and} \quad \mathrm{Var}[X(t_i) - X(t_j)] &= E[(X(t_i) - X(t_j))^2] \\ &= 2\gamma(|t_1 - t_2|) = 2\gamma(\tau) \end{aligned} \tag{18}$$

The conditions above are called the *intrinsic hypothesis*. In classical works on turbulence and also in meteorology, the function equation (18) is named *structure function* (Kolmogorov, 1941). It is also called *variogram* (Matheron, 1965) and $\gamma(\tau)$ is accordingly called *semivariogram* (sv), that is,

$$\gamma(\tau) = \tfrac{1}{2} E[(X(t_1) - X(t_2))^2] \tag{19}$$

The intrinsic assumption is more general than the demand for second-order stationarity (weak stationarity). If the condition for weak stationarity is satisfied, that is, the variance exists and equals $B(0)$, the following relation between the semivariogram and covariance functions can be established:

$$\gamma(\tau) = B(0) - B(\tau) \tag{20}$$

The semivariogram is not commonly used for analyzing temporal data in hydrology. It is treated more in detail in the section for the analysis of spatial data below.

The covariance $\hat{B}(k)$ and correlation functions $r(k)$ of the sample are estimated by (stationarity is assumed):

$$\hat{B}(k) = \hat{B}(k\ \Delta t) = \frac{1}{N-k} \sum_{k=1}^{N-k} x(t_j)x(t_{j+k}) - \overline{x}^2; \quad k = 0, \ldots, K \tag{21}$$

$$r(k) = \frac{r(k\ \Delta t) = \hat{B}(k)}{s^2};\ k = 0, \ldots, K \tag{22}$$

where k is the time lag in terms of the interval Δt between observations in time and K is the maximum lag. The standard errors grow with increasing lag as fewer and fewer observations are available for estimation. A rule of thumb is to set $K = 0.1{*}N$ as only a few foremost terms can be known with some acceptable confidence. An estimate of the sample semivariogram $\hat{\gamma}(k)$ when data are available at regular time intervals is

$$\hat{\gamma}(k) = \hat{\gamma}(k\ \Delta t) = \frac{1}{2(N-k)} \sum_{k=1}^{N-k} (x(t_j) - x(t_{j+k}))^2; \quad k = 0, \ldots, K. \tag{23}$$

The estimation of the sample spectral function is more complicated. There exist two principal approaches. One relies on the Wiener–Khinchin equation (15) and the spectral function is calculated from the sample autocorrelation function by numerical integration of this equation. The other is founded on an expansion of the observed data in terms of Fourier series, resulting in a so-called *periodogram*. Very fast algorithms are available, that is, FFT (fast Fourier transform) for this purpose. The highest frequency that can be represented by the sample spectral function is the so-called *Nyquist frequency* $f_N = 1/(2\Delta t)$. Low-frequency components with wavelengths in the order of magnitude of the total period of observations ($T = N{*}\Delta t$) or larger are estimated with poor accuracy and are numerically filtered out. The sample spectrum thus cover frequencies for the range $\frac{K}{N} 1/T < f < 1/(2\Delta t)$, where K as before is the truncation level for the time lag. Figure 6 illustrates the estimated acf, sv, and sf of the discharge data from the Göta River, Sweden (Figure 1). This river drains a large lake Vänern, which explains the very high autocorrelation in these series both for the annual and the monthly time step. A seasonal variation pattern as well as a strong between year variability is noted. Note that the Nyquist frequency of 0.5 in the lower left diagram for annual data relates to a period of 2 years, while the corresponding lower right diagram for monthly data relates to a period of 2 months.

How far can the information about the variability of the studied process contained in the acf, sv, and sf be interpreted, that is, which model can be applied? This question is linked to the discussion in the introductory section about the existence of variability in data across a range of scales. A traditional approach, as already commented on, has been to divide the variability in time series into two parts, namely, one related to deterministic variations and the remaining one to random fluctuation. The goal in this approach has been to be able to describe the random part by a stationary random process. The deterministic part in its turn may be described by long-term trends as well as purely periodic fluctuations. A common model for this case would look as follows:

$$X(t) = D_t + P_t + S_t \varepsilon(t) \tag{24}$$

where D_t denotes the trend, P_t and S_t represent the periodic elements in the mean value and standard deviation respectively, and $\varepsilon(t)$ is the random fluctuations. The random component is found by means of rearrangement:

$$\varepsilon(t) = \frac{X(t) - D_t - P_t}{S_t} \tag{25}$$

which then is assumed to be a stationary process. It can be described by a simple Markov process like an autoregressive model of order one, AR(1), or two, AR(2). The correlation function for these latter two models has the form:

$$\rho(\tau) = \rho(1)^\tau \tag{26}$$

$$\rho(\tau) = \frac{(1-\rho(1)^2)\rho(\tau-2) - (\rho(1) - \rho(1)\rho(2))\rho(\tau-1)}{\rho(2) - \rho(1)^2} \tag{27}$$

The first one exponentially decays towards zero. For the second one, it is more difficult to deduct its performance. It can be shown that it also decays exponentially for large lags towards zero from the positive side if both the lag one and lag two correlations are positive or as a periodically damped oscillation around zero when the two correlations have different signs. The corresponding spectra have the form:

$$S_X(f) = \sigma_X^2 \frac{1-\rho(1)^2}{1+\rho(1)^2 - 2\rho(1)\cos(2\pi f)} \tag{28}$$

$$S_X(f) = \sigma_X^2 \frac{(1-b_1^2)(1+b_2)/(1-b_2) - b_2^2}{1+b_1^2+b_2^2 - 2b_1(1+b_2)\cos(2\pi f) - 2b_2\cos(4\pi f)} \tag{29}$$

where b_1 and b_2, are the parameters of the AR(2) scheme $x_t = b_1 x_{t-1} + b_2 x_{t-2} + \varepsilon_t$. This is simplified to $x_t = b_1 x_{t-1} + \varepsilon_t$ for the AR(1) case for which $b_1 = \rho(1)$.

The AR(1) and AR(2) models are both examples of Markov models or "short memory processes" and as such they are members of the larger family of ARIMA (auto regressive integrated moving average) models (Box and Jenkins, 1970), which have been widely in use in hydrology.

Another development in stochastic hydrology has been initiated by the findings of Hurst (1951) when analyzing the long record of water level information from the Nile River and also other long-term geophysical observation series. Hurst studied asymptotic behavior of the range of cumulative departures from the mean for a given sequence

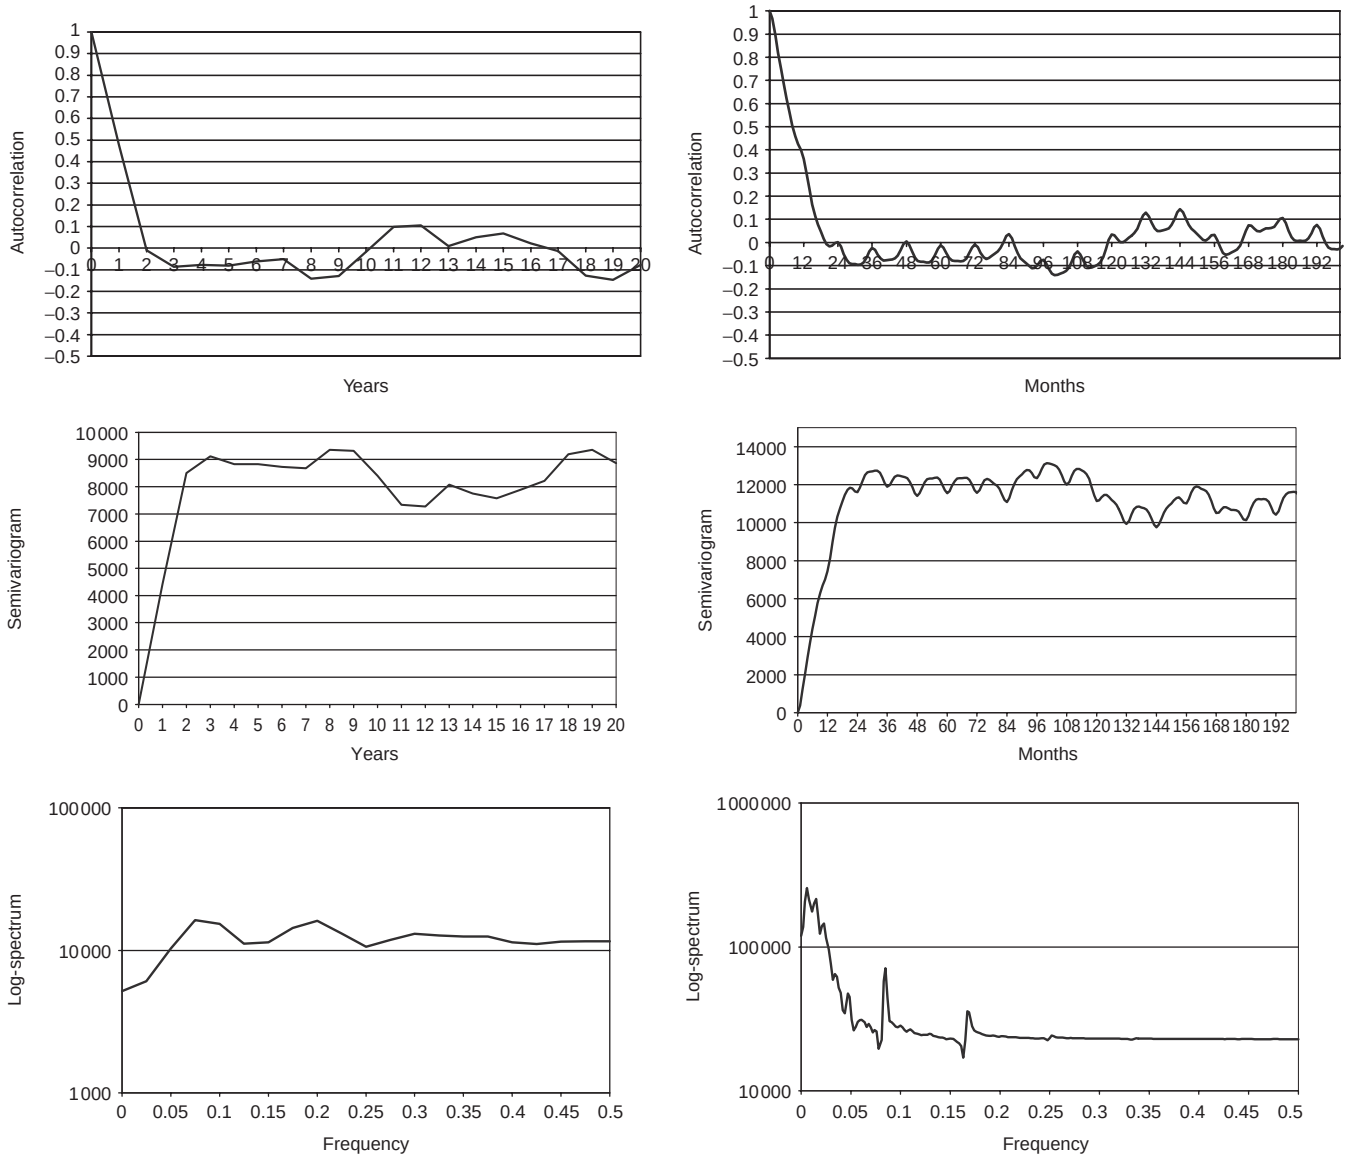

Figure 6 Autocorrelation, semivariograms, and spectral functions for annual and monthly data from the Göta River, Sweden. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

of runoff for N years. In case of a Markov model, this statistics will grow as $N^{0.5}$, where N is the number of years of observations. Hurst found that the growth of the rescaled range with the number of years rather followed a relation N^H, with $H > 0.5$, where H is named the *Hurst coefficient*. A scientific discussion followed with a focus on the ability of random models to reproduce the so-called Noah and Joseph effects of natural series, that is, the ability to reproduce extreme extremes and the tendency of long spells of dry and wet years. A natural mechanism inducing a long memory to the system was proposed as a possible explanation to this behavior and a fractional Gaussian noise (fGn) model containing such a "long memory" component was developed by Mandelbrot and Wallis (1968, 1969a,b). fGn is able to generate synthetic data with H different from 0.5. The correlation function and the spectral function respectively have the expressions:

$$\rho(\tau) = \tfrac{1}{2}[(\tau - 1)^{2H} - (\tau + 1)^{2H}] - \tau^{2H} \qquad (30)$$

$$S(f) = cf^{1-2H} \qquad (31)$$

A recent contribution to this discussion is provided by Koutsoyiannis (2002, 2003), who especially criticizes the notion of "deterministic trends" in the model equation (18) and also gives an alternative interpretation of the Hurst phenomenon: "It relies on an 'absence of memory' concept

rather than a 'long memory' concept. The hypotheses proposed is that not only does the system disremember what the value of the process was 100 years ago, but it further forgets what the process mean value at that time was". The idea is thus a *composite random process* with variations at several timescales (Vanmarcke, 1988). Koutsoyiannis (2003) shows that a Markovian underlying process with random fluctuations of the process mean at different scales yields a process very similar to fGn, the composite process being stationary. In the same sense, it can be argued that trends cannot be deterministic, but rather reflect this variability at a range of scales. Looking back at the times series in Figure 1, a trend can for sure be identified in the data for a period of time of, say, 30 years. For the next 30-year period, the trend has changed and continues to change for subsequent 30-year periods.

Are then the periodic components in hydrologic time series to be considered as deterministic ones? Indeed, the astronomic periodic fluctuations originating from the Sun and the Moon ranging from half a day to 10th of thousands of years with the annual cycle being the most important are of a deterministic character and might contribute to the variability of hydrologic records. The strength of these signals to the outer atmosphere is filtered through a complex chain of processes, resulting in an often weak oscillation entering the surface hydrologic system with an intensity that may changeover time. The annual cycle, the seasonal variation, is anyhow strong for most climates. River flow regimes, and related seasonal patterns in precipitation, show large variations around the globe and maybe useful for classification of hydrological regional features. The regime is usually defined as the average seasonal pattern over many years of observations. The assumption is that the hydrologic regime is stable and shows the same average pattern from year to year. There indeed exist flow regimes for which this is true, for example, snowmelt fed regimes in cold climates. However, many flow regimes show instability (Krasovskaia and Gottschalk, 1992; Krasovskaia, 1996, Krasovskaia *et al.*, 1999), that is, the seasonal patterns alternate among several flow regime patterns during individual years in a chaotic way. Climate change accentuates this instability and gives rise to a change over time in the frequency of different seasonal patterns observed at a site.

It is important to underline the difference in working with the statistics of a random variable and that of a random process (here time series). The autocovariance in data, independent of whether it reflects a short or a long memory process, introduces a loss in the precision in parameter estimation and also in biases. Accepting that our process is described by an AR(1) model, the standard error of the mean value is (Hansen, 1971):

$$\sigma_{\overline{X}} = \frac{\sigma_X}{\sqrt{N}} \left[1 + \frac{2\rho(1)}{N} \frac{N(1-\rho(1)) - (1-\rho(1))^N}{(1-\rho(1))^2} \right]^{1/2} \tag{32}$$

This standard error can be compared with that for the mean of a random variable equation (11). This comparison allows defining the "equivalent number of independent observations", N_e, that is, the number of independent observations that have the same precision in the estimate of the mean:

$$N_e = N \left[1 + \frac{2\rho(1)}{N} \frac{N(1-\rho(1)) - (1-\rho(1))^N}{(1-\rho(1))^2} \right]^{-1} \tag{33}$$

For an AR(1) process, the variance estimate is

$$\tilde{\sigma}_X^2 = \sigma_X^2 \left[1 - \frac{2\rho(1)}{N(N-1)} \frac{N(1-\rho(1)) - (1-\rho(1)^N)}{(1-\rho(1))^2} \right] \tag{34}$$

which is a negatively biased estimate. The fact that data are correlated does thus hamper the process from showing its full range of variability during a short observation period. For an AR(1) process, the characteristic integral scale is $\theta_X = -\Delta t/\ln[\rho(1)] \cong 0.5\Delta t(1+\rho(1))/(1-\rho(1))$, where Δt is the time step. It was noted when discussing the ergodicity concept that the process needs to be observed during an interval that is at least 10 times this scale to secure that the true variability of the process is not underestimated.

Turning back to the Göta River data with a lag one correlation coefficient of 0.476, this means that the 131 years of observations is replaced by 47 years of equivalent independent data. The estimated timescale is $\theta_X = 1.35$ years and the variance is underestimated by about one per cent.

Koutsoyiannis (2003) gives the corresponding standard error estimate of the mean for a "long memory" process:

$$\sigma_{\bar{X}} = \frac{\sigma_X}{N^{1-H}} \tag{35}$$

The corresponding "equivalent number of independent years" would then be

$$N_e = N^{2-2H} \tag{36}$$

A corresponding expression for a "long memory" process for an unbiased estimate of the variance is (Beran, 1994):

$$\tilde{\tilde{\sigma}}_X^2 = \frac{N-1}{N - N^{2H-1}} \sigma_X^2 \tag{37}$$

that is, an underestimation of the real variability of the process.

Random Vector

Data sampled at several fixed sites in space over time with regular intervals: $x(\mathbf{u}_i, t_k)$ at M stations at points

$\mathbf{u}_i$, $i = 1, \ldots, M$ at N points of time, t_k, $k = 1, \ldots, N$ might be considered as a realization of a random vector. This is a common situation in meteorology and hydrology. It is possible to determine the first- and second-order moments at each site and between sites from this data set. A special case is when only one observation at each site is available, common in hydrogeology. It is then not possible to estimate individual moments for a single site. The characterization of variability between sites is done in terms of a semivariogram. The general situation is treated first.

Let the M random variables $X_1, X_2, \ldots, X_M$ denote the elements of the random vector **X.** The mixed second order moment – the covariance B_{ij} –between two elements of X_i and X_j is defined as the expected value of the product of the deviations from respective mean values:

$$\begin{aligned} \mathrm{Cov}[X_i, X_j] = B_{ij} &= E[(X_i - m_i)(X_j - m_j)] \\ &= E[X_i X_j] - m_i m_j \end{aligned} \tag{38}$$

If we divide B_{ij} by $\sigma_i \sigma_j$, the dimensionless correlation coefficient between X_i and X_j is obtained as follows:

$$\rho_{ij} = \rho_{X_i X_j} = \frac{\mathrm{Cov}[X_i, X_j]}{\sigma_i \sigma_j} = \frac{B_{ij}}{\sigma_i \sigma_j} \tag{39}$$

It follows from the definition that $B_{ij} = B_{ji}$, $\rho_{ij} = \rho_{ji}$ and that $|\rho_{ij}| \leq 1$ (and consequently that $B_{ij} \leq \sigma_i \sigma_j$). Independence of two random variables means that there is no correlation, while the opposite is not valid. The correlation coefficient is a measure of the degree of linear dependence. The covariance of M random variables $X_1, X_2, \ldots, X_M$ (which are elements of the vector **X**) can be arranged in a symmetrical M by M covariance matrix $\mathbf{B} = \mathbf{B}_X$:

$$\mathbf{B} = \begin{bmatrix} B_{11} & B_{12} & \ldots & B_{1M} \\ B_{21} & B_{22} & \ldots & B_{2M} \\ \vdots & \vdots & \vdots & \vdots \\ B_{M1} & B_{M2} & \ldots & B_{MM} \end{bmatrix} \tag{40}$$

The Spatial Correlation Function

In the applied situation, first- and second-order sample moments are determined from the observations $x(\mathbf{u}_i, t_k)$ in M stations at points $\mathbf{u}_i$, $i = 1, \ldots, M$ at k points of time, t_k, $k = 1, \ldots, N$. As a first step, the time means can be calculated for each station as

$$\overline{x_i} = \frac{1}{N} \sum_{k=1}^{N} x(u_i, t_k), \quad i = 1, \ldots, M \tag{41}$$

The variance can be obtained as

$$\hat{B}_{ii} = s_i^2 = \frac{1}{N} \sum_{k=1}^{N} x(u_i, t_k)^2 - \overline{x}_i^2, \qquad i = 1, \ldots, M \tag{42}$$

pairwise covariances as

$$\hat{B}_{ij} = \frac{1}{N} \sum_{k=1}^{N} x(u_i, t_k) x(u_j, t_k) - \overline{x}_i \overline{x}_j; \qquad i, j = 1, \ldots, M \tag{43}$$

and pairwise correlation coefficients as

$$r_{ij} = \frac{\hat{B}_{ij}}{(s_i s_j)}; \qquad i, j = 1, \ldots, M \tag{44}$$

The only condition for these calculations is that observations are stationary in time.

A second step would be to investigate the relationship between moments for two points in dependence on the distance between them, direction, and also special physiographic characteristics at these points. Figure 7 shows diagrams illustrating pairwise correlation coefficients r_{ij} in dependence on the distance h_{ij} between the observation points for precipitation events in the Oslo region. The data sample has been divided in dependence on the precipitation type into two parts – frontal and convective, respectively.

A third step in the analysis is a check of the validity of the assumptions. Performing such a check, it is important to bear in mind that moments estimated empirically might have statistical errors. A large scatter in the correlation coefficients' values can be noted in Figure 7, but, in general, these values lie within the boundaries of a confidence interval for a theoretical correlation function. The premises of homogeneity and isotropy are hardly always satisfied. It is common that the correlation structure demonstrates homogeneity, while the covariances do not. An appropriate model in this case will be

$$B_{ij} = \sigma_i \sigma_j \rho(h_{ij}) \tag{45}$$

We can cope with the condition of anisotropy by a simple linear transformation of the coordinate scale, assuming an elliptical form of the direction dependence. The problem of nonhomogeneity in the mean and variance can be handled by means of a respective normalization and standardization of the initial data. This is actually not a complete solution as it is necessary to find an approach for interpolation of the mean and, alternately, mean and variance. These statistical parameters, however, can be expected to have a more even and uniform spatial distribution than the initial observations and their map representation does not absolutely require application of stochastic interpolation methods.

The model equation (45) assumes that it is possible to find an analytical expression $\rho(h_{ij})$ that can be fitted to the ensemble of points in the diagrams in Figure 7. A choice of this correlation function is not totally free, however. The following conditions must be satisfied (Christakos, 1984):

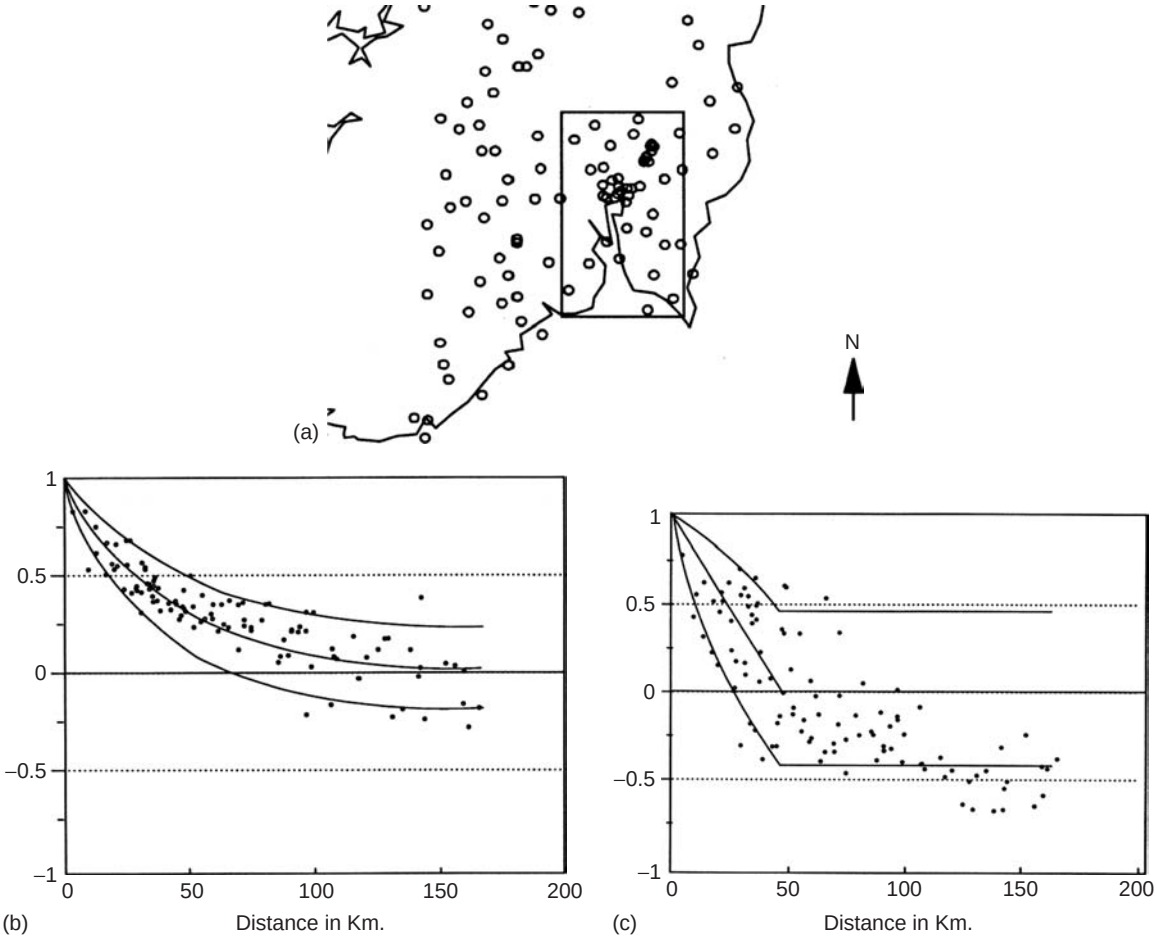

Figure 7 Dependence of the values of pairwise correlation coefficients on the distance between observation points for precipitation events of frontal precipitation (a) and convective precipitation (b). Data from the Oslo region, marked by the rectangle on the map, have been used. The circles on the map show the location of the observation points. (from Skaugen T, Personal communication 1993)

1. The standardized covariance $\rho(h)$ must be a real, even, and continuous function (possibly, except for $h = 0$) for which it is valid for each h that

$$\rho(-h) = \rho(h) \tag{46}$$

   Thus, only functions of positive h can be considered.
2. The standardized covariance $\rho(h)$ always has an upper boundary

$$|\rho(h)| \leq \rho(0) = 1 \tag{47}$$

3. The decay for $h \to \infty$ is determined by the following expression:

$$\lim_{h\to\infty} \frac{\rho(h)}{|h|^{(1-D/2)}} = 0 \tag{48}$$

   where D is the dimension of the vector $\mathbf{u}$ (thus, here $D = 2$).
4. Variances of linear combinations of variables $X(\mathbf{u}_i)$, $i = 1, \ldots, M$, should be positive, which is guaranteed if the standardized covariance function is positively definite, that is,

$$\sum_{j=1}^{M}\sum_{k=1}^{M} \lambda_j \lambda_k \rho(h_{jk}) > 0 \tag{49}$$

   for all M and real coefficients $\lambda_1, \ldots, \lambda_M$ (different from zero).

Matérn (1960) presents different methods to derive "appropriate" isotropic correlation functions. Below follow some frequently used expressions for correlation functions:

$$\rho(h) = \exp(-\alpha^2 h^2) \qquad \text{"Gaussian"} \tag{50}$$

$$\rho(h) = \left(\frac{1+h^2}{\alpha^2}\right)^{-n}, \quad n > 0 \tag{51}$$

$$\rho(h) = \frac{1}{2^{n-1}\Gamma(n)}(\alpha h)^n K_n(\alpha h), \alpha > 0, n > 0 \quad (52)$$

where α and n are parameters and K_n is the modified Bessel function of the second type. The latter expression describes the so-called Matérn class of correlation functions for an isotropic random process (Handcock and Stein, 1993). $\alpha > 0$ is a scale controlling the range of correlation. The smoothness parameter $n > 0$ (which, for the general case, is a real number) directly controls the smoothness of the random field. The following cases are of a special interest:

$$n = \frac{1}{2};\ \rho(h) = \exp(-\alpha h) \quad (53)$$

that is, the exponential function which in one dimension represents a fist-order autoregressive process (Figure 8a);

$$n = 1;\ \rho(h) = \alpha\ hK_1(\alpha\ h) \quad (54)$$

which corresponds to equation (53) in two dimensions (Figure 8b);

$$n = 1\frac{1}{2};\ \rho(h) = (1 + \beta h)\exp(-\alpha h) \quad (55)$$

the linear exponential function which corresponds to a second-order autoregressive process in one dimension (Figure 8c).

As $n \to \infty$, the expression equation (52) approaches the Gaussian function equation (50). This model forms the upper limit of smoothness in the class and will rarely represent natural phenomena because realizations from it are infinitely differentiable. Parameters α and n, in principle, can be determined by means of least square methods for an ensemble of pairwise correlations. In practice, a manual "try and error" fitting is applied, relying totally on visual criteria. Data are usually too sparse to allow identifying the true structure of the studied spatial process. The importance of the choice of theoretical covariance model is revealed only when using the identified covariance structure for simulation of spatial fields. Figure 9 shows the results of simulations with equal spatial integral scales of the model, but with the two extremes of smoothness, exponential, and Gaussian, respectively. The difference is striking and underlines the importance of the choice of theoretical correlation to be used for simulations.

The Semivariogram

In the situation when only one observation $x(\mathbf{u}_i)$ is at hand at each site in space $\mathbf{u}_i$; $i = 1, \ldots, M$, site-specific mean values and standard deviations remain unknown. This is a frequent case in (hydro)geology. The semivariogram

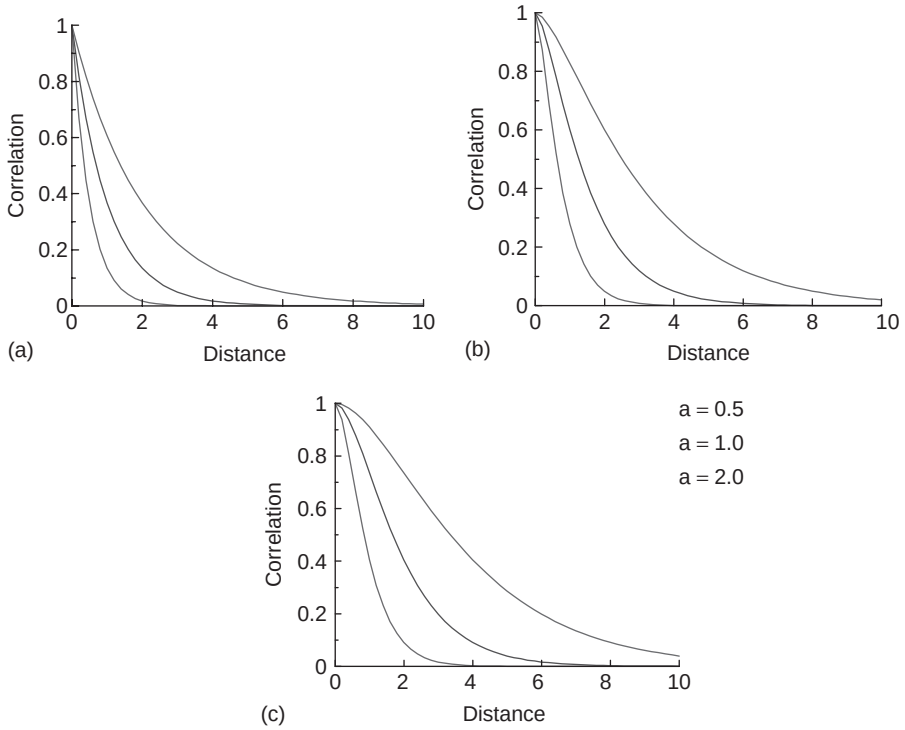

Figure 8 Examples of theoretical correlation functions: exponential function (equation 53) (a); modified Bessel function (equation 54) (b); linear exponential function (equation 55) (c). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

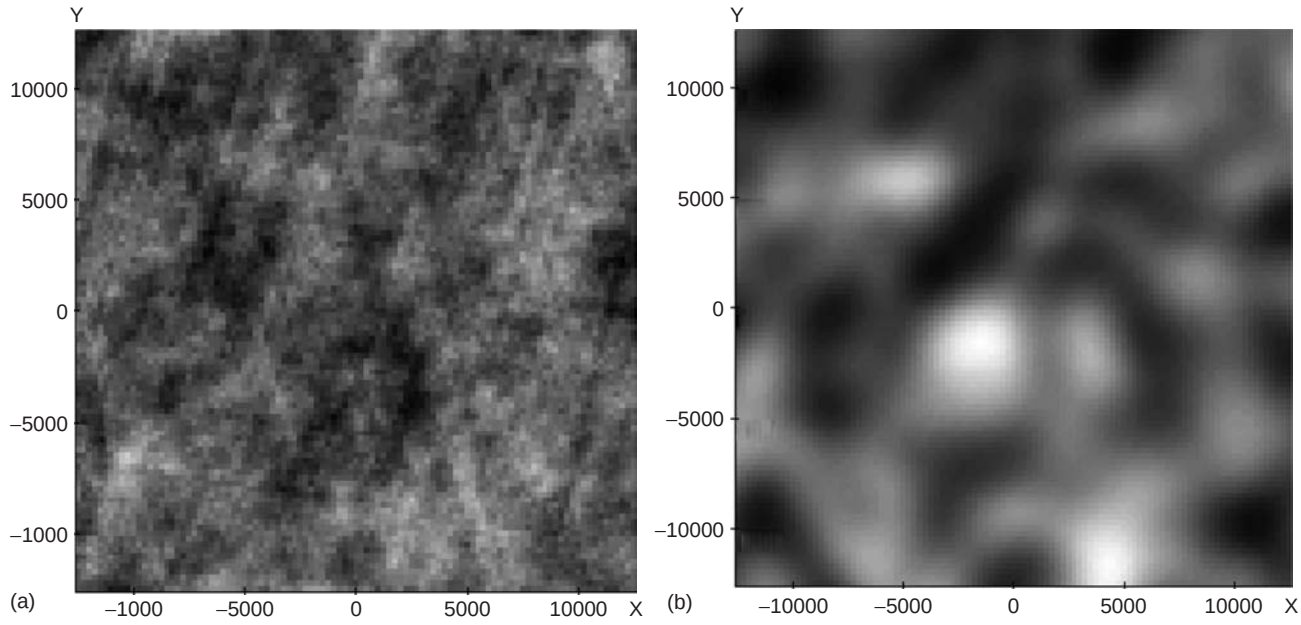

Figure 9 Simulated data in space with the turning band method (a) with an exponential correlogram model and (b) with a Gaussian correlogram model

is the appropriate alternative to the covariance (which assumes these moments to be known) to describe spatial dependency, that is,

$$\gamma(\mathbf{h}) = \frac{1}{2}E[(X(\mathbf{u}_i) - X(\mathbf{u}_i + \mathbf{h}))^2] \tag{56}$$

The sample semivariogram is estimated form empirical data as

$$\hat{\gamma}(\mathbf{h}) = \frac{1}{2N(\mathbf{h})} \sum_{(i,j)\in R(\mathbf{h})}^{N} [x(\mathbf{u}_i) - x(\mathbf{u}_j)]^2 \tag{57}$$

where $R(\mathbf{h}) = \{(i, j) : |\mathbf{h}\text{-}\varepsilon| \leq |\mathbf{u}_i\text{-}\mathbf{u}_j| \leq |\mathbf{h} + \varepsilon|\}$ and $N(\mathbf{h})$ is the number of elements in distance class $R(\mathbf{h})$. A diagram that shows $\hat{\gamma}(\mathbf{h})$ and a corresponding value of $\mathbf{h}$ is in a general case a function of vector $\mathbf{h}$, which can depend on both magnitude and direction of $\mathbf{h}$. In the latter case, when semivariograms are different for different directions, the phenomenon studied demonstrates anisotropy. An anisotropic semivariogram has to be transformed into an isotropic one in order to be used (Journel and Huijbregts, 1978). In the following, isotropy will be assumed and, thus, distance can be handled as a scalar h.

It can be expected that the difference $[X(i) - X(i + h)]$ increases with the distance between observations, h. Observations, situated in the vicinity of each other, can be expected to be more alike than those far away. However, in practice, $\gamma(h)$ often approaches some positive value C_0, called the *nugget-effect*, when h approaches zero. This value reveals a discontinuity in the semivariogram in the vicinity of the origin of coordinates at the distance that is shorter than the shortest distance between observation points. This discontinuity is caused by variability in a scale smaller than the shortest distance and also by observation errors.

The procedure of estimation of a theoretical model to an experimental variogram depends on discrete empirical values at specified distances. It can involve a certain degree of subjectivity. Procedures for automatic estimation are least square estimation (LSE), maximum likelihood (ML), and Bayesian estimators (Smith, 2001). Such automatic methods are becoming more frequent in hydrology but, still, subjective trial-and-error fitting dominates. An experimental variogram is very sensitive to errors and uncertainties in data (Gottschalk *et al.*, 1995).

Similar to the premises that have been formulated for a theoretical correlation function, the following conditions should be satisfied for a theoretical semivariogram (Christakos, 1984):

1. A semivariogram $\gamma(h)$ should be a real, even, and continuous function (possibly with the exception of $h = 0$) for which the following condition is valid for any h:
$$\gamma(-h) = \gamma(h) \tag{58}$$
2. The value of this function should follow the following dependency when h approaches infinity:
$$\lim \frac{\gamma(h)}{|h|^2} = 0|h| \longrightarrow \infty \tag{59}$$
3. Variance of linear combinations of variables $X(\mathbf{u}_i)$, $i = 1, \ldots, M$, must be positive, which is satisfied when

– $\gamma(h)$ is conditionally positively definite, that is,

$$\sum_{j=1}^{M}\sum_{k=1}^{M}\lambda_j\lambda_k\gamma(h) > 0 \text{ when } \sum_{j=1}^{M}\lambda_i = 0 \text{ for all } M \tag{60}$$

In this case, it can be noted that there is no demand that $\gamma(h)$ should have some upper boundary as in the case of the correlation (covariance) function, which might be seen as an advantage of using the semivariogram.

Depending on the behavior of the semivariogram for large values of h, theoretical models can be subdivided into two categories: models with a so-called "sill" and those without it. Presence of a sill means that h increases from zero to a specified value, sill, and is constant thereafter (Figure 10). The value of $\gamma(h)$ at this distance h, say, a, is approximately equal to the observation's variance. a is called *range*. The range a is an important characteristic as this distance indicates that observations are correlated within it, while they are independent at larger distances. If the range a is smaller than the shortest distance between observations, a pure nugget-effect is observed, that is, data are independent. The phenomenon studied demonstrates in this case a completely random pattern with respect to the distances between observation points available.

Below, five often used theoretical semivariograms are presented: (i) linear; (ii) spherical; (iii) Gaussian; (iv) exponential; and (v) fractal. The nugget-effect is denoted by C_0, sill is denoted by $C_0 + C_1$ and range by a:

1. Linear (Figure 11a)

$$\gamma(h) = C_0 + B * h0 \le h < a$$
$$\gamma(h) = C_0 + C_1 \; h \ge a \tag{61}$$

where B is the slope for $0 \le h \le a$.

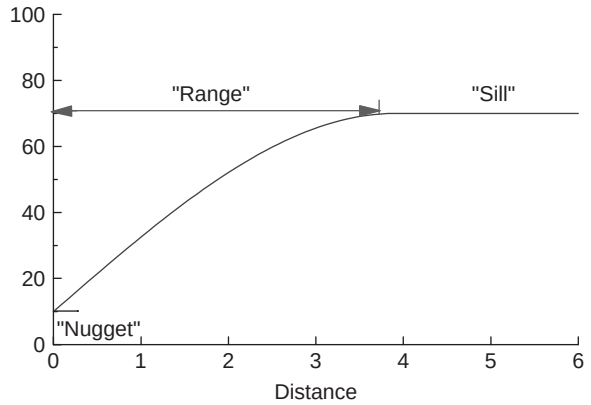

Figure 10 A semivariogram and its parameters. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

2. Spherical (Figure 11b)

$$\gamma(h) = C_0 + C_1\left(\frac{3}{2}\frac{h}{a}\right) - \frac{1}{2}\left(\frac{h}{a}\right)^3 \; 0 \le h \le a$$
$$\gamma(h) = C_0 + C_1 h \ge a \tag{62}$$

3. Gaussian (Figure 11c)

$$\gamma(h) = C_0 + C_1\left[1 - \exp\left(\frac{-h^2}{a_0^2}\right)\right] \tag{63}$$

The parameter a_0 is related to the range as $a_0 = 1/(\sqrt{3}a)$, where a is estimated visually as a distance at which the experimental semivariogram becomes stable.

4. Exponential (Figure 11d):

$$\gamma(h) = C_0 + C_1\left[1 - \exp\left(\frac{-h}{a_0}\right)\right] \tag{64}$$

Exponential semivariogram converges asymptotically towards a sill.

5. Fractal (Figure 11e):
Finally, there are models without a sill that describe the phenomenon with, in principle, infinite variance and therefore these models can be associated with phenomena variations at all scales, a fractal process. A theoretical semivariogram model has the following form:

$$\gamma(h) = C_0 + A * h^b; \quad 0 < b < 2 \tag{65}$$

The parameter b must be strictly greater than zero and strictly smaller than 2. It can be shown that it is related to Hurst H, which has been used before for characterization of fractal phenomena, as $b = 2H$.

The existence of an upper boundary, sill, means that the variance is limited. Therefore, the relationship $\gamma(h) = B(0) - B(h)$, where $B(0)$ corresponds to the sill, C_0, is also valid. Furthermore, if the covariance is standardized as $\rho(h) = B(h)/B(0) = 1 - \gamma(h)/B(0)$, the theoretical expressions for spatial correlation function $\rho(h)$ (equations 50–55) can be directly related to those for $\gamma(h)$ above. It can be noted that the Gaussian model equation (63) corresponds to equation (50) and the exponential model (equation 64) to equation (53). No discontinuity for $h = 0$ (nugget) has been included in the correlation functions, however. The choice of models is, thus, somewhat different in meteorology/hydrology and hydrogeology. It is, of course, possible to choose any of the semivariogram models referred to earlier and/or correlation functions with or without a nugget. The only exception is the fractal model equation (65), which does not have a bounded variance.

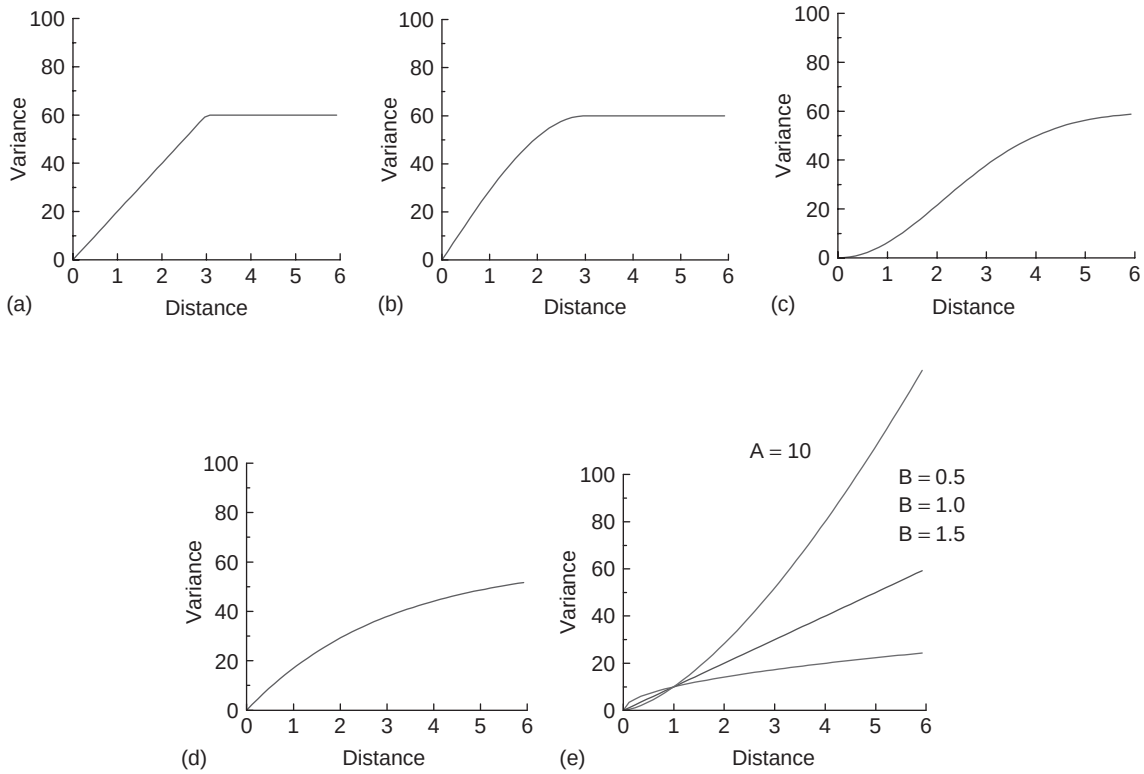

Figure 11 Examples of theoretical semivariograms: (a) linear, (b) spherical, (c) Gaussian, (d) exponential, (e) fractal. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

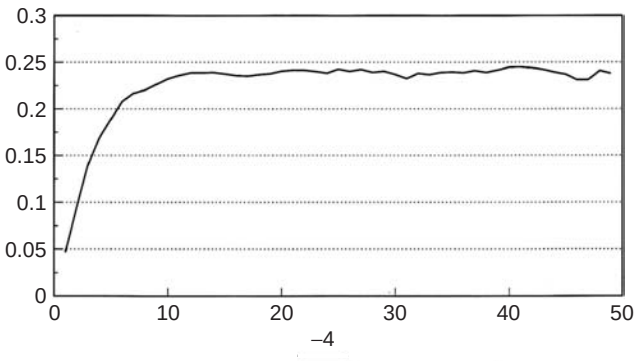

Figure 12 Estimated semivariogram of the ''sand class'' of GPR data (Figure 2) for at tilt of 4 degrees of the geological layers

Figure 12 shows the estimated empirical semivariogram of the "sand class" of GPR data illustrated in Figure 2. The amount of data is for this case extensive (1 00 000 data points) and they are observed in a regular network. That is why the resulting empirical semivariogram is so regular. We note that in case of a geological structure soil classes are described by set functions (present–not present) and need to be studied separately (e.g. Langsholt *et al.*, 1998).

A more common situation is illustrated in Figure 13 with groundwater levels in Gardermoen aquifer northeast of Oslo, Norway. Groundwater levels were recorded in 185 observation points in May 1993. The observations are relatively few, irregular, and clustered, and this has a significant influence on the resulting estimated empirical semivariograms (Figure 14).

The estimated global semivariogram from these data is presented in Figure 14a. Figure 14b shows the four directional semivariograms (note the difference in scale for the variogram between the two figures). Irregular and limited amount of data results in irregular empirical semivariograms. It is an evidence of the uncertainty in specifying spatial dependence in the same manner as the scatter of estimates of spatial correlation in Figure 7.

Spatial-temporal Random Processes

The most general case is a random process in time as well as in space. The observations are thus not realizations of a random vector as in the previous case, but rather a set of time series for each site of observation. In the general case, the joint time-space dynamics of the process under study needs to be considered in terms of two-dimensional time-space covariance functions. Common examples are the development of precipitation over an area at a timescale

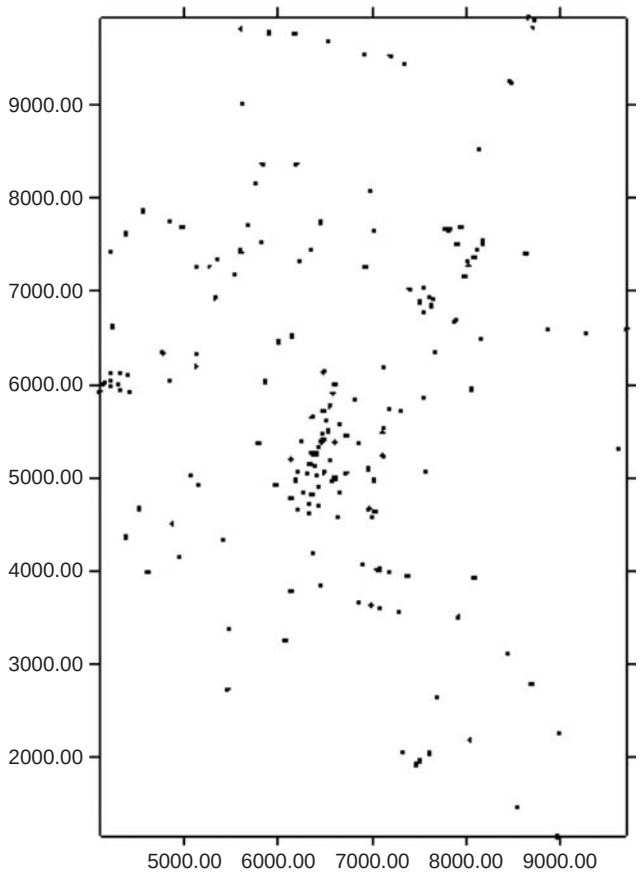

Figure 13 Location of 185 observation points of groundwater levels in the Gardermoen area in May 1993 (Reproduced from Engen, 1995, by permission of University of Oslo)

of minutes or hours and runoff at an hourly timescale for a small catchment. At larger timescales say a week, a month, or a year in most hydrologic situations there exists no dynamic link between the processes in space and time and they can be treated separately by a covariance structure in space and another in time. The methods that are developed below in Section "Karuhnen–Loève expansion" of this article are well suited to handle this latter situation. For the general case, a dynamic spatial-temporal model needs to be formulated. Models for precipitation may serve as examples (e.g. Northrop *et al.*, 1999). For simple linear hydrologic systems expressed in terms of an ordinary or partial differential equation, it is possible to directly derive a theoretical covariance function from these equations (Gottschalk, 1977, 1978). Here, only some simple examples of time-space correlation functions are treated.

For the general formulation of a time-space process, Vanmarcke (1988) distinguishes between three important special types of two-dimensional covariance functions, namely,

- the covariance structure is separable, that is, $\sigma^2\rho(h,\tau) = \sigma^2\rho(h)\rho(\tau)$ and an example is $\sigma^2\rho(h,\tau) = \sigma^2\exp\{-(h/k_1)^2 - (\tau/k_2)^2\}$
- the correlation structure is isotropic, that is, the covariance structure can be expressed in terms of the "radial" covariance function where $r = \sqrt{h^2+\tau^2} : \sigma^2\rho^R(r) = \sigma^2\rho(r,0) = \sigma^2\rho(0,r) = \sigma^2\rho(h,\tau)$
- the covariance structure is ellipsoidal, that is, by appropriate scaling and rotation of the coordinate axes random fields with ellipsoidal covariance structure can be reduced to isotropic random fields.

Gandin and Kagan (1976) suggest a covariance model similar to the second type for use in meteorology and climatology:

$$\mathrm{Cov}[h,\tau] = \sigma^2\rho\left(\left|\left(\frac{h}{v}\right)+\tau\right|\right) \tag{66}$$

where v is a velocity and h/v can be interpreted as a time of travel. Bass (1954) refers to a similar expression for application in turbulence theory.

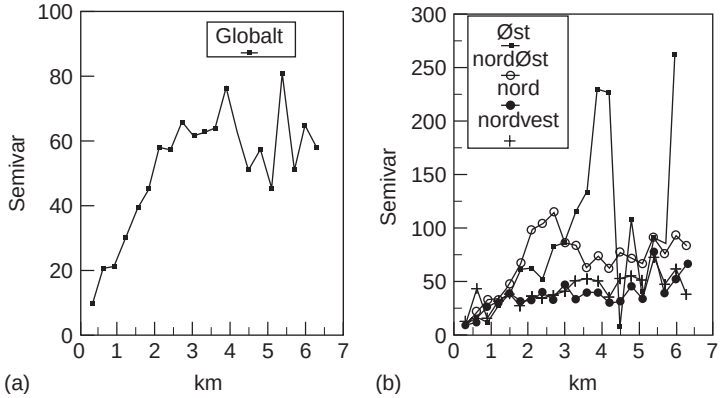

Figure 14 Estimated global semivariogram (a) and four direction variograms (b) (Reproduced from Engen, 1995 by permission of University of Oslo)

KARUHNEN–LOÈVE EXPANSION

Introduction

A technique of expanding a deterministic function $f(t)$, defined on a finite interval $[a, b]$, into a series, based on some special deterministic orthogonal function (e.g. a Fourier series), is well known from mathematics. The problem can be generalized also to two dimensions, where function $f(\mathbf{u})$ is defined for an area Ω (e.g. two-dimensional Fourier series). In a similar manner, a random function can be expanded in terms of random variables and deterministic orthogonal functions. The "proper orthogonal decomposition theorem" (Loève, 1945) states the following: "A random function $X(t)$ continuous in quadratic mean on a closed interval has on this interval an orthogonal decomposition:

$$X(t) = \sum \lambda_n \ \xi_n \ \psi_n \ (t) \tag{67}$$

with

$$E[\xi_m \xi_n] = \delta_{mn}, \tag{68}$$

$$\int \psi_m(t) \ \psi_n(t) \, \mathrm{d}t = \delta_{mn} \tag{69}$$

if, and only if, the $|\lambda_n|^2$ are the proper values (eigenvalues) and the $\psi_n(t)$ are the orthonormalized proper functions (eigenfunctions) of its covariance. Then the series converges in quadratic mean uniformly on I".

The eigenfunctions, which, as noted from the above theorem, are the eigenfunctions of the covariance, are thus determined from the following equation (a Fredholm's integral equation of the first type):

$$\int B(t, t') \ \psi_n(t') \, \mathrm{d}t' = |\lambda_n|^2 \ \psi_n(t) \tag{70}$$

Furthermore, the covariance can be written as a series expansion

$$\mathrm{Cov}[X(t) \ X(t')] = B(t, t') = \sum |\lambda_n|^2 \ \psi_n(t) \ \psi_n(t') \tag{71}$$

which for the variance reduces to the simple expression

$$\mathrm{Var}[X(t)] = B(t, t) = \sum |\lambda_n|^2 \tag{72}$$

The ξ_n s are random variables and are derived from the relation

$$\lambda_n \xi_n = \int X(t) \ \psi_n(t) \, \mathrm{d}t \tag{73}$$

The covariance between the random function $X(t)$ and ξ_n is

$$\mathrm{Cov}[X(t) \ \xi_n] = \lambda_n \ \psi_n(t) \tag{74}$$

The representation equation (67) of a random function is widely used under the name "Karhunen–Loève expansion". It appears to have been introduced independently by a number of scientists (see Lumley, 1970): Kosambi (1943), Loève (1945), Karhunen (1946), Pougachev (1953) and Obukhov (1954). In case of normally distributed data, the statistical orthogonality equation (68) is equivalent to independence and the projection equation (73) is equivalent to conditioning. Karhunen–Loève expansion is used for analyzing data in terms of a "spectral" representation for reconstruction and simulation of data. It might also be an effective tool for dimensionality reduction of large data sets to eliminate redundant information.

Harmonic (Spectral) Analysis

In physics, the most important orthogonal decomposition is the harmonic one, for, loosely speaking, it yields "amplitudes", and hence "energies", corresponding to various parts of the "spectrum" of the random function. Following Loève's strict formulation, the random function has an imaginary as well as a real part. A more physical approach avoids complex number algebra (Vanmarcke, 1988). In this latter case, the stationary random function $X(t)$ is expressed as a sum of its mean $m = c_0/2$ and $2K$ sinusoids with positive and negative frequencies $f_k = \pm k f_1$, random amplitudes c_k and phase angles θ_k, $k = 1, \ldots, K$.

$$X(t) = \frac{1}{2} c_0 + \sum_{k=-K}^{K} c_k \cos(2\pi f_k t + \theta_k) \tag{75}$$

All random amplitudes and phase angles are mutually independent random variables and the phase angles are uniformly distributed over $[0,2\pi]$. Every single term in the sum has a mean zero and the variance $\sigma_k^2 = (1/2)E[c_k^2]$., and the total variance

$$\mathrm{Var}[X(t)] = \sum \frac{1}{2} E[c_k^2] \tag{76}$$

Equations (75) and (76) have there direct parallels to equations (67) and (72) above. Generalizing to a continuous spectrum for a homogeneous process, that is, with $B(t, t') = B(|t - t'|)$, we derive the two-sided spectral function equation (16). It can be rewritten with the help of known trigonometric relationships and taking into consideration that $S(f)$ is an even function, as

$$S(f) \, \mathrm{e}^{i2\pi f t} = \int_{-\infty}^{\infty} B(|t' - t|) e^{i2\pi f t'} \, \mathrm{d}t' \tag{77}$$

This expression can be compared with equation (70). Similar results can be obtained if $[a, b]$ is finite, as long as the spectrum $S(f)$ is a rational function. Analytical

expressions for this case can be found in Davenport and Root (1958) and Fortus (1973).

Wavelet Analysis

In the Fourier series representation, the orthonormal base function $\psi_n(t)$ is generated by dilation of a single function $\psi(t) = e^{it}$, that is, $\psi_n(t) = \psi(nt)$. For any integer n with large absolute value, the wave has high frequency, and for n with small absolute value, the wave has low frequency. So every function is composed of waves with different frequencies. The sinusoidal function is defined on one period of 2π and the condition for the existence of a series expansion is that the random function is absolute integrable over this period.

$$\int_0^{2\pi} |X(t)|^2 \, \mathrm{d}t < \infty \tag{78}$$

In case of wavelets, the point of departure is also an orthogonal decomposition in accordance with equation (67) (Chui, 1992). The difference first of all lies in the fact that the random function is defined on the real line and that the random function thus satisfies the condition

$$\int_{-\infty}^{\infty} |X(t)|^2 \, \mathrm{d}t < \infty \tag{79}$$

The two function spaces are quite different since, in particular, the local average of every function must decay to zero at $\pm\infty$ and the sinusoidal (wave) functions do not satisfy this condition. Waves that can satisfy this condition should decay to zero at $\pm\infty$, and, for all practical purposes, the decay should be fast. Small waves or "wavelets" are thus appropriate. It is preferred to have one single generating function, like in Fourier series (mother wavelet or analyzing wavelet $\psi(t)$). But, if the wavelet has a very fast decay, how can it cover the whole real line? The answer is to allow shifts along the real line. The power of two is used for frequency partitioning

$$\psi(2^j t - k) \tag{80}$$

It is obtained from a single wavelet function by binary dilation (i.e. dilation by 2^j) and dyadic translation (of $k/2^j$). Normalization results in

$$\psi_{j,k}(t) = 2^{j/2}\psi(2^j t - k) \tag{81}$$

The normalizing equation corresponding to equation (69) has the form

$$\int_{-\infty}^{\infty} \psi_{j,k}(t)\psi_{l,m}(t) \, \mathrm{d}t = \delta_{jl} \, \delta_{km} \tag{82}$$

The series expansion is written as

$$X(t) = \sum_{j=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} \beta_{j,k}\psi_{j,k}(t) \tag{83}$$

The coefficients in the series expansion are determined from

$$\beta_{j,k} = \int X(t) \; \psi_{j,k}(t) \, \mathrm{d}t \tag{84}$$

A simple example is the Haar function

$$\psi_H(t) = \begin{cases} 1 & 0 \le t < \frac{1}{2} \\ -1 & \frac{1}{2} \le t < 1 \\ 0 & \text{else} \end{cases} \tag{85}$$

Similar to the harmonic analysis, we can turn over to a continuous representation and define a wavelet transform as (Chui, 1992):

$$W(\tau, s) = \int_{-\infty}^{\infty} x(t) \frac{1}{\sqrt{|s|}} \psi * \left(\frac{t - \tau}{s} \right) \mathrm{d}t \tag{86}$$

where $\psi^*(t)$ is the complex conjugate of ψ (t). The inverse transform of equation (86) for reconstruction of $x(t)$ is written down as

$$X(t) = \frac{1}{C_\psi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} W(\tau, s) \frac{1}{s^2} \psi \left(\frac{t - \tau}{s} \right) \mathrm{d}\tau \, \mathrm{d}t \tag{87}$$

where C_ψ is a constant of admissibility, which depends on the wavelet used and needs to satisfy the condition:

$$C_\psi = \int_{-\infty}^{\infty} \frac{|\hat{\psi}(\omega)|^2}{|\omega|} \mathrm{d}\omega < \infty \tag{88}$$

($\hat{\psi}(\omega)$ is the Fourier transform of ψ (t)).

Basic works introducing wavelets are those by Grossman and Morlet (1984) and Meyer (1988). Wavelet decomposition has found many applications in, for instance, image processing and fluid dynamics and turbulence. Wavelets also provide a convenient tool for studying scaling characteristics of a random process (Mallat, 1989; Wornell, 1990; Kumar and Foufoula-Georgiou, 1993). A simple example from Feng (2002) illustrates the application to hydrologic data (Figure 15). In this case, a quadratic spline function is used as mother wavelet to be able to reconstruct and simulate observed periodic hydrological time series.

Principal Component Analysis (pca)

The basic matrix equation for the principal component analysis of a random function is expressed as

$$\mathbf{B}_X \Psi = \Psi \Lambda \tag{89}$$

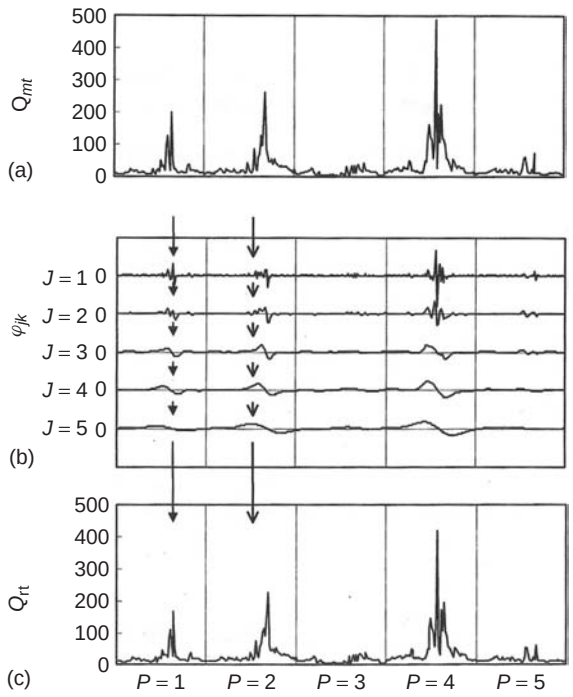

Figure 15 Illustration of traditional wavelet decomposition and reconstruction: (a) shows measured time series with five main periods; (b) decomposed wavelet series $\psi_n(t)$; and (c) reconstructed series (from Feng, 2002)

where in the general case $\mathbf{B}_X$ is a covariance matrix, Ψ a coefficient matrix of eigenvectors, and Λ a diagonal matrix of eigenvalues. Each M by M symmetrical positively definite covariance matrix $\mathbf{B}_X$ has a set of M positive eigenvalues. Furthermore, there exists a linear transformation $\mathbf{Z} = \Psi^{\mathbf{T}}\mathbf{X}$ of the original observation matrix $\mathbf{X}$, which has a diagonal covariance matrix $\mathbf{B}_Z$. $\Psi^{\mathbf{T}}$ is an M by M coefficient matrix representing the eigenvectors of $\mathbf{B}_X$. The variables $\mathbf{Z}$ are named *Principal Components*. The observation matrix $\mathbf{X}$ can now be expressed as a linear combination of the principal components:

$$\mathbf{X} = \Psi\ \mathbf{Z} \tag{90}$$

The coefficient matrix Ψ is orthogonal, that is, $\Psi\Psi^{\mathrm{T}} = \mathbf{I}$. The principal components $\mathbf{Z}$ have the following covariance matrix:

$$\mathbf{B}_Z = \frac{1}{n}\mathbf{Z}\ \mathbf{Z}^{\mathrm{T}} = \Psi^{T}\ \mathbf{B}_X\Psi = \Lambda \tag{91}$$

where $\mathbf{B}_X$ is, as before, the covariance matrix of $\mathbf{X}, \mathbf{B}_X = (1/n)\mathbf{X}\mathbf{X}^{\mathrm{T}}$ and Λ is the diagonal matrix of eigenvalues $\lambda^2{}_j$, $j = 1, \ldots, M$. If equation (90) is written as a sum:

$$x_{jt} = \sum_{k=1}^{M} \psi_{jk} z_{kt} = \sum_{k=1}^{M} \psi_{jk}\lambda_k z'_{kt};$$
$$j = 1, \ldots, M; t = 1, \ldots, n \tag{92}$$

where z'_k is the normalized values of z_k with respect to its variance λ_k. Parallels to equation (67) can be seen clearly by a simple exchange of symbols. From equation (91), we have

$$\frac{1}{n}\sum_{t=1}^{n} z_{jt}z_{kt} = \lambda_k^2\delta_{jk};\ \frac{1}{n}\sum_{t=1}^{n} z'_{jt}z'_{kt} = \delta_{jk}j, k = 1, \ldots, M \tag{93}$$

and using the condition of orthogonality of the coefficient matrix Ψ we get

$$\frac{1}{M}\sum_{l=1}^{M} \psi_{jl}\psi_{lk} = \delta_{jk}; \quad j, k = 1, \ldots, M \tag{94}$$

Finally, multiplying equation (91) by Ψ from the left yields

$$\sum_{l=1}^{M} B_{jk}\psi_{lk} = \lambda_j\psi_{jk},\ j = 1, \ldots, M \tag{95}$$

Also, here there are parallels to equations (68), (69), and (70), respectively, if a symbol change is done.

The method of pca representation is usually carried out in terms of the solution of the matrix equation (89) of very general applicability. Principal component analysis (factor analysis) has its root in psychometrics. The classical work is the one by Hotelling (1933). The generality of the method might be a strength for many applications, but with caution. Hydrological time series data are as a rule collected at regular time intervals. For this case, we can apply the matrix equation as a simple approximation of the more general equation (70). In the case of application to spatial data in meteorology, as pointed out by Buell (1971), there are very strong geometrical elements (in the general case, the covariance matrix represents covariances between irregularly spaced observation points) that can be advantageous, but which are missing in the matrix formulation. Hydrological applications have, as a rule, the same strong geometrical elements and $\mathbf{B}_X$ is usually the covariance matrix (equation 40) with elements $B_{ij} = \mathrm{E}[(x_i - m_i)(x_j - m_j)]$, $i, j = 1, \ldots, M$, covariances between values x_i measured at point $\mathbf{u}_i$ and x_j measured at point $\mathbf{u}_j$.

It is found appropriate to differ between situations when geometrical aspects of the problem are strong and when they are not. In the latter case, the pca matrix formulation equation (89) is appropriate. In the other case, the point of departure is equation (70) and, for discrete data, a numerical solution of this equation should be developed. The name for this situation that will be used here is empirical orthogonal functions (eof).

Empirical Orthogonal Functions (eof)

The notion of *empirical orthogonal functions* was first introduced in the classical work by Lorenz (1956). Other

earlier applications of this technique in meteorology are those by Obukhov (1960) and Holmström (1963) (without using the name "eof"). Already Lorenz mentions the parallel in the problem with that of factor analysis (principal component analysis) used by psychologists quoting the classical work by Hotelling (1933). The point of departure for the development of this technique for Lorenz was dimensionality reduction, that is, getting rid of the large amount of redundant information contained in meteorological data. In psychology, on the other hand, the central point was to interpret psychological tests into observed behavior of their patients. Today both approaches are used in meteorology and climatology as well as in hydrology and a difference can be traced in the interpretation of the empirical functions – are those only mathematical constructions or can they be interpreted in some process oriented way. In the latter case, this has led forward to the use of rotations of the principal components yielding possibilities for a better interpretation of results (*see* Richman, 1986 and Jolliffe, 1990, 1993 for an overview). Long unfruitful discussions about the possible distinction between pca and eof can be found in the climatological literature. One such distinction should be related to how the normalization is performed.

The point of departure in the works by Lorenz and Holmström is a random process $X(\mathbf{u},t)$ that develops in space $\mathbf{u} = (u_1, u_2)$ over a certain domain in space Ω and time t. Equation (70) is for this case generalized to a process in space:

$$\int_{\Omega} B(\mathbf{u}, \mathbf{u}')\ \psi_n(\mathbf{u}')\, \mathrm{d}\mathbf{u}' = |\lambda_n|^2\ \psi_n(\mathbf{u}) \tag{96}$$

It is important to emphasize that this integral equation formulation is the appropriate one for problems like in meteorology and hydrology dealing with a random function X on a continuum in space. The geometrical relations involving the domain of integration and the relations between the points $\mathbf{u}_i$, $i = 1, \ldots, M$ are completely ignored in the matrix formulation. The fact that function values are obtained from measurements at discrete points (perhaps sparsely located) is a practical limitation to the numerical solution of the problem (e.g. Obled and Creutin, 1986).

$X(\mathbf{u},t)$ is expanded into double orthogonal series of the form

$$X(\mathbf{u}, t) = \sum_n z_n(t)\ \psi_n(\mathbf{u}) \tag{97}$$

where eigenfunctions $\psi_j(\mathbf{u})$ and $\psi_k(\mathbf{u})$ as before are analytically orthogonal:

$$\int_{\Omega} \psi_k(\mathbf{u}) \psi_j(\mathbf{u})\, \mathrm{d}\mathbf{u} = \delta_{kj} \tag{98}$$

that is, $\psi_k(\mathbf{u})$ can be regarded as a deterministic function. It is determined by numerical solution of equation (96). The functions $\psi_k(\mathbf{u})$ depend both on the covariance function and the area Ω.

$z_j(t)$ and $z_k(t)$, on the other hand, are statistically orthogonal or uncorrelated:

$$E[z_k(t) z_j(t)] = \delta_{kj} \lambda_k^2 \tag{99}$$

where δ_{kj} is Kronecker's delta and λ_k^2 is the eigenvalue as before.

The function $z_k(t)$ is obtained as

$$z_k(t) = \int_{\Omega} X(\mathbf{u}, t) \psi_k(\mathbf{u})\, \mathrm{d}\mathbf{u} \tag{100}$$

that is, by means of projection of the realization at time t on the k-th eigenfunction.

For a given analytical expression for the autocorrelation function, eigenfunctions corresponding to it can be found. Fortus (1975) and Braud (1990) show an analytical solution for the case when Ω is a circle. $B(\mathbf{u},\mathbf{v})$ can be written as a series expansion:

$$B(\mathbf{u}, \mathbf{v}) = \sum_n |\lambda_n|^2 \psi_n(\mathbf{u}) \psi_n(\mathbf{v}) \tag{101}$$

in correspondence with equation (71). The expansion equation (97) can be truncated till, say, N terms as

$$\hat{X}_N(\mathbf{u}, t) = \sum_{n=1}^{N} z_n(t) \psi_n(\mathbf{u}) \tag{102}$$

which minimizes the variance in the estimation error of X by $\hat{X}_N$:

$$E\left[\int_{\Omega} \left\{X(\mathbf{u}, t) - \hat{X}_N(\mathbf{u}, t)\right\}^2\right] \mathrm{d}\mathbf{u} \tag{103}$$

and which obtains the value $\sum_{n=N+1}^{\infty} \lambda_k^2$. In case of high redundancy in the data the expansion equation (102) converges rapidly, which indicates a possibility of truncating the series expansion after rather few terms. This is the idea behind the use of eof for dimensionality reduction. The functions $z_k(t)$, often called *amplitude functions*, represent time series that are not linked to any specific points of the domain Ω. On the other hand, they can be used to construct $X(\mathbf{u}_k, t)$ for a point $\mathbf{u}_k$ if the functions $\Psi_n(\mathbf{u}_k)$, $n = 1, \ldots, N$ are known at this point. Figure 16 illustrates the principle where the eof method is applied to monthly runoff data from the Rhône basin in France. Amplitude functions are shown as well the results of prediction of the runoff pattern for independent stations to the right (Sauquet *et al.*, 2000). Figure 3 in the introduction of this article shows a prediction of the monthly flow patterns for the whole river system.

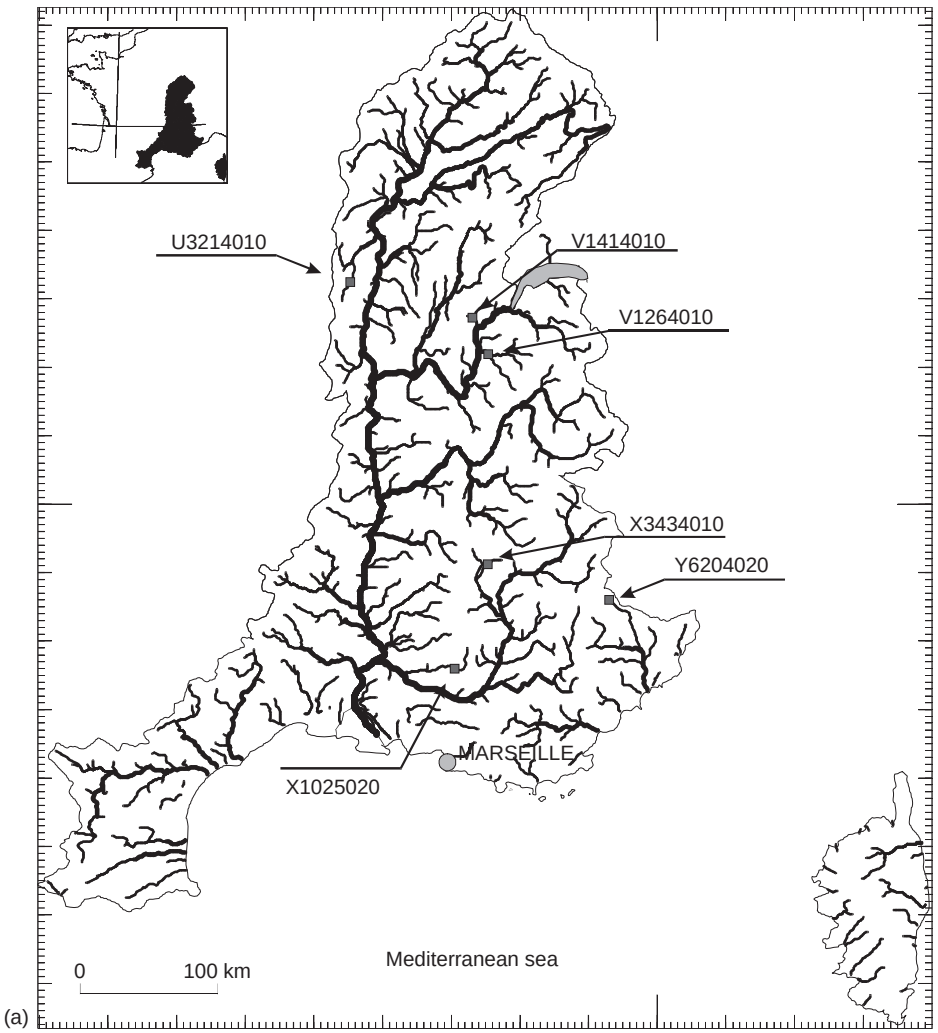

Figure 16 Example of spatial interpolation of monthly runoff patterns for the Rhone basin in France (a). The first six amplitude functions are shown in (b) and the result of prediction of the runoff pattern for independent stations in (c) (Reproduced from Sauquet *et al.,* 2000 by permission of the European Geosciences Union). CONCLUDING REMARKS

In the introductory part of this article, it was adopted to use a *partial characterization* of the random process under study in accordance with three different schemes:

1. Characterization by distribution function (one dimensional).
2. Second-moment characterization.
3. Karhunen–Loève expansion, that is, a series representation in terms of random variables and deterministic functions of a random process.

This should not be understood so that one replaces the other. On the contrary, these three schemes for partial characterization complement each other. All methods of analyzing variability developed in this article are applied in practice without consideration of the parent distribution of the data. On the other hand, all these methods have a strong theoretical base if normality can be assumed. For instance, as already noted, normally distributed data weak homogeneity equals strict homogeneity. For normally distributed data, statistical orthogonality is equivalent to independence and a projection onto a system of orthogonal axes is equivalent to conditioning. Furthermore, the assumption of normality opens up for related statistical tests. Analyzing the distribution function of the data is therefore a logical first step (after "looking at data"). If the data are far from normally distributed, it might be worthwhile to utilize a transformation to normal. The following transformations to normality

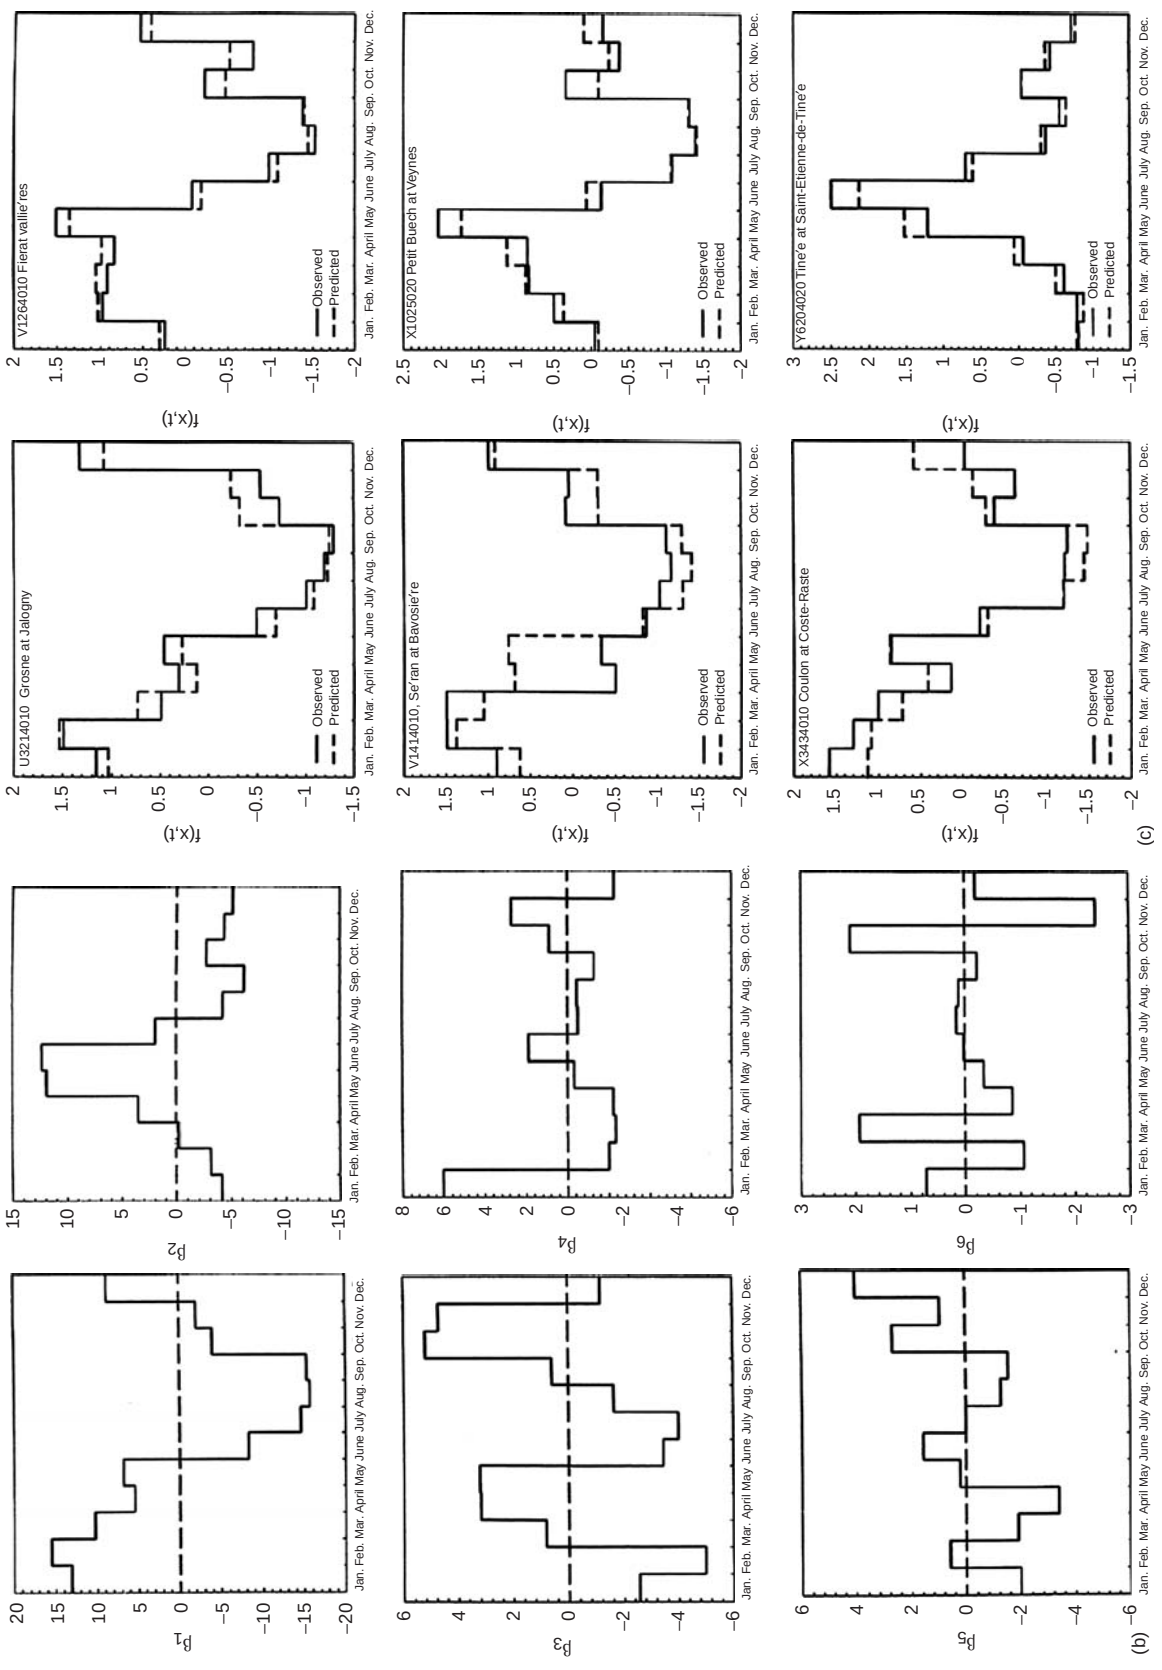

Figure 16 (*Continued*)

are often used in hydrology: (i) ln(x) in case of lognormally distributed data; (ii) The cube root $(x/\overline{x})^{1/3}$ (Wilson and Hilferty, 1931) transformation in case of gamma distributed data; and (iii) the more general power transformation $[(x+c)^h - 1]/h$, where h and c are parameters (Box and Cox, 1964).

The characterization by second moments allows establishing the structure of the data in space and time and its scale of variability. It also gives the possibility of testing basic hypothesis of homogeneity and stationarity. By means of normalization and standardization, data can be transformed into new data sets owing these properties. The characterization by series representation in its turn assumes homogeneity with respect to the variance–covariance function. It is as such a tool for analyzing spatial-temporal variability relative to the first- and second-order moments in terms of new sets of common orthogonal random functions.

The conclusions is thus that the approaches developed here form logical steps in a sequential analysis of variability: (i) looking at data, exploring data; (ii) analyzing the distribution of data; (iii) analyzing first- and second-order moments; (iv) analyzing data by means of series expansion.

8: Fractals and Similarity Approaches in Hydrology

LUCA G LANZA[1] AND JOHN GALLANT[2]

[1]Department of Environmental Engineering, University of Genoa, Genoa, Italy
[2]Butler Laboratory, Commonwealth Scientific and Industrial Research Organisation, Land and Water, Canberra, Australia

The application of fractals and similarity concepts in hydrology has given rise to a better understanding of the space-time organization of forms and processes that are relevant to the hydrologic cycle. Indeed, a variety of literature results support the conjecture that scaling holds for most hydrological variables in time and space.

This chapter concentrates on fields where fractals and similarity approaches have proved helpful in fostering advances in specific hydrological studies. In particular, precipitation and drainage network morphology are addressed. A few specific applications to the study of natural forms and patterns relevant to the hydrological sciences are presented first, while the application of scaling concepts to the study of processes themselves is later discussed.

Because of its highly irregular behavior, the rainfall process is one ideal candidate to be approached by means of self-similarity and/or (multi)fractal description models. Such models involve increasing complexity and computational burden as soon as the interest moves from the one-dimensional time series to the three-dimensional case, where the full space-time pattern of rainfall is considered. Examples of recent interesting results are presented with reference to the one-, two-, and three-dimensional approaches to rainfall modeling based on similarity concepts.

INTRODUCTION

As a geophysical science, hydrology investigates both natural forms and processes. Forms are the underlying physical matrix where hydrological processes actually take place. Forms may be shaped by the host processes themselves, for example, according to some energy expenditure criterion. Therefore, both forms and processes evolve in time and space, although the (space and/or time) scales of significant variations of forms are usually orders of magnitude larger than those of the dynamics of most hydrological processes (*see* **Chapter 3, Hydrologic Concepts of Variability and Scale, Volume 1**).

The wide range of self-similarity approaches, presently exploited in hydrology, found on the pioneering intuition by Mandelbrot (1983) that the description of natural forms and processes can hardly be bounded within the limits of the regular Euclidean geometry, since, for example, "clouds are not spheres…", with analogue statements applying to most of the objectives of scientific investigation in the geophysical sciences. He developed the idea of fractals, or fractal sets, in order to achieve a more suitable mathematical description – and, therefore, a deeper interpretation and understanding – of the observed forms and processes in nature.

Similarity approaches in general allow the transfer of information between scales (*see* **Chapter 11, Upscaling and Downscaling – Dynamic Models, Volume 1**) or between places, and are frequently based on similarity indices – ratios or dimensionless numbers – that characterize some aspect of the hydrological processes. Two catchments with the same set of similarity indices should have a similar hydrological response. Fractals describe the situation where the similarity indices change predictably with scale.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Indeed, the application of fractals and similarity concepts in hydrology has given rise to a better understanding of the space-time organization of many processes within the hydrologic cycle, including precipitation (*see* **Chapter 28, Clouds and Precipitation, Volume 1**), evaporation (*see* **Chapter 45, Actual Evaporation, Volume 1**), soil moisture (*see* **Chapter 72, Measuring Soil Water Content, Volume 2**), runoff production (*see* **Chapter 111, Rainfall Excess Overland Flow, Volume 3**), and groundwater flow (*see* **Chapter 145, Groundwater as an Element in the Hydrological Cycle, Volume 4**). This chapter concentrates on a few examples of cases where fractals and similarity approaches have proved helpful to foster advances in specific hydrological studies, although it is evident that analogous "scaling" approaches actually span over the whole panorama of hydrological investigations with promising results and, sometimes, very exciting perspectives. Such fields of investigation also include, for example, stream chemistry, where chloride concentration in stream flows (*see* **Chapter 91, Water Quality, Volume 3**) is shown to exhibit fractal scaling (Kirchner *et al.*, 2000), and snow hydrology (*see* **Chapter 159, Snow Cover, Volume 4**), the related scaling issues being discussed by Blöschl (1999).

The basic theoretical concepts of fractals and self-similarity are initially recalled in the following, and additional resources for deeper insights into such fundamentals are provided. Specific applications to the study of some natural forms and patterns relevant to the hydrological sciences are then presented, focusing mainly on the supporting physical matrix of most hydrological processes, that is, the drainage network in case of surface processes. The application of scaling concepts to the study of processes themselves is later discussed with reference to the rainfall process in both time and space (*see* **Chapter 28, Clouds and Precipitation, Volume 1**), this being the driving motor for the land phase of the hydrological cycle (*see* **Chapter 2, The Hydrologic Cycles and Global Circulation, Volume 1**). Finally, a few comments are provided in the conclusions about the role of fractals and similarity approaches based on the results obtained in the various fields of investigation and their effective contribution in advancing our knowledge in the hydrological sciences.

FRACTALS AND SELF-SIMILARITY CONCEPTS

The concept of similarity is used to describe any object (and its generating process) that is invariant under ordinary geometric similarity (change of scale), and the object is therefore termed *self-similar*. This implies that the whole object can be split into N parts, obtained from it by a similarity of ratio r (after some geometric transformation) so that the latter is expressed as:

$$r(N) = \frac{1}{N^{1/D}} \tag{1}$$

and the similarity dimension is:

$$D = -\frac{\log N}{\log r(N)} \tag{2}$$

This definition also applies for common objects such as a line, a square, or a cube. Self-similar objects are also called *scaling objects* in the literature.

In nature, objects are seldom self-similar in the strict sense; rather, they may show statistical self-similarity, in the sense that random variations may affect the similarity of the smaller parts with respect to the original shape. Also, these smaller parts may be skewed by uneven reduction of scales in the different directions, and are called *self-affine objects* in this case.

A stochastic process P is said to be self-similar according to the above definitions when, once averaged at two different scales, it displays the following property:

$$\{P_{\lambda T,\lambda X}(t,x)\} \overset{d}{=} \lambda^H \{P_{T,X}(t,x)\} \tag{3}$$

where the symbol $\overset{d}{=}$ indicates equality in the probability distribution, λ is a scale factor, and H is the scaling exponent, which under suitable conditions can be related to D with simple relationships (Feder, 1988). Equation (3) indicates that the probability distribution of the averaged process is independent of the scale used for integration, and, therefore, the averaged quantities $P_{T,X}(t,x)$ and $P_{\lambda T,\lambda X}(t,x)$ display the same distribution when rescaled by a factor of λ^H. As a consequence of this property, we can also state that the raw moments of any order are scale invariant, so that $E[P^q_{\lambda T,\lambda X}] = \lambda^{qH} E[P^q_{T,X}]$, with q denoting the moment order. These properties are also referred to as simple scaling in the literature.

It is important to note that scaling properties usually apply in nature over a certain range of scales commonly bounded by a lower limit (the inner scale) and an upper limit (the outer scale).

The scaling exponent H is also termed the *Hurst exponent*, since the fractal behavior is an indication of long-term persistence or large spatial correlations, which is indicated as the Hurst phenomenon in the literature (see Hurst, 1951; Mesa and Poveda, 1993 for a discussion on the estimation of the Hurst exponent).

Hurst observed that the annual flows of rivers in successive years were not statistically independent but exhibited long-term dependence, with years of high and low flow tending to cluster together rather than be randomly

interspersed. This has important implications for reservoir design, and the cause of the phenomenon continues to be the subject of much debate – is it due to long-term persistence or does it result from an overlaying of multiple sources of variation having different timescales?

Similarity approaches were initially developed as empirical relationships based on observations of, for example, drainage network properties (Horton, 1945) and annual flow in rivers (Hurst, 1951). These relationships were given a mathematical foundation by Mandelbrot (1967, 1983) who developed the idea of fractals – processes or objects with fractional dimension whose distinguishing characteristics are variability and structure at all scales and the absence of a characteristic scale.

The similarity dimension equals the fractal or Hausdorff dimension (see Mandelbrot, 1983 for definitions) only for strictly self-similar fractals. However, fractals needs not be self-similar in general, and the Hausdorff dimension is a more general definition of the fractal dimension.

In a Euclidean framework, the topological dimension D_T – in simplified terms the "intuitive" dimension that represents the number of independent coordinates required in order to identify a generic location on the object in hand – is always an integer, while the so-called "critical" Hausdorff dimension D need not be an integer. They just satisfy the inequality $D \geq D_T$.

Following Mandelbrot (1983), a fractal is, by definition, a set for which the Hausdorff dimension D strictly exceeds the topological dimension D_T, so that in such cases, $D > D_T$. Every set with a noninteger D is a fractal (e.g. the Cantor set), although fractals may have an integer D (e.g. the Brownian motion), still not greater than the Euclidean dimension but strictly greater than D_T.

The most common methods to determine the Hausdorff dimension of a physical object are the Richardson (1961) and the box counting methods. The first one is also known as the *compass method*, as it simply requires to represent in a log–log plot, for several different compass sizes, the number of compass lengths needed to cover the object in hand. In case of scale-invariant behavior, this exercise will result in a straight line with negative slope that can be represented as a power law, and the slope itself is the sought fractal dimension. This method was first applied by Richardson to handle the popular issue of measuring the length of a coastline.

In the box counting method, a grid is placed over the investigated object and the number of boxes covering at least part of the fractal object are counted. The procedure is repeated after varying the dimension of the grid, and a log–log plot of the box counts over the grid size is used to derive a power law as in the previous method. Again, the slope of the derived straight line is assumed to be the fractal dimension of the object investigated.

Only the power law probability distribution is scale invariant and is, therefore, occasionally termed the *fractal distribution*. A characteristic scale in terms of space and/or time (see e.g. Skøien *et al.*, 2003 for a discussion based on the analysis of variograms) is, on the contrary, involved in other commonly used distributions such as the Gaussian or the Exponential. Fractal or self-similar processes are sometimes described by non-Gaussian distributions, and the observed power law behavior of a given variable is often the signature of some underlying scaling characteristic of the associated physical process. In general, however, a fractal has a power law probability distribution in the limit, that is, this behavior is observed as an asymptotic limit for the tail of the distribution (see e.g. Harris *et al.*, 1996).

In the particular case when the spatial scales of length, L_i and L_j, and the temporal scales, T_i and T_j, of a physical system are governed by a power law in the form

$$\left(\frac{T_i}{T_j}\right) = \left(\frac{L_i}{L_j}\right)^z \tag{4}$$

then the system is characterized by scale invariance in the dynamic sense or dynamic scaling, and z is the dynamic scaling exponent.

Another basic aspect of interest for hydrological applications is the concept of multifractality, or multiscaling behavior. The multifractal theory (see e.g. Feder, 1988; Schertzer *et al.*, 2002) was initially developed for describing the fluctuations of the velocity field in turbulent flows and later extended to geophysical processes such as rainfall and river networks.

Multiscaling can be seen as a departure from simple scaling, for example, in case the relation between raw moments at different scales is given as $E[P^q_{\lambda T,\lambda X}] = \lambda^{\varphi(q)} E[P^q_{T,X}]$, with the scaling exponent $\varphi(q) = qH \cdot \alpha(q)$ now being a function of the moment order q. Simple scaling is here the special case when $\alpha(q) = 1$, while for dissipative systems, $\alpha(q)$ is a convex function of q.

In order to further argument on this concept, let us introduce the so-called structure function of order q, that for a given set of observed data y_i of size N is defined as:

$$S_q(\tau) = \langle |y_{i+\tau} - y_i|^q \rangle, \qquad q > 0 \tag{5}$$

with $\langle . \rangle$ denoting the ensemble average. As it is evident from the case when $q = 2$, the structure function is a generalized correlation function, although q in the general definition can be any real (positive or negative) number.

In case the structure function should obey a scaling law, that is, the process is scale invariant, it would be written in the general form:

$$S_q(\tau) \propto \tau^{\zeta(q)} \tag{6}$$

where the exponent $\zeta(q)$ indicates a multifractal behavior in case it is a nonlinear function of the moment order q. This

behavior is termed *anomalous scaling* or *multifractality*. In short, it can be said that multifractality is evidenced by a curve when plotting $\zeta(q)$ over q, while a straight line in the same graph would indicate a mono-fractal behavior. Note that the Hurst exponent is here a function of q, namely $\varphi(q) = \zeta(q)/q$, and calculation of $\varphi(q)$ allows the identification of persistence as well as the mono-fractal or multifractal nature of the process.

Among the many other methods available to investigate the scaling properties of a physical process, the power spectrum is worth mentioning here due to its wide use, for example, in the study of rainfall time series. Again, if the frequency spectrum $E(f)$ of a given signal can be expressed by a power law in the form:

$$E(f) \propto f^{-\beta} \tag{7}$$

with f the frequency and β a suitable exponent, this indicates the absence of a characteristic scale in the range where the power law holds, and is, therefore, an indication of a possible scale-invariant behavior.

NATURAL FORMS AND PATTERNS

Mandelbrot's inspiration for the development of fractal geometry was the complexity of natural forms that are poorly described by the building blocks of Euclidean geometry: straight lines, smooth curves, spheres, and so on. Mandelbrot's demonstration that complex natural forms and patterns could be described and reproduced using simple mathematical techniques inspired a wide range of applications of fractal methods in the natural sciences, including hydrology and geomorphology. Two of the inspirations for Mandelbrot's theories were from these fields: Hurst's description of long-term persistence of river-flow rates over multiannual time periods (Hurst, 1951), and Richardson's reporting of the variation of the apparent length of coastlines when measured at different scales (Richardson, 1961).

The fractal model can be applied to natural terrain in two different ways: the fractal characteristics of the terrain surface itself, and the fractal characteristics of natural drainage networks.

Fractal Terrain

Elevation appears to obey power law scaling across a broad range of scales: the variance of elevation increases with increasing distance, and the relationship obeys a power law. Mandelbrot and others demonstrated that this relationship was consistent with a fractal model and much use was made of the fractal model as an explanation of the scaling properties of topography.

The scaling exponent, and hence the fractal dimension of terrain surfaces, is usually measured using spectral analysis

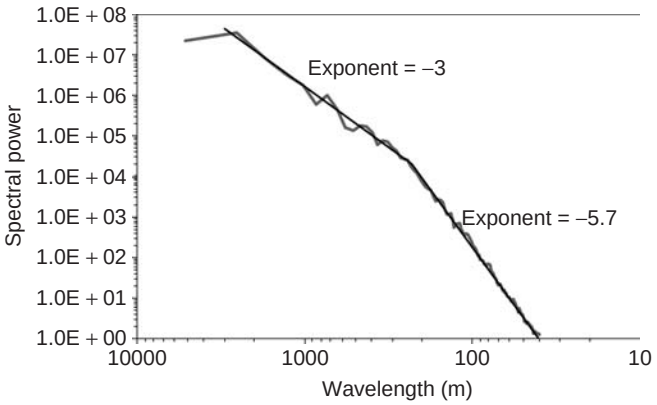

Figure 1 Power spectrum of surface topography based on 20 m resolution data showing the different scaling behaviour at coarse and fine scales (Livingstone Creek area near Wagga Wagga, NSW)

(Turcotte, 1989) or semivariogram (Mark and Aronson, 1984) techniques. One advantage of the spectral technique is its ability to identify surfaces smoother than the fractal model permits, indicated by a spectral exponent less than -3 (Gallant *et al.*, 1994). Many studies have found that the scaling exponent of the power law varies with scale, with a more rapid change of variance with distance found at distances less than about 200 m (Mark and Aronson, 1984; Gilbert, 1989; Tate, 1998). Over distances larger than about 200 m, the power law scaling conforms to a fractal model, but at the finer scales, the surface is smoother than the fractal model allows, as shown in Figure 1.

The length scale of about 200 m appears to correspond to the length of hillslopes in the landscape. The relative smoothness at scales finer than the hillslope length is probably due to diffusive processes that tend to obliterate small variations (Culling and Datko, 1987). At the broader scale where the drainage network dominates the form of the landscape, fluvial processes tend to exaggerate and perpetuate small variations.

It is worth noting that Mandelbrot's analysis of coastlines used length scales of 1 km and longer, so the relative smoothness of the landscape at finer scales was not noticed in his development of fractal models for topography.

Although land surfaces do not exactly fit the fractal model, the fractal dimension does appear to be a useful geomorphic parameter for distinguishing different landscape types, especially if used in conjunction with a measure of relief at a reference scale (Klinkenberg, 1992; Outcalt *et al.*, 1994).

The implications of a fractal model (at least over certain scales) for topography are many. The most important implication is that any finite resolution representation of the land surface fails to resolve the full variability of the real surface. This has the further implication that any estimate involving the derivatives of the surface, such as

slope or curvature, will vary with the resolution of the data. Measured slope, for example, has been demonstrated to consistently decrease with coarser resolution data (Moore *et al.*, 1993).

Drainage Networks

The self-similar properties of drainage networks were recognized from the 1940s (Horton, 1945; Strahler, 1952; Shreve, 1967) with the observation that the dendritic drainage network of a small catchment is similar to that of the larger catchment containing it. Horton established that the similarity across scales goes beyond appearances: the number of stream segments, their length, and the area drained all depend on stream order in a systematic way.

The ratios of these quantities between successive stream orders tend to remain constant over several levels of stream order and have been used to characterize the geomorphology of drainage networks. This self-similarity of drainage networks is a clear example of a natural fractal, and the fractal dimension of the drainage network can be readily derived from the Horton ratios.

The fractal dimension d of individual streams (a measure of the tendency towards meandering of a water course) and the fractal dimension D of the stream network (a measure of the tendency of river networks to fill the space when depicted as plan views) are usually of interest in hydrology, since they "can be used to investigate the scaling properties of the attributes and parameters describing drainage basin form and process" (La Barbera and Rosso, 1989). The following expressions were derived by La Barbera and Rosso (1989) and Rosso *et al.* (1991) on the basis of a quantitative analysis of river networks by means of the Horton's laws of network composition:

$$d = \max\left(1, 2\frac{\log R_L}{\log R_a}\right) \tag{8}$$

$$D = \min\left(2, \max\left(1, \frac{\log R_b}{\log R_L}\right)\right) \tag{9}$$

with R_a, R_b, R_L being respectively the Horton's area, bifurcation, and length ratios. A comprehensive although synthetic review of these and further developments in the fractal theory of stream networks can be found, for example, in the work by Schuller *et al.* (2001).

Self-similarity has also been found in regional drainage systems containing multiple independent but conterminous drainage basins along a coastline in both theoretical studies based on network generation models (Sun *et al.*, 1995) and measurements of natural drainage basins (La Barbera and Lanza, 2001).

In the latter work, the cumulative probability distribution of basin areas along a coastline, that is usually expressed in the form of a power law (see e.g. Perera and Willgoose (1998), La Barbera and Lanza (2000)) as:

$$P[A > a] \propto a^{-\gamma} \tag{10}$$

is related to the regional area ratio R_A and the multiplicative factor R_C defined as the regional analogues of the Horton's area and bifurcation ratios, in the form:

$$\gamma = \frac{\log R_C}{\log R_A} \tag{11}$$

Figure 2(a), 2(b) shows the observed variability across scales of the R_A and R_C ratios for independent drainage basins in the Liguria region of Italy. Figure 3 illustrates the cumulative distribution function of catchment areas for the same geographic region.

Variations in the Horton ratios from one catchment to another should affect the hydrological response, and this link was formalized by Rodriguez-Iturbe and Valdes (1979) then extended by several authors, culminating in the major work of Rodriguez-Iturbe and Rinaldo (1997).

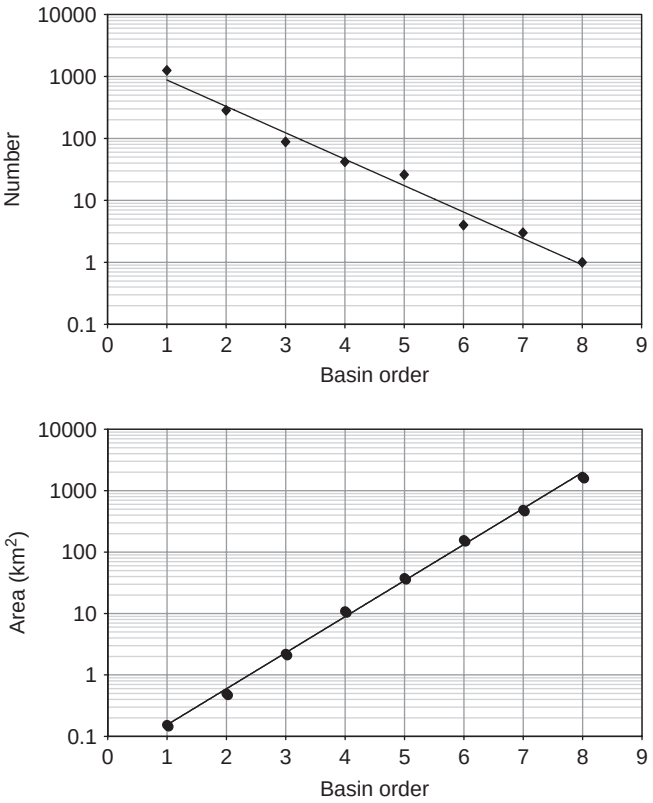

Figure 2 Scaling properties of a regional drainage network in terms of (a) the multiplicative factor R_C and (b) the area ratio R_A, defined in analogy with the Horton's bifurcation and area ratios, for independent drainage basins along the coastline of the Liguria region of Italy

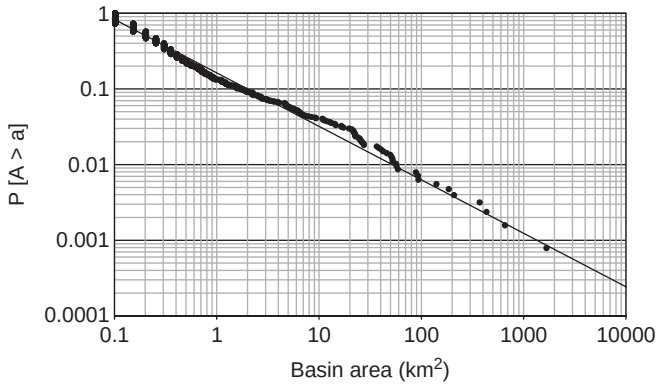

Figure 3 Power law fitting of the cumulative distribution function of catchment areas for independent drainage basins along the coastline of the Liguria region of Italy

The hillslope length or area of first-order catchments acts as the fine-scale limit of fractal scaling for both topographic surfaces and the drainage network. However, no other connection has been established between the fractal dimensions of surface topography and the drainage network except for theoretical models of drainage basin evolution (e.g. Sun *et al.*, 1994).

Hydraulic Geometry

Hydraulic geometry describes the relationships between channel form and flow regimes such as mean annual discharge or mean annual flood. The underlying principle of hydraulic geometry is that channels adjust to the flow within them reflecting the dynamic equilibrium between erosional power (*see* **Chapter 82, Erosion Prediction and Modeling, Volume 2**) and resistance, with bank-full discharge acting as the channel-forming flow. This condition is generally true only for alluvial channels that are in equilibrium with hydrologic conditions (Mosley and McKerchar, 1992).

Channels tend to become wider and deeper and have lower slope as flow increases further down the catchment, and the variations of width, depth, and slope with flow (or catchment area) tend to follow a consistent pattern (Leopold *et al.*, 1964, chapter 7; Sweet and Geratz, 2003). The relationships between channel width, depth, slope, and catchment area provide the basis for extrapolating measured streamflow at one location to different parts of a catchment, for inferring streamflow in a nearby catchment with similar rainfall, geology, and geomorphology or for estimating channel form from terrain analysis (typically catchment area and slope) for the purpose of modeling hydrologic response. In many situations, the imprecision of these relationships prevents accurate estimation of unknown quantities.

Catchment Similarity Indices

The use of similarity is not always connected with similarity across scales. Many different ratios and indices can be calculated for a catchment that can be used to assess similarity in hydrologic response, ranging from simple topographic ratios such as circularity and slope to complex hydroclimatic indices. Catchments with similar index values are expected to have a similar hydrologic response, although the degree to which this works in practice depends on the degree to which the catchment matches the assumptions of the index. Hydrologic similarity indices can also be computed at different locations within catchments to determine hydrologic similarity of particular sites, such as the $\ln(a)/\tan(\beta)$ index (topographic wetness index) originated by Beven and Kirkby (1979). This index is the basis of the TOPMODEL approach to hydrological modeling (*see* **Chapter 127, Rainfall-runoff Modeling: Distributed Models, Volume 3**) (Quinn *et al.*, 1995).

Milly (1993, 1994) and Woods (2003) developed several catchment similarity indices relating directly to hydrologic response. Woods' starting point is the climate dryness index R defined as the ratio of mean evaporation rate to mean rainfall rate. Seasonality of the balance between rainfall and evaporation is measured by the index S, with small values indicating little seasonality. A uniformly wet climate is characterized by $R < 1$ and $S < 1 - R$ while a seasonally wet climate has $S > \max(1 - R, R - 1)$. Other indices represent the effects of canopy interception, root zone storage, subsurface flow, and surface saturation, and the analysis leads to a combined storage-seasonality index S_r^* that is claimed to provide a concise definition of similarity among catchments.

These indices are yet to be widely adopted but have the potential to provide a common set of measures used to describe catchments and a means for identifying the dominant sources of variations in hydrologic processes between catchments.

Porous Media

The physical properties of porous media controlling the subsurface flow of fluids (*see* **Chapter 149, Hydrodynamics of Groundwater, Volume 4**) and the transport of contaminants (*see* **Chapter 152, Modeling Solute Transport Phenomena, Volume 4**) are seldom characterized by smoothly varying functions of position, and they rather exhibit spatial fluctuations over a wide range of scales (Hewett and Behrens, 1989) (*see* **Chapter 147, Characterization of Porous and Fractured Media, Volume 4**). The spatial variability of the hydraulic conductivity K has been widely investigated in order to understand flow and transport processes in heterogeneous systems.

In this context, fractal models are generally characterized by variograms or correlation measures of the relevant

variables that increase as a power law with the separation distance. A unifying framework for scaling models of such heterogeneities in porous media has been recently proposed by Painter (2001) and suitable references can be found therein.

The development of scaling models largely derives from the empirical evidence provided by the analysis of measured hydraulic conductivity fields. However, Liu and Molz (1997) observed that a mono-fractal model for the log-conductivity $logK$ cannot represent all types of heterogeneities and suggested to treat $logK$ as a multifractal field. Boufadel *et al.* (2000) argued that K itself should be treated as multifractal.

Tennekoon *et al.* (2003) analyzed the scaling properties of the hydraulic conductivity of three sites in North America and, by investigating the structure function of the data while varying the moment order q, found that K exhibits multifractality in both the vertical and the horizontal directions.

Mukhopadhyay and Cushman (1998) studied the effect of heterogeneities on the spreading of pollutants from a nonaqueous phase liquid trapped in a soil by modeling heterogeneities as a self-similar fractal process. Zhu and Sykes (2000) developed expressions for flow variances and macrodispersivities in a fractal semiconfined aquifer in terms of the leakage factor. A fractal model for total solute transport, assuming power law retention times, is proposed by Schumer *et al.* (2003) who provide a wide set of references for further reading on this subject.

HYDROLOGICAL PROCESSES

Rainfall

The rainfall process, as many other geophysical processes deriving from the superposition and interaction of different scales of motion, presents high space-time variability (*see* **Chapter 28, Clouds and Precipitation, Volume 1**) and non-Gaussian probability distributions for most of its characteristic variables (rain intensity, event duration, interarrival periods, etc.). The actual variability and complexity of the phenomenon are, however, often masked by the strong limitations and sampling characteristics of the observation methods (*see* **Chapter 35, Rainfall Measurement: Gauges, Volume 1**, **Chapter 63, Estimation of Precipitation Using Ground-based, Active Microwave Sensors, Volume 2** and **Chapter 64, Satellite-based Estimation of Precipitation Using Microwave Sensors, Volume 2**). Additionally, the shortage of data strongly impinges upon the conclusions derived. The uncertainties associated with our many requirements in terms of simulation and forecasting are usually dealt with by modeling rainfall as a random process (*see* **Chapter 31, Models of Clouds, Precipitation and Storms, Volume 1**).

Due to the above-mentioned characteristics, the rainfall process is one ideal candidate to be approached by means of self-similarity and/or fractal description models. Such models involve increasing complexity and computational burden as soon as the interest moves from the one-dimensional case, that is, the analysis of rainfall time series at a single point in space, to the two-dimensional case, that is, the analysis of the rain field in space at a frozen instant in time, and, finally, to the three-dimensional case where the full space-time pattern of rainfall is considered. Examples are given below, together with a short mention of an interesting application of the scaling approach to the description of rainfall extremes in terms of their intensity, duration, and frequency characteristics for application in the hydrological practice.

Time Series

In this section, we concentrate on the statistical behavior of rainfall in time without explicitly considering the spatial distribution and organization of the precipitation field.

The investigation of the highly irregular behavior of the local rainfall process led many authors to obtain some positive evidence of the fractal nature of rainfall in time – see, for example, Lovejoy and Mandelbrot (1985), Hubert *et al.* (1993), Olsson (1995), Svensson *et al.* (1996), and Tessier *et al.* (1996) – and provided a widely accepted indication that a multifractal approach seems to be appropriate for the description of rainfall time series. Evidence of this is reported in Figure 4 for a 10-min time series recorded in Genova (Italy) in terms of the normalized scaling exponent of the structure function $\zeta(q)/\zeta(2)$ as a function of the moment order q, while in Figure 5, the normalized spectral density function for the

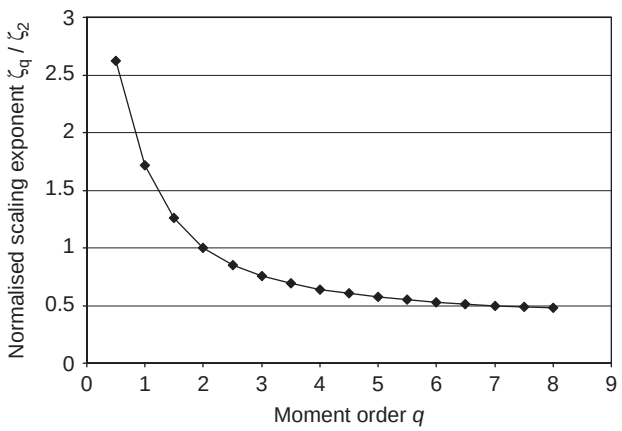

Figure 4 Example of the multiscaling behavior of 10-min rainfall data over a 10-year period at the rain gauge station of Genova (after Molini, 2001)

same data set is presented (see e.g. Molini, 2001 and Molini *et al.*, 2005a).

The conceptual relevance of such indication is the possibility of evaluating useful properties or synthetic parameters over a wide range of aggregation scales, in this way answering the basic requirement of many hydrological applications where the rainfall input is known (measured) at a different scale than those of interest for the problem in hand – see, for example, the downscaling (*see* **Chapter 11, Upscaling and Downscaling – Dynamic Models, Volume 1**) operational problem addressed in Molini *et al.* (2005b). On the modeling side, the observed multiscaling behavior yields the possibility of generating suitable local rainfall scenarios by employing random cascade algorithms, based on the analogy with the energy cascade that is used to describe the dynamic behavior of turbulence (see e.g. Menabde and Sivapalan, 2000; Olsson, 1995, 1998; Svensson *et al.*, 1996; Güntner *et al.*, 2001).

An interesting approach to rainfall modeling in time has been recently proposed by Veneziano and Iacobellis (2002), who presented a pulse-based representation of temporal rainfall with multifractal properties at small scales and deviations from scaling in the transient regime from small to large scales. The model is able to reproduce the observed on/off properties as well as the behavior of rain-intensity fluctuations with a parsimonious parameterization (i.e. employing few parameters that can be calibrated more easily and make the model more robust than non-fractal models) in the range from 20 min to a few days.

Design Rainfall

The similarity approach has direct practical implications in the statistical analysis of extreme rainfall events, aimed at the assessment of design rainfall as a function of duration, area, and the return period (*see* **Chapter 37, Rainfall Trend Analysis: Return Period, Volume 1**) – namely, the Depth-Duration-Frequency (DDF) curves. This also allows the derivation of a theoretical formulation of the ARF (Area Reduction Factor), a widely used parameter in hydrology and water resources-related disciplines where area-average rainfall statistics are required for application and design purposes.

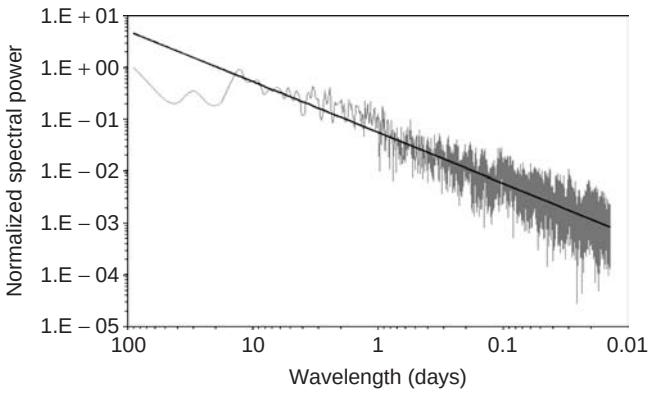

Figure 5 Normalized spectral density function for 10-min rainfall data over a 10-year period at the rain gauge station of Genova (after Molini, 2001)

A comprehensive approach to the derivation of a theoretical formulation for the DDF curves based on a scaling framework has been provided by Burlando and Rosso (1996) and Menabde *et al.* (1999). In the first work, the scale invariance properties of extreme storm probabilities are shown to underlie the derivation of a distribution-free formulation for the DDF curves based on the simple scaling and multiscaling properties of temporal rainfall, for example, in the first case in the form:

$$h(d, T) = a(1 + cv \cdot K_T) \cdot d^n \qquad (12)$$

where h is rainfall depth, d is the duration, T the return period, cv the coefficient of variation, K_T the frequency factor (Chow, 1951), and a, n two suitable parameters.

Veneziano and Furcolo (2002) recently presented an in-depth discussion of the above mentioned simple scaling behavior of the DDF curves and evidences of multifractality in rain time series, and provided a link between the scaling exponents of the curves and the moment scaling function of the rainfall time series.

The advantage of the scaling approach over the traditional one lies in the possibility of estimating the DDF parameters from relatively short time series of coarse rainfall data and to be able to use them for prediction of extreme storm characteristics over a range of technical interest that usually spans from 1 to 24 h in duration.

Space-Time Rainfall

The modeling of rain fields is traditionally approached by investigating the spatial statistical properties of rainfall accumulation on a fixed time window, without explicitly taking into account the evolution in time of the observed spatial patterns.

The conjecture that the rain field is scale invariant over a broad range of spatial and temporal scales is inspired by the statistical theory of turbulence, with reference to the atmospheric processes that originate rainfall, and supported by increasing empirical evidence.

Time-frozen or space-frozen rain fields can be suitably interpreted within a scaling framework, and a few examples are described, for example, by Lovejoy and Mandelbrot (1985) and Lovejoy and Schertzer (1985). However, it is evident that such a frozen field interpretation is not able to fully characterize the variety of observed rainfall structures (Deidda *et al.*, 2004) and suitable models are required to reproduce statistical properties jointly observed at different space and time scales.

An extensive analysis of space-time scaling properties of the rain field was recently performed by Deidda *et al.*

(2004) based on data from the well-known TOGA-COARE experiment, with results showing evidence of multifractality under self-similar transformations in space and time.

Multifractal models are available in the literature in order to provide a tool for parsimonious generation of realistic space-time rainfall scenarios (see e.g. Gupta and Waymire, 1990; Marsan *et al.*, 1996; Over and Gupta, 1996; Venugopal *et al.*, 1999a,b).

The space-time pattern of rainfall is indeed relevant to hydrological applications such as flood forecasting (*see* **Chapter 123, Rainfall-runoff Models for Real-time Forecasting, Volume 3**), especially when the meteorological predictions provided by physically based prognostic models of the atmosphere are obtained at much coarser scales than those required by catchment-scale hydrologic rainfall-runoff models used for flood warning purposes, so that suitable downscaling must be performed. The knowledge of scale-invariant properties in high-intensity storms is suitable to accomplish the need of rainfall downscaling methods in order to disaggregate large-scale rainfall forecasts to the smaller response scales of hydrological catchment models (see e.g. Deidda, 2000; Venugopal *et al.*, 1999a; Turner *et al.*, 2004).

CONCLUSIONS

Hydrological processes operate over a wide range of scales in time and space. Describing these processes and how they vary across scales has been a significant challenge in hydrology. Similarity approaches look for robust relationships between scales and hydrological parameters to allow the estimation of properties at a range of scales based on observations or measurements at one or few scales, and a variety of literature results support the conjecture that scaling holds for most hydrological variables in time and space.

The wide range of scales present in hydrology and other natural systems can be thought about in two distinct ways: as a series of distinct hierarchical levels or as a continuum of scales.

The hierarchy approach conceives of the range of scales as nested levels and focuses on the separation of different scales of variation and different processes at different scales. Such an approach commonly lists a number of hierarchical levels, each with its distinct characteristics. In hydrology, these might range from the scale of the experimental column through plots, hillslopes, small catchments, large catchments to the global hydrological cycle.

The continuum view conceives of the range of scales as a continuum with a focus on a single characterization across all (or a wide range of) scales. The fractal model is one such model that seeks to explain (or at least describe) the range of variations at different scales using a single model with one or two parameters. The continuum view tends to assume that the characterization is valid across all scales; this assumption has the corollary that there is no characteristic scale.

The weakness of the hierarchical view is that real systems may not exhibit a consistent hierarchy (some levels may be missing, or duplicated) and the division between levels of the hierarchy may be difficult to discern. The corresponding weakness of the continuum scaling view is that, in practice, scaling laws only operate over restricted ranges of scales. These two views can be reconciled by considering levels of the hierarchy as scale regimes within which scaling laws apply (Lewis, 1995). This composite view usually leads to a hierarchy with fewer levels, and to scaling laws with well-defined limits of applicability.

9: Statistical Upscaling and Downscaling in Hydrology

GÜNTER BLÖSCHL

Institute for Hydraulic and Water Resources Engineering, Vienna University of Technology, Vienna, Austria

Upscaling and downscaling methods are needed to transfer information from small-scale data to large-scale predictions and vice versa. There are two types of methods; methods focusing on how the equations and parameters of dynamic models change with scale, which are treated in other articles of this Encyclopedia, and methods focusing on how to best represent variability statistically, which is the subject of this article. This article gives a brief overview of scale concepts and illustrates first-order effects of upscaling and downscaling. The most important statistical upscaling/downscaling methods are then reviewed for various hydrological processes – rainfall, floods, soil moisture, and subsurface flow and transport.

INTRODUCTION

Hydrological analyses and predictions build on two strands of information; prior knowledge, which is usually embodied in some kind of model, and local data. The local data collected in the area of interest and for the time period of interest are used to specify the exact form of the model outcome through use of the inputs and choice of the model parameters (by model calibration), and sometimes through the choice of the model structure as well (**Chapter 10, Concepts of Hydrologic Modeling, Volume 1**). The spatial and temporal scales at which the predictions are needed may be different from those of the data, and in some instances model output from one scale needs to be combined with models at a different scale. In both cases, some scale adjustment or scale transfer is needed, either upwards in scale (termed *upscaling*) or downwards in scale (termed *downscaling*).

There exists an immense body of literature on upscaling and downscaling methods in the various subdisciplines of hydrology. Summary reviews include Blöschl and Sivapalan (1995) and Bierkens *et al.* (2000). More specific reviews of land surface parameters and porous media are provided in Shuttleworth *et al.* (1997) and Farmer (2002), respectively, and conference proceedings or collections of papers include Rodríguez-Iturbe and Gupta (1983), Gupta *et al.* (1986), Kalma and Sivapalan (1995), Stewart *et al.* (1996), Blöschl *et al.* (1997), Sposito (1998), and Pachepsky *et al.* (2003).

There are two generic types of upscaling and downscaling methods. The first type of method involves dynamic models of parts of the hydrologic cycle where the upscaling and downscaling issue is how the model equations and model parameters change with scale. This is beyond the scope of this article and is dealt with in articles **Chapter 11, Upscaling and Downscaling – Dynamic Models, Volume 1**, **Chapter 29, Atmospheric Boundary-Layer Climates and Interactions with the Land Surface, Volume 1**, **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2**, **Chapter 147, Characterization of Porous and Fractured Media, Volume 4**, and **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**.

The second type of method consists of statistical descriptions where the focus is on how to best represent random variability in both space and time at various scales. This is the focus of this article. The section "Scale, upscaling, and downscaling" of the present article gives a brief overview of scale concepts and introduces the simplest case of statistical upscaling/downscaling methods (first-order effects). The section "Types of statistical upscaling/downscaling methods" summarizes the most important types of methods. The

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

section "Statistical upscaling and downscaling methods" reviews statistical upscaling/downscaling methods that are currently of most interest in different subareas of the hydrological sciences, that is, rainfall (Sections "Upscaling point rainfall to catchments, temporal disaggregation of rainfall, statistical downscaling of the output of global circulation models"), floods (Section "Flood frequency as a function of catchment scale"), soil moisture (Section "Upscaling and downscaling soil moisture"), and subsurface hydrology (Section "Subsurface media characterization and generation"). Section "Concluding remarks" summarizes the main aspects of the methods.

SCALE, UPSCALING, AND DOWNSCALING

Processes, Sampling, and Modeling

Natural variability can be characterized statistically by spatial or temporal probabilities or their moments (such as the mean and the variance). In the simplest case of focusing on the second moments (*see* **Chapter 7, Methods of Analyzing Variability, Volume 1**), the scale of the underlying variability can be represented by the integral scale which is the average distance over which a variable is correlated (Skøien *et al.*, 2003). A sampling exercise will rarely reveal the underlying natural variability in full detail because of instrument error and because the spatial and temporal dimensions of the instruments or measurement setup will always be finite (*see* **Chapter 3, Hydrologic Concepts of Variability and Scale, Volume 1** and **Chapter 6, Principles of Hydrological Measurements, Volume 1**). Blöschl and Sivapalan (1995) suggested to term the dimensions of the measurements *the sampling scale triplet* consisting of the spacing, extent, and support of the data. In dedicated studies, soil hydraulic conductivity measurements, for example, may have spacings of decimeters, while rain gauges in a region are typically spaced at tens of kilometers. The extent, which is the overall size of the domain sampled, may again range from meters to hundreds of kilometers in hydrological applications. The support is the integration volume or area of the samples ranging from, say, $1\,\mathrm{dm}^2$ in the case of time domain reflectometry *in situ* probes (*see* **Chapter 72, Measuring Soil Water Content, Volume 2**), to hectares in the case of groundwater pumping tests (Anderson, 1997) or micrometeorological studies of the atmosphere (Schmid, 2002), and square kilometers in the case of remotely sensed data (Western *et al.*, 2002). In hydrology, the catchment area can also be thought of as a support scale (Bierkens *et al.*, 2000).

In case of a model, the notion of a scale triplet is similar. For example, for a spatially distributed hydrologic model the scale triplet may have typical values of, say, 25 m spacing (i.e. the grid spacing), 1 km extent (i.e. the size of the catchment or aquifer to be modeled), and 25 m support (the cell size). Analogue scales apply to the temporal domain.

The important point in the context of upscaling and downscaling is that the sampling scale triplet will have some bearing on the data and the modeling scale triplet will have some bearing on the predictions. Generally, if the spacing of the data is large, the small-scale components of the natural variability will not be captured by the measurements (*see* **Chapter 6, Principles of Hydrological Measurements, Volume 1**). If the extent of the data is small, the large-scale variability will not be captured and will translate into a trend in the data. If the support is large, most of the variability will be smoothed out and the data will appear very smooth. These sampling scale effects can be thought of as some sort of filtering in that the true patterns are filtered by the properties of the measurements (Cushman, 1984, 1987; Beckie, 1996; Di Federico and Neuman, 1997; Blöschl, 1999). In case of the modeling, the scale effects can be conceptualized in a similar way.

The different types of upscaling and downscaling (depending on what component of the scale triplet is changed) are illustrated in Figure 1. Downscaling in terms of spacing (i.e. decreasing the spacing) is usually referred to as *interpolation*, with the opposite being *singling out*. Upscaling in terms of extent (i.e. increasing the extent) is usually referred to as *extrapolation*; the opposite is, again, *singling out*. Upscaling and downscaling in terms of the support are referred to as *aggregation* and *disaggregation* respectively, particularly if the spacing is changing at the same time as the support. The scheme in Figure 1 can relate to both the sampling step (upscaling/downscaling from the underlying distribution to the data) and to the modeling step (upscaling/downscaling from the data to the model predictions). These two steps are conceptually similar.

First-order Scale Effects

To illustrate the effects of the scale triplet, both in sampling and modeling, the simplest case of linear upscaling and downscaling of a two-dimensional stationary random field such as that in Figure 1(a) will be examined first. It is assumed that the field can be fully characterized by a variogram of the form:

$$\gamma(h) = \sigma^2 \left(1 - \exp\left(\frac{-h}{\lambda}\right)\right) \tag{1}$$

where λ is the correlation length, σ^2 is the variance and h is the distance between two points in the random field (*see* equation 15 in **Chapter 7, Methods of Analyzing Variability, Volume 1**). For clarity, the random field is assumed to have zero mean and unit variance $\sigma^2 = 1$. An important assumption for first-order scale effects is that the variable of interest aggregates linearly or in other words, simple arithmetic averaging applies. In hydrology there are

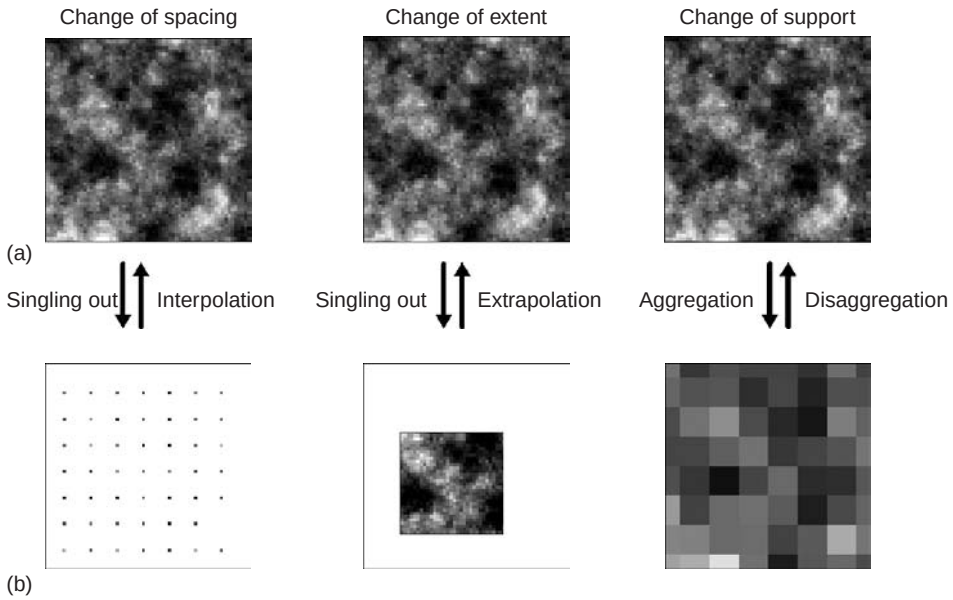

Figure 1 Schematic of upscaling and downscaling by changing the scale triplet. (a) represents the underlying natural variability with the sizes of the patches of the patterns being related to the integral scale. (b) shows the actual information reflected in the samples (or a model). Modified from Bierkens *et al.* (2000)

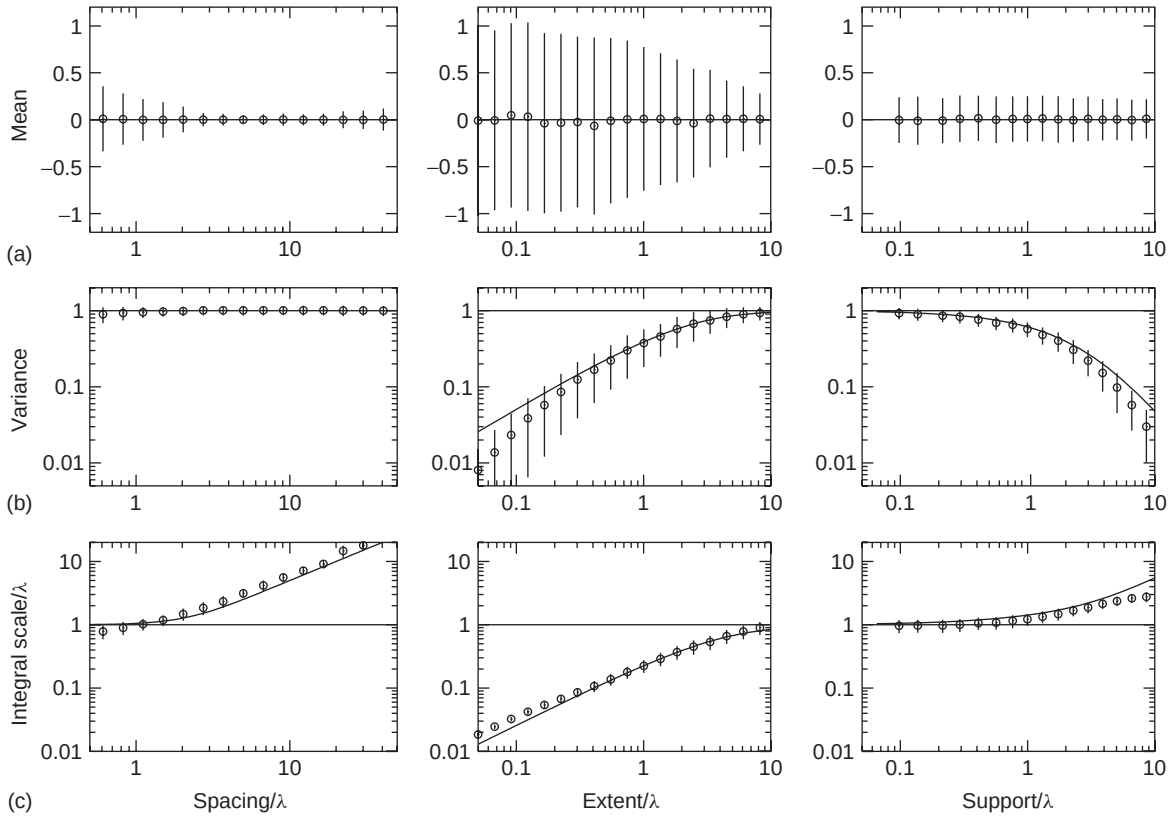

Figure 2 Effect of the sampling scale triplet on the sample mean, variance, and integral scale for the case of a two-dimensional stationary random field. λ is the correlation length of the random field. The circles show the ensemble mean and the error bars represent the standard deviation around the ensemble mean for 100 gridded samples from a Monte Carlo study. The solid lines show the predictions for the ensemble mean. From Skøien and Blöschl (2005)

variables where linear averaging is meaningful, such as precipitation, because a conservation law (e.g. of mass) holds. Other variables such as hydraulic conductivity do not average linearly. In Darcy's law, for example, the average hydraulic conductivity over an area does not give the average flux over the same area, so alternative, nonlinear methods are needed (*see* **Chapter 11, Upscaling and Downscaling – Dynamic Models, Volume 1** and **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**).

To examine the effects of the scale triplet, Skøien and Blöschl (2005) performed a Monte Carlo analysis and generated a large number of realizations of two-dimensional random fields from which hypothetical samples at fixed locations conforming to a certain sampling scale triplet were drawn. These were used to estimate the sample mean, spatial variance, and integral scale for each realization. For each of these three characteristics, the mean over all realizations (the ensemble mean) and the standard deviation around the ensemble mean were calculated. Figure 2(a) shows the results for the sample mean. If the ensemble mean of the sample mean is zero, the estimates of the mean are unbiased. If the standard deviations (shown as error bars) are small, the uncertainty of the mean is small. The results suggest that the mean of the samples will be unbiased irrespective of the sampling scale triplet, but it will be highly uncertain if the extent of the domain is small relative to the correlation length of the underlying variability. This is because all samples are heavily correlated and very little is learned about the variability of the population. Figure 2(b) shows the results for the sample variance. If the ensemble mean of the sample variance is unity, the estimates of the variance are unbiased. Figure 2(b) indicates that large spacings (relative to the correlation length of the underlying variability) do not bias the variance, but small extents do and will lead to an underestimation of the variance. Large supports will reduce the variance and this is related to the smoothing effect of the support mentioned earlier.

Figure 2(c) shows the results for the sample integral scale. The integral scale is the average distance over which a variable is correlated and in the case of a variogram of the form of equation 1, the integral scale of the random field is equal to the correlation length λ (*see* equation 10 in **Chapter 7, Methods of Analyzing Variability, Volume 1**). In Figure 2, the sample integral scale has been scaled by λ, so if the ensemble mean of the scaled sample integral scale is unity, the estimates of the integral scale are unbiased. The results suggest that the integral scale will always be biased. It will be overestimated in the case of large spacings and large supports and underestimated in the case of small extents relative to the correlation length of the underlying variability. This is because in the case of large spacings and supports, the small-scale variability is not sampled, while in the case of small extents, the large-scale variability is not sampled. Figure 2 is for the case of gridded sampling. There are numerous other sampling schemes (Thompson, 2002) with slightly different biases and uncertainties for the case of large spacings. Random sampling, for example, will reduce the biases of the integral scale but will increase its uncertainty. The analysis in Figure 2 examines how well the characteristics of the underlying random field (i.e. the population) can be estimated from a limited number of samples. Skøien and Blöschl (2005) also examined how well the characteristics of a single (unknown) realization can be estimated and indicated that some of the biases and random errors will be different from the case shown here.

It is clear that spacing, extent, and support are all scales, but they have a different role in upscaling and downscaling methods. For example, the variance of, say, precipitation tends to increase with scale if scale is defined as extent, but decreases with scale if scale is defined as support because of the filtering involved.

To a first approximation, the effect of the filter will be closely related to the ratio of the sampling scale and the characteristic scale of the underlying process (the correlation length), which is consistent with dimensional reasoning. Geostatistical methods (Journel and Huijbregts, 1978) allow the estimation of the sampling biases in a consistent manner (see lines in Figure 2, taken from Western and Blöschl, 1999) and are the basis for some of the statistical upscaling/downscaling methods. The reduction in variance as a result of increasing support is widely used for linear aggregation methods and may also give some guidance for nonlinear cases such as extreme value analyses of rainfall and model parameter aggregation in subsurface hydrology.

TYPES OF STATISTICAL UPSCALING/ DOWNSCALING METHODS

Any upscaling or downscaling exercise involves the following steps: (i) analyzing the local data and scrutinizing the literature to decide on the model type; (ii) estimating the parameters from the data; (iii) verifying the upscaling/downscaling model against an independent data set; and (iv) performing the actual downscaling and upscaling step. Methods of upscaling and downscaling differ in terms of how they represent hydrologic variability.

Representing Variability

The simplest option is to represent the variability as a random variable that is fully characterized by its covariance (or equivalently its variogram, as the variogram can be expressed by the covariance and *vice versa*). Again, the simplest assumption in this case is that the random variable is multi-Gaussian and stationary which means that all linear

combinations of the variable sampled at any set of locations are normally distributed and there is no spatial/temporal trend. In zero dimensions (no spatial/temporal correlations), this type of variability is used in distribution models of soil moisture downscaling; in one dimension, for disaggregating annual rainfall into monthly values; in two dimensions (Figure 1a), for estimating catchment rainfall; and in three dimensions, for representing subsurface media characteristics. Representations of multi-Gaussian variability used in hydrology usually exhibit one single scale of variability (e.g. λ, if the variogram is of the form of equation 1). An alternative is to recognize that variability may occur at many scales. The variability may still be fully characterized by a variogram, but this time it is of the form:

$$\gamma(h) = a \cdot h^b \tag{2}$$

where h is the spatial (or temporal lag) and a and b are constants. This is termed *fractal variability* and is nonstationary, that is, the variance increases gradually with the extent of the field (*see* **Chapter 8, Fractals and Similarity Approaches in Hydrology, Volume 1**). This representation of variability can be used in a similar way as the multi-Gaussian concept discussed earlier, although with additional mathematical complexity, and has been widely used in hydrology, in particular, for rainfall where the presence of variability at many scales is most obvious.

There are more complex types of variability than those that can be exhaustively represented by a variogram (*see* **Chapter 1, On the Fundamentals of Hydrological Sciences, Volume 1** and **Chapter 3, Hydrologic Concepts of Variability and Scale, Volume 1**). The most important case is discontinuous (or intermittent) variability. Rainfall is discontinuous in both time and space (wet and dry), and subsurface media are discontinuous when there is a sharp transition of media properties between different facies or different soil types. This type of variability can be represented by Boolean methods where objects (such as storms, sand lenses, fractures) are placed in space (and in time in the case of storms) according to specified statistical distributions. Alternatively, discontinuous variability can be represented by transition probabilities (i.e. Markov chains) where a value is generated as a function of its neighboring value, both in time (in rainfall) and in space (e.g. subsurface media).

More complex forms of organization include the presence of connectivity or a tree structure, which can be represented by percolation characteristics or, in the case of soil moisture, by terrain indices. Another type of variability, gleaned from turbulence, is multifractal behavior where most of the variability is concentrated in singularities (Sreenivasan, 1991). This means, it is the peaks that control the upscaling/downscaling behavior which has been found to represent a wide range of hydrological characteristics very well, including rainfall, streamflow, and subsurface characteristics (Lovejoy and Schertzer, 1991; Gupta *et al.*, 1994; Menabde *et al.*, 1997; Veneziano and Essiam, 2003). It has been suggested that there may exist a causal relationship with turbulent processes in all of these cases. Multifractal model types include multiplicative cascades with the additional advantage of a small number of parameters, which facilitates parameter estimation.

Whatever the type of variability that is present, the important thing is that the methods of upscaling and downscaling represent these variabilities well. In other words, selection of one or the other method should be guided by an analysis of the underlying variability of interest in a particular case.

Modes of Application

Methods of upscaling and downscaling also differ in the way they are applied in the upscaling/downscaling step depending on what information – statistical characteristics or space-time patterns – is required.

The first generic task is to derive the statistics of a variable at one scale from the statistics of the same (or another) variable at another scale. Here, scale is usually the support scale in both instances. Examples include the downscaling of the output from global circulation models (GCMs), the areal reduction from point to catchment rainfall, and the effective parameter problem in subsurface and catchment hydrology (*see* **Chapter 11, Upscaling and Downscaling – Dynamic Models, Volume 1**; **Chapter 133, Rainfall-runoff Modeling of Ungauged Catchments, Volume 3**, and **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**). The first task can be upscaling or downscaling depending on which way one proceeds. Methods range in complexity from regressions between the variables at different scales to upscaling theory of stochastic hydrogeology (*see* **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**).

The second generic task is to generate spatial patterns (or time series) given the statistical characteristics of the variable one means to represent. This can be either through interpolation between a number of samples (using methods such as kriging with or without auxiliary data) or disaggregation. In the disaggregation case there are three variants (Deutsch and Journel, 1992; Bierkens *et al.*, 2000):

1. *Unconditional simulations (no data points given)*: Here the interest is in obtaining a number of realizations of the variable of interest that all exhibit the same statistics (e.g. the variogram) as inferred from the data. The patterns are not conditioned by the data points which means that the values of the simulated patterns at the locations of the data may be different from the data. Methods include the turning bands method for generating random fields and stochastic rainfall models for generating sequences of rainstorms.

2. *Conditional simulations (data points given)*: These are similar to unconditional simulations but they fit exactly to the individual data points. There is also some similarity with interpolation, but with the important difference that in interpolation one is interested in the most likely pattern while in conditional simulations one is interested in obtaining many realizations with the most realistic statistical characteristics.

3. *Conditional simulations (averages given)*: These are similar to the above but now the patterns are conditioned on the averages over support areas or time periods. Examples include the generation of subsurface media patterns by disaggregating pumping test data and the generation of monthly rainfall time series by disaggregating annual rainfall.

The opposite scale transfer of obtaining averages from patterns is nontrivial only in the case of processes that average nonlinearly as most model parameters do. The two main types of averaging methods are volume averaging (where a model parameter and/or an equation is averaged over a support volume) and ensemble averaging (where the model parameters and/or equations are averaged over all possible realizations of an ensemble at a single point). This, however, is beyond the scope of this article and the reader is referred to **Chapter 11, Upscaling and Downscaling – Dynamic Models, Volume 1** and **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**.

STATISTICAL UPSCALING AND DOWNSCALING METHODS

This section reviews statistical upscaling and downscaling methods for a number of hydrological application areas. Research into upscaling and downscaling rainfall, historically, has followed three routes. The first has been driven by the need for estimating catchment averages of extreme rainfall from point data for hydrologic design, the second from the need of estimating, say, daily rainfall from monthly data both in applied and theoretical contexts, and the third has been triggered by the interest of deriving local rainfall from estimates of average rainfall over tens of thousands of square kilometers provided by GCMs in the context of climate impact assessments (Sections "Upscaling point rainfall to catchments", "Temporal disaggregation of rainfall", and "Statistical downscaling of the output of global circulation models"). In flood frequency analysis, the challenge has been, and still is, to transfer flood characteristics between catchments of different scales and here the main focus of the more involved methods has been on a better understanding of regional flood generation processes (Section "Flood frequency as a function of catchment scale"). An important issue in catchment hydrology and, increasingly, in climate modeling is how to upscale and downscale measurements and simulation results of near-surface soil moisture (Section "Upscaling and downscaling soil moisture"). In subsurface hydrology, one of the main issues is how to represent the media characteristics be it in soils, porous aquifers, or in fractured rocks from data at different scales as the heterogeneities control the dynamics of flow and transport (Section "Subsurface media characterization and generation").

Upscaling Point Rainfall to Catchments

One of the classical upscaling problems in catchment hydrology is how to obtain catchment rainfall from observed point rainfall data to drive runoff models. Because of the averaging effects, extremes of catchment rainfall tend to be smaller than those of point rainfall. To account for this effect, areal reduction factors (ARFs) have been introduced which are defined as the ratio of catchment rainfall and point rainfall. Two kinds of ARFs are presently in use (Srikanthan, 1995).

1. Fixed-area (also known as *geographically fixed*) ARFs relate rainfall at any arbitrary point, that is, a point rainfall estimate to an average over a catchment, which is fixed in space. They are estimated by constructing from all available station rainfall data, the time series of catchment average rainfall (e.g. using the Thiessen polygon method), performing an extreme value analysis on them as well as on the point data, and finally relating the catchment rainfall intensities to the point values, for the same return period and duration.
2. Storm-centered ARFs refer to a given storm. They represent the ratio of average storm depth over an area (defined by the rainfall isohyets) and the maximum rainfall depth for the storm (at the storm center). Storm-centered ARFs are usually somewhat smaller than fixed-area ARFs. Storm-centered ARFs are used more commonly in the estimation of probable maximum floods, while the fixed-area ARFs are used for designing hydraulic structures for flood control, for example, bridges and culverts.

The main controls on reduction factors are the storm type with small-scale convective storms producing a more pronounced decrease of the ARF with area than large-scale storms, and duration with shorter durations being associated with a stronger decrease of the ARF with area (Srikanthan, 1995). The original concept of the ARFs has been a purely empirical one but a number of recent contributions have attempted to provide a sounder theoretical basis for them. Bacchi and Ranzi (1996) derived ARFs on the basis of the crossing properties of the rainfall process aggregated in space and time assuming that the number of crossings of high rainfall intensity levels is Poisson-distributed. The

ARFs so obtained showed a power-law decay with respect to area and duration of the storm, and they showed a slight decrease with respect to the return period. In a somewhat related analysis, Skaugen *et al.* (1996) analyzed the fraction of a catchment with rainfall depths greater than a threshold for different thresholds, which allowed them to derive catchment average rainfall. De Michele *et al.* (2001) derived ARFs from power law or fractal characteristics of the underlying process in space and time. In an alternative approach, Sivapalan and Blöschl (1998) derived ARFs from the spatial correlation structure of rainfall. They averaged the parent distribution of point rainfall over a catchment area making use of the variance reduction with support (Figure 2) and then transformed it to the corresponding extreme value distribution, using the asymptotic extreme value theory of Gumbel (1958). Figure 3 shows the ARFs so obtained for a duration of 24 h. It is interesting that, similar to Bacchi and Ranzi (1996), there is a tendency for the ARFs to decrease with return period, which is related to decreasing correlation lengths of rainfall as the storms increase in magnitude.

There have been a number of attempts at linking the areal reduction factor concept to other representations of areal precipitation. Booij (2002), for example, linked the Sivapalan and Blöschl (1998) ARFs to statistical downscaling methods (see Section "Statistical downscaling of the output of global circulation models"), and Venugopal *et al.* (1999) proposed a downscaling scheme that preserves both the spatial and temporal correlation of rainfall as grid size changes, which is closely related to deriving ARFs from the correlation structure of rainfall. In principle, ARFs can be derived from multisite stochastic rainfall models (see Sections "Temporal disaggregation of rainfall", "Statistical downscaling of the output of global circulation models"). The latter may be physically more realistic but involve significantly more parameters than empirically derived ARFs. A large number of parameters may be difficult to estimate from limited data.

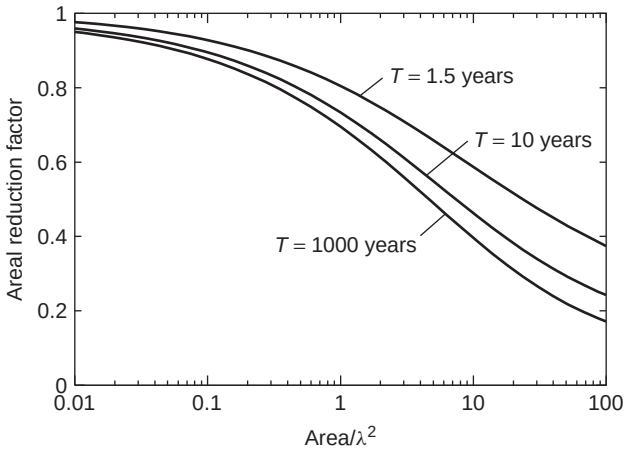

Figure 3 Areal reduction factors derived from the rainfall spatial correlation structure (Sivapalan and Blöschl, 1998). The time interval is 24 h, A/λ^2 is the catchment area scaled by the square of the rainfall correlation length and T is the return period

Temporal Disaggregation of Rainfall

Rainfall data with low temporal resolution (large temporal supports) often are available at more stations and over a longer time period than high-resolution records. Disaggregating them in time by stochastic rainfall models is therefore attractive for a range of practical purposes including the simulation of reservoir operation, urban drainage, and design, but is also interesting from a theoretical perspective for understanding rainfall processes. As with most other downscaling methods, there are two basic cases – disaggregating observed time series under mass constraints for each observed time step, that is, conditional simulations, and generating time series with small temporal supports with given statistical characteristics, that is, unconditional simulations. A range of model types have been developed (Foufoula-Georgiou and Georgakakos, 1991; Foufoula-Georgiou and Krajewski, 1995; Srikanthan and McMahon, 2001):

1. *Linear disaggregation models*: The classic model of disaggregating annual rainfall into monthly rainfall has been proposed by Valencia and Schaake (1973). It is a linear disaggregation model which assumes that the monthly values can be estimated by a linear combination of the annual values plus an additive error term. These are conditional simulations. The model has been extended in a number of ways (see Salas, 1993, pp. 19–32) and has probably been the most widely used scheme for stochastic disaggregation problems in hydrological applications. However, schemes of this kind are not suitable for the disaggregation of rainfall for timescales finer than monthly due to the skewed distributions and the intermittent nature of the rainfall process at fine timescales (*see* **Chapter 7, Methods of Analyzing Variability, Volume 1**).

2. *Two-part models*: Two-part models consist of a model for the occurrence of dry and wet days and a model for the generation of rainfall amount on wet days. Models of rainfall occurrence are of two main types, those based on Markov chains and those based on alternating renewal processes. Markov chains specify the state of each day as "wet" or "dry" and develop a relation between the state of the current day and the states of the preceding days. Long-term persistence can be represented by Hidden State Markov models (Thyer and Kuczera, 2003). In alternating renewal models (Grace and Eagleson, 1966, Sivapalan *et al.*, 2005), sequences of event and between-event periods are simulated. The wet and dry spells are usually assumed to be independent and may conform to different distributions

that may also vary with the season. The rainfall amount models use various distribution types such as the Gamma distribution or the Levy-stable distribution (Menabde and Sivapalan, 2000). Total event rainfall amount can then be disaggregated to, say, hourly time steps by traditional mass curves. In mass curves, the traces of cumulative storm depths normalized by total storm depth versus cumulative time since the beginning of a storm normalized by the storm duration are assumed to follow a set pattern (Huff, 1967). Within-event rainfall patterns can also be obtained by random disaggregation (Woolhiser and Osborn, 1985).

3. *Point process models*: These are models where the stochastic process is completely characterized by the position of its events (Eagleson, 1978; Waymire and Gupta, 1981; Smith and Karr, 1985). Among the point process models, the most widespread methods have been the cluster-based models such as the Neyman-Scott rectangular pulse model (Favre *et al.*, 2004) and the Bartlett-Lewis rectangular pulse model (Onof and Wheater, 1993). In these models, storm arrival follows a Poisson process and each storm gives rise to a cluster of rain cells with each cell having a random time location, duration, and intensity. These models have been extended to multiple sites (e.g. Fowler *et al.*, 2005) but this is at the cost of increased mathematical complexity and potential problems with parameter estimation. The seasonal variation in rainfall is an important factor. Some of the models deal with seasonality by assuming that the parameters vary seasonally, in other models the parameters have been linked to weather types, and there are also combinations of these two options (see Section "Statistical downscaling of the output of global circulation models"). **Chapter 125, Rainfall-runoff Modeling for Flood Frequency Estimation, Volume 3** discusses point process models in the context of flood frequency analysis. Point process models are usually applied as unconditional simulations.

4. *Multiplicative cascades*: The idea in multiplicative cascades is that an initial rainfall depth over a time period is split into two subperiods and these subperiods are split again and so forth. In an analogous way, rainfall over an area is split into subsequently smaller subareas. Multiplicative cascades are based on the notion that the underlying variability is multifractal. The main strength of multiplicative cascade models is that they have relatively few parameters and hence these can be estimated more robustly than is possible with point process models. The other advantage of multiplicative cascade models is that they are more easily able to reproduce observed rainfall characteristics over a wide scale range than other models (Foufoula-Georgiou and Krajewski, 1995). Most of the recent research has hence focused on models where at least one variability aspect is represented by multiplicative cascades. Examples include Olsson and Berndtsson (1998), Güntner *et al.* (2001), and Seed *et al.* (1999) who proposed a space and time model for design storm rainfall. Multiplicative cascade models lend themselves naturally to disaggregating storm rainfall (i.e. conditional simulations) and have been linked to the mass curves concept by Koutsoyiannis and Foufoula-Georgiou (1993) and Koutsoyiannis and Mamassis (2001).

5. *Combined models*: The above classification of models has been based on their statistical concepts, and there a number of models that combine some of these concepts. Jothityangkoon *et al.* (2000), for example, use a Markov chain in the time domain and multiplicative cascades in the space domain. Another example has been furnished by Koutsoyiannis *et al.* (2003) who proposed a multisite rainfall generation framework based on a combination of methods. There exists a range of rather simple and practical disaggregation methods that combine still other concepts. These methods are used in a number of countries at a national level and include regression methods (Canterford *et al.*, 1987) and the quadrant method (Grebner, 1995) where within-day temporal patterns of rainfall are transposed from the neighboring recording raingauge stations on the basis of a similarity measure. The strength of these simple methods are their robustness, although their accuracy relative to other methods has not yet been fully evaluated.

Statistical Downscaling of the Output of Global Circulation Models

Outputs of climate simulations from global circulations models (GCMs) cannot be directly used for hydrological impact studies of climate change because of a scale mismatch. The spatial grid resolution (i.e. support) of GCMs in use today is on the order of tens of thousands of square kilometers. The useful grid box size is even larger as GCMs are inaccurate at the scale of a single grid box. In contrast, the spatial scale at which inputs to hydrologic impact models are needed is on the order of tens or hundreds of square kilometers. Because of the scale mismatch, the statistical characteristics of the GCM output may be vastly different from those of the local (surface) variable that shares the same name. For example, the maximum rainfall intensities simulated by GCMs tend to be much smaller than those at the point scale. There will also be local effects induced by topography, land cover, and so on, which are not captured in the GCM. Downscaling methods can be used to transfer the large-scale GCM output to small-scale variables and to account for local effects.

There are two approaches to downscaling GCM output (IPCC, 2001; Yarnal *et al.*, 2001). The first is dynamic downscaling where deterministic regional climate models are nested into GCMs. This means the initial conditions

and boundary conditions to drive the regional climate model are taken from the GCMs. Dynamic downscaling is discussed in **Chapter 32, Models of Global and Regional Climate, Volume 1** and is not dealt with in this article.

The second approach is empirical or statistical downscaling, which will be briefly reviewed here in a hydrological context. In empirical or statistical downscaling, explicit relationships between the large-scale GCM output and the observed small-scale or local station data such as precipitation are used. Unlike dynamic downscaling, statistical downscaling methods are computationally inexpensive. They can thus be used to generate a large number of realizations to assess the uncertainty of predictions. They can also use climate data from individual stations directly, so local information can be accounted for in an efficient way. The method, however, hinges on the assumption that the statistical relationships developed for present day climate also hold under the different forcing conditions of possible future climates, and this assumption is essentially unverifiable. The relationships can indeed be unstable for many reasons as short-term relationships can be conditional on longer-term variations in the climate system (Charles *et al.*, 2004). Application of the method consists of four steps as follows (Yarnal *et al.*, 2001):

1. *Selection of the local variable*: The most common variables to be estimated by downscaling procedures are precipitation and air temperature, either at daily or monthly timescales. The corresponding data are usually collected at individual climate stations in the area.

2. *Selection of the large-scale GCM-derived variable or variables (termed "predictors")*: This selection step is less obvious and depends on the downscaling relationship used. Ideal predictors exhibit high predictive power, are accurately simulated by the GCM, and are associated with relationships that are time stable. The most widely used predictor is sea level pressure because of its long record, which aids model development. Geopotential heights are also frequently used. Most common is 500 hPa, a level representing midtropospheric circulation and storms tracks. When empirical downscaling of precipitation is the goal, it is also useful to include a predictor of atmospheric moisture because changes in the hydrologic cycle are likely to be the underlying cause of future changes in precipitation. It is important to note, however, that GCMs tend to provide less accurate simulations of atmospheric moisture than of surface pressure and geopotential heights (Yarnal *et al.*, 2001). Wilby and Wigley (2000) and Wilby *et al.* (2002) discuss the relative merits of predictors currently in use.

3. *Deriving relationships between the observed small-scale or local station data and the large-scale GCM-derived variable*: The relationships (i.e. the downscaling models), generally, belong to one out of three types of methods (IPCC, 2001).

(a) Regression techniques are the most widely used methods. The simplest is linear regression using grid-cell values from the GCMs as predictors (e.g. Wilby *et al.*, 1998) or principal components of the predictor fields (Hewitson and Crane, 1996). Canonical correlation analysis and singular-value decomposition are other methods that condense the spatial patterns into a few values amenable to the regressions (von Storch and Zwiers, 1999). In addition to linear regression, nonlinear models such as nonlinear interpolation (Brandsma and Buishand, 1997) and artificial neural networks (Hewitson and Crane, 1996) have been developed. In the regression models, for each time step the "best" value of the local variable is generally estimated from the large-scale variables at the same time step.

(b) Stochastic models and weather typing: Stochastic models have been discussed in Section "Temporal disaggregation of rainfall" of this article. They do not estimate a best value for each time step but generate possible realizations of time traces of precipitation that are consistent with the statistics of the observations, given the probabilities derived from the GCM output. In the context of GCM downscaling, most models of this type condition the probabilities of the local variable of interest on weather types (e.g. Hay *et al.*, 1991). A number of weather classification schemes are in use (*see* **Chapter 26, Weather Patterns and Weather Types, Volume 1**, also see Tveito and Ustrnul, 2003), such as the Lamb weather types for the United Kingdom (Conway and Jones, 1998) and the Central European Großwetterlagen (Stehlik and Bardossy, 2002). The classification of each day can be either manual or automatic, involving various statistical methods based on the patterns of geopotential pressure heights and other synoptic variables (Yarnal *et al.*, 2001). The time step of the stochastic models is usually a day. Wilks and Wilby (1999) and Srikanthan and McMahon (2001) review stochastic climate models with an emphasis on precipitation.

(c) The analog method is, again, based on a classification procedure, but no stochastic model is involved. The method consists of identifying, from a pool of historical circulation patterns, the one that is most similar to the circulation pattern on the day of interest (Lorenz, 1969). The local variables observed on the most similar day within the pool are then assigned to the day of interest. The similarity of the large-scale circulation patterns can be defined in various ways. Zorita and von Storch (1999), for example, proposed Empirical Orthogonal Functions to reduce the

degrees of freedom of the large-scale atmospheric circulation. While there may rarely exist perfect analogs from the past, the method does not require any transformation of the local variable, which is a particular advantage for the case of precipitation. This method generates physically feasible spatial patterns of the surface variables but the predicted pattern is restricted to the observed values.

All of the methods need to be tested whether the relationships remain stable over time, which is usually done by split-sample testing involving nonoverlapping periods for parameter estimation and verification.

4. As a final step in the downscaling procedure, the relationships derived are applied to the GCM output for changed climate scenarios to estimate the local variables for a changed climate. These local variables (mainly precipitation and air temperature) can then be used to drive hydrological models in an impact assessment.

Flood Frequency as a Function of Catchment Scale

Regional analyses of flood frequency are used in practical contexts for estimating floods at ungauged sites and improving flood estimates at gauged sites (Cunnane, 1988), and in more theoretical contexts for advancing the understanding of the spatial variability of hydrologic fluxes (Pilgrim, 1983; Blöschl and Sivapalan, 1995; Gupta, 2004). To sharpen the focus on the pure scale effect, one usually assumes that the spatial trends of the flood characteristic are either small, or average out when a sufficiently large ensemble of catchments is considered. Spatial trends are dealt with separately in regional flood frequency analysis (e.g. Institute of Hydrology(IH), 1999; Merz and Blöschl, 2005).

The flood frequency curve is likely to change with catchment size because of a number of factors that are related to rainfall (e.g. rainstorms of different sizes may become important) and catchment processes (e.g. different runoff processes may become important). The main effect of catchment size is that the specific mean annual flood (i.e. the mean of the maximum annual flood peaks divided by catchment area) tends to decrease with catchment scale (Eaton *et al.*, 2002) and this is related to the smoothing effects of support scale as illustrated in Figure 2. The steepness of the flood frequency curve (which is closely related to the coefficient of variation, CV) changes with catchment size in a less predictable way and hence has recently attracted considerable attention in the literature.

Some practical methods, such as the index flood method (Dalrymple, 1960), imply that the CV in any homogeneous region does not change with catchment area (Gupta *et al.*, 1994), but there is evidence to the contrary from two avenues of enquiry.

1. The first are quantile-based analyses where floods of a given return period (i.e. flood quantiles) and catchment area are often formulated as a power law:

$$Q_T = c(T) \cdot A^{\theta(T)} \tag{3}$$

where Q_T are the flood quantiles, c is a factor, T is the return period, A is catchment area, and θ is an exponent. Data analyses from a range of climates suggest that there is a tendency for θ to decrease with return period (e.g. Gupta and Waymire, 1998). Typically, θ varies between 0.6 and 0.9 for $T =$ 2 years and between 0.4 and 0.6 for $T >$ 100 years. This dependence on the return period implies a decrease of CV with catchment area.

2. The second type of analysis examines the flood moments. Flood data in the central Appalachians indicated that the CVs tend to increase with catchment scale from 1 to 100 km^2 and decrease between 100 and 25 000 km^2 (Smith, 1992). Smith (1992) proposed two interpretations. First, the data on the small basins may be unrepresentative due to possible systematic errors in stream gauging or sampling artifacts, which would suggest that CV tends to always decrease with catchment scale. Second, the peak in CV at a catchment size around 100 km^2 may be real and is related to the organization of extreme storm rainfall and the downstream development of the channel/floodplain system. Gupta and Dawdy (1995) provided an additional interpretation. On the basis of rainfall runoff simulations they suggested CV at small catchment scales to be controlled by basin response, and based on a comparison of snow melt and rainfall dominated catchments they suggested CV at large scales to be controlled by rainfall variability. A similar interpretation has been furnished by Robinson and Sivapalan (1997) based on a derived flood frequency model. They suggested that the increase in CV in small catchments is due to the interaction between timescales of storm duration and catchment response while the decrease in CV in large catchments is due to the spatial rainfall characteristics. Blöschl and Sivapalan (1997) used a similar model and noted that the interactions between timescales of storm duration and catchment response may be hidden by other processes such as nonlinear runoff generation.

While these findings were obtained by an upward approach (Sivapalan *et al.*, 2003) of deriving the flood frequency statistics from rainfall statistics, an alternative, downward route for explaining the change of the flood frequency curve with catchment scale has been taken by Merz and Blöschl (2003). They classified 12 000 flood peaks in Austria into long-rain floods, short-rain floods, flash-floods, rain-on-snow floods, and snow-melt floods and then examined the flood statistics separately for each of the groups (Figure 4). They found that the CV of the snow-melt flood type exhibited the flattest decrease with

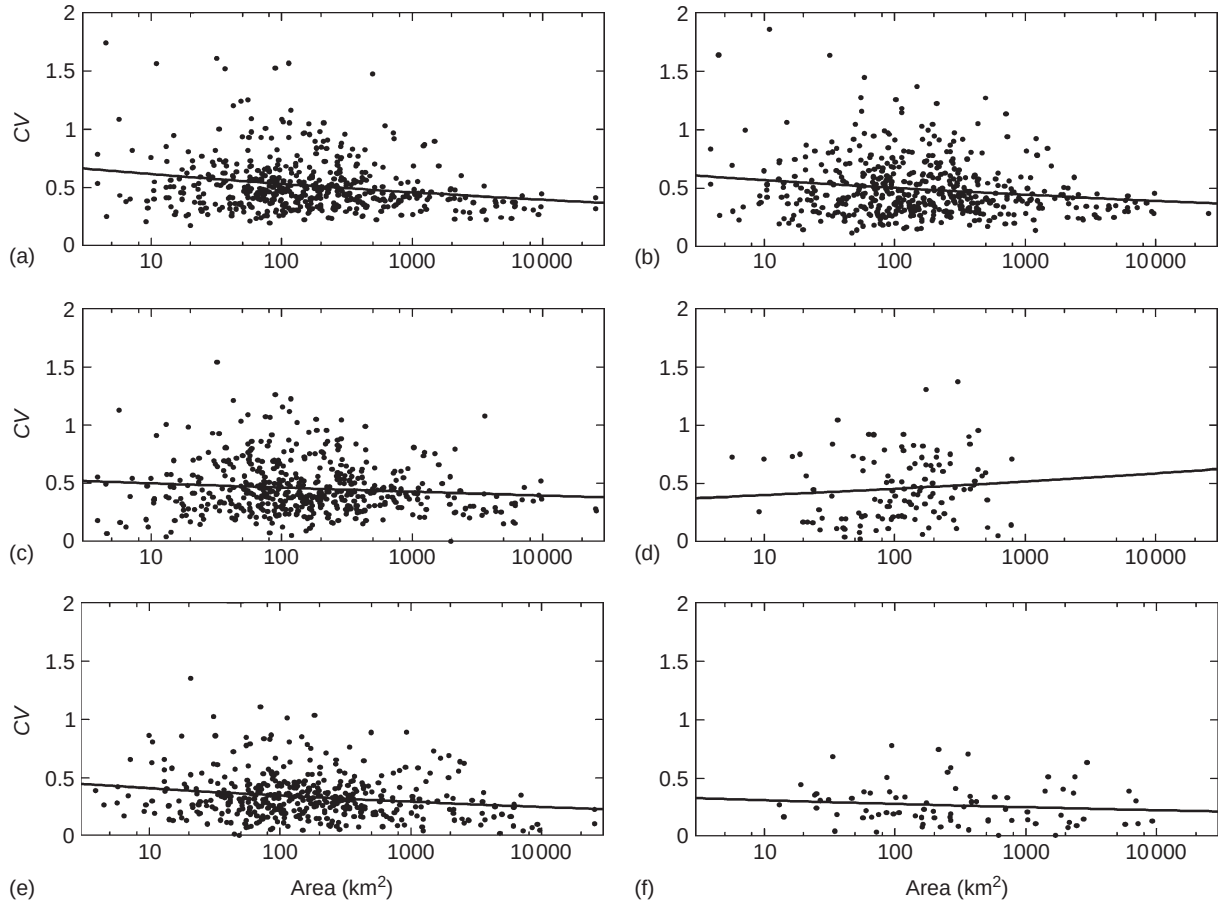

Figure 4 Coefficient of variation of annual floods in Austria stratified by process type and plotted versus catchment area. (a) all flood types; (b) long-rain floods; (c) short-rain floods; (d) flash-floods; (e) rain-on-snow floods; and (f) snow-melt floods. Regression lines are shown. From Merz and Blöschl (2003)

catchment area (Figure 4f) which is consistent with the usually large extent of snow melt. The *CV* of the flash-flood process type, however, tended to increase with catchment area (Figure 4d), which was interpreted as been related to the nonlinearity of runoff generation associated with fast hillslope response.

An extension of the moment-based analyses to higher order moments has been performed by a number of authors (e.g. De Michele and Rosso, 2002). These analyses generally suggest that the flood statistics exhibit fractal or multifractal characteristics depending on how the exponents change with the order of the moment (*see* **Chapter 8, Fractals and Similarity Approaches in Hydrology, Volume 1**). These methods of analysis are similar to those used in rainfall disaggregation based on multiplicative cascades (Section "Temporal disaggregation of rainfall").

Upscaling and Downscaling Soil Moisture

An accurate representation of the spatial variability of near-surface soil moisture is critically important both for representing hydrological fluxes in the subsurface at various scales (Zehe and Blöschl, 2004) and for linking hydrological processes with atmospheric processes (*see* **Chapter 29, Atmospheric Boundary-Layer Climates and Interactions with the Land Surface, Volume 1**; also see Ronda *et al.*, 2002; Montaldo and Albertson, 2003). There are two basic issues of soil moisture upscaling/downscaling in the hydrological sciences. The first is how to best estimate average catchment soil moisture (or spatial distributions) from point soil moisture measured in the field (*see* **Chapter 6, Principles of Hydrological Measurements, Volume 1**), the second is how to best estimate patterns of soil moisture from catchment average soil moisture as simulated by a hydrologic or atmospheric model. The first issue is an upscaling task while the second one is downscaling. In both instances one can use deterministic process-based models which is dealt with in **Chapter 11, Upscaling and Downscaling – Dynamic Models, Volume 1**; **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2**; **Chapter 133, Rainfall-runoff Modeling of Ungauged Catchments, Volume 3**,

and in the literature (e.g. Blöschl and Grayson, 2000; Pitman, 2003). Alternatively, one can use simplified statistical descriptions that aim at representing the most important controls and these will be briefly reviewed here. These methods can either exploit the spatial statistics of soil moisture or make use of auxiliary information in terms of a moisture index (Western *et al.*, 2002, 2003).

1. *Methods based on the spatial statistics*: A number of authors have suggested that the spatial distribution function of soil moisture can be approximated by a normal distribution although the shape of the distribution does change with climate (e.g. Mohanty *et al.*, 2000; Nyberg, 1996). The variance of the spatial distribution of soil moisture, when taking the numerous studies around the world together (Western *et al.*, 2003), tends to depend on mean catchment moisture, indicating a pattern of variance that increases from near zero at wilting point to a peak at moderate moisture levels and then decreases to near zero as the mean moisture approaches saturation. Understanding of the spatial distribution of soil moisture has been used in distribution models to estimate runoff generation and evaporation (Beven, 1995; Wood *et al.*, 1992; Zhao, 1992). It is interesting that the shape of the distribution functions varies widely between models, but the models are similarly successful in predicting catchment runoff.

Studies on the spatial correlation of soil moisture have been summarized by Western *et al.* (2004). Typical correlation lengths vary between 1 m and 600 m and there is a tendency for the correlation lengths to increase with extent and spacing of the data as would be expected given the sampling scale effects illustrated in Figure 2. While some of the small-scale catchment studies suggest that the spatial soil moisture variability is stationary (similar to equation 1), analyses of remotely sensed soil moisture have found a fractal behavior (e.g. Hu *et al.*, 1997). Ground-based point data collected over large areas in the former Soviet Union, Mongolia, China, and the United States suggest that soil moisture variation could be represented as a stationary field with a correlation length of about 400 to 800 km (Entin *et al.*, 2000). Part of the differences in correlation lengths in small-scale and large-scale studies may again be related to sampling effects, although there also appear to exist important changes in the process controls with scale causing such differences. Over short scales, climate may be relatively uniform and the variation may be mainly related to differences in soils and vegetation (Seyfried, 1998), while at larger scales climate may be a dominant source of soil moisture variability. Methods of upscaling and downscaling that are based on the spatial statistics involve a wide spectrum of geostatistical methods to obtain spatial patterns or averages from point data or to obtain spatial patterns from (simulated) catchment average soil moisture (e.g. Deutsch and Journel, 1992). These methods include conditional simulation methods based on the assumption that soil moisture is a Gaussian random field. Geostatistical methods can also be used to derive analytical estimates of how, say, the runoff contributing area in a distributed model will change with grid size (Western and Blöschl, 1999).

2. *Index approach*: In the index approach, spatial organization can be imposed on the soil moisture field that goes beyond the Gaussian random field of the previous method by using landscape characteristics. These characteristics are usually condensed into an index for numerical efficiency guided by the understanding one has about the movement of water in the landscape (Moore *et al.*, 1991). In humid climates, lateral redistribution of moisture by shallow subsurface flow can be an important process and in this case, indices reflecting upslope area, slope, or convergence should be related to the soil moisture. The most commonly used index is the topographic wetness index of Beven and Kirkby (1979) (see also O'Loughlin, 1986) which is defined as

$$w = \ln\left(\frac{a}{\tan(b)}\right) \tag{4}$$

where a is the specific contributing area and b is the surface slope. Terrain data are widely available and there exists sophisticated terrain analysis software (*see* **Chapter 15, Digital Elevation Model Analysis and Geographic Information Systems, Volume 1**; Wilson and Gallant, 2000). Because of this, equation 4 is widely used for upscaling and downscaling soil moisture. The index involves a number of assumptions, some of which have been relaxed recently. Barling *et al.* (1994), for example, relaxed the steady-state assumption and Woods *et al.* (1997) relaxed the assumption of uniform recharge. Western *et al.* (1999) examined the predictive ability of various terrain indices against soil moisture data collected in a small humid catchment in southeastern Australia. The wetness index (equation 4) typically explained 50% of the spatial soil moisture variance during the wet season (Figure 5a) and there were other indices that showed a similar performance such as the tangent curvature of the terrain (Figure 5b). The largest soil moisture values were collected in the gullies that exhibit large specific contributing areas and strongly negative tangent curvature. However, as the catchment dried out, the explanatory power of the indices dropped off rapidly. Western *et al.* (1999) also summarized tests of terrain indices in various climates and noted that their predictive ability varies substantially, depending on whether their main assumptions are satisfied.

All of these indices can be used to estimate a spatial pattern (or a spatial distribution) from average catchment soil moisture (i.e. downscaling) and to estimate a spatial

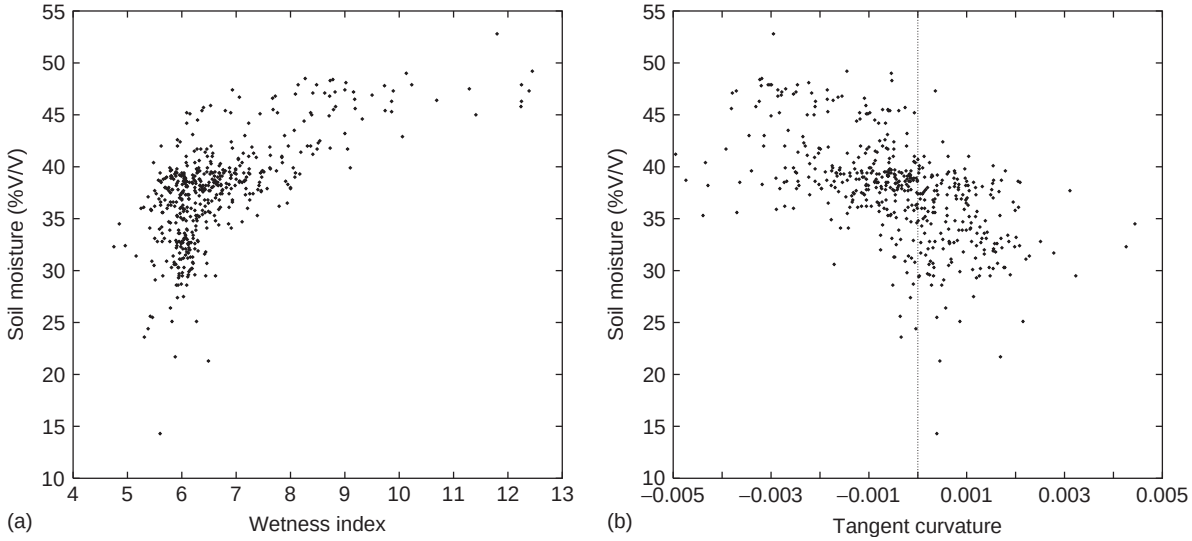

Figure 5 Relationship between volumetric soil moisture in the top 30 cm of the soil profile and wetness index, and tangent curvature for September 27, 1995 in the Tarrawarra catchment, Australia. From Western *et al.* (1999)

pattern from point measurements. In the latter case, similar geostatistical methods can be used as discussed above, but they are extended to accommodate the index as an auxiliary variable. Methods include external drift kriging, cokriging, and georegression (e.g. Grayson and Blöschl, 2000). Examples of applications include those by Viney and Sivapalan (2004) who disaggregated areal average soil moisture into spatial patterns and by Green and Erskine (2004) who compared a geostatistical analysis with linear georegression using terrain indices. In spite of the considerable progress that has been made in the past decades on soil moisture upscaling and downscaling, there is still significant uncertainty involved because of the large natural variability in soil moisture and its controls. If only a few point soil moisture measurements are available in a catchment, the errors associated with upscaling them to catchment averages can be enormous (Grayson *et al.*, 2002). An interesting extension of the index approach has therefore been proposed by Grayson and Western (1998). They suggested that concepts of time stability, applied to catchments with significant relief, could be used to identify certain parts of the landscape that consistently exhibit mean behavior irrespective of the overall wetness. They denoted these areas as *catchment average soil moisture monitoring* (CASMM) sites. This approach promises to assist in the upscaling issue if point measurements of soil moisture can be located in these areas.

Subsurface Media Characterization and Generation

One of the important tasks in subsurface hydrology is to reconstruct the spatial distribution of subsurface characteristics from limited data from boreholes, outcrops, water tables, and perhaps tracer tests. Knowledge on the subsurface characteristics is critical for understanding the movement of contaminants in the subsurface be it through conceptual analyses or through groundwater flow and transport models. Once the type of variability is known, one can derive the aggregated characteristics of the flow system either by analytical methods of stochastic hydrogeology or by performing flow and transport Monte Carlo simulations based on the generated media (*see* **Chapter 147, Characterization of Porous and Fractured Media, Volume 4** and **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**). Methods of characterization and generating subsurface media have been summarized by Koltermann and Gorelick (1996) and Anderson (1997). Findikakis (2002) and Zhang (2002) provide a collection of recent contributions, and Wang (1991) summarizes methods for the case of fractured rocks. Nonfractured sedimentary deposits can be represented by either continuous or discrete methods:

1. *Continuous heterogeneity*
   (a) Gaussian models for representing the spatial variability have been the starting point in stochastic theories of estimating hydraulic conductivity and dispersion coefficients for various supports (Gelhar and Axnes, 1983; Dagan, 1989; **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**). A range of methods are in use to generate media including conditional and unconditional stochastic simulations (Deutsch and Journel, 1992).
   (b) Fractal models: Subsurface heterogeneity may occur at a range of scales for which a fractal representation

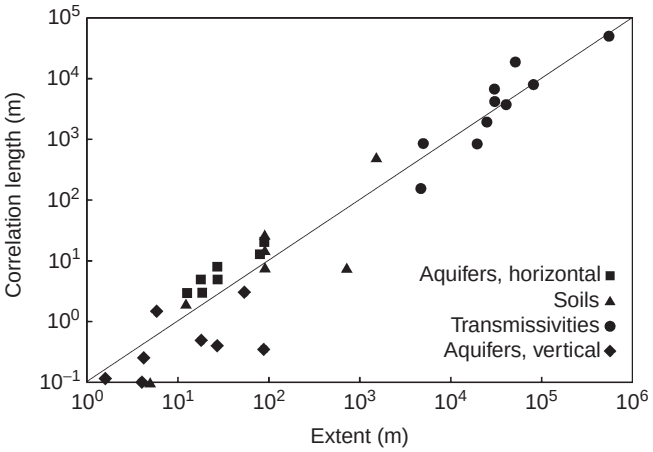

Figure 6 Correlation lengths of natural log hydraulic conductivities and transmissivities at various sites versus extents of the fields. Data from Gelhar (1993, Table 1). Line shows correlation length equal to 10% of the extent

may be more appropriate. Correlation lengths of hydraulic conductivity of aquifers (Figure 6) tend to increase with the extent of the study areas, which has been interpreted in two ways. The first interpretation is the existence of a fractal variogram of the form of equation 2. This type of variability has been used widely for media characterization and generation (Hewett, 1986; Hewett and Deutsch, 1996; Rubin and Bellin, 1998) and for stochastic theories of upscaling (e.g. Neuman, 1990, 1993). However, the conceptual difficulty with this is that geologic features observable in the field do indicate the existence of distinct scales in cores, fluvial deposits, alluvial basins, and in interbasin aquifers (Anderson, 1991). As an alternative interpretation, Gelhar (1993, p. 295) suggested that the variogram may be nested, consisting of a linear combination of variograms of the form of equation 1 with different λ_i which in the limit for many scales may resemble equation 2. It should also be noted that there may exist sampling biases and inference issues (Gallant *et al.*, 1994; Gray, *et al.*, 1993). Indeed, Figure 2 indicates that for a limited number of samples, the correlation length will always be on the order of 10% of the extent of the domain irrespective of the underlying correlation structure.

2. *Discrete heterogeneity in nonfractured sedimentary deposits*

(a) At some scale, geological media are not continuous but exhibit facies transitions and/or geological structures that affect the hydraulic conductivity field. Facies are units of similar characteristics. Geological structures include large-scale features such as faults and finer scale features such as bedding planes (Bierkens and Weerts, 1994). Conceptual models of the shapes and relative relations of the facies in a particular geological setting can be used for both upscaling and downscaling by assigning media characteristics to each of the facies (Anderson, 1997).

(b) Indicator geostatistics have been used to exploit these facies models for generating media characteristics in a consistent way. Indicator variograms are variograms of binary values (1 or 0 depending on whether the variable is above or below a threshold) and so may exhibit different shapes for different magnitudes of the variable of interest. These variograms can then be used for unconditional and conditional simulations as well as for interpolation between borehole data. Desbarats (1987), for example, generated a dual conductivity field of sandstone with small-scale shale features based on the indicator approach. Ritzi *et al.* (2000) compared the indicator approach with other methods of representing facies in a buried-valley aquifer setting.

(c) The spatial connectivity of high conductivity regions, both in soils and in aquifers, can be critically important to flow and solute movement at various scales. While it has been suggested that the indicator approach can also capture connectivity (e.g. Journel and Alabert, 1989; Gómez-Hernández and Wen, 1997), Western *et al.* (1998, 2001) noted that its ability is rather limited and it may be more efficient to use methods that directly capture connectivity such as connectivity functions based on percolation characteristics. Such a connectivity function represents the probability that two points are connected as a function of distance and hence is a reflection of preferential flow paths. Media patterns can then be generated by optimization methods such as simulated annealing where an image is generated iteratively by swapping pixels in a way that a given connectivity function is reproduced (Koltermann and Gorelick, 1996). An alternative to it is the use of Markov chains where transition probabilities between facies sequences are used to generate three-dimensional media with realistic internal architecture (Weissmann *et al.*, 1999). These transition probabilities can be estimated from boreholes and outcrops. Other methods are Boolean methods where objects (such as sand lenses) are randomly placed onto the domain to generate patterns with a given connectivity (Scheibe and Freyberg, 1995; Jussel *et al.*, 1994). The probability distribution of the spacings and sizes of the objects can again be estimated from outcrops. Subsurface media have also been characterized by the multifractal approach (Veneziano and Essiam, 2003), which is able to represent high conductivity features.

(d) Depositional simulation: While the above methods do not explicitly represent the physics that has lead to the subsurface deposits, there are also methods that attempt to mimic the depositional processes (Koltermann and Gorelick, 1996). The model of Tetzlaff and Harbaugh (1989), for example, simulates alluvial fans and deltas using the physical equations of water and sediment movement. This type of model is driven by paleoclimate which, however, may be very difficult to specify in a realistic way. Anderson (1997) also noted that there are difficulties with calibrating this type of model.

3. *Fractured rocks*

(a) Discrete-fracture approach: The most obvious method of generating fractured rock media is to explicitly consider flow through discrete fractures. Fractures provide conduits for the movement of groundwater and contaminants through an otherwise relatively impermeable rock mass. Each fracture in the network is specified by its location, shape, orientation, and hydraulic characteristics. The fractures are often represented by disks (Long *et al.*, 1985). To reduce computation time in solving the groundwater flow and transport equations, the three-dimensional network of disks has been replaced by a network of pipes (Cacas *et al.*, 1990). Of particular interest is the distribution of the connectivity of the fractures for which fractal concepts have been applied (Acuna and Yortsos, 1995; Renshaw, 1999). The media can be used directly to drive simulations models.

(b) Continuum approach: An alternative is the continuum approach where the fracture network is represented as if it were a granular porous medium. Often, multiple interacting continua are used, each of them representing fractures of a certain size class and one of them representing the solid rock mass (Bai *et al.*, 1993). The effective (upscaled) properties can be derived from the characteristics of the fractures (e.g. Bogdanov *et al.*, 2003) or can be found by calibrating a groundwater model.

CONCLUDING REMARKS

Even though the physical mechanisms of the various processes discussed here are clearly different, there exists a remarkable similarity in the statistical upscaling and downscaling methods. Most methods have traditionally started from assuming Gaussian random variability because of mathematical tractability. Here the most important scale effect is the reduction of variance with increasing support scale. Recognizing that hydrological variability can be more complex, the methods have subsequently evolved into more sophisticated ways of representing variability. Fractal representations are appealing because of their parsimony and because of the obvious presence of natural variability at all scales, but there is some controversy about the physical processes causing such type of variability. Multifractals are very attractive and appear to still merit further development in the different branches of hydrology because of their ability to represent singularities – spikes controlling the upscaling and downscaling characteristics – and again the parsimony and hence robustness of parameter estimation. There is also growing awareness that different parts of the subsurface (facies) and different situations (weather types, flood types) operate differently and there are merits of dealing with them separately.

There also seems to exist some convergence of methods in different application areas. In rainfall upscaling and downscaling, for example, the three historic strands – catchment rainfall estimation, temporal disaggregation, and climate model downscaling – seem to converge through the use of stochastic space-time rainfall models, although some of them are still at an early research stage. Similarly, geostatistical models that allow physically realistic structure to be represented – be it in soils or aquifers – seem to converge in the various application areas. Focusing on upscaling and downscaling methods may help cross-fertilize ideas within the hydrological subdisciplines (Blöschl, 2001).

Finally, as noted in the introduction, the focus of this article has been on how statistical upscaling and downscaling methods represent random variability in space and time at various scales. An alternative view is the dynamic upscaling and downscaling approach where the interest resides in how the model equations and model parameters change with scale, which is dealt with in **Chapter 11, Upscaling and Downscaling – Dynamic Models, Volume 1**; **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2**; **Chapter 133, Rainfall-runoff Modeling of Ungauged Catchments, Volume 3**, and **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**.

Acknowledgments

I would like to thank the numerous individuals who have contributed to the organization of the ideas in this article through discussions over the years, including Murugesu Sivapalan, Rodger Grayson, Andrew Western, Ralf Merz, Jon Skøien, Dieter Gutknecht, Erwin Zehe, and Lars Gottschalk. I am also grateful to Marc Bierkens for providing very helpful comments on the manuscript. Funding from the Austrian Academy of Sciences Project HÖ 18 is gratefully acknowledged.

10: Concepts of Hydrologic Modeling

DAN ROSBJERG[1] AND HENRIK MADSEN[2]

[1]*Environment & Resources DTU, Technical University Denmark, Kongens Lyngby, Denmark*
[2]*River & Flood Management, DHI Water & Environment, Hørsholm, Denmark*

Hydrological modeling is introduced as an indispensable tool for testing new hypotheses and obtaining a better understanding of hydrological processes and their interaction. The difficulties in developing generic model tools because of natural heterogeneity and multiscaling are emphasized, and the concept of appropriate modeling is introduced for the application of a parameter parsimonious model that ensures a realistic simulation or prediction including assessment of the uncertainty. In model development, the basic conceptualization of a model is governing the crucial choices of scale, dimension, discretization, and process delimitation. Hydrological models are classified according to their primary application area. In model calibration and validation, the use of split sampling techniques and automatic calibration procedures is underlined. The sources of model uncertainty are presented and different assessment techniques including first-order analysis, Monte Carlo-based methods, the GLUE framework, and Bayesian procedures are briefly introduced along with data assimilation techniques to enhance the predictive capabilities.

INTRODUCTION

Hydrological models for descriptive and predictive purposes have been developed over more than 100 years. Early examples are the rational method for peak flow prediction (Mulvaney, 1850), the diagram for determination of storage requirements (Rippl, 1883) and the unit hydrograph method for transformation of rainfall into runoff (Sherman, 1932). Analytical and simple numerical models were gradually developed, but the emergence of electronic computers changed the situation completely. The development and application of models are now moving ahead at a speed that was unthinkable 50 years ago.

Today, the progress in hydrological sciences is closely connected to modeling. Although experimental hydrology is extremely important, it is in combination with modeling that the real new insight is achieved. Modeling is a framework for testing new theories and hypotheses in order to improve our understanding of the hydrological processes and how the different processes interact.

A model is a simplified description of nature developed or adjusted for a specific goal. Models can be more or less general, but so far no model can be assumed universal. There are many reasons for that. So many processes are involved in the cycling of the water that only the most important ones can be taken into account in the modeling efforts. In a given application, the most important ones will depend on the purpose of the modeling. Here, we shall only emphasize a few basic facts that make hydrological modeling a never-ending story. The hydrological cycle covers an immense range of spatial and temporal scales that make a single model approach impossible. Moreover, at any scale there is a subset of smaller scales such that the heterogeneity of the land surface and the subsurface can never be completely described. Finally, it should be emphasized that many of the physical processes governing the hydrological cycle are far from being completely known.

Thus, we may consider hydrological modeling as an art, in which the artist has to decide on very crucial matters regarding scale, heterogeneity, temporal, and spatial discretization and so on. In some cases, a continuum approach may suffice, while in other situations a very detailed description of the heterogeneity may be needed. Again the purpose of the modeling indirectly gives the answer.

For process understanding, the descriptive abilities of hydrological models are very important. A good fit of a model to measured data, however, may be obtained

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

through an over-parameterization of the different processes involved. Thus, the concept of parameter parsimony in process description is paramount. This is maybe even more important when applying models for predictive purposes. Reliable predictions can only be achieved with models using a set of well-identified parameters that reflect the fundamental governing mechanisms.

We shall end these introductory remarks by introducing the concept of *appropriate modeling*. This means the development or selection of a model with a degree of sophistication that reflects the actual needs for modeling results. It means a parameter parsimonious model with a discretization in space and time that ensures a realistic simulation or prediction of the requested variables. Although distributed physically based models have great advantages, a highly distributed model does not necessarily always ensure the most reliable answer because of the many parameters involved. In some cases, a simple lumped description may do a better job. Conversely, if a detailed picture of state variables in space or time is requested, the distributed models will have their force. For one particular site the simulation may not be very precise but, despite that, the general variation in space and time may appear satisfactory.

MODEL DEVELOPMENT

Basically, any kind of modeling can be looked upon as an input to a system that transforms the input into an output. To exemplify, the well-known unit hydrograph model is a linear transformation of the effective rainfall into runoff.

The system is identical to the mathematical/numerical formulation of the hydrological processes included in the modeling efforts. The modeling system can have a firm physical basis built on theories and physical laws of the various hydrological processes, for example, the Boussinesq equation for groundwater flow or the St. Venant equations for channel flow. Alternatively, one can analyze the input and output data and build empirical models that describe the observed relations using, for example, deterministic artificial neural networks (ANN) or autoregressive-moving average (ARMA) linear stochastic models. Between these two opposite approaches, a broad spectrum of modeling systems can be formulated using different process conceptualizations that have a certain degree of physical content, but need observation data to tune or calibrate the model parameters. Examples of different modeling systems are shown in Figure 1.

Depending on the degree of physical considerations involved in the process description, it has been common to divide models into black box (empirical), grey box (conceptual), and white box (physically based) models. This, however, may not suffice today. A grey box model at one particular scale may tend to become a white box model at another scale and vice versa. A model must be appropriate for its particular use and not chosen because of a black, grey, or white label. Moreover, white box models are in reality an illusion. A purely physically based model does not exist. Simplifications of the physics and lack of complete knowledge about the processes are problems we always have to face.

In the development of a hydrological model, a number of crucial questions have to be addressed. As already emphasized above, the answers to these questions should be governed by the contemplated use of the model. First, which part of the hydrological cycle is incorporated in the model? Second, in what detail should the involved hydrological processes be described? And third, what will be the input or, in other words, the initial and boundary conditions forcing the model?

Hydrology is strongly related to a number of other geoscience disciplines (geology, meteorology, etc.), and there is a multitude of internal relations between the state variables of hydrological processes that can be either included or disregarded by the modeler. We shall mention just a few of the most important aspects to consider in the choice of process description, or, in other words, in the parameterization or conceptualization of the model.

There are fundamental decisions to be taken regarding the temporal as well as the spatial scale in a model. In the temporal regime, the model can be event based (as the unit hydrograph model) or it can be developed for continuous time application. Should the model describe a steady-state situation, or will the variability in time be important? If the time-step chosen is less than a year, the annual cycle must be addressed. The answers to these questions will point to very different conceptualizations.

In the spatial domain, the options are several. The most simple is the lumped description with only one unit to consider. This can be extended gradually from combinations of lumped sub-models to models with 1D, 2D, or 3D grid cells of any size. Some components may have a 1D spacing, while other elements may have 2D or 3D grids. The multitude of choices is obvious already at this stage, as any of the temporal solutions can be combined with any spatial distribution.

Further, complexity will be added depending on which processes are taken into account in the modeling. Should only surface or subsurface processes be included, or should one consider an integrated approach where the different processes are dynamically linked? Is it only the liquid water that is our concern, or are the other phases in the form of snow and ice and water vapor also important to describe? Moreover, do we need to consider the constituents transported by the water, or even to expand basic hydrology into, for example, ecohydrology by including modeling of habitats and so on? For each process component that is included, different model descriptions can be chosen, ranging from complex descriptions that solve the governing

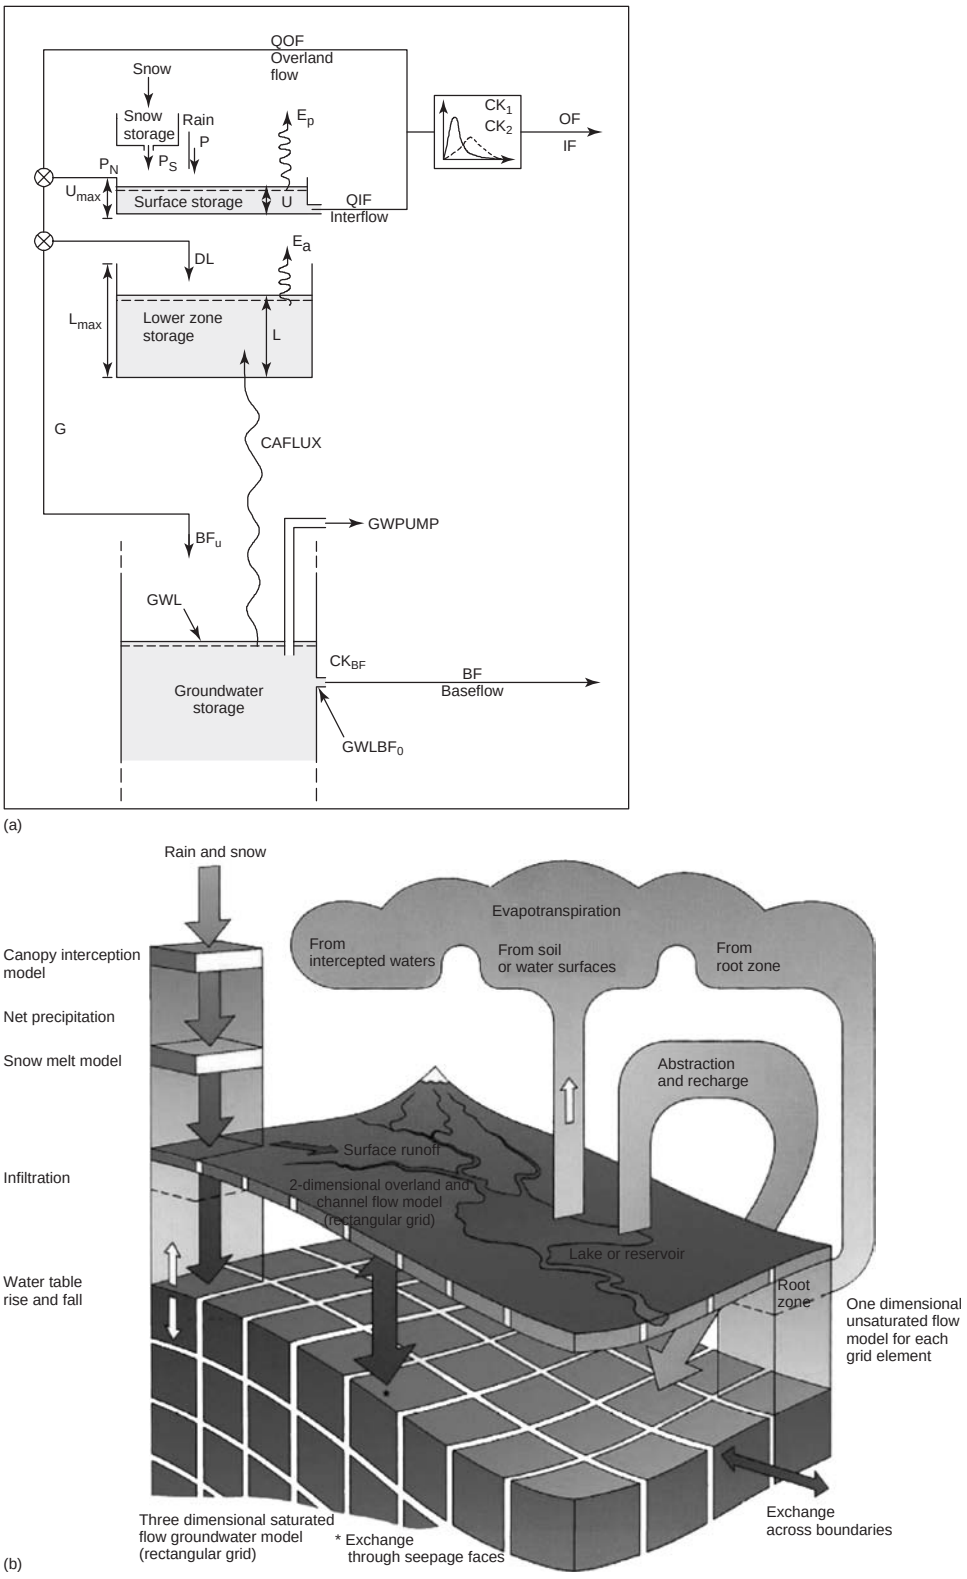

Figure 1 Examples of different hydrological modeling systems. (a) the MIKE 11/NAM lumped, conceptual rainfall-runoff model (Havnø *et al.*, 1995). (b) the MIKE SHE distributed and integrated modeling system (Refsgaard and Storm, 1995). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

partial differential equations to more simple, conceptual box-model descriptions.

In many cases, the forcing of a hydrological model consists of meteorological time series. In river or reservoir studies, it may suffice to use runoff time series as input, and in groundwater modeling the forcing is often dominated by constant head or flux boundaries. The initial values of the state variables are crucial in some model applications, but in other cases the first part of the simulation should be considered a warming-up period ensuring that the state variables gradually attain realistic values.

In the development of a hydrological model, it is very important to be aware of its intended future application. It is of crucial importance to know whether the model will be run with forcing similar to the data used in the development phase, or the model will be forced with input outside this range. In studies of climate change, impact scenarios are developed that deviate substantially from the present-day situation. This put much stronger requirements to the model conceptualization and parameterization. The validation procedure will be much more cumbersome as well, as illustrated in a later section.

MODEL CLASSIFICATION

Many different schemes for classification of hydrological models have been introduced during time. Often models have been classified according to contrasting properties like deterministic versus stochastic, lumped versus distributed, steady state versus time variable and so on; see, for example, the model monographs by Singh (1995) and Abbott and Refsgaard (1996). As shown above, these properties are extremely important to consider in the model development phase, but we prefer to classify the final products, the models, according to their primary application area. In the following, a set of model classes will be presented along with a brief description of the main features of each class.

River and Reservoir Models River models can be simple routing models like the Muskingum model, used in the HEC-1 Flood Hydrograph Package (Feldman, 1995), but also advanced hydrodynamic models that solve the full St. Venant equations, for example, the MIKE 11 model (Havnø *et al.*, 1995). They are well suited for calculation of flood wave propagation and the impact of structures in rivers. They can be expanded to interact with the flood plain and amended with modules for sediment transport and river morphology as well as advection–dispersion processes and water quality indicators. In recent years, wetland and habitat models are being developed, reflecting the growing interest in combining hydrological and ecological expertise. Reservoir models for design are simple continuity models, which, however, make use of advanced methods for generation of synthetic inflow series. River models in forecast mode are used on-line for managing flood waves and as a basis for issuing emergency warnings.

Rainfall-runoff Models, or in a wider sense *catchment* or *watershed models*, can be unit hydrograph models or simple lumped conceptual models like the Sacramento model (Burnash *et al.*, 1973; Burnash, 1995), the HBV model (Bergström and Forsman, 1973; Bergström, 1995) and the NAM model (Nielsen and Hansen, 1973; Havnø *et al.*, 1995). On the basis of meteorological data, the temporal variation of runoff at the outlet of a catchment can be calculated with a quite good precision, given a well-calibrated model. With a much higher degree of spatial resolution, the so-called *distributed models* have the advantage of being able to take into account the variation of several state variables at a number of locations distributed in the catchment. The data requirements, however, grow rapidly with increasing spatial resolution. In order to manage the data efficiently, the use of GIS-based methods is now becoming standard. Well-known examples of distributed catchment models are the TOPMODEL (Beven *et al.*, 1995; Beven, 1997), the MIKE SHE model (Refsgaard and Storm, 1995) and the SWAT model (Arnold *et al.*, 1998). These models take into account the complete land phase of the hydrological cycle, but use quite different approaches. While the TOPMODEL puts emphasis on a detailed topographical description, the MIKE SHE uses an integrated approach where emphasis can be put on different processes, including for instance a full 3D groundwater component, a 2D diffusive wave approximation for the overland flow, and a 1D full dynamic component for the flow in the river system. Depending on the actual use of the various models, these differences can become more or less pronounced. Catchment models can be combined with river models and expanded to include a number of transported constituents. Soil erosion processes can be included as well. As an example, SHETRAN (Bathurst, 2002) has been used for sediment transport and sediment yield modeling. Recently, some catchment models are being further developed for coupling with atmospheric models. This requires a joint description of both water and energy fluxes as done in the so-called *land-surface schemes*, which for long time has been used in general and regional circulation models. The increasing resolution of the atmospheric models now makes it possible to use an advanced hydrological model in the coupling.

Groundwater models are confined to the subsurface part of the hydrological cycle. There are several model systems available, and among them many are built on the well-known MODFLOW concept (e.g. Anderson and Woessner, 1992). When abstraction of groundwater is of primary interest, a steady-state groundwater model is usually applied. In the analysis of pollution plume movement in combination with different degrees of remediation action, a steady-state

groundwater model is usually supplemented with a transient advection–dispersion module, and in many cases also with modules for geochemistry and biochemical degradation. Groundwater models that take into account reactive transport are now becoming standard tools (Kinzelbach and Schäfer, 1994). Also, models with transient flow descriptions are now more and more frequently used, often in a combined modeling of the unsaturated and the saturated zone. In groundwater modeling, the main problem is the description of the heterogeneity in the soil and the aquifers. A complete knowledge can never be obtained, and the optimal use of the available pedological and geological information is therefore paramount. To this effect, geostatistically based methods are often included in the models (e.g. de Marsily, 1986).

Design and Management Models In the assessment of hydrological design values, frequency models have traditionally been used for return periods up to 500–1000 years. With the development of advanced statistical tools it has now become standard not just to calculate the T-year event estimate, but also to assess the uncertainty of the estimate (e.g. Cunnane, 1987; Stedinger *et al.*, 1993; Rosbjerg and Madsen, 1998). By including regional information, design at ungauged sites can be accomplished, and the precision can be improved at sites with short data records (e.g. Hosking and Wallis, 1997; Madsen and Rosbjerg, 1997a,b). Design for very rare events requires comprehensive modeling tools that combine meteorological and hydrological assessments. How to do this, and how to avoid both under- and over-design, are still unsolved questions in hydrology. In the management of the water resources, dedicated water allocation models in a GIS framework have shown their strength, especially when supplemented with water quality modules. The use of systems analysis has a long tradition in hydrology. The new generation of powerful computers has ensured a much wider application of these tools. Decision support and expert systems, in many cases combined with optimization routines, which a few years ago was impossible to apply within a reasonable time frame, are now coming into practice. Sustainable water resources management is a primary objective in policy development and in the implementation of water action plans (e.g. Loucks, 2001). This has brought rural and urban hydrology closer together and has led to hydrological management models that link up to, or even integrate socioeconomic models.

Emerging Models Although still valid, the above classification of hydrological models may become less obvious in the future. A new generation of hydrological models are being developed, where a specific model is being created for each specific purpose, that is, flexible and tailor-made models can be assembled without the huge efforts necessary so far. For the different hydrological processes to be included in the analysis, a number of different model options will be available in order to ensure an optimal combination given the actual application. Eventually, this may help in achieving the ultimate goal of appropriate modeling.

MODEL CALIBRATION AND VALIDATION

In the section on model development, the first steps leading to model application were delineated. First, the model frame must be conceptualized and parameterized, and second the involved hydrological processes must be given an appropriate mathematical/numerical formulation corresponding to the chosen temporal and spatial discretization. The outcome of these efforts is a model code that should be verified to the extent possible. In cases where analytical solutions exist, the complete code, or subsets of it, should be able to reproduce the analytical results with a reasonable accuracy. This code verification should not be mixed up with the model validation described below.

In a given model application, the actual value of the model parameters are generally unknown, or only known to be within a certain range of realistic values. Thus, there is a need for calibration of the model, that is, a procedure leading to adoption of an acceptable set of model parameters. Usually the available data are split into two subsets, such that one of the subsets can be used for calibration and the other for a subsequent validation. This highly recommendable split-sample technique should always be used, if the amount of data allows it. Following the split-sample validation, a final calibration using all available data should be accomplished.

In the calibration process, the parameters are varied such that certain chosen norms for correspondence between the simulated and measured outcome are fulfilled to the extent possible. This can be a simple visual judgment of the goodness of fit, but often some mathematical measures are used, for example, the correlation coefficient, the mean square error, or the Nash–Sutcliffe model efficiency (Nash and Sutcliffe, 1970). By changing the parameters iteratively, the calibration result is approached.

Until recently, the dominating calibration procedure was "trial and error". After each model run, the modeler changes the parameter values in order to get a better fit. For an experienced modeler, it is usually possible to obtain a good calibration result without too much effort, but for less experienced hydrologists it can be a very time-consuming method. Now automated procedures for determination of optimized parameter values are getting strong attention. Here the parameter set, or a subset of parameters that minimizes one or more mathematically formulated objective functions is selected as the calibration result.

While gradient search and other local search techniques often work quite well in groundwater modeling (e.g. Carrera, 1988), they usually fail when applied to catchment models. However, new global search techniques based on population-evolution algorithms have been developed and

shown to have a good performance in cases where the local search breaks down (e.g. Duan *et al.*, 1992; Vrugt *et al.*, 2003). Automated calibration has a number of advantages. First of all, automatic calibration allows a fast and objective calibration. In addition, it clearly shows if there is a problem with the identifiability of a model parameter, and it gives an assessment of the accuracy by which a parameter is estimated. The main disadvantage is related to the definition of an appropriate objective function that takes into account all the characteristics of the modeled system that are used by the hydrologist for evaluating the goodness of fit. The recent advancement of multiobjective calibration, where several objective functions can be optimized simultaneously (e.g. Gupta *et al.*, 1998; Madsen, 2000), allows the hydrologist to formulate specific objectives to be optimized depending on the model application being considered. State-of-the-art automatic calibration procedures perform favorably compared to expert manual calibrations (Gupta *et al.*, 1998; Madsen *et al.*, 2002; Madsen, 2003).

In order to test the generality of the hydrological model, and to assess if the estimated parameter values in fact are generic values, the calibrated model should be run with an independent set of data. If the correspondence between the simulated and measured outcome is acceptable in comparison to the result obtained during the calibration period, the model is said to be validated. In the strict sense, it can be questioned whether a model can be validated at all. What is achieved is only that based on the given level of information on which the model performs satisfactorily, and for that reason it should not be rejected. Thus, if more information becomes available, it may then lead to rejection of the model, or, more likely, to restriction of the range within which the model should be applied.

Depending on the anticipated use of a model, the validation criteria should be more or less demanding. Obviously, if a model is calibrated for humid conditions and is to be applied for arid conditions, it must be validated on such a data set. A comprehensive set of validation schemes has been developed by Klemes (1986) and applied in a systematic way by Refsgaard and Knudsen (1996).

MODEL UNCERTAINTIES

Uncertainty is an unavoidable and inherent element in hydrological modeling. The main uncertainty sources are related to (i) errors in the model forcing, (ii) use of an incomplete model structure, (iii) use of nonoptimal model parameters, and (iv) errors in the measurements used for the model calibration. It is now generally accepted that these uncertainties and their effect on the model predictions should be quantified as part of a hydrological modeling exercise. A reliable estimate of the prediction uncertainty is crucial for making efficient decisions on the basis of model simulations.

How to include and combine appropriately all the different error sources in hydrological modeling is a very complex and yet unsolved problem. Ideally, the joint probability distribution of all the important sources should be quantified and used as input to the model to derive probability distributions of the model predictions. However, quantification of the probability distributions for the different error sources is a difficult task, and hence simplifications are needed.

The classical statistical approach for evaluating model prediction uncertainty is a first-order analysis where the covariance of the model input (forcing and/or model parameters) are propagated through the model using a first-order Taylor series approximation of the model operator. For assessing parametric uncertainty, the covariance is usually estimated using a multinormal approximation of the probability density function of the model around the estimated optimum based on a gradient-based search.

While the first-order approach is an efficient solution to quasi-linear models, the method fails when applied to highly nonlinear models. In such cases, Monte Carlo-based procedures have been put forward. In these methods, the statistical properties of the model input are represented by an ensemble estimate, and this ensemble is then propagated through the model to produce an ensemble of model outputs from which confidence limits on the model predictions can be derived. The main shortcoming of the Monte Carlo approach is the slow convergence of the ensemble to the true probability distribution (proportional to the inverse of the ensemble size), and hence the method has huge computer processing (CPU) requirements. Alternative sampling strategies have been proposed such as Latin Hypercube Sampling, which allows a more efficient sampling in the model input space.

Another shortcoming of the Monte Carlo-based procedure is the explicit use of a joint probability distribution for the model input. Other sampling procedures have been proposed that are conditioned on the observations of the modeled system for evaluating the model prediction uncertainties. These methods include importance sampling such as the generalized likelihood uncertainty estimation (GLUE) procedure (Beven and Binley, 1992) and Markov Chain Monte Carlo sampling (e.g. Kuczera and Parent, 1998; Vrugt *et al.*, 2003).

The GLUE framework addresses the problem of nonuniqueness in model calibration. That is, many different parameter combinations are equally acceptable in reproducing the observed system behavior, and these parameter sets may often come from very different regions in the parameter space. Beven and Binley (1992) refer to this situation as model equifinality. In such cases, the multinormal approximation of the model parameters around an estimated optimum is inadequate to represent the parameter uncertainty.

Most of the model calibration and uncertainty propagation procedures implicitly assume a correct model structure, and only parameters within that structure are allowed to vary. When significant model structural errors are present, such procedures will provide biased model parameter estimates and unreliable uncertainty predictions. Model structural errors may be qualitatively addressed within a multiobjective calibration framework. The tradeoff between different objective functions of the Pareto optimal solutions will provide an indication of possible model errors (Gupta *et al.*, 1998). Quantification of these errors is much more complicated, since model structural errors are difficult to isolate from the errors originating from parameter uncertainty. Bayesian statistical inference methods have been proposed to consider jointly the different error sources in a simplified functional form (e.g. Kennedy and O'Hagan, 2001). For groundwater flow and transport modeling, Neuman (2003) proposed a Bayesian model averaging procedure to combine the predictions of several alternative conceptual hydrogeological models and to assess their joint probability. The GLUE method and Markov Chain Monte Carlo sampling offer another framework to address jointly different error sources, but so far have considered mainly parameter uncertainty. Butts *et al.* (2004) proposed a general modeling framework for considering different model structures to address the effect on model predictions and compared with the prediction uncertainties from other error sources. They showed that model structure uncertainty is at least as large as uncertainties caused by errors in model parameters, model forcing, and observations.

As an alternative to error propagation using the deterministic model equations, the governing differential equations can be treated as stochastic differential equations and error propagation can be analyzed by means of perturbation theory. This approach has been particularly addressed in groundwater flow and transport modeling. Under certain simplifying assumptions, analytical solutions for the prediction uncertainties can be developed (Dagan, 1989; Gelhar, 1993). For transient phenomena, Dagan (1989) has calculated approximate moments in the time domain, while (Gelhar, 1993) has focused on the asymptotic behavior using spectral theory.

Although discrepancies between model results and measured values may be minimized in the calibration process, the predictive capabilities of the hydrological model may be significantly improved by adaptively updating the model when new data become available. This is particularly important in real-time applications, where measurements are used for updating the model prior to the time of forecast and for correcting model predictions in the forecast period. Model updating or, in more general terms, data assimilation can be classified according to the variables that are modified in the data assimilation feedback process, that is, input variables (model forcing), model states, model parameters, and output variables (WMO, 1992). Updating of output variables, also known as *error correction*, is the most widely used procedure in operational hydrological forecasting (WMO, 1992; Refsgaard, 1997; Toth *et al.*, 1999). Recent methodological advances of data assimilation in meteorology and oceanography, and the advent of new data sources from remote sensing instruments has put more focus on the use of data assimilation in hydrological modeling (McLaughlin, 2002).

CONCLUDING REMARKS

Hydrological models are being developed for application at widely different temporal and spatial scales. A basic request is that the models efficiently address the dominant hydrological processes at the chosen scales such that sufficient descriptive and predictive abilities are preserved. This requires parameter parsimonious models and appropriate procedures for model calibration. Moreover the model must pass a validation test, if the results should be considered reliable. Finally, an up-to-date modeling effort necessitates an assessment of the uncertainty range for the output variables.

This can be summarized in the request for *appropriate modeling*, where the actual purpose of the modeling is governing the choice of scales, the sophistication level in process description and parameterization, the calibration and validation procedures, and the uncertainty assessment.

Model development will continue, and still more comprehensive models will emerge taking into account, for example, multiscale heterogeneities including methods for assessing the effects of sub-grid heterogeneity and water quality including chemical and biological processes. The predictive abilities of the models will become a keypoint with strong requests for reliable predictions even in a changed climate. This puts high demands on hydrological modelers and sets the scene for a challenging future development of hydrological models.

11: Upscaling and Downscaling – Dynamic Models

MARK WIGMOSTA AND RAJIV PRASAD

Environmental Technology Division, Pacific Northwest National Laboratory, Richland, WA, US

Transferring information from one spatial or temporal scale to another (scaling) presents one of the most daunting scientific challenges in hydrology. This is particularly true in hydrological modeling where disparities in scale exist in nearly every phase of model development and application. This article discusses scales, hydrological processes, heterogeneity, upscaling, and downscaling as applied to dynamic hydrological modeling. It is not meant to be an exhaustive discussion covering the entire range of scale issues in hydrology, or of hydrological modeling, rather it attempts to summarize the relevant issues and illustrate some approaches using specific examples to address upscaling and downscaling in hydrological model development and application.

INTRODUCTION

Transferring information from one spatial or temporal scale to another (scaling) presents one of the most daunting scientific challenges in hydrology. This is particularly true in hydrological modeling where disparities in scale exist in nearly every phase of model development and application. Models are typically developed for a specific temporal (subdaily, daily, storm event, monthly, etc.) and spatial (point, laboratory, hillslope, basin, etc.) scale, while they are often calibrated and applied at larger or smaller scales. Observations used to drive a model, such as precipitation, may be collected at a small scale, and then distributed at a larger scale for model input. A watershed model may be run at a smaller scale (e.g. DEM grid or hillslope) and validated against discharge at the basin scale. Conversely, a groundwater model may be run at a larger scale and validated against small-scale borehole measurements.

The dominant hydrological processes may also vary with scale. At the laboratory scale, the flow through pores of the soil matrix may be the dominant mode of water transport. At the hillslope scale, macropores associated with cracks or root holes may transport the bulk of the flow. However, soil moisture and precipitation intensity must be great enough to allow the macropore network to become connected. Under these circumstances, upscaling a model formulated at the laboratory scale to the hillslope scale would require a different mathematical representation of subsurface flow. Such a formulation should also account for the influence of soil moisture and precipitation intensity on the effectiveness of the macropore network. Under the above circumstances, the original model, however, cannot actually be scaled up or simply extrapolated, but must be reformulated to include previously neglected processes.

Hydrological processes are normally represented in a model using mathematical equations composed of state variables (e.g. soil moisture) and parameters such as the soil-saturated hydraulic conductivity. The model is driven using observed or estimated input variables, localized (made appropriately suitable for application at a specific site) using estimated or calibrated parameters, and produces outputs that may be validated with observations. The large natural heterogeneity in catchment features and spatial/temporal variability in hydrological processes may require changes in model parameters, state variables, and even the fundamental equations when a model developed for one scale is upscaled to a larger scale or downscaled to a smaller scale.

Scaling is defined as a procedure that transfers information and implementations from one scale to another. Upscaling is defined as the procedure that transfers information and implementations from a small scale (higher resolution) to a larger scale (lower resolution). Downscaling is

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

the opposite, and transfers information and implementations from a large scale to a smaller scale. This definition of scaling is broader than that usually applied to the aggregation and disaggregation of model outputs. As defined here, scaling also has implications for model formulations, since data as well as process descriptions undergo a scale change simultaneously.

Scale can refer to the *extent* of the modeling domain: for example, with respect to space, a field plot, a small zero-order subbasin, a large river basin, and so on, and with respect to time, the total period of concern, seconds, days, years, or decades. Scale can also refer to *resolution* (e.g. a 30-m digital elevation model, a hydrography coverage mapped at 1 : 24 000 scale, etc.). A finite element of space and a finite duration of time are always implicitly involved in descriptions of all observations, hydrological processes, and model implementations, whether acknowledged explicitly or not. All hydrological observations require a control volume (for variables that refer to a three-dimensional piece of space, for example, soil moisture content), a control area (for variables that refer to a two-dimensional piece of area, e.g. leaf area), or a control length (for variables that refer to a one-dimensional curvilinear piece, e.g. fetch length) and are made over a sampling time period (e.g. hourly precipitation, daily pan evaporation, monthly discharge, annual change in reservoir storage, etc.). In this context, scale can also refer to *support*. It is the largest volume, area, length, or time interval for which the property is considered homogeneous within the interval. Thus, when applied to any aspect of hydrological modeling, scale can refer to extent, resolution, or support of observations, of processes, or of model implementations (Blöschl, 1996).

This article discusses upscaling and downscaling as it applies to physically based hydrological modeling. It is not meant to be an exhaustive discussion covering the entire range of scale issues in hydrology (*see* **Chapter 3, Hydrologic Concepts of Variability and Scale, Volume 1** for more detail), or hydrological modeling (*see* **Chapter 10, Concepts of Hydrologic Modeling, Volume 1**), rather it attempts to summarize the relevant issues and illustrate some approaches used to address upscaling and downscaling in model development and application. This discussion draws heavily from the work of Bierkens *et al.* (2000), Blöschl (1996), Blöschl and Sivapalan (1995), and Grayson and Blöschl (2000). The first section discusses scales, hydrological processes, and heterogeneity in the context of model development and application. The second gives an overview of hydrological models and defines some basic terminology required for following discussions on upscaling and downscaling. Upscaling and downscaling are discussed next. The article concludes with a discussion of scaling issues and possible future directions.

SCALES AND PROCESS REPRESENTATION

Natural catchments typically exhibit a great degree of heterogeneity in physical features such as topography, soil characteristics, geology, and vegetation. Likewise, precipitation may also exhibit great spatial and temporal variability. Often, relatively small-scale heterogeneities are responsible for the most dramatic hydrological response. For example, in many locations the average soil permeability exceeds the average storm rainfall intensity. It is those locations with lower than average infiltration capacities that generate overland flow during peak rainfall. At the same time, the bulk of the soil erosion associated with this runoff may be transported in rills that occupy a small fraction of the surface area. Thus, the averaging associated with moving the model to a larger spatial/temporal scale may cause the model to ignore this runoff mechanism unless model input (spatial/temporal distribution of precipitation), soil parameters, and state variables (e.g. soil moisture) are developed to "capture" the influence of the (now) smaller-scale variability.

Hydrological processes occur over a wide range of spatial and temporal scales from the relatively small-scale process of infiltration to large-scale groundwater movement. Runoff generated from infiltration excess operates on short spatial (point) and temporal scales, beginning in portions of the catchment where the rainfall intensity exceeds the local infiltration capacity. Saturation excess runoff and return flow operate at the hillslope scale and longer temporal scales associated with the time required for a perched water table to develop and intersect the ground surface (Blöschl and Sivapalan, 1995). Regional groundwater flow has large spatial scales and temporal scales from a few months to hundreds of years. It has been noted that small temporal scales are typically associated with small spatial scales and vice versa (e.g. Blöschl and Sivapalan, 1995).

At the small to medium size catchment scale (tens to hundreds of km^2), hillslope processes dominate the timing and magnitude of the runoff hydrograph in most watersheds. At this spatial scale, the residence time for water in the channel system is small compared to the surrounding hillslopes and, in most cases, the channel network plays a minor role in the hydrological response of the watershed. At larger spatial scales, the residence time in the channel system is greater and there is a stronger influence of the channel networks on the timing and shape of the outflow hydrograph. Although hillslope processes still determine the volume of water input to the channel system, the spatial distribution of hillslope runoff production becomes less important. Therefore, at the larger scale, the importance of hydrological processes begins to shift from the hillslope to the channel network.

HYDROLOGICAL MODELS

Hydrological models are always implemented at specific spatial and temporal scales, whether explicitly stated as so or not (Beven and Binley, 1992). A hydrological model is driven using observed (sometimes also estimated or synthesized) data (the input variables), it keeps track of state variables, is localized (made appropriately suitable for application at a specific site) using a set of estimated or calibrated parameters, and produces outputs that are validated using observations of one or more state variables. The spatial and temporal scales of all inputs, state variables, and parameters must match. For example, an hourly time step, regular grid-based hydrological model must be inputted using hourly observations at the grid scale. The model implementation usually ensures that state variables are tracked and output is generated at the modeling scale. The process descriptions must also be developed (and their corresponding parameters estimated) at the modeling scale. Spatial and temporal modeling scales are readily obvious in model implementations, usually called *spatial and temporal resolutions of the model* (modeling element size used to discretize the modeling domain and the time step used for solution of model equations).

Input variables and output variables can change in space and in time. The state variables are related to the input and output variables through the model parameters. Model parameters (e.g. saturated hydraulic conductivity) represent the intrinsic properties of the model. They may vary in space and most typically are constant in time, although some models may use parameters that also vary with time, such as temporal changes in Leaf Area Index to represent seasonal changes in deciduous canopy cover. The values of parameters can also change with scale as they connect variables that may change in space and in time (Bierkens *et al.*, 2000). Constants (e.g. acceleration due to gravity) do not change in time or in space. The form of the model, expressed in terms of its process representation (i.e. descriptive equations) may need to be changed with scale. For example, a Darcy's Law–based approximation of soil matrix flow may be adequate to represent saturated flow at the laboratory scale, but may be insufficient to account for preferential flow paths at the hillslope scale.

Models may also be classified by how they represent spatial heterogeneities in model input variables, parameters, and state variables. Lumped models typically treat the entire system (e.g. a hillslope) as a single unit, either effectively ignoring spatial variability or tying to incorporate the effect of spatial variability into lumped parameters, while distributed models attempt to explicitly account for spatial variability at a given scale by subdividing the landscape into a number of model elements at that scale. Physically based models employing distributed parameters for describing system variability are the most challenging to scale.

Empirical models, such as the Rational Method simply define an input–output relationship with limited or no attempt to describe the physical behavior of the underlying hydrological processes. Conceptual models (e.g. Hydrologic Simulation Program Fortran, USEPA, 1984) represent (or conceptualize) basic hydrological processes using simplified algorithms with parameters and state variables that may not have a physical basis. Physically based models (e.g. SHE, Abbott *et al.*, 1986a,b) attempt to represent the basic biophysical processes of the modeled system using parameters with physical analogs that can be measured.

Each type of model introduces a somewhat distinct problem with respect to scaling. Empirical models should not be scaled beyond the original range of development, conceptual models may introduce more or fewer phenomena as scale is changed, and physical models have to confront the problem of variability as the resolution changes. It is generally easier, in the third type, to go upward by averaging or aggregating outputs obtained at finer resolution, but very difficult – perhaps impossible – to project down from a coarse rendition (e.g. estimation of local or watershed-scale precipitation from global precipitation predictions obtained by atmospheric models). The problem is one of recovering details that were not present at the original scale. Physical models are usually formulated with the presumption that all relevant processes are included, or at least the neglected processes are appreciated.

Physically based modeling involves the consideration of definite mass and flux balance equations relating specific physical processes believed to describe the system of interest at a particular scale. Mathematical scaling is required to extrapolate hydrological balance equations. Note that statistical scaling, however, involves the search for probabilistic invariance of a system's description and is applicable to a description in terms of statistics of random components comprising the representation. This subject is discussed in **Chapter 9, Statistical Upscaling and Downscaling in Hydrology, Volume 1**, and is not addressed here, except to recognize that the variable quantities defining some needed model parameters may naturally or expediently be described as random (in space or in time).

Physically based models imply a certain deterministic interrelationship of component physical processes; however, their variables or parameters may often be conveniently viewed as randomly distributed or variable in a certain sense. Thus, in performing scaling it is helpful to employ mathematical tools that can be of utility in quantifying the variability of parameters. A reader will find that certain mathematical theories or methods have come to be associated with the scaling problem: probability theory and certain basic geostatistical methods, fractals, fuzzy sets, genetic algorithms, chaos theory, and others. Moreover, sometimes, analog models of mathematical structure can be substituted for the actual systems because they

have well-characterized mathematical attributes that can be studied instead of working directly with an incompletely known actual hydrological system. For instance, tree models of stream–river networks connected with their drainage basins are studied mathematically to understand the origins of similarity and scaling properties, or the invariances that are discovered in the measurements of the system response to inputs.

When process equations of the model remain nearly invariant under downscaling or upscaling of its variables, the model can be said to be scalable. Even if the form of model equations remains the same under scaling, the parameters that describe the basic process interactions may, and likely will, require reevaluation to encompass the influences of spatial or temporal variability encountered at the extrapolated scale. Scaling techniques must be used to properly account for the variability that was not originally incorporated in the model's conceptualization. This article discusses some of those mathematical techniques.

UPSCALING

Depending on the application and the model involved, there are four general methods that are typically employed for upscaling:

- *Averaging of input or output* data if the model is linear, or if it is viewed as amenable to a direct averaging procedure applied over many locations or time steps.
- *Effective parameters* if the model has the same form when extrapolated to another scale, using either deterministic or stochastic parameter values.
- *Average model equations* if the larger-scale model can be analytically derived from the smaller-scale model.
- *Fully Distributed Numerical Modeling* if no other appropriate upscaling techniques yield sufficiently resolved predictions or if detailed spatial information (input and parameters) is required to achieve the modeling objectives.

These approaches are discussed in more detail below.

Averaging Input or Output

Simple averaging of input or output provides a viable technique for upscaling under a limited set of conditions. It may be used to upscale linear models such as the Rational Method to estimate steady-state peak discharge from a homogeneous surface under constant rainfall and infiltration:

$$Q = CAP \tag{1}$$

where Q is the peak discharge ($m^3\ s^{-1}$), C is a runoff coefficient, A is the area (m^2), and P is the constant rate of precipitation ($m\,s^{-1}$). For example, consider discharge Q_2 from support A_2 composed of n smaller support areas (tributaries), A_i. The discharge can be obtained either by summing the output of n applications of equation (1):

$$Q_2 = \sum_{i=1}^{n} C_i A_i P_i, \tag{2}$$

or through the use of an average runoff coefficient

$$C_2 = \sum_{i=1}^{n} C_i Ar_i Pr_i \tag{3}$$

in equation (1), where Ar_i is the ratio of subarea i to the total area and Pr_i is the ratio of precipitation on subarea i to precipitation on A_2 (equals 1.0 for uniform precipitation over A_2). If the model is nonlinear, but can be applied independently at many locations and/or time steps, the model is run at the smaller scale and the output at the larger scale is obtained by averaging (or summing) the outputs from the smaller scale.

Effective Parameters

Most hydrological models, in particular those that are physically based, are too complex and nonlinear to allow simple averaging of the parameters as a means for upscaling. However, if the equations used to describe processes at the smaller scale remain valid at the larger scale, it may be possible to upscale the model using effective parameters. An effective parameter is used to capture the influence of smaller-scale heterogeneity at the larger scale. They are single values that reproduce the bulk behavior of a finite area or volume (Grayson and Blöschl, 2000). If the small-scale variation is known completely, deterministic methods may yield effective values. Typically, information about the parameter is only known at a limited number of locations (or times) and some function must be assumed that describes the spatial or temporal variation of the property at the smaller scale within the larger scale. This function can be either deterministic or stochastic.

Bierkens *et al.* (2000) illustrate the general approach and limitations associated with estimating effective parameters, in this case finding the representative conductivity for blocks in a numerical model of groundwater flow. The intent is to upscale fine resolution (small support) conductivity to the larger model blocks to decrease run time. Darcy's law is used to describe groundwater flow as:

$$q(x) = -k(x)\nabla h(x) \tag{4}$$

where x is the spatial coordinate, q is the groundwater flux vector, h is the hydraulic head, ∇h is the hydraulic

head gradient vector, and k is a tensor containing the fine scale hydraulic conductivities (in the different directions). Let $\overline{k(x)}$, $\overline{\nabla h(x)}$, and $\overline{q(x)}$ denote the average conductivity, average hydraulic head gradient vector, and average groundwater flux vector, within a larger-scale block respectively. The values of each of these variables within the block can be written as an average plus a deviation from the average: $k(x) = \overline{k(x)} + k'(x)$, $\nabla h(x) = \overline{\nabla h(x)} + \nabla h'(x)$, and $q(x) = \overline{q(x)} + q'(x)$, where the average of each deviation term is zero (e.g. $\overline{k'(x)} = 0$). Substituting these representations into Darcy's Law yields:

$$\overline{q(x)} + q'(x) = -(\overline{k(x)} + k'(x))(\overline{\nabla h(x)} + \nabla h'(x)) \quad (5)$$

The block average flux is obtained from equation (5) by taking the average of both sides (and noting the average of the deviation terms is zero):

$$\overline{q(x)} = -(\overline{k(x)}\ \overline{\nabla h(x)}) - \overline{k'(x)\nabla h'(x)} \quad (6)$$

Looking for a representative parameter with $\overline{q(x)} = K_e\overline{\nabla h(x)}$ implies from equation (6) that this effective conductivity must obey the relation:

$$K_e\overline{\nabla h(x)} = (\overline{k(x)}\ \overline{\nabla h(x)}) + \overline{k'(x)\nabla h'(x)} \quad (7)$$

Thus, the expression for representative conductivity consists of a term containing the block averages of the conductivity and head gradient, and another term involving the averaged covariation of the (small scale) deviations of the conductivity and head gradient. The solution depends on both properties of the porous medium and on the boundary conditions. As noted by Bierkens *et al.* (2000), specification of boundary conditions in the third term of equation (7) requires knowledge of flow at the small scale (i.e. for $\nabla h'(x)$), the very problem we were trying to avoid. In addition, these boundary conditions depend on both conditions within the block and on conditions outside the block, making the solution "nonlocal". To overcome this problem, a particular set of boundary conditions is assumed (e.g. uniform flow), allowing a local solution. Analytical solutions require further simplified representations of the porous medium. As a result, most solutions are both nonunique and approximative.

Deterministic Methods

If information about the small-scale heterogeneity is sufficient, it may be possible to derive effective parameters under limited conditions through theoretical considerations or from experience. For example, it is known from various applications (and from theory) that the effective saturated hydraulic conductivity for uniform, two-dimensional flow (K_e) is well represented by the geometric average of the smaller-scale conductivities, K_i (Bierkens *et al.*, 2000; Desbarats, 1991):

$$K_e = \exp\left[\frac{1}{n}\sum_{i=1}^{n}\ln K_i\right] \quad (8)$$

When information about the parameter, however, is only known at a limited number of locations (or times), some function must be assumed that describes the spatial or temporal variation of the property at the smaller scale within the larger scale. Then a deterministic function (e.g. inverse distance weighting, spline functions, or some other such interpolation) yields one upscaled value to represent the (unknown) small-scale variation associated with an area or volume in the larger domain. Such deterministic effective parameters are nonunique, because they depend on the particular interpolation used. Equation (8) is an example of deterministic upscaling, because it yields a single set of parameters. This upscaling is based on a supposition that data is available to directly compute a set of effective parameters, which are assumed to be deterministically established, but are not necessarily uniquely known. Therefore, the term deterministic applies only to the scaling rule that yields a single upscaled value given a specific set of parameter values at the smaller scale. Also, parameters obtained by inverse methods of matching a model's predictions with measurements or observations of its outputs for given inputs can be included as being of a deterministic effective type. Here the model itself provides the averaging metric. Moreover, the effective parameters obtained by inverse fitting are dependent of the hydrological model's conceptualization, or, are specific to the model.

Stochastic Methods

Stochastic methods acknowledge the nonuniqueness associated with interpolation and attempts to account for this uncertainty by fitting a family of functions through the observations. Each function has similar statistical properties that are estimated from the observations (i.e. mean, variance, etc.), and is assumed to have the same probability of representing the true small-scale variation. The family of equally probable functions is called the *stochastic function*, and each particular function within the family is called a *realization* (Bierkens *et al.*, 2000). Instead of a single parameter value for a given portion of the larger-scale domain, the stochastic approach yields estimates of the small-scale values corresponding to each realization of the stochastic function, resulting in a probability distribution expressing the uncertainty about the effective conductivity due to the imperfectly known small-scale variation.

Upscaling rules for stochastic effective parameters are applied to each realization of the small-scale values to produce a realization of the upscaled value for the larger scale. This approach contrasts with applying equation (8)

as a deterministic upscaling procedure, because only a single effective parameter set was obtained. The probability distribution of the upscaled values can be estimated from these realizations, reflecting the uncertainty in the upscaled values due to the imperfectly known small-scale variation. Each realization of the upscaled value can then be used with the model in a Monte Carlo simulation to generate a suite of model outcomes. These alternative outcomes can then be used to estimate the probability distribution expressing the uncertainty in model output or state variables associated with the upscaled effective parameter. The probability distribution estimated for the upscaled value as well as that for the model output or state variables is just an estimate of the true probability distribution of these quantities. It is, in general, impossible to know the true probability distribution of these quantities. Nevertheless, some indication of the accuracy of model predictions can be established by comparing the distribution of predictions to the corresponding observed hydrological response.

Averaging Model Equations

In some cases the model itself can be upscaled, instead of finding effective parameters or averaging output. The upscaling is achieved through spatial or temporal averaging of the basic model equations at a smaller scale. Spatial averaging of infiltration has been the focus of considerable research (Maller and Sharma, 1981; Dagan and Bresler, 1983; Montoglou and Gelhar, 1987; Chen *et al.*, 1994, Nachabe *et al.*, 1995). The general approach is to use a local (point) infiltration equation and specify the spatial frequency distribution of its parameters. This approach typically involves defining the areal soil hydraulic conductivity frequency, $f(K_s)$. The lower tail of $f(K_s)$ represents soils with low conductivity, whereas the upper tail may represent a fraction of the surface with high conductivity. Nachabe *et al.* (1995) assume $f(K_s)$ follows a lognormal distribution (Nielsen *et al.*, 1973) and increases with elevation. They use Philip's infiltration equation:

$$I_p(t) = \frac{1}{2}\left(\frac{H\Delta\theta K_s}{b}\right)^{1/2}[t - (t_p - t_e)]^{-1/2} + K_s \qquad (9)$$

where $I_p(t)$ is the ponded infiltration rate at time t, H is the effective capillary drive, $\Delta\theta$ is the difference between initial and saturated soil moisture contents, $b \cong 0.55$ for most soils, t_p is the time to ponding, and t_e is an equivalent ponding time. At time t, the ponded fraction of the surface ($F_p(t)$) is:

$$F_p(t) = \int_0^{K_s'(t)} f(K_s)\,dK_s \qquad (10)$$

where $K_s'(t) = r[1 - (1 - t/(t + a))^{1/2}]$, the soil hydraulic conductivity at and below which ponding occurs, and $a = H\Delta\theta/4br$. The mean infiltration rate over the ponded area is:

$$\overline{I_p(t)} = \frac{\int_0^{K_s'(t)} I(K_s, t) f(K_s)\,dK_s}{F_p(t)} \qquad (11)$$

where r is the rainfall rate and $I(K_s, t)$ is given through equation (9). The area-averaged infiltration rate ($I_a(t)$) at t is:

$$I_a(t) = r[1 - F_p(t)] + \overline{I_p(t)}F_p(t) \qquad (12)$$

The first and second terms on the right-hand side of equation (12) represent the contributions of nonponded and ponded infiltration, respectively.

Nachabe *et al.* (1995) also consider cases where K_s decreased with elevation, and where K_s was assumed to vary randomly. In both cases, a spillover of excess rain from ponded areas to nonponded areas occurs. The fraction of ponded surface increased the fastest when K_s decreased with elevation, followed by the case of random K_s. They also used an effective K_s equal to the arithmetic and geometric means of the spatial conductivity field. The arithmetic mean was found to overestimate the infiltration rate, while the geometric mean underestimated the infiltration rate. It should be noted that this solution, like most upscaled equations, is nonunique and is an approximation to the true infiltration rate.

Fully Distributed Numerical Modeling

If the biophysical system to be modeled is one for which no appropriate upscaling techniques yield sufficiently resolved predictions or detailed spatial information is needed (which may be lost in an upscaling method), fully distributed modeling is required. Distributed parameter models attempt to represent hydrological variability by subdividing the model domain into a number of subareas or model elements. Input and model parameter values are required for each element. The response for individual elements is coupled by routing equations (e.g. Darcy's Law for saturated subsurface flow).

Hydrological processes with length scales smaller than the element size are represented implicitly, while processes with length scales larger than the element are represented explicitly by element-to-element variations (Blöschl and Sivapalan, 1995). The simplest (and perhaps most common) approach to expressing subelement variability of model parameters is to assume that a single value is valid for the whole element. The initial value is typically taken from limited measurements, perhaps at a different scale than the model element, with the final value obtained through calibration. With this approach, the parameter no longer represents a point value, rather, an effective parameter that attempts to reproduce the bulk behavior of the element (Grayson and Blöschl, 2000).

Subelement variability can also be expressed using distribution functions, where a distribution of values is used in the model equations, rather than a single value. Normally, this approach is applied to a limited number of input variables or parameters that control the dominant processes that operate at a subelement scale. Moore (1985) used a probability distribution of storage elements to model runoff production. Entekhabi and Eagleson (1989) used distribution functions of rainfall intensity and infiltration rate to calculate infiltration excess runoff. In many cases, the distribution is represented with a number of discrete classes. For example, elevation classes are used to express important subelement differences in air temperature and precipitation rates that govern snow accumulation and melt in mountainous regions.

The subelement variability may also be parameterized directly. Moore and Burch (1986) represented the effect of rills in a model element by the lumped equation:

$$R = F\ A^m \tag{13}$$

where R is the hydraulic radius (m), A is the cross-sectional area of flow (m^2), and F and m are parameters. The parameter m can be derived directly for simple cross-sectional geometries, or both F and m can be calculated from a graph of R versus A obtained from a microtopographic survey (Grayson and Blöschl, 2000).

DOWNSCALING

Downscaling is often required in hydrology to transfer large-scale observations or model predictions to a smaller scale. Examples include (i) estimation of local soil moisture from the catchment average (typically this example involves downscaling in space at a given instant in time), (ii) estimation of rainfall intensity pattern from bulk storm properties (typically this example involves downscaling in time at a specific location in space), and (iii) estimation of monthly streamflow at several locations within a catchment when only annual or seasonal catchment aggregate outflow may be available (this example involves downscaling both in space and in time).

Usually, downscaling involves disaggregation. Note, however, that some underlying properties of the system or laws governing the physical processes must be known to disaggregate the aggregate value at the larger scale into constituents at smaller scale. When the underlying system properties or governing laws can be expressed deterministically using mathematical relationships, these relationships can be used to disaggregate the larger-scale value into a unique pattern at the smaller scale. This procedure is classified as *deterministic downscaling*. However, when the underlying system properties can only be expressed probabilistically, there may be infinitely many disaggregated patterns that all obey the probabilistic system laws and aggregate up to the same larger-scale value. This latter procedure is called *stochastic downscaling* (the original definition of the term stochastic refers to random processes that change in time, but here we use the term more broadly that it may also include time independence).

Deterministic

The TOPMODEL Example

TOPMODEL was developed as a catchment-scale hydrological model (Beven and Kirby, 1979) that also contains a parameterization for local soil moisture deficit as a function of the catchment average. There are certain simplifying assumptions made (see Barling *et al.*, 1994) that allow this elegant analytical formulation. This formulation can be used to estimate the local soil moisture deficit at any modeling time step from the catchment average soil moisture deficit. It also allows prediction of areas of surface saturation within a catchment.

The final form of the soil moisture deficit relationship can be expressed as

$$d_i = d_{\text{avg}} + \frac{1}{f}\left[\frac{1}{A}\int_0^A \ln\left(\frac{a_i}{\tan\ \beta_i}\right)\,\mathrm{d}A - \ln\left(\frac{a_i \cdot T}{T_i \cdot \tan\ \beta_i}\right)\right] \tag{14}$$

where d_i is the local depth to the perched water table at location i (m), d_{avg} is the catchment average depth to the perched water table (m), f is a catchment average parameter that describes the exponential rate of reduction in soil transmissivity with depth, A is the catchment area (m^2), a_i is specific contribution area at location i (m), β_i is the angle of topographic slope at location i, T_i is soil transmissivity at location i ($m^2\ s^{-1}$), and T is the catchment average soil transmissivity ($m^2\ s^{-1}$). The distribution of the topographic index ln(a/tan β) has since been used as a surrogate for the spatial pattern of soil moisture within catchments.

As pointed out by Barling *et al.* (1994), the simplifying assumptions used during the development of equation (14) are not always appropriate. The most limiting of these, the assumption of steady-state subsurface flow, can be relaxed as shown by Barling *et al.* (1994), which allows for dynamic redistribution of soil moisture under variable rainfall rates while retaining most of the simplicity and elegance of the formulation. Beven and Freer (2001) developed a modified version of TOPMODEL that includes a dynamic specific contribution area in its governing equations. In the original TOPMODEL, there would always be some downslope flow, regardless of the soil moisture deficit. In the modified version, an additional parameter was used to indicate a limiting soil moisture deficit for downslope flow to start. The modifications also include downslope moisture redistribution between groups of landscape elements that

are hydrologically distinct. These landscape elements must be obtained using some form of classification based on distributions of landscape, soil, and vegetation information. Connectivity among these elements was determined from digital terrain analysis. The model retained the ability to estimate local soil moisture deficit.

Storm Precipitation Pattern

The use of design storms is a common occurrence in surface water hydrology. Foster and Lane (1987) suggest that the maximum information required to represent a design storm consists of the total storm amount and duration, average intensity, ratio of peak intensity to average intensity, and time to peak intensity. A double exponential function is fitted to the normalized intensity pattern of each storm, $i(t)$,

$$i(t) = \begin{cases} i_p \exp(b(t - t_p)) & 0 < t \le t_p \\ i_p \exp(-d(t - t_p)) & t_p < t \le 1 \end{cases} \quad (15)$$

where i_p is the ratio of peak intensity to the storm average intensity, t_p is the ratio of time to peak intensity to the storm duration, and parameters b and d are to be determined. Intensity-duration-frequency data developed from detailed precipitation data are typically used to prescribe i_p on the basis of storm duration and frequency. Integration of equation (15) over the appropriate limits results in two equations

$$1 - \exp(bt_p) = \frac{bt_p}{i_p} \qquad \text{at } t = t_p \quad (16)$$

$$1 - \exp(d(1 - t_p)) = \frac{d(1 - t_p)}{i_p} \qquad \text{at } t = 1 \quad (17)$$

that must be solved for b and d. From equation (15), $i(0)$ is equal to $i(1)$ so that $d = bt_p/(1 - t_p)$, and we only need to solve equation (16) for b to have the entire solution. Newton's method may be used to solve for b, given i_p and t_p.

The integral $I(t)$ of equation (15) can be written as

$$I(t) = \begin{cases} \frac{a}{b}[\exp(bt) - 1] & 0 < t \le t_p \\ \frac{c}{d}[\exp(-d(t_p - t)) - 1] & t_p < t \le 1 \end{cases} \quad (18)$$

where from above $a = i_p \exp(-bt_p)$ and $c = i_p \exp(dt_p)$. Notice that it must be that $0.0 < I(t) < 1.0$. If we subdivide the $I(t)$ interval [0,1] into n equal subintervals and call the right endpoint of these subintervals $F_1, F_2, \ldots, F_n$, then we can define specific time values as $T_1, T_2, \ldots, T_{n+1}$. These values of $T_1, T_2, \ldots$ can be defined by inverting the $I(t)$ function, such that $T_i = \text{inverse} I(F_i)$, for i from 1 to n.

The average normalized intensity over the interval $[T_i, T_{i+1}]$ is then calculated as $I_i = (F_{i+1} - F_i)/(T_{i+1} - T_i)$. The result of these calculations is an array of ordered pairs $[T_i, I_i]$ that are normalized time-intensity values. However, because the values of F_i are on a regular subinterval, the time intervals $(T_{i+1} - T_i)$ vary inversely with $I(t)$. That is, when $I(t)$ is high, then $(T_{i+1} - T_i)$ is small and when $I(t)$ is low, $(T_{i+1} - T_i)$ is large. This means that the method of disaggregation described here is unique in that values of F_i are all equal but the values of $\Delta t = (T_{i+1} - T_i)$ vary with rainfall intensity so that the highest intensity portion of the storm is always described by small Δt's. Moreover, a small number of intervals (n) can be used to describe storms or various durations. If we use n subintervals, then the dimensionless disaggregated time-intensity data are: $T_1, I_1, \ldots, T_{n+1}, I_{n+1}$. To restore the original dimensions, one must multiply each T_i by the storm duration and each I_i by the ratio of total storm precipitation and the storm duration. Calculations for a 6-h, 30.2 mm design storm with $t_p = 0.5$ and $i_p = 18$ are shown in Table 1.

Downscaling of RCM Precipitation

Hydrological modeling is often required to estimate the impact of climate change for water resources management and planning. This impact assessment requires us to drive

Table 1 Disaggregated 6 h, 30.2 mm design storm with $t_p = 0.5$ and $i_p = 18$

hydrological models using meteorological predictions from regional climate models (RCM). Typically, RCM grid cells are large compared to the extent of regions where water resources impacts need to be evaluated. While using spatially distributed hydrological models, a basis for downscaling the RCM predictions to the hydrological model grid scale is needed. Here we present an example that shows how precipitation predictions at the RCM grid scale may be downscaled to a hydrological model grid scale.

Typically, RCMs can only use a simplified description of land surface topography. Precipitation is highly correlated with topographic features. Land surface topography can be highly heterogeneous within the extent of an RCM grid cell. Owing to the simplified representation of topography, the RCM is only able to account for large-scale topographic features. A monthly precipitation patterns dataset, called Parameter-elevation Regressions on Independent Slopes Model (PRISM), for the continental United States has been developed using multivariate regression analysis of long-term precipitation observations and other topographic properties of the region (Daly *et al.*, 1994), and are available from Oregon State University.

Since the RCM grid cell is large compared to the hydrological model grid cell, a probability distribution of elevation as well as precipitation exists within the RCM grid cell. We make a simplifying assumption that the RCM-predicted precipitation can be assumed to correspond to the median of the distribution of precipitation within the RCM grid cell. This assumption gives us a basis to downscale the RCM-predicted precipitation from the RCM grid scale to the hydrological model grid scale using the probability distribution of the PRISM precipitation. Figure 1 shows the schematic representation of the downscaling approach.

Consider that for any time step P_{RCM} is the precipitation predicted by the RCM. We find the median PRISM precipitation, P_{PRISM}, from the distribution of PRISM precipitation for the same month to which the time step belongs, within the RCM grid cell. The downscaled precipitation at any hydrological model grid cell P_g is then expressed as

$$P_g = \frac{P_{\mathrm{PRISM},g}}{P_{\mathrm{PRISM}}} \times P_{\mathrm{RCM}} \tag{19}$$

where $P_{\mathrm{PRISM},g}$ is the PRISM monthly precipitation at the hydrological model grid cell g. Note that in this downscaling approach, the spatial pattern within the RCM grid cell as defined by the PRISM dataset is preserved during downscaling. Also, as the RCM predictions of precipitation change with time, the downscaled precipitation field also changes, although the spatial pattern remains the same for time steps that belong to the same month. The hydrological model is inputted with this downscaled precipitation field.

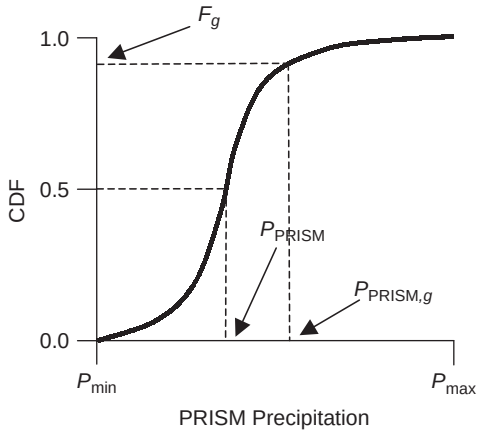

Figure 1 Schematic representation of an RCM precipitation downscaling approach. The cumulative density function (CDF) represents the probability distribution of precipitation within an RCM grid cell. P_{min} and P_{max} define the range of precipitation within the RCM grid cell. P_{PRISM} is the median PRISM precipitation within the RCM grid cell and $P_{\mathrm{PRISM},g}$ is the PRISM precipitation (corresponding to a cumulative density of F_g) at a hydrological model grid cell *g*, located within the RCM grid cell

Stochastic

Downscaling Hydraulic Conductivity in Space

One of the most frequent problems in spatially distributed hydrological modeling is the estimation of hydraulic conductivity of soil in space. Usually, only a few point measurements are available, while the model needs specification of hydraulic conductivity at all grid cells. Since measurement of hydraulic conductivity at the grid scale is infeasible, the point measurements must be downscaled to produce hydraulic conductivity at the grid scale.

The spatial correlation structure of hydraulic conductivity is used as the underlying law governing its distribution. Under isotropic conditions, a single, direction-independent semivariogram may be developed from measurements (e.g. Clark, 1979). A semivariogram quantifies the expected difference between values of hydraulic conductivity at two points in space. An interpolation scheme, such as kriging (see Journel and Huijbregts, 1978; Delhomme, 1978) can then be used to estimate the hydraulic conductivity values over the modeling grid.

An alternative to estimating the hydraulic conductivity field or map at the grid scale using kriging is to simulate these fields using statistical properties of the semivariogram with the Monte-Carlo procedure. These simulations produce equally probable fields of hydraulic conductivity by using the probability distribution of hydraulic conductivity while preserving measured values (Desbarats, 1996). These simulated fields can be used to quantify the uncertainty in the behavior of the hydrological system due to our imperfect knowledge of subsurface properties.

Another approach toward determination of hydraulic conductivity fields is to condition these fields on auxiliary measurements of state variables like the pressure head, using a mathematical subsurface flow model. These methods are also referred to as solutions to the inverse problem (estimation of subsurface properties given measurements of state variables); a large body of literature exists on this topic and more details can be found in **Chapter 147, Characterization of Porous and Fractured Media, Volume 4**.

One of the most critical problems related to estimation or simulation of spatial distribution of hydraulic conductivity is the occurrence of contiguous regions of high or low conductivity (e.g. macropores, fractures, and sand or clay lenses). These "anomalies" result in preferential flow pathways within the subsurface. Statistical methods that rely on one-point (e.g. the probability density function) and two-point statistics (e.g. correlation, semivariogram, anisotropy) described above do not address these structures or "organization" adequately (Blöschl, 1996).

FUTURE DIRECTIONS FOR SCALING

There is no substitute for having sufficient data to perform hydrological modeling. Ideally, hydrological modeling requires measurements rich in both spatial as well as temporal coverage. However, many hydrological datasets that are rich in spatial coverage have poor temporal coverage and the reverse is also true. This limitation in hydrological datasets stems from several reasons: (i) there is a lack of measurement techniques that can provide both spatially as well as temporally rich datasets, (ii) there are very few accurate inferential methods that can be applied to infer variables of interest from observations of surrogates, and (iii) maintaining a hydrological measurement network is expensive. Until there are significant advances in hydrological measurement programs that address these issues, hydrologists will have to deal with extrapolation in space and in time.

One consequence of extrapolation (both while upscaling and downscaling) is that observations at the extrapolated scale may not be readily available to validate the predictions directly. It may be possible to obtain measurements at intermediate scales and validate the predictions at these intermediate scales to provide some indication whether the extrapolation produces reasonable agreements with observations across scales. In the absence of rigorously derived mathematical scaling laws, we must acknowledge that uncertainty in modeling predictions may be introduced as a result of this extrapolation. A detailed uncertainty analysis can then be performed to provide a measure of the uncertainty introduced into the predictions.

Since the goal of model scaling is an extrapolation of predictions, certain modern mathematical paradigms or constructs may find utility when applied to this problem. It seems unlikely that any scaling procedure can introduce accurate fundamental information that was not already present in an adequate measurement of input variables or estimation of the parameters describing the variability present in a hydrological system. However, there may be some mathematical methods that can at least facilitate the scaling extrapolation. Some mathematical constructs might even help a further understanding of the implications of scaling and some specific mathematical tools can be pointed out as potential contributors to treating the scaling problem. In addition to those mentioned below, certainly there are many other mathematical tools that are useful in hydrological model building and evaluating scaling properties, but we limit the following discussion to a few modern paradigms that show some special insights or utilities for the future of the scaling problem.

The contribution of the fractal theory in describing invariances under the self-similarity of a system's geometry may be useful to scaling. A fractal perspective has contributed to understanding rainfall sequences over space and time (Deidda, 2000), for example. Fractal structure can also be used to describe river networks (Rodriguez-Iturbe and Rinaldo, 1997; Tarboton *et al.*, 1988, 1992).

Fuzzy set theory may allow the variability of parameters and variables to be built into a hydrological model directly, without the need to consider the probability distribution of outputs associated with random inputs. It might provide a formulation to help accomplish scaling while accounting for variability. Bardossy (1996) has discussed the possible utility of fuzzy mathematics applied to hydrology. As another example, fuzzy set theory has found considerable use with the climate downscaling problem. Fuzzy conceptual rainfall-runoff models were described by Ozelkan and Duckstein (2001).

Neural networks have the potential for simplified and more efficient calculation of the nonlinear interactions between subunits of a system. The scaling of subunits into to a composite model unit might be made more computationally manageable. Whitley and Hromadka (1999) give an example of the use of neural networks for the study of flood prediction.

Percolation theory has found use in the study of the scale-dependent behavior of hydraulic conductivity (Hunt, 2003). It might find application in a further understanding of transport of water-borne constituents at larger scales.

An understanding of chaos theory has the possibility of replacing a complicated probability distributed description of hydraulic parameters by a more efficient deterministic generation. Chaos theory is finding use in hydrology, especially with evaluating a rainfall time series (Sivakumar, 2000). It may aid in understanding the scaling of rainfall over several timescales.

Kalman filtering may help with forecasting and improving the predictions of hydrological models. This may

help in testing model scaling and correcting predictions. An example of a Kalman filter application in evaluating soil moisture distribution is discussed by Walker *et al.* (2002).

Genetic algorithms may enhance the calculation of effective parameters in hydrological models to fit more extensive data records. Wang (1991) describes the use of a genetic algorithm to calibrate a rainfall-runoff model. McKinney and Lin (1994) discuss the use of a genetic algorithm to treat groundwater management and parameter selection.

At this time, we foresee scaling as the most challenging problem in hydrological modeling. We hope that this article provides a review of current practices in hydrology as they apply to scaling, fosters greater thinking on part of the reader, and generates spirited discussions within the hydrological community.

Acknowledgment

We appreciate the careful review and improvements to the manuscript suggested by C.S. Simmons.

The myriad of interactions between the vegetation, the soil, the climate, and the air involve transfers of energy and matter between the atmosphere and the lithosphere. In this article, these interactions are investigated mainly from the perspective of the vegetation. Most of the water taken up from the soil by plants is evaporated from the leaves via stomata during the process commonly referred to as transpiration. Transpiration of water is necessary for the uptake of carbon dioxide from the atmosphere for photosynthesis. Through transpiration and photosynthesis, the vegetation links the energy, water, and carbon and other biogeochemical cycles. This linkage provides the backbone to the article. Sections deal with: energy and water limitations to transpiration and plant growth at the catchment scale; the relationship between plant water use and photosynthesis; ecological strategies and temporal variability of water use and volume of soil involved in exchange with the atmosphere; soil water holding capacity and mineral nutrient availability; and catchment scale relationships between vegetation, soil, and climate. In the final sections, the concept of optimality between climate, vegetation, soil, and air is introduced, and the potential application of the optimality approach to hydrology is reviewed.

INTRODUCTION

The vegetation, the soil, the air, and the climate evolve together through a series of interactions involving transfers of energy and matter (Figure 1). The hydrological cycle is intimately involved in all of these interactions. Although each component in Figure 1 affects, and is affected by, all of the others, studies of the interactions have traditionally focused on particular interactions, for example, vegetation–climate (Budyko, 1974; Holdridge, 1967; Walter, 1979), plant–soil (Eyre, 1968; Black, 1968; Russell, 1973), soil–climate (Jenny, 1941; Brady and Weil, 2002) and air–climate interactions (see any climatology text). The interactions between the air and the vegetation and soil, and the feedbacks to the climate, have only recently become a research priority. This has been driven primarily by interest in the effects of the increasing concentration of carbon dioxide in the atmosphere resulting from anthropogenic combustion of fossil fuels.

As with any "new" field, the participants are on a steep learning curve. The prime difficulty is that one has to come to grips with several disciplines, for example, hydrology, ecology, climatology, atmospheric physics, biogeochemistry, and so on. This has prompted a need for interdisciplinary studies (e.g. Eagleson, 1986). Accordingly, the aim of this article is to present a brief overview of the principal interactions between the various components in Figure 1. Our overall approach is mainly from the point of view of the vegetation. Our hope is that by following this approach we will present the biological component of

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

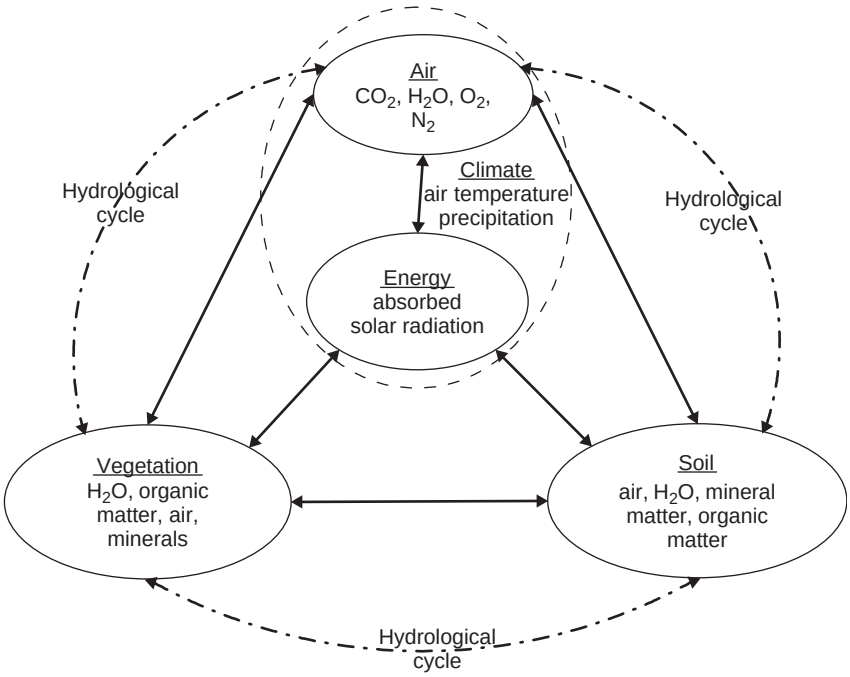

Figure 1 Relationship between the vegetation, the soil, the air, and climate. The climate is generally described in terms of the air temperature and precipitation, factors that depend on the energy and moisture content of the air. The most important components of the air, soil, and vegetation are italicized

Figure 1 in a way that is sympathetic to the needs of both practicing and research hydrologists. For example, we only briefly consider those topics that are traditionally close to hydrology (e.g. surface energy balance), but conversely, we spend more time on, for example, the biochemical basis for the observed differences in water-use efficiency between different vegetation types.

MASS AND ENERGY BALANCE

The processes in Figure 1 can be described in terms of transfers and stores of energy and mass (e.g. hydrological cycle, carbon cycle, nitrogen cycle). As mass and energy are conserved, the change in the store of mass and/or energy over a period of time within the air, the vegetation, or the soil must be equal to the difference between the input and the output. For a more detailed description of global energy and water balances, (*see* **Chapter 2, The Hydrologic Cycles and Global Circulation, Volume 1**, **Chapter 25, Global Energy and Water Balances, Volume 1**).

Surface Energy Balance

The absorbed solar radiation is the ultimate source of energy for the terrestrial processes in Figure 1. The amount of solar radiation absorbed at the surface of the Earth is dependent on the quantity of solar radiation received at the top of the atmosphere, and consequently on the solar output and the geometry of the orbit of the Earth around the Sun, as well as on the Earth's atmospheric and surface properties. Only a portion of the solar irradiance arriving at the top of the atmosphere, Q_a, actually reaches the surface. The shortwave radiation flux that arrives at the surface is referred to as the global irradiance, Q_s. The remainder is absorbed or backscattered by molecules, aerosols, or clouds within the atmosphere. Data presented by Roderick (1999) indicate that on cloudless days in places having no atmospheric pollution, Q_s/Q_a may reach $\sim$0.80, but with increasing cloud the ratio may fall to $\sim$0.10. A proportion of Q_s is reflected back to space, and the fraction reflected back is referred to as the surface albedo, α. In addition to Q_s, the surface receives a flux of long-wave radiation $R_l \downarrow$ emitted by the molecules, clouds, and aerosols in the atmosphere. The surface also emits an upward flux of long-wave radiation, $R_l \uparrow$.

The overall radiation balance at the surface determines the net radiation, R_n, defined as the difference between the absorbed and emitted fluxes:

$$R_n = Q_s - \alpha Q_s + R_l \downarrow - R_l \uparrow \qquad (1)$$

The outgoing fluxes in equation (1) (αQ_s and $R_l \uparrow$) are largely controlled by surface properties. Values of α for terrestrial surfaces (Sturman and Tapper, 1996) vary from a maximum of $\sim$0.95 for clean, fresh snow to $\sim$0.05

for dark and wet soil and dense evergreen forest. As the vegetation canopy cover (or surface soil wetness) decreases, α increases from 0.05 towards the dry soil or desert value which can range from 0.20 to 0.45. Although the canopy cover of forests and cereal crops may be similar, forests often have a lower albedo than cereal crops, possibly because radiation reflected by leaves within forest canopies is absorbed by other leaves (Budyko, 1974).

The surface temperature largely determines $R_l \uparrow$ as given by the Stefan–Boltzmann law:

$$R_l \uparrow = \varepsilon \sigma T_s^4 \tag{2}$$

where ε is the emissivity of the surface relative to that of a full radiator or black body (for which ε is unity), σ ($5.67 \times 10^{-8}\,\mathrm{Wm^{-2}K^{-4}}$) is the Stefan–Boltzmann constant and T_s is the absolute temperature of the surface. There is a tendency for ε to decrease with increasing α (see data presented in Oke, 1987). T_s is dependent on the partitioning of net radiation through the heat balance and on the thermal properties of the soil. A detailed treatment of this subject is provided by Oke (1987).

The net flux of radiation to the surface (R_n) provides the energy to evaporate water (potential energy), to convectively heat the overlying air (kinetic energy), to heat the soil near the lithosphere/atmosphere interface (thermal energy), and to drive photosynthesis. In terms of these processes, the energy balance at the surface over a given time interval is:

$$R_n \cong \lambda E + H + G + A \tag{3}$$

where R_n is the net radiation ($\mathrm{J\,m^{-2}\,s^{-1}}$), λ is the latent heat of vaporization ($\mathrm{J\,kg^{-1}}$ H_2O), E is the evaporation rate ($\mathrm{kg^{-1}}$ $H_2O\,\mathrm{m^{-2}\,s^{-1}}$), H is the flux of energy convected away from the surface as sensible heat, G is the heat flux into the soil and A is the flux of energy transformed into energy of chemical bonds during photosynthesis ($\mathrm{J\,m^{-2}\,s^{-1}}$). As A is very much smaller than R_n, it is often ignored. However, A is coupled to the transpiration component of λE (see Section "Catchment mass balance"). Over the annual period:

$$G \cong 0 \tag{4}$$

and equation (3) can be simplified to:

$$R_n \cong \lambda E + H. \tag{5}$$

Catchment Mass Balance

The water balance of the active layer of the soil where water exchange generally occurs can be written as:

$$\frac{dS}{dt} = P - E - r \tag{6}$$

where P is the precipitation, E is the evaporation, r is the net (surface and ground) runoff and S is the storage of water in the active layer.

The evaporation (E) can be partitioned into three components: evaporation of intercepted water (E_I), evaporation from the soil (E_S), and evaporation via the stomata of plants, commonly referred to as transpiration (E_T).

$$E = E_I + E_S + E_T \tag{7}$$

The measurement and calculation of water balance parameters including these evaporation fluxes are described in **Chapter 35, Rainfall Measurement: Gauges, Volume 1**, **Chapter 40, Evaporation Measurement, Volume 1**, **Chapter 42, Transpiration, Volume 1**, **Chapter 43, Evaporation of Intercepted Rainfall, Volume 1** and **Chapter 45, Actual Evaporation, Volume 1**.

The vegetation can potentially modify all parameters in equations (6) and (7) above. The roots of plants commonly extend the thickness of the active layer of the soil involved in water exchange. Water is extracted by the roots from this extended active layer to furnish the transpiration requirements (E_T) of the vegetation. The transpired vapor may contribute to subsequent precipitation. For example, it has been estimated that about 48% of the annual transpiration in the Amazon Basin is recycled as rain (Salati and Vose, 1984). The canopy serves to increase the surface area for precipitation interception and consequently increases E_I. By reducing the exposure of the soil surface, the canopy usually reduces E_S. For example, for a rainforest in the Amazon Basin, E_T, E_I and E_S respectively comprised 75%, 19%, and 6% of the annual mean E of $1526\,\mathrm{mm\,yr^{-1}}$ (Costa and Foley, 1997). The values for grassland in the same region ($E = 1292\,\mathrm{mm\,yr^{-1}}$) were E_T61%, E_I20%, and E_S19%.

The catchment mass balance is a very useful tool in hydrology. For example, Costa and Foley (1997) observed a 12% reduction in annual E following the replacement of woody vegetation with grassland in the Amazon basin. In terms of the mass balance (equation 6), the reduction in E must be balanced by an increase in runoff and/or soil moisture storage in the active zone, or a decrease in P. These feedbacks are discussed in more detail in the Section "Individual plants and ecological strategy".

Budyko's Approach to Catchments

By assuming that over annual and longer periods the change in water storage (dS/dt) is zero, equation (6) can be simplified to:

$$P = E + r \tag{8}$$

In order to explain the geographic zonality of soils and vegetation, Budyko (1974) combined equations (5) and (8).

Using that approach:

$$E \cong \frac{R_n - H}{\lambda} \cong P - r \tag{9}$$

In equation (9), evaporation over the annual period is constrained by the availability of energy or water. The energy constraint limits the maximum possible evaporation to the value of R_n/λ which, according to Budyko (1974, Figure 99), is approximately equivalent to the annual potential evaporation, E_p, calculated from the atmospheric humidity deficit and temperature differences between the active surface and the air. As data for catchment r and E were not commonly available, Budyko derived a semiempirical equation (based on the available catchment measurements) to estimate E from P and R_n over the Earth's surface at the catchment scale from annual data:

$$E = \left[\frac{R_n P}{\lambda} \tanh\frac{\lambda P}{R_n}\left(1 - \cosh\frac{R_n}{\lambda P} + \sinh\frac{R_n}{\lambda P}\right)\right]^{1/2} \tag{10}$$

Very similar numerical values of E are obtained using the computationally simpler formulation, (Choudhury, 1999):

$$E = \frac{P}{\left[1 + \left(\frac{P}{R_n/\lambda}\right)^{2.6}\right]^{1/2.6}} \tag{11}$$

There is close agreement between E calculated with equations (10) and (11), and E determined by field observations for nine regions representing a wide range of global environments in the data set collated by Choudhury (1999, Figure 2). The relationship between calculated E (equation 11) and the water and energy budget over the annual period is summarized in Figure 2.

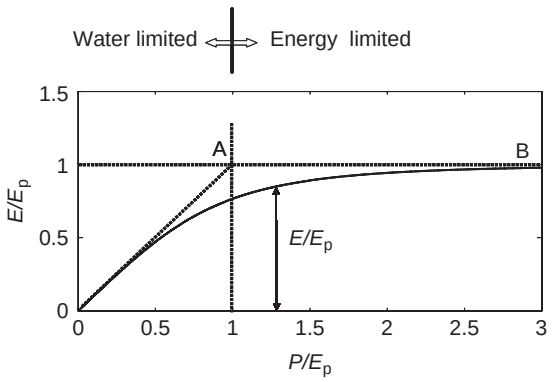

Figure 2 Dependence of the ratio of mean annual evaporation (E) on precipitation (P) and the radiation balance (E_p, where $E_p = R_n/\lambda$) following the approach of Budyko (1974). The line AB shows the energy limitation to evaporation. The solid line is drawn from equation (11)

Budyko (1974) named the ratio $R_n/\lambda P$. the *radiative index of dryness* and subsequently constructed a map of this index for the entire global land surface. By comparing this map with the available vegetation and soil maps he demonstrated that the availability of water and energy greatly influenced the geographic distribution of vegetation and soil types. The relationship between the radiative index of dryness and the geobotanic zonality of the Australian vegetation is shown in Figure 3. The relationships in Figure 3 between the vegetation structure and energy/water show the same pattern as those described by Budyko (1974).

VEGETATION

Most of the water that is removed from the soil by plants is ultimately transpired. As noted in Section "Surface energy

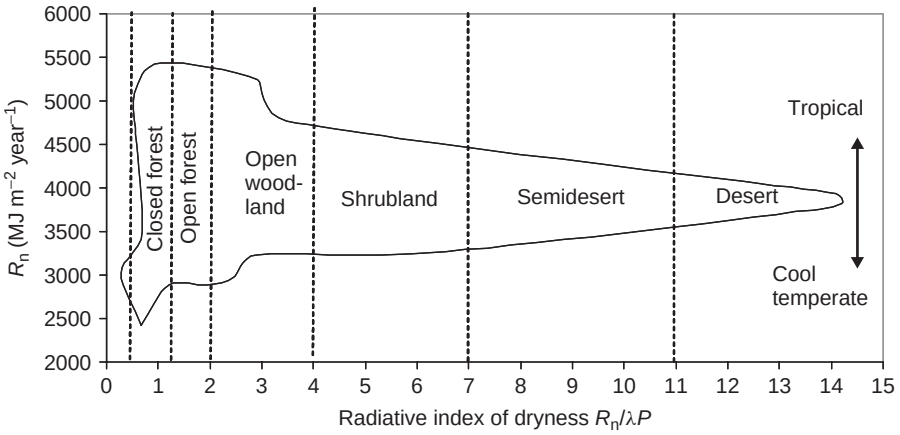

Figure 3 Relationship between vegetation structure, Budyko's radiative index of dryness and annual sum of net radiation for Australia. The continuous line describes the boundaries of values for the land surface. The net radiation and radiative index of dryness values were determined from gridded (0.05° × 0.05° latitude/longitude) data over the continent. Vegetation cover data are from the Natural Vegetation Map (AUSLIG, 1990). Data are from Berry and Roderick (2004)

balance" a very much greater amount of energy is involved in transpiration compared to that which is transformed to energy of covalent bonds by photosynthesis. However, the two processes are tightly coupled. Hence, in order to understand transpiration it is necessary to understand photosynthesis. For terrestrial plants, transpiration is a necessary part of photosynthesis (Section "Biological overview"), the source of energy and organic carbon molecules that sustains all life forms. The biochemistry of photosynthesis is similar in all plant species. However, modifications to the process of CO_2 uptake (Section "Leaf biochemistry") allow some plants to minimize transpiration per unit CO_2 uptake in water-limited environments, or to more efficiently scrub the air for CO_2 when this is in short supply. The amount of photosynthesis that can be done depends on the availability of the resources required for the construction and operation of the photosynthetic tissues. A range of ecological strategies have evolved (Section "Individual plants & ecological strategy") to allow plants to efficiently utilize resources. Resource availability is affected by soil properties (Section "Soil: water and nutrient cycles") as well as climate dynamics. Variations in photosynthesis and ecological strategies, and soil properties all ultimately affect the dynamics of the hydrological cycle over intra-annual and annual periods (Section "Catchment").

Biological Overview

The terrestrial plant consists of three basic parts: a canopy of leaves that act to capture light and carbon dioxide from the atmosphere; a network of roots which serve to anchor the plant into the soil, and to obtain water that is required by the leaves and mineral nutrients required for biochemical processes; and a stem which serves to elevate the leaves into the light, and is a conduit for the passage of water and nutrients from the soil to the leaves (through xylem conducting tissues), and a sugar solution from the leaves to the roots (via the phloem conducting network).

Through the process of photosynthesis, the canopy converts a small amount of the solar radiation that reaches the Earth's surface into the chemical energy of high energy C–C and C–H bonds. The source of the carbon is atmospheric CO_2 taken up by the leaves. The source of hydrogen is H_2O and this is taken up mostly by the roots (a small amount may be absorbed by the leaves). The numerous reactions of photosynthesis can be summarized:

$$n\mathrm{CO_2} + n\mathrm{H_2O} \xrightarrow{\text{light}} (\mathrm{CH_2O})_n + n\mathrm{O_2} \qquad (12)$$

Although the reactions of photosynthesis require water either directly (equation 12), or indirectly as the solvent, approximately 90% (Raven *et al.*, 1971) of the water absorbed by the roots is transpired. Water that is absorbed by the plant roots passes into the vascular tissues where it is transported by an elaborate hydraulic network (xylem vessels and/or tracheids) to the leaves. At the termini of the vascular bundles (i.e. the ends of the xylem conduits in the leaves), the water moves (by capillary flow) into the cell walls of the cells that surround the intercellular air spaces of the stomatal cavity (Crafts *et al.*, 1949) as shown in Figure 4. At the same time, CO_2 from the air within the stomatal cavity dissolves into the water that wets these cell walls.

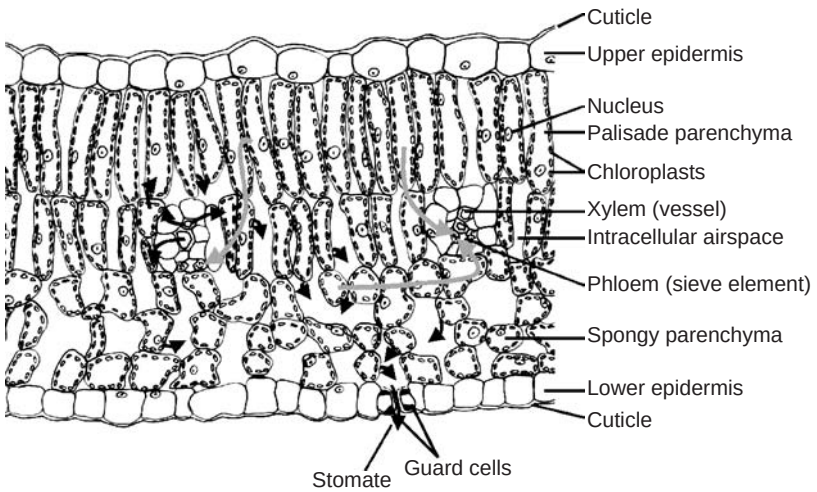

Figure 4 Diagram showing the arrangement of cells within a leaf and the pathways followed by water molecules (black arrows) and sugar molecules manufactured during photosynthesis (grey arrows). Photosynthesis takes place in the chloroplasts. The pathway of CO_2 molecules through the intracellular airspace is in the opposite direction to the water molecules

The dissolved CO_2 passes through the interstices of the cell wall, across the plasma membrane and into the chloroplasts where photosynthesis occurs. Whilst the stomata are open to allow CO_2 to diffuse into the intercellular airspace from the air outside of the leaf, the air within the intercellular airspace is almost saturated with water vapor, and there is a net evaporative flux of water molecules from the wet cell surfaces to the overlying air, and a net flux of water vapor to the exterior of the leaf. This flux of water vapor from the plant tissues to the air constitutes the transpiration. Transpiration is controlled by the guard cells at the entrance to the stomatal cavity. By closing the stomata, the guard cells block the flow of CO_2 into, and H_2O out of the intercellular airspace, and thus allow the plant to make conservative use of the available water. The ratio of net CO_2 uptake to net H_2O loss is referred to as the water-use efficiency of photosynthesis (WUE_{ph}), a parameter which links the carbon and water cycles. Sugar molecules manufactured in the chloroplasts, that are superfluous to the needs of the local tissues, are transported through the interconnected network of living parenchyma cells to the phloem tissues of the vascular system. From there the sugar molecules may be transported to developing stem and leaf tissues, or to the roots.

The energy obtained by the plant through photosynthesis is subsequently metabolized to build new molecules and to provide energy to maintain cellular processes. Metabolic processes that involve the oxidative breakdown of C–C and C–H bonds to release energy (and CO_2) are also referred to as respiration (Raven *et al.*, 1971). The overall reaction for the respiration of glucose to CO_2 and H_2O is the reverse of photosynthesis:

$$(CH_2O)_n + nO_2 \longrightarrow nCO_2 + nH_2O + \text{energy} \qquad (13)$$

The chemistry of photosynthesis and metabolism involves a wide array of biomolecules that contain a range of chemical elements in addition to carbon, hydrogen, and oxygen, as integral structural and/or functional components. These elements are generally classified as macronutrients (nitrogen, potassium, calcium, phosphorus, magnesium, and sulfur) required in relatively large quantities, and micronutrients (e.g. iron, chlorine, copper, manganese, zinc, molybdenum, boron), also essential for plant function but required in lesser amounts. Some plants also require cobalt and/or sodium (Raven *et al.*, 1971). For a comprehensive review of plant mineral nutrition, see Chapin (1980). The primary source of these nutrients is the soil, and their availability for uptake by plants is dependent on factors including soil parent material, physical and chemical properties, and the presence of soil microbes. The availability of nutrients may be modified by the anthropogenic addition of fertilizers or substances to amend excess soil acidity or alkalinity. Soil moisture is of paramount importance to nutrient availability as it is required to sustain hydration of soil organisms as well as being the solvent for soil chemical processes.

When all resources required for plant growth are well supplied the vegetation can form a dense canopy that intercepts most of the photosynthetically active radiation incident upon it. If resources are generally well supplied, except for an essential nutrient such as nitrogen or phosphorus, a less luxuriant canopy having lower photosynthetic capacity will result. Whilst limitations to photosynthesis and growth arising from insufficient availability of mineral nutrients and light are important, at the catchment scale the availability of water usually has the greatest impact. It is for this reason that Budyko's index of radiative dryness is correlated with vegetation cover (Figure 3).

Leaf Biochemistry

In water-limited environments the rate of transpiration relative to the rate of carbon assimilation in leaf tissues is affected by the biochemical pathways initially utilized by the leaf tissues prior to the bulk of the photosynthesis reactions that are invariant between plant species. The various initial pathways, known as C_3, C_4, and (crassulacean acid metabolism) CAM, reflect evolutionary processes that confer enhanced probability of survival and growth on plants under a range of water and atmospheric CO_2 concentration scenarios. The C_3 pathway is discussed first, as this is utilized by most plant species.

The equation for photosynthesis (equation 12) summarizes a complex series of reactions that occur within the chloroplasts, organelles of specialized cells (photosynthetic parenchyma) within plant leaves. The reactions take place in two stages, a light dependent and a light-independent stage. Energy generated by the light reactions is used to reduce carbon dioxide molecules to sucrose during the dark (light independent) reactions. During the initial stages of the dark reactions, a molecule of CO_2 is bound onto the enzyme (ribulose 1,5-biphosphate carboxylase/oxygenase) commonly referred to as Rubisco. Rubisco catalyzes the reaction of the molecule of CO_2 with the 5 carbon ribulose 1,5-biphosphate (RuBP) molecule to produce 2 molecules of the 3-carbon compound, 3-phosphoglycerate. When most plants are exposed to $^{14}CO_2$ in the light, the first detectable radioactive compound produced is 3-phosphoglycerate (PGA). These plants are referred to as C_3 plants and they comprise about 93% of plant species (Nobel, 1994).

In C_3 plants, not all of the carbon that is initially taken up by the Rubisco enzyme is incorporated into glucose molecules. Some is reoxidized to CO_2 by a process known as *photorespiration* and this reduces the WUE_{ph}. Photorespiration occurs because the Rubisco enzyme can also take up O_2 molecules. When an O_2 molecule reacts with the RuBP molecule, one molecule of the 3-carbon

PGA and one molecule of the 2-carbon phosphoglycolate are formed. Only the PGA molecule enters into the dark reactions of photosynthesis. Through a series of reactions, some of the carbon in the phosphoglycolate molecule is saved and the rest is ultimately oxidized. The overall stoichiometry is that 2 oxidations causes the release of one molecule of CO_2 (Farquhar *et al.*, 1980a).

The amount of O_2 that is taken up by Rubisco, and consequently the amount of CO_2 released by photorespiration, depends on the relative concentrations of O_2 and CO_2. As O_2 is approximately 600 times more abundant in the atmosphere than CO_2, the ratio of O_2:CO_2, is much more sensitive to a small change in the concentration of CO_2 than O_2. As the concentration of CO_2 in the atmosphere has increased from $\sim$280 μmol mol^{-1} to $\sim$375 μmol mol^{-1} over the past two centuries, there should have been a concomitant increase in the WUE_{ph} of the vegetation over this period. Where evaporation is limited by water supply, this increase in WUE_{ph} would allow the available water to support more vegetation and more photosynthesis per unit area. Where evaporation is limited by energy supply and further increases in canopy cover are suppressed by light limitation, an increase in photosynthesis would still be expected. However, this may not translate into an increase in WUE_{ph} as transpiration may also serve to dry out the soil (and hence increase aeration) in the root zone in wet environments. This would be expected in environments in which evaporation is limited by energy supply, but photosynthesis is limited by the availability of nutrients and/or root respiration is limited by the availability of oxygen.

Losses to photorespiration are avoided or minimized in the 1% of species that utilize the C_4, and the 6% that utilize the CAM photosynthetic pathway (Nobel, 1994). Although few species utilize the C_4 pathway they are responsible for approximately 25% of the primary productivity of the global vegetation (Sage, 2004). A large component of the primary productivity of C_4 plants (e.g. maize, millet, sugarcane, and sorghum) is appropriated by humans for food for themselves or their livestock.

C_4 photosynthesis is a series of biochemical processes that act to concentrate the absorbed CO_2 around the Rubisco enzyme (Hatch *et al.*, 1971; recently reviewed by Sage, 2004). In C_4 plants, as the CO_2 passes into the cytoplasm of the mesophyll cells, it is converted to HCO_3^- by the enzyme, carbo-anhydrase, and this is subsequently bound to a (3-carbon) phosphoenol pyruvate molecule (PEP) in a reaction catalyzed by the PEP carboxylase enzyme (Larcher, 1995). The resultant 4-carbon compound is transferred to chlorenchyma cells (away from direct contact with the air, and O_2) and subsequently decarboxylated to form pyruvate and CO_2. The CO_2 is then taken up by Rubisco and bound to a RuBP molecule. The reactions of photosynthesis then proceed as for C_3 plants.

The C_4 pathway may be advantageous in environments having a low concentration of CO_2 in the atmosphere because the mesophyll cells of C_4 plants are able to extract almost all of the CO_2 from the intercellular air (Ehleringer *et al.*, 1991). The pathway may also be advantageous in arid environments, as the combination of effective scrubbing of CO_2 from intercellular air, and the absence of photorespiration, result in greater water-use efficiency of C_4 plants (Ehleringer *et al.*, 1991). This reduced requirement for water could also confer advantages in saline or toxic environments. As less Rubisco is needed for C_4 photosynthesis, the nutrient requirements of C_4 plants are potentially reduced (Larcher, 1995). Additionally, the C_4 pathway appears to be energetically more efficient than the C_3 pathway in environments where the concentration of CO_2 in the atmosphere is similar to or less than the present ambient concentration (Nobel, 1994).

The C_4 pathway is utilized by plants that grow in a range of environmental conditions. It is used by annual herbaceous plants, especially those that grow in tropical regions, and summer annuals further from the equator. It also occurs in some aquatic plants and some shrubs (Larcher, 1995), in addition to the perennial grasses that inhabit arid tropical and subtropical environments. C_4 photosynthesis makes it possible for perennial grasses in semiarid and arid regions to take up CO_2 when there is very little water available for transpiration. C_3 shrubs and trees survive in these regions by having very deep root systems that enable them to access water stored several meters below the surface. By contrast, the C_4 grasses can survive in dry conditions by using less water.

C_4 plants are also commonly found in tropical and temperate environments where there is abundant but seasonal precipitation (Ehleringer *et al.*, 1991). This suggests that the C_4 pathway may provide plants with other benefits in addition to increased WUE_{ph}. The increased efficiency of water and nutrient use appears to be of little benefit to C_4 plants such as maize and sugarcane. These crop plants are profligate consumers of both water and nutrients (Masefield *et al.*, 1969). Under optimal conditions and current atmospheric CO_2 concentration ($\sim$370 ppm), the maximal rate of net CO_2 uptake for fast-growing, highly productive, cultivated C_4 crops is about 1.25 times the rate for C_3 crops grown under comparable conditions (Nobel, 1994). The C_4 pathway may benefit these species that grow in dense stands by allowing them to assimilate more CO_2 (due to more efficient scrubbing of CO_2 from the atmosphere within the stand) during the day.

While C_4 plants separate CO_2 uptake from the photosynthetic carbon reduction cycle (i.e. the dark reactions of photosynthesis) in space, CAM (crassulacean acid metabolism) plants separate it in time (Larcher, 1995). The $\sim$6% of plant species that utilize the CAM pathway include most cacti and succulent leaved plants (Nobel, 1994). The stomata of CAM

plants open for CO_2 uptake at night. The initial process of CO_2 fixation to produce 4-carbon acids is the same as in C_4 plants. However, whilst in C_4 plants, the 4-carbon acids are exported to other cells, in CAM plants the acids are stored overnight in the vacuole of the same cell. The following day (while the stomata are closed), the acid is decarboxylated to provide CO_2 to the chloroplasts of the same cells. The CO_2 is then taken up by Rubisco and the reactions of photosynthesis proceed as for C_3 plants.

By taking up CO_2 at night, plants that utilize the CAM pathway are able to minimize water loss. According to Nobel (1994), the water-use efficiency of CAM plants is about six times that of typical C_3 plants. During periods of severe drought CAM plants are able to keep their stomata closed day and night, and capture and recycle CO_2 released by respiration (Larcher, 1995). Plants that use the CAM pathway can also take up CO_2 during the day using the C_3 pathway (Nobel, 1994). The CAM pathway provides an alternative mechanism by which plants can minimize water and nutrient use (because of the reduced Rubisco requirement) and thus survive in extreme (arid or saline) environments.

Individual Plants and Ecological Strategy

With the exception of the C_4 and CAM modifications to CO_2 uptake, the basic process of photosynthesis is reasonably conserved across the plant kingdom. Over a unit area, the availability of resources (carbon dioxide, water, light, mineral nutrients) at a given time to the plant tissues that require them limits the potential amount of photosynthesis and transpiration that can occur and this limits the extent of the vegetation canopy.

There are many possible ways in which the photosynthetic tissues forming the canopy can be arranged in space and time; these different arrangements can be conveniently called *ecological strategies*. Successful ecological strategies allow individuals, or species, to persist at a site over years to decades to centuries. The main strategies are summarized in Table 1. One or more of these strategies may be utilized by the vegetation at a site or within a catchment. The Budyko framework (Section "Budyko's approach to catchments") focuses on energy and water and does not apparently need to consider the ecological strategy of the vegetation in a catchment. This seems to be a useful approximation at the annual scale. However, hydrologists are also interested in the time course of events, for example, the magnitude and timing of peak and base flows, and these can be altered by the ecological strategy of the vegetation in a catchment (Figure 5). That is the subject of this section.

Dynamics of the catchment water flows are affected by the ecological strategies in two basic ways: (i) through separation in time of the evaporation flux from the precipitation flux; and (ii) through changes in the volume of the active soil layer that is involved in water exchange. Plants that utilize the annual or ephemeral strategy produce leaves and carry out their photosynthesis and transpiration when there is sufficient moisture and energy content in the upper soil profile. When annual or ephemeral plants can no longer access moisture because the soil is drying, or because the increased viscosity of cold water (Roderick and Berry, 2001) slows the flow of water sufficiently to drought the leaf tissues (Daubenmire, 1974), the stems and leaves die. The leaves of annuals and ephemerals are capable of very high rates of photosynthesis but are short-lived (weeks to <6 months). The deciduous strategy is similar to the annual strategy, except that the stems persist from year to year, and the woody root system allows deciduous plants to obtain moisture from a larger volume. The evergreen woody, perennial, and cacti/succulent strategies allow for plant survival by using the available water at a slower rate over a longer period (e.g. Hollinger, 1992). By retaining a canopy, these plants can exclude some light from deciduous and annual plants. The longer-lived leaves typical of evergreen plants have less tissue involved in photosynthesis and more structural tissue. Depending on the proportions of these two basic tissue types, the evergreen vegetation may be mesic (relatively low proportion of structural tissue) or sclerophyllous (relatively high proportion of structural tissue) (Berry and Roderick, 2002b). As perennial herbaceous plants obtain their moisture requirements from upper soil layers they must survive dry periods by conservative use of water. Some woody evergreens may also utilize this strategy. However, many woody evergreen plants growing in water-limited environments have extensive root systems to access water several meters below the soil surface. Water may also be stored in plant tissues for later use by the plant. For example, Waring *et al.* (1979) estimated the total water storage capacity of plant tissues in four stands of Scots pine forest in northeastern Scotland to be 124, 147, 153, and 212 $m^3\,ha^{-1}$. They found that the transpiration flux from these forests during the summer rarely exceeded 3 $mm\,day^{-1}$, and the stored water contributed 30–50% of

Table 1 Ecological strategies utilized by plants

Leaf longevity	Plant form and ecological strategy
Usually <6 months	Herbaceous (grasses and forbs) **Annuals and ephemerals** Woody (trees, shrubs, and vines) **Deciduous**
1 year or longer	Herbaceous (grasses and forbs) **Perennial herbs** Woody (trees, shrubs, and vines) **Evergreens**
No leaves, use stems for photosynthesis	Store water in fleshy stems **Cacti and succulents** Leafless woody (trees, shrubs, and vines) **Evergreens**

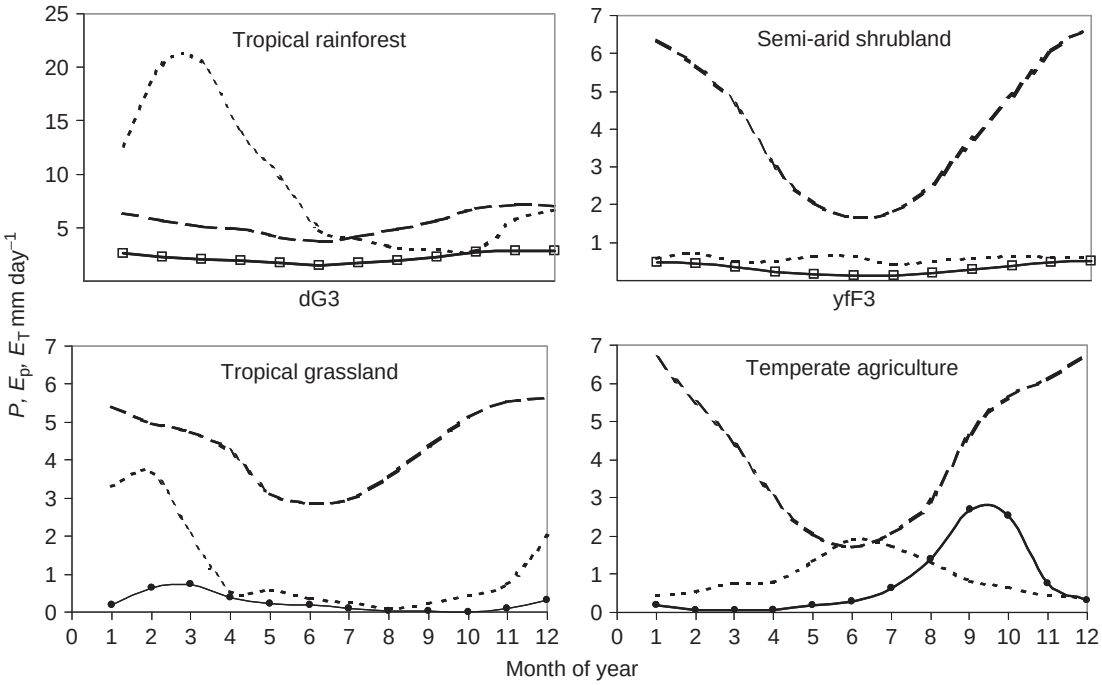

Figure 5 Estimated annual course of transpiration (E_T), precipitation (P) and potential evaporation (E_p) for four vegetation types of contrasting ecological strategy. Solid line, transpiration; open squares, evergreen woody; filled circles, annual herbaceous; Short dashes, precipitation; Long dashes, Potential evaporation. Data from Berry and Roderick (2004). Site locations are tropical rainforest 145.9 °E, 17.9 °S; tropical grassland 142.2 °E, 21.1 °S; semiarid shrubland 140.1 °E, 32.9 °S; temperate agriculture (winter wheat) 118.6 °E, 32.1 °S

the transpired water. In these forests, assuming a 30–50% contribution of stored water to a 3-mm day^{-1} transpiration flux, 150 m^3 ha^{-1} of stored water in plant tissues (equivalent to a 15-mm depth of water over the surface) would be depleted in 10–15 days. In water-limited environments, the utilization of water stored within the plant tissues or well below the soil surface allows the evaporation of water during periods of little or no precipitation (Fritts, 1976; O'Grady *et al.*, 1999).

Whenever evaporation is limited by water availability (see Figure 2), changes to the dominant ecological strategy (Table 1) associated with land use change may alter the hydrological balance. It has been commonly observed that the stream flow increases with reductions in forest canopy cover associated with fire or timber harvesting (Bosch and Hewlett, 1982). This has been observed in environments where evaporation is limited by water availability or energy availability (Malmer, 1992). Subsequent forest regeneration results in a decrease in stream flow to preclearance amounts (Fahey and Jackson, 1997; Langford, 1976).

In terms of the catchment mass balance, the observed changes in stream flow (runoff, r) could result from changes in $\mathrm{d}S/\mathrm{d}t$, P, or E (see equation 6). For practical hydrological purposes, the store of water in plant tissues may be considered part of $\mathrm{d}S/\mathrm{d}t$. As changes in r have been observed in paired catchment experiments (i.e. having a control and a treatment site; e.g. Malmer, 1992; Fahey and Jackson, 1997; Cornish and Vertessy, 2001) that allow P to be normalized, the residual (and large) changes in r must arise from changes in $\mathrm{d}S/\mathrm{d}t$ and E.

A decrease in the amount of water stored in the active layer where exchange occurs, $\mathrm{d}S/\mathrm{d}t$, would be expected when deep rooted vegetation is replaced by shallow rooted vegetation. This decrease would result from a reduction in the thickness of the layer of soil involved in active exchange and a reduction in the storage capacity of plant tissues. This is commonly observed when woody vegetation is cleared for pasture and agriculture, and replaced with annual herbaceous vegetation. When that happens, the dynamics of water flow are affected by both the decrease in the volume of soil involved in exchanges with the atmosphere, and the increase in the temporal variance of the transpiration flux (and a decrease in E) over the annual period (see the temperate agricultural example in Figure 5). This often results in a rise in the height of the water table (the top of the zone of water saturation) and the attendant problems of wet season waterlogging in low-lying parts of the landscape (Brady and Weil, 2002).

In environments where evaporation is limited by the availability of energy the soil profile typically remains wet throughout the year. Consequently, $\mathrm{d}S/\mathrm{d}t$ remains near zero and any change in r must result from a change in E.

In that case, a change in E may result from a change in net radiation (R_n, equation 5), arising from a change in albedo (α, equation 1) associated with the land cover change. This effect will be small when Q_s is small, for example, at high latitudes where the top of atmosphere solar irradiance is small, and/or very cloudy or polluted locations where the atmospheric transmittance is low.

Soil: Water and Nutrient Cycles

The formation of soil results from the interaction of the climate and the biota (vegetation and organisms) with the parent rock material. The soil comprises material in the solid (mineral and organic particles), liquid (water, minerals, and organic matter in solution), and gaseous (soil air) phases. The volume fractions of these three phases changes over time through the accumulation and leaching of solid particles, and with wetting and drying cycles.

Water in soils may be (i) bound to the soil solids as water of hydration (bound water), (ii) hydrogen bonded to other water molecules in capillary spaces (capillary water), or (iii) associated only with other water molecules or solutes (i.e. salts in solution), and free to flow through the soil pores (free water). The free water is only present when the soil is saturated, thus all of the pores are filled with water. When the soil is at field capacity, the macropores are filled with air and the water in the soil is held against gravity as bound and/or capillary water. At field capacity, only the capillary water is available to plant roots (Brady and Weil, 2002).

The water holding capacity (WHC) of soils is greatly affected by soil properties including the soil porosity, and the soil texture. The porosity is the volume fraction of the soil that is not occupied by solids. It can be estimated from measurement of the bulk density, which is the mass of dry soil per unit of bulk volume (soil plus pore space). The soil texture is a measure of the size distribution of soil particles.

There is a consistent trend of many soil properties to vary with particle size. Some of these are shown in Figure 6. Sand particles pass through a 2-mm sieve but are retained by a 0.05-mm sieve (Brady and Weil, 2002). They are usually comprised of quartz (SiO_2), so provide few mineral nutrients for plants. Being relatively large and globular in shape, they have a low ratio of surface area: volume (SA:V). Sandy soils lacking in organic matter have a low WHC. The large pores between the sand particles allow water to flow through rapidly, so sandy soils tend to drain freely following saturation as there are few capillary spaces.

Silt particles pass through a 0.05-mm sieve but are retained by a 0.002-mm sieve. These particles are basically microsand particles, dominated by quartz minerals (Brady and Weil, 2002). Although the particles are similar in shape to sand, they have a much larger SA:V ratio. The presence of capillary-sized spaces between the particles gives silt a much greater WHC than sand.

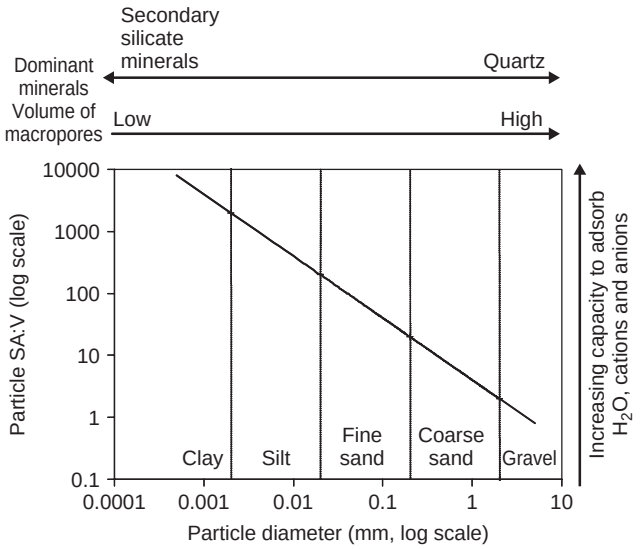

Figure 6 Relationship between soil particle size and general trends in soil properties

Clay particles are smaller than 0.002 mm and have a very large ratio of SA:V (Figure 6). Clay particles have internal as well as external surfaces, as they are structured as a stack of adhering layers (like a stack of plates). Consequently, there is an extremely large surface area onto which water molecules, anions, and cations can be adsorbed. The pores in clay soils are minute, and some kinds of clay swell on wetting. These properties give clays a very large WHC. Some of the capillary water is not available to plants in fine-textured clay soils as some of the capillary spaces are too small to allow root access. Consequently, the wilting point (i.e. the moisture content of the soil below which water is no longer accessible to plant roots) in clay soils occurs at higher soil moisture content than in the coarser soil types.

Although in the forgoing discussion the properties of individual soil particle size fractions were considered, soils may comprise one or a mixture of these particle size classes and thus display properties intermediate to the extremes. The mass fractions (dry mass basis) of the three components can be used to describe textural classes. The textural classes are generally illustrated in soil textbooks (e.g. Brady and Weil, 2002) using a ternary diagram, also known as the *texture triangle*. Whilst the soil texture is broadly related to soil WHC, soil aeration, and the potential availability of mineral nutrients required by plants, many other factors including climate, land use, and management, the chemistry of the parent material, and the vegetation also influence these soil properties. A more detailed discussion of these processes is provided by Brady and Weil (2002) and Schlesinger (1997).

The vegetation modifies soil properties by: (i) creating macropores through, for example, old root channels;

(ii) providing food for the soil biota; and (iii) producing organic compounds that resist decay and form the soil humus fraction. The formation of macropores by root penetration assists the percolation of water to deeper soil layers, reducing surface runoff. Soil biota serve many functions including the decomposition of organic compounds to release mineral nutrients, and improved soil aeration (e.g. through worm tunnels). Particles of humus have a similar size and ratio of SA:V to fine clay particles. The presence of humus greatly increases the WHC and nutrient holding capacity of soils. In low nutrient, excessively wet (anaerobic) environments the organic matter accumulates to form the upper soil horizons.

Catchment

At the catchment scale, the relationship between the vegetation, soil, and climate is sufficiently consistent to allow coarse resolution soil maps to be constructed from vegetation distributions. (For a detailed discussion of the relationships between vegetation formations and soil types see Eyre, 1968). In energy-limited environments (Figure 2), the vegetation has access to a plentiful supply of soil moisture throughout the year. In these environments, provided that the soil is not waterlogged and that the water is not frozen (e.g. as permafrost or snow), the vegetation forms a closed canopy (closed forest, Figure 3). The leaf properties (e.g. composition, morphology, capacity for photosynthesis and longevity) of the canopy reflect the availability of carbon (atmospheric CO_2 and light) relative to mineral nutrients (soil factors). As the concentration of CO_2 does not vary spatially at the catchment scale, the availability of mineral nutrients largely determines the type of vegetation forming the closed forest. The availability of nutrients is affected by factors such as the decomposition rate of organic material, as well as properties related to soil texture.

In water-limited environments (Figure 2), the canopy becomes increasingly more open as the water deficit increases (e.g. $R_n/\lambda P > 1$, Figure 3). In these environments, there is seasonal variability in the availability of water resulting from seasonality of precipitation and/or run-on and/or seasonal variation in solar radiation. As the environment becomes increasingly arid, the ecological strategy of the vegetation is dictated by the availability of soil moisture to plants (Stephenson, 1990). The plant available soil moisture (PAM, the difference between the moisture content at field capacity and at the wilting point) is affected by soil properties (see Section "Soil: water and nutrient cycles") and the volume of soil involved in water exchange with the atmosphere, as well as by the climate. The ecological strategies (Table 1) of the natural vegetation reflect the PAM and the inter- and intra-annual variability of PAM. This variability can be expressed as the coefficient of variation in PAM, or V_{PAM}, which is the standard deviation of PAM expressed as a percentage of the mean. Over the annual period, PAM is highly correlated with P/E_p (Walker and Langridge, 1997). (According to Budyko, 1974, the potential evaporation, E_p, can be equated to R_n/λ. Thus P/E_p is the reciprocal of Budyko's radiative index of dryness, $R_n/\lambda P$ in Figure 3.) Woody evergreen trees occur when P/E_p is moderate to low and plants can access moisture (perhaps at variable depths within the soil profile) throughout the year. With increasing aridity evergreen trees are replaced by evergreen shrubs. Deciduous trees and shrubs dominate at low to moderate P/E_p at higher V_{PAM}. This variability in PAM may be due to seasonal water deficit within the rooting zone of the plants associated with a soil moisture deficit (e.g. in monsoonal wet/dry tropics), or a seasonal energy deficit (and perhaps freezing of the soil) at high latitudes. As water cools, its viscosity increases and the water molecules become more strongly bound to the soil particles and the adjoining hydration layers. Thus, although water is present in the soil it may not be available to the plant at the rate required to meet the transpiration demand (Daubenmire, 1974). The herbaceous strategies dominate where woody plants cannot survive. C_3 perennial herbaceous plants dominate at moderate to high P/E_p where the soil is seasonally saturated in winter and PAM is low in summer due to a soil moisture deficit exacerbated by clay soils. C_4 perennial herbaceous plants dominate in environments that are too arid for woody vegetation but where PAM is sufficiently available (Section "Leaf biochemistry"). When there is high within year V_{PAM} resulting from the interaction of seasonal precipitation and clay soils, and P/E_p is moderate to low the annual herbaceous strategy is dominant. In low P/E_p environments having high within year V_{PAM} but reliable (but low) seasonal annual rainfall, cacti and succulents survive by storing water in their stems. In low P/E_p environments having high between-year V_{PAM} only, the ephemeral herbaceous strategy is viable.

TOWARDS OPTIMALITY

From the observation that there are repeatable patterns between the natural vegetation cover, climate, and soil properties (Sections "Budyko's approach to catchments" and "Catchment"), and between canopy cover and soil moisture availability (Stephenson, 1990; Specht, 1972; Woodward, 1987), it can be inferred that natural vegetation tends to some type of "optimality". Of course, that should not be a surprise because the Darwin–Wallace concept of natural selection ("survival of the fittest") includes the idea of optimality. However, the Darwin–Wallace theory is still largely qualitative. Hence, it is not surprising that many different optimality schemes have been used to try and predict the vegetation in terms of climate, along with the properties of the soil and the air. In some respects, these approaches are pragmatic in that they use the concept of optimality to simplify the problem at hand. For example,

one widely used idea is that the "natural" vegetation is arranged in space/time so that the photosynthetic uptake is optimized (e.g. Woodward, 1987). This, or similar approaches, are fundamental to many vegetation models (Schimel *et al.*, 1996; Schimel *et al.*, 1997).

In this section, we briefly review how the idea of optimality can be used in hydrology. Following that, we present some of the previous work on vegetation optimality from hydrology (Eagleson, 1982, 2002; Eagleson and Tellers, 1982), plant physiology and biophysics (Cowan and Farquhar, 1977), and ecology (Berry and Roderick, 2002a). After that, we briefly review a new and somewhat different approach that is based on a combination of fluid mechanics, thermodynamics, and an engineering philosophy of purposeful design (Bejan, 2000). This latter approach has not to our knowledge been applied in classical hydrology (or ecology), but we believe that it has the potential to be applicable throughout the hydrological sciences.

Some Simple Optimality Concepts

Perhaps the simplest way to introduce the idea of "optimality" is to return to the mass and energy balances of the Section "Mass and energy balance". For example, when E is limited by the availability of water, the photosynthetic uptake is limited by the capacity of the vegetation to access water for transpiration (E_T). In this case, an optimal vegetation cover (and mixture of ecological strategies) will act to maximize the appropriation of precipitation to the transpiration flux.

Alternatively, when E is limited by the availability of energy, the photosynthetic uptake is limited by the capacity of the canopy to access light (photosynthetically active radiation). In this case, an optimal vegetation cover (and mixture of ecological strategies) would maximize energy capture. One way of doing this is to increase the total single-sided leaf area per unit of land surface (known as the *leaf area index*). In light-limited environments a multilayered canopy is common.

Optimal Canopy Cover Based on Energy and Water Limitation to Plant Growth

Eagleson (1982) proposed theory and formulated hypotheses to predict the optimal projected foliage cover of the vegetation (PFC) from average annual water balance parameters and some basic soil hydraulic properties. In that and subsequent formulations it was assumed that there is always a nonlimiting supply of CO_2 and mineral nutrients. Also, the PFC is considered to be a surrogate for productivity which is in turn proportional to E_T. It was hypothesized (Eagleson, 1982) that when water limited, the optimal vegetation cover has a PFC that minimizes the "water demand stress" (i.e drought) under the local climate conditions. This requires that the optimal canopy uses the available water conservatively so that soil moisture is maximized whilst PFC and productivity are also maximized. The formulation was tested using catchment-scale estimates of the water balance along with canopy cover. The results were encouraging (Eagleson and Tellers, 1982). This is the second paper from the series and this has resulted in more research along this line (Eagleson, 2002).

One of the main aims for the original work by Eagleson was to avoid the need to collect vast amounts of detailed soil and vegetation information which is either impractical or impossible to achieve. Hence, the work must be viewed in that context. Further, the pioneering nature of the work meant that Eagleson made many simplifying assumptions. For example, that nutrients and CO_2 are nonlimiting. Hence, one could not use the Eagleson approach to assess the impact of increasing atmospheric CO_2 on the transpiration from catchments. Despite any shortcomings (e.g. Kerkhoff *et al.*, 2004), the Eagleson approach does demonstrate that the idea of optimality is potentially useful in hydrology and ecology.

Optimality of Canopy Water-use Efficiency of Photosynthesis

Cowan and Farquhar (1977) and Cowan (1982) proposed that there has been an evolutionary tendency for optimization of CO_2 uptake relative to water loss by plants that exist in water-limited environments. This is achieved by varying the transpiration rate throughout the day by movements of the stomata so that a given CO_2 uptake (and carbohydrate production) is achieved with the lowest possible loss of water. Equivalently, for a given water loss, the maximum amount of CO_2 is taken up. In their formulation, the optimum occurs when the partial derivative of transpiration (E_T) with respect to assimilation (A) is equal to a constant, τ;

$$\frac{\partial E_T}{\partial A} = \tau \tag{14}$$

If real leaves (and canopies) followed equation (14), then the assimilation would be a maximum for a given amount of transpiration, despite the within-day variations that may occur in the concentration of CO_2 and the vapor pressure of H_2O in the air surrounding the leaf. There is substantial experimental evidence (e.g. Farquhar *et al.*, 1980b; Williams, 1983; Hari *et al.*, 1999) that the behavior of stomata over an entire day is consistent with the Cowan–Farquhar optimality model. The outcome from this optimization is more rapid growth without a reduction in the probability of survival.

Unlike the Eagleson approach, nutrients and CO_2 are both explicitly included in the Cowan–Farquhar scheme via the involvement of nutrients and CO_2 in photosynthesis. The Cowan–Farquhar scheme has recently been further developed to incorporate optimization of nitrogen allocation

within the canopy to maximize the carbon gain from photosynthesis (Farquhar *et al.*, 2002; Buckley *et al.*, 2002). This allows for the prediction of changes in canopy leaf area in response to changes in the availability of water.

A Qualitative Approach Based on Plant Community Dynamics

One of the distinguishing features of natural vegetation is that monocultures are rare. Instead, ecological communities are usually composed of a mixture of species having different ecological strategies (Section "Individual plants and ecological strategy"). This can lead to difficulties for the Eagleson-type approach. For example, the productivity of a shrubland growing on a nutrient impoverished soil will be much less than that of a forest having the same PFC but growing on relatively fertile soil. The differences between the shrubland and forest noted above are largely described by differences in the longevity of the leaves (Roderick *et al.*, 2000) and hence the ecological strategy. Describing these differences is the main thrust of community ecology.

One recent empirical approach that explicitly recognizes the importance of different ecological strategies has used satellite observations to separate canopies into three classes of leaves according to leaf longevity (Berry and Roderick, 2002a,b). The basic tenet of this approach is that many of the physiological attributes of leaves are known to be consistently correlated with leaf longevity (Roderick *et al.*, 2000), and as noted above, are thereby also correlated with the ecological strategy. By comparing their results with existing vegetation maps, Berry and Roderick (2002a) found that the satellite-derived estimates of leaf longevity were realistic. The implication is that the properties of soil need not be known as they are already contained in the observations of the canopy. (This is consistent with one of the basic tenets of the Eagleson approach.) Berry and Roderick also showed how the framework could be used to make predictions, for example, what would be the impact of changes in disturbance or atmospheric CO_2 on the vegetation assemblage. The utility of their approach is that the leaf longevity classes provide a direct link back to the underlying physiology and the ecological strategy. Thus, this largely empirical approach could be used as the basis for understanding the relationships between ecological strategy and the dynamics of the water balance at landscape (and larger) scales.

One criticism of the Berry–Roderick approach is that optimality is implicitly assumed but is not made explicit because there is as yet no formal mathematical framework like the Eagleson and Cowan–Farquhar approaches that can be applied to a community of plants. This remains a major challenge to ecologists (and hydrologists) and one possible approach may be through the application of the "constructal" theory of Bejan which we discuss in the following section.

Potential Hydrological and Ecological Applications of Bejan's Theory

"Constructal" theory is the name given by A. Bejan to an approach that seeks to rationalize both engineered and natural flow systems (Bejan, 2000). Bejan has proposed that both engineered and natural flow systems "evolve" towards optimal states and has derived optimality criteria to describe those states. Note that the engineered systems "evolve" because the engineers designing the systems are always seeking to improve the system performance. The theory was originally conceived and developed in traditional engineering applications, and uses methods familiar to engineers (e.g. fluid mechanics, thermodynamics) but has not to our knowledge yet been applied in traditional hydrological applications (e.g. water balance, runoff estimation). Nevertheless, the theory (Bejan, 2000) provides a number of examples of flow systems directly relevant to hydrology. Some examples include the geometric configuration of river flow, flow through (engineered and biological) trees and networks of channels, along with derivations of the scaling laws that govern those flows (see Bejan (2000) for further examples). Because the Bejan theory addresses flow systems, and the optimal states for those flow systems, we believe that it has many potential applications in hydrology (and ecology). However, we only give a very brief introduction to this new work here. Interested readers should consult Bejan (2000) for more information.

The basic principal of constructal theory is that engineered (e.g. heat exchangers) and natural flow (e.g. botanical trees) systems contain regions of low and high flow resistances. For example, a typical heat exchanger has a solid casing (region of high resistance) and fluid flowing through channels (regions of low resistance). Constructal theory considers both the flow of matter and energy and proposes that the high and low resistance regions are geometrically distributed in an optimal way. The term "constructal" is derived from this idea, that is, real, finite-sized systems are "constructed" from smaller components.

The approach of Bejan (2000) has potential application to the formulation of many of the difficult practical problems in catchment-scale hydrology. For example, a long-standing problem in hydrology is how to characterize the permeability (in the Darcy sense) of a catchment. As is well known, the difficulty is that many catchments are composed of regions of relatively impermeable material but have smaller regions of preferential flow, for example, flow of water through root channels in the soil. Consequently, it is very difficult (if not impossible) to estimate the catchment permeability using point scale measurements because the regions of preferential flow cannot be adequately sampled. Prof. Jeff McDonnell (personal communication to MLR, October, 2003) has proposed that we might be able to use Bejan's approach to characterize the permeability of a catchment by assuming that a natural catchment would

"evolve" towards an optimal state. The optimal state would have a balance between the storage of water (the high resistance flow path) and drainage of water from the catchment (the low resistance flow path). Hence, catchments in very wet places would "evolve" to shed the water by the low resistance flow path, and so on. While speculative, this idea seems worth pursuing.

As stated above, we believe that Bejan's ideas may have widespread applicability in hydrology. The reason is that there is already some evidence for this from ecology – specifically – the flow of water through tree stems. For example, wood scientists and foresters have long known that the density of the solid material that makes up wood is near constant at about $1.5\,g\,cm^{-3}$. (This is more or less the density of cellulose that is listed in any materials handbook.) However, wood scientists and foresters have also long known that the density of dry wood (dry mass per unit total volume) varies from about 0.1 up to $1.1\,g\,cm^{-3}$. It follows that these differences must arise because of differences in the volume fraction of the solid material. For example, a "light" wood like Balsa has a very low volume fraction of solid material while a heavy wood like a tropical hardwood has a very high volume fraction of solid material. The significance is that if the tropical hardwood has a high volume fraction of solid, then it must have a low volume fraction of liquid and/or gaseous phases, and these phases are where most of the flow (and biochemistry) occurs. (The reverse case applies to Balsa.) Quite independently from Bejan's theory, Roderick and Berry (2001) used the above facts to derive physical expressions to describe the flow rate of water through tree stems assuming laminar (Poiseuille) flow. The resulting theory predicted amongst other things that (i) for a given pressure gradient the flow of water through wood would increase as the wood density declined and (ii) if the flowing water were cold, and therefore had a higher viscosity, that the wood density should decline. The common occurrence of "softwoods" (i.e. low density wood) in cold climates is consistent with the above prediction. Subsequent work on this theory in the field (Barbour and Whitehead, 2003; Atwell *et al.*, 2003) and in laboratory experiments (Thomas *et al.*, 2004) has found the theory to be in accord with observations. At the time that the above-noted theory was derived, the authors were not aware of Bejan's constructal theory. Nevertheless, in retrospect, the Roderick and Berry (2001) theory is in general accord with the ideas underlying Bejan's constructal theory.

CONCLUSION

Primarily as a consequence of interest in the effects of the increasing concentration of carbon dioxide in the atmosphere, an understanding of interactions between the vegetation, soil, climate, and air has now become a research priority. These interactions are complex and in this article we have sought to describe them through transfers of energy and matter across the atmosphere-lithosphere boundary, mainly from the perspective of the vegetation. Through this approach, the role of the terrestrial vegetation as an active (rather than a passive) link between the atmosphere, lithosphere, and hydrosphere becomes evident. By altering the surface properties, the vegetation can modify the outgoing fluxes of solar and terrestrial radiation (Section "Surface energy balance") and the partitioning of net radiation into latent and sensible heat (Section "Surface energy balance" and "Individual plants & ecological strategy"). The vegetation can also potentially modify all components of the hydrological balance (Section "Catchment mass balance"). Rainfall that may otherwise accumulate in the soil store or contribute to runoff if vegetation was absent is returned to the atmosphere by the transpiration flux from the leaves. The ecological strategy of the vegetation affects the dynamics of catchment water flows through temporal separation of the evaporative (transpiration) flux from the precipitation flux, and through changes in the volume of the active layer of soil involved in exchange of water with the atmosphere (Section "Individual plants & ecological strategy"). Organic matter has a high water holding capacity and its incorporation into the soil thus alters the soil hydrological properties (Section Soil: water and nutrient cycles). In the first three sections of this article, we discussed the vegetation in a general way. However, in the eco-hydrological context, vegetation implies a collection of individual plants that grow to form repeatable structural patterns (representing one or more ecological strategy) that relate to the availability of water and energy and soil properties. These repeatable patterns have long been recognized by natural scientists. For example, most vegetation mapping is based on the idea of repeatable (structural) assemblages. We discussed how these repeatable patterns had been described in terms of "optimality" (Section "Towards optimality"). One widely used approach to "optimality" is to assume an extremum principle based on, for example, maximization of the conversion of energy from solar radiation into chemical energy of covalent bonds (i.e. gross primary productivity, GPP). Other optimality approaches might also prove useful and we expect this to be a key research thrust of both hydrologists and ecologists over the coming decades.

13: Pattern, Process and Function: Elements of a Unified Theory of Hydrology at the Catchment Scale

MURUGESU SIVAPALAN

Centre for Water Research, The University of Western Australia, Crawley, Australia

Catchment hydrology is presently operating under an essentially reductionist paradigm, dominated by small-scale process theories. Yet, hydrology is full of examples of highly complex behavior, including strong nonlinearities and thresholds, and paradoxes that defy causal explanation through these small-scale process theories. There are strong interactions and feedbacks between processes, leading to apparent simplicities in the overall catchment response, yet the laws governing these feedbacks are not well understood. Routine measurements and specialized field experiments have been valuable for observing catchment responses and understanding the underlying process controls, but there has been little progress in extrapolating the local knowledge and understanding gained from these well studied (or gauged) catchments to ungauged catchments. Efforts at generalization are hampered by the lack of an appropriate quantitative framework, for example, a classification system, to help identify interesting and useful patterns in the observations. There are many theories governing different elements of catchment hydrology, but not a unified theory that connects these seemingly disparate elements. This article presents the broad outlines of an emerging new, unified theory of hydrology at the catchment scale, and the approaches being used to develop it. The new theory embraces multiscale heterogeneities as a natural and intrinsic part of catchment hydrology. Instead of relying solely on current process theories, it seeks to discover new catchment-scale process theories that embed within them the effects of natural heterogeneities. Instead of attempting to prescribe in detail the actual patterns of heterogeneity in every catchment, it will seek to incorporate the geomorphic or landforming processes that may have generated them in the first place, and their ecological, pedological, and geomorphological functions. Instead of using our rather meagre observations to calibrate complex models that are based on small-scale theories, the theory will emphasize the use of patterns in the observations to formulate and test alternative hypotheses about the underlying process controls. Instead of using field measurements to learn more and more about individual catchments, it will seek to find connections between observations in different catchments, to identify broad-scale or general patterns. The defining feature of the new theory of catchment hydrology will be a sharp focus on the interconnection and feedbacks between pattern and process, over a range of scales, and their interpretation in terms of their "function", that is, the reason that these connections arise. The renewed focus on pattern, process, and function will revolutionize hydrology, elevate its place within the earth system sciences, and strengthen the scientific foundations of its practice.

INTRODUCTION

Owing to its focus on water, the science of hydrology holds a unique and central place in the field of earth system science, intimately intertwined with other water-related disciplines such as meteorology, climatology, geomorphology, hydrogeology, and ecology. As an applied science, hydrology is highly relevant to the management of the world's water resources and water quality, and for the prediction, prevention, and amelioration of water-related

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

natural hazards, such as floods and droughts. Thus, hydrology should be an exciting field of study, yet it appears to be fragmented, deeply rooted in empiricism, and struggling to realize its full potential.

Hydrology boasts of many theories, for each of its many constituent processes (e.g. infiltration, evaporation, overland flow, groundwater flow etc.), but there is an almost complete lack of an holistic theory unique to hydrology itself, unifying these many varied theories. In spite of the sophistication of the individual process theories, there has been little progress toward understanding the laws governing the interactions and feedbacks between these processes, so much so that models based on current process theories often cannot explain or reproduce key patterns of observed hydrological behavior (Tromp-van Meerveld and McDonnell, 2005). The reliance on individual process theories, and the lack of a unifying theory governing process interactions and feedbacks, have led to a proliferation of complex hydrological models, which suffer from overparameterization and high predictive uncertainty. As an applied science, hydrology derives many of its methods of analysis and predictive tools from the experience gained through specializations such as engineering hydrology, agricultural hydrology, urban hydrology, and so on. However, there is little, if any, common ground amongst these different perspectives, nor between these perspectives and the advances made in fundamental process understanding. Scientific progress and advances in hydrological practice have both been hampered due to the lack of a unified theory of hydrology at the catchment scale.

There have been frequent calls for a new unified theory of hydrology, as it would considerably improve our understanding of hydrological phenomena, including a more holistic understanding of their function within the entire earth system, and improve the scientific management of water resources, water quality, and water-related natural hazards (Dooge, 1986; Dunne, 1998; Sivapalan, 2003a). There has been an increasing recognition of the presence of natural, multiscale heterogeneities in hydrology, and of the need for an holistic, rather than fragmented description of these heterogeneities in hydrological theory and practice (Gupta, 2000). It has been suggested that with the advent of a new unified theory, we would not need to appeal to different, and often contradictory, conceptual models to explain (physical and chemical) phenomena that coexist in the same catchment (Kirchner, 2003).

This article presents a broad review of the current theoretical foundations of hydrology, the possible approaches to developing a more coherent and unified theory, and a brief survey of the progress that has already been made. On the basis of this review and a survey of current global trends in the scientific arena, the article identifies new opportunities and challenges that may be poised to accelerate the development of a new unified hydrological theory.

Subject Matter of Catchment Hydrology

In this article, we limit ourselves to the theory of hydrology pertaining to catchments, which are widely recognized as being the most fundamental landscape unit for the cycling of water, sediments, and dissolved geochemical and biogeochemical constituents. Catchments integrate all aspects of the hydrological cycle within a clearly defined area in a way that can be studied, quantified, and acted upon (Wagener *et al.*, 2004). It is for this reason that we choose catchments as the building block for the development of a new hydrological theory.

While practitioners of catchment hydrology approach the field from many different perspectives, all of them still have as their basis, the need to understand, manage and/or deal with space-time variability of catchment responses to climatic inputs (water and energy) at the land surface. Understanding of the spatial and temporal variability of hydrological processes aggregated to the catchment scale, their extremes, and their scaling behavior both in time and space, is important for a number of applications: for example, flood estimation, drought mitigation, water resources systems analysis. The pathways that water takes in its passage through the catchment, their spatial and temporal variabilities, and the associated residence times, are important for water quality predictions and for managing the health of aquatic ecosystems.

Hydrologists are also concerned with the need to understand and predict alterations to these hydrological responses due to changes at the earth's land surface and to the earth system as a whole, due to human impacts and any global change. Predicting the effects of human impacts, such as urbanization and deforestation, is important from the perspectives of water resources assessment, mitigation of natural hazards, and water quality management. Exchanges of water and energy between the land surface and the atmosphere, their sensitivity to long-term climate changes, and their impact on global water and energy circulations and teleconnections, are important for the study of global hydrology and of the global climate system. Therefore, improvements to the theory of catchment hydrology will have positive ramifications beyond hydrology, contributing to the sustainable management of land and water resources and aquatic ecosystems, and to managing global change.

Catchments as "Complex Systems with Some Degree of Organization"

Hydrological processes arise as a result of interactions between climate inputs and landscape characteristics that occur over a wide range of space and timescales (*see* **Chapter 3, Hydrologic Concepts of Variability and Scale, Volume 1**). In the time domain, these may range from a few seconds needed to capture turbulent exchanges of mass, energy, and momentum between the land surface

and the atmosphere, to intermediate timescales governing runoff generation processes during storm events, for example, overland flow and subsurface stormflow, and long timescales governing deep groundwater flow, seasonal variations of climate and annual water balances, and interannual and interdecadal variabilities. In the space domain, the length scales may range from an individual soil pore, leaf blade or surface gully, to small hillslopes, to river basins as large as the Mississippi, to whole climatic or geographic regions, all the way to the entire globe.

Due to the tremendous heterogeneities in landscape properties and climatic inputs, the resulting hydrological processes are highly variable and complex at all scales. It is not practical, or even feasible, to routinely observe hydrological processes at the scale of a soil pore or a surface gully, or at the scale of a hillslope, in all catchments. For both scientific and practical reasons, routine observations of hydrological processes are made only at the catchment scale, leading to a gap between the scales at which processes actually occur, and the scale at which routine observations are made and predictions are required. Catchments thus qualify as *complex* or *poorly defined* systems. This means that while process understanding at all scales, especially at scales smaller than catchment scale, is very valuable in guiding or underpinning predictions of catchment responses, actual predictions must still be based and/or conditioned on observations at the catchment scale.

On the other hand, the catchment is a self-organizing system, whose form, drainage network, ground and channel slopes, channel hydraulic geometries, soils, and vegetation, are all a result of adaptive, ecological, geomorphic or landforming processes. As a result, they lend themselves to regular geometric patterns, which, if understood and embraced, may actually lead to a simplification of catchment descriptions to be used in analysis and predictions. Dooge (1986) categorizes catchments as "complex systems with some degree of organization" (Figure 1).

Hence a holistic theory of hydrology at the catchment scale must be founded on a synthesis of process understanding and process theories *at all scales*, with empirical theories derived from the analysis of observations at the catchment scale, mediated by theories governing the natural organization and self-similarity underlying the spatial heterogeneities in landscape properties. The next three subsections will give a brief overview of the current status of process theories, empirical theories, and theories relating to natural organization of landscape properties.

Current Status of Process Theories

In view of the central role of both water movement and storage in the catchment, which take place on the land surface including in river channels, in various parts of the soil, as well as in vegetation, catchment hydrology currently derives many of its laws from sister disciplines such as open

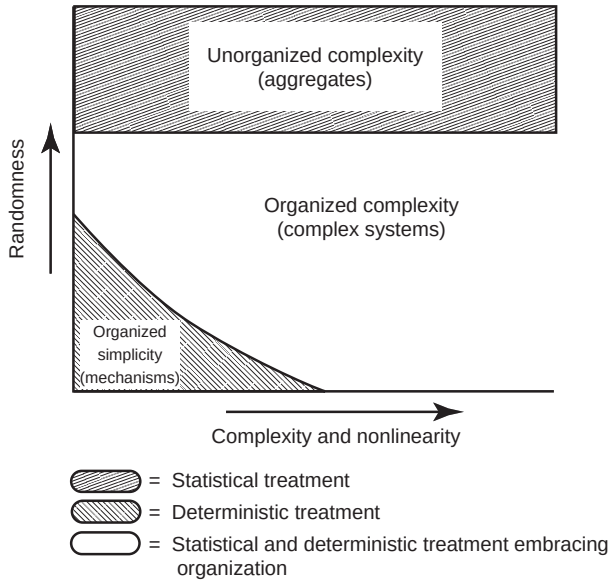

Figure 1 Catchments as complex environmental systems, that is, complex systems with some degree of organization. Adapted from Weinberg (1975) and Dooge (1986)

channel hydraulics, soil physics and chemistry, groundwater flow, crop micrometeorology, plant physiology, boundary layer meteorology, and so on. These laws and associated governing equations are used to quantitatively describe hydrological processes such as overland flow, snowmelt, channel flow, infiltration, recharge to the water table and capillary rise, evaporation, root water uptake and transpiration, and contaminant movement. Some examples include Darcy's law, Fick's law of diffusion, Manning and Chezy equations, the Saint Venant equations governing surface flows, Richards equation governing subsurface water movement, and the Penman and Penman–Monteith equations governing evaporation and transpiration. Detailed descriptions of these governing equations and their derivations have been presented elsewhere in this encyclopedia (*see* **Chapter 5, Fundamental Hydrologic Equations, Volume 1**), and in many standard textbooks, and will not be repeated here.

Considerable research has been carried out in the last 50 years toward the development and application of the governing equations, leading to significant advances in the understanding and description of many individual hydrological processes. Sophisticated numerical models have been developed on the basis of these governing equations, and the resulting numerical models have gained the status of physically-based models. However, it is often overlooked that the constituent process theories are essentially derived at the laboratory or other small scales. They are underpinned by assumptions of homogeneity, and uniformity, and time invariance of various flow paths, over the land surface and in channels, and through soils and vegetation (e.g. roots, stems, and leaves). In reality, catchments are

highly heterogeneous, dynamic and evolving entities (with respect to vegetation, soil structure, and morphology), responding dynamically to climatic inputs, which also exhibit tremendous variability in both space and time. One way that the catchment response can be modeled is by splitting the catchment into elements that are small and homogeneous enough so that the process theories can still be deemed to be applicable: this is the current paradigm (e.g. Abbott *et al.*, 1986a,b; Wigmosta *et al.*, 1994 and *see* **Chapter 11, Upscaling and Downscaling – Dynamic Models, Volume 1**). Another way is to develop the balance equations for mass, momentum, and energy directly at the catchment scale. Some progress has been made in this direction (Reggiani *et al.*, 1998; Reggiani *et al.*, 1999); however, the needed closure relations at the catchment scale, to replace the current ones based on Darcy's law, Fick's law, and so on still remain to be developed to complete the specification of the governing equations.

The difficulty, or even fallacy, of the reductionist paradigm that has dominated hydrological science for the past 25 years has been discussed and debated at length in recent times (Beven, 1989a, 1993, 2000a,b, 2001, 2002). For example, it is highly impractical, using current and even future technologies, to describe in full the natural heterogeneity exhibited in catchments; in the unlikely case in which we can, the resulting models will be overly complex, and pose a huge computational burden. In the more likely situation in which the model parameters cannot be estimated *a priori* from observable landscape properties, the resulting models will pose a huge parameter estimation problem (Beven, 1989a).

An even greater difficulty arises from the fact that, on their own, traditional process theories cannot account for processes and process interactions that may occur at the catchment scale in the presence of natural heterogeneities and the natural self-organization underlying these. For example, while our best models are predicated on porous media flow theory based on Darcy's law and Richards equation, we observe non-Darcian flow in the field (Tromp-van Meerveld and McDonnell, 2005) due to the presence of preferred pathways such as macropores. The use of passive tracers, for example, stable isotopes, chloride, and so on has demonstrated in many catchments that while streamflow responds promptly to rainfall inputs, fluctuations in the passive tracers are strongly damped, indicating the stormflow is mostly "old" water (Sklash, 1990; Turner and Macpherson, 1990; Buttle, 1994). The old water paradox – the fact that catchments store water for considerable periods of time and then release it promptly during storm events – cannot be explained by these small-scale process theories (Kirchner, 2003). A variety of concepts have been invoked in attempts to explain this phenomenon – piston flow, kinematic waves, transmissivity feedback, exchange between matrix and macropores (Beven, 1989b; McDonnell, 1990; Bishop, 1991; Kendall *et al.*, 1999), but with limited success. Clearly, mechanisms other than contained in our current process theories, must be at work here.

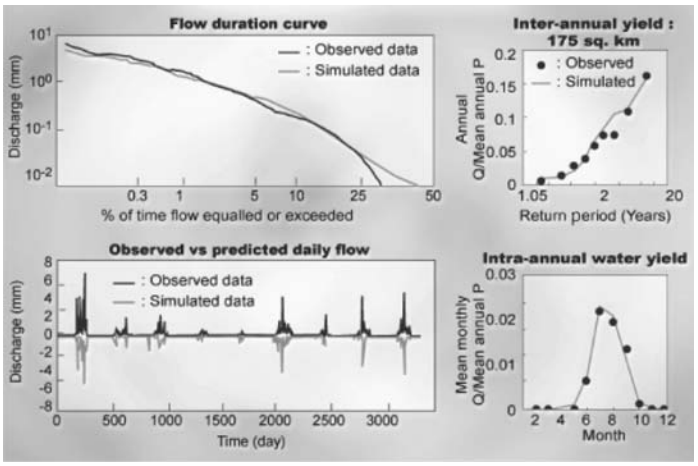
Current Status of Empirical Theories

Given that hydrological processes vary over a broad range of space and timescales, the business of hydrology is to understand, explain, and characterize hydrological variability, in space and time, including how this variability changes with time or space scale. Usually, this variability is characterized as a space-time field of the quantity of interest, be it streamflow, soil moisture, groundwater table depth, or rates of evaporation. Increasingly, we are also interested in the pathways that the water takes to arrive at the catchment outlet, the distribution of travel times, and the age of the water that exits the catchment as these are indicators of the underlying space-time variability of hydrological processes, and have implications for water quality predictions (Vache and McDonnell, 2005).

In the context of empirical data analysis, the role of theory is to provide a robust, quantitative, and reproducible framework to relate descriptors or *signatures* of hydrological variability to properties of the catchments and climatic inputs, which we might call *predictor variables*. When such robust relationships are established, we can then hope to predict the responses of catchments with confidence, given only the relevant climatic parameters and catchment properties. Therefore, the value of these signatures is not so much what they tell us about individual catchments, which is still considerable, but what they can tell us about differences between catchments. A robust and reproducible theory will evolve only when we broaden the search from ever more detailed explorations of processes *within* individual catchments toward quantitative and causal explanations of the differences *between* catchments.

Descriptors (Signatures) of Hydrological Variability

In order to develop coherent theories to underpin empirical data analysis, we need *signatures* of variability that are physically meaningful, and also useful in a practical context (*see*, **Chapter 3, Hydrologic Concepts of Variability and Scale, Volume 1**). Focusing on streamflow response, some of the commonly used measures of hydrological variability include interannual (between-year) variability of annual streamflow, and intraannual (within-year) variabilities, such as mean monthly variation (i.e. regime curve), the flow duration curve and annual rainfall-runoff relationships. These describe the character of temporal streamflow variability in one catchment, examples of which are presented in Figure 2(a). Other measures of temporal variabilities include the flood frequency curve, and the low flow (drought) distribution. In hydrology we are also interested in between-catchment variabilities of the measures listed earlier in the text, either within the same region, or between different hydroclimatic regions. Figure 2(b) presents the



(a)

(c)

Figure 2 Signatures of hydrological variability: (a) interannual, intraannual (mean monthly variation and flow duration curve); (b) mean annual water balance as a function of the climatic dryness index, E_p/P: crosses refer to locations in Australia and New Zealand; and (c) geographical variation of annual runoff versus annual precipitation for South and South-East Asia: the numbers refer to different vegetation types (Reproduced from L'vovich, 1979 by permission of American Geophysical Union)

geographical variation of E/P, the ratio of mean annual actual evaporation to mean annual precipitation, as a function of the ratio of the mean annual potential evaporation (surrogate for net radiant energy) and annual precipitation, E_p/P. This is known as *the Budyko curve* (Budyko, 1974), and shows that climate, as exemplified by E_p/P, is a good first-order predictor of annual water balance. Geographical variations of the relationship between annual runoff and annual precipitation are presented in Figure 2(c), taken from L'vovich (1979), with the differences between different regions attributed to differences in climate (seasonality, storminess etc.), soils and vegetation, including the way that native vegetation adapts to water stress, such as leaf shedding and deep rooting. Other measures of spatial variability include scaling behavior of flood frequency curves, with respect to the size of catchments in the same region. Analysis of data from around the world has thrown up interesting patterns in many of these signatures. For example, L'vovich (1979) and McMahon *et al.* (1992) have presented a compendium of interhemispherical and interregional comparisons of interannual variability of annual runoff volumes, intraannual variations of streamflow (the regime and flow duration curves), and annual maximum flood peaks. There is tremendous value in exploring their underlying process controls, which will assist in developing a coherent new theory of hydrology.

Other signatures, besides measures of streamflow variability, include distributions of residence time or water age, temperature, isotopic composition, concentrations of tracer chemicals such as chloride or nitrate, although measurements of these are not as widespread as streamflow. Some of these chemical signatures may be strongly distinctive, and diagnostic of important differences between catchments and need to be predicted correctly. Patterns of vegetation cover, in both space and time, can also be excellent indicators of hydrological variability since they provide a window into the underlying water balance (Boer, 1999; Boer and Puigdefábregas, 2005), although, in the past, they have only been utilized as prescribed inputs to hydrological models. In a similar vein, patterns of other hydrological response data such as soil moisture and snow cover have been shown to provide powerful indicators to the understanding of catchment behavior (Grayson and Blöschl, 2000).

Predictors of Runoff Variability

Examples of the *predictors* of catchment responses include, but are not limited to:

- Climate: aridity/humidity, seasonality, especially, the relative seasonality of precipitation and potential evaporation, measures of storminess, ratio of interstorm period to storm duration, nature of within-storm variability of rainfall intensity,and so on;
- Catchment area and shape, drainage density;
- River network: length and shape of channel network;
- Soil properties: soil depth, soil texture (well drained or poorly drained soils, saturated hydraulic conductivity etc.), and their spatial distributions;
- Geology: fractured or monolithic rock, its influence on the subsurface hydrogeology, layering, relationship to topography, and so on;
- Topography: steepness (surface and stream slopes), mean elevation, curvature;
- Vegetation: type and density, spatial patterns, and temporal variability.

At the present time, our ability to infer or learn from observations through systematic data analysis is not well advanced. Progress in developing robust, quantitative relationships between the signatures of hydrological variability described above and the predictor variables (various climate parameters and landscape properties), toward the development of a general and reproducible theory at the catchment scale, has been hampered for a number of reasons. Firstly, the signatures of variability presented above can be thought of as reflecting processes occurring at or below the catchment scale, and providing a window into the interactions and feedbacks between different processes and between the various constituent elements of the catchment. To date, most of these signatures are not yet understood, and have not been explored in terms of the underlying processes. One consequence of this is that, as yet, we are not even able to choose predictor variables with clear, causal connections to the signatures.

Secondly, a prerequisite for making inferences from observations is the availability of a physically meaningful classification system, which can be used to guide empirical data analysis, to organize the data in such a way as to elicit interesting and useful patterns. Such a classification system, and a theory of inference based on the analysis of patterns in the observed data, is almost nonexistent in catchment hydrology at the present time (McDonnell and Woods, 2004; Woods, 2002). Dooge (1986) has suggested that hydrology is in the same position of confusion as the field of hydraulics had been before the Reynolds and Froude numbers were proposed; almost two decades on, there has been no real advance in this direction, notwithstanding the work of Milly (1994).

Much of the data analysis that is presently carried out is model focused, for example, during the calibration of models based on small-scale process theories, constrained by assumptions about processes upon which the models are based. This may explain why data analyses in the past have not been very revealing, and possibly even why there are too many models. Indeed, it can be said that the increasing sophistication of models based on small-scale process-based theories and the increasing power of computers may even have contributed to a neglect of systematic and thoughtful data analyses, and the role of data has been relegated to its use in model calibration only.

Current State of Theories Regarding Organization

The role of organization in catchment response has been widely acknowledged over the years (e.g. Blöschl *et al.*, 1993; Blöschl and Sivapalan, 1995). At the most fundamental level, climate acts as the unifying global force in the coevolution of landscapes and vegetation. An illustration of this, is the fact that the world's broad vegetation classes can be predicted by the combination of just two climatic variables: temperature and rainfall (Figure 3a, Shuttleworth, 1983; Woodward, 1987). Observed precipitation patterns demonstrate space-time variability over a wide range of scales, including but not limited to such definable units as cells, small mesoscale areas, large mesoscale areas,

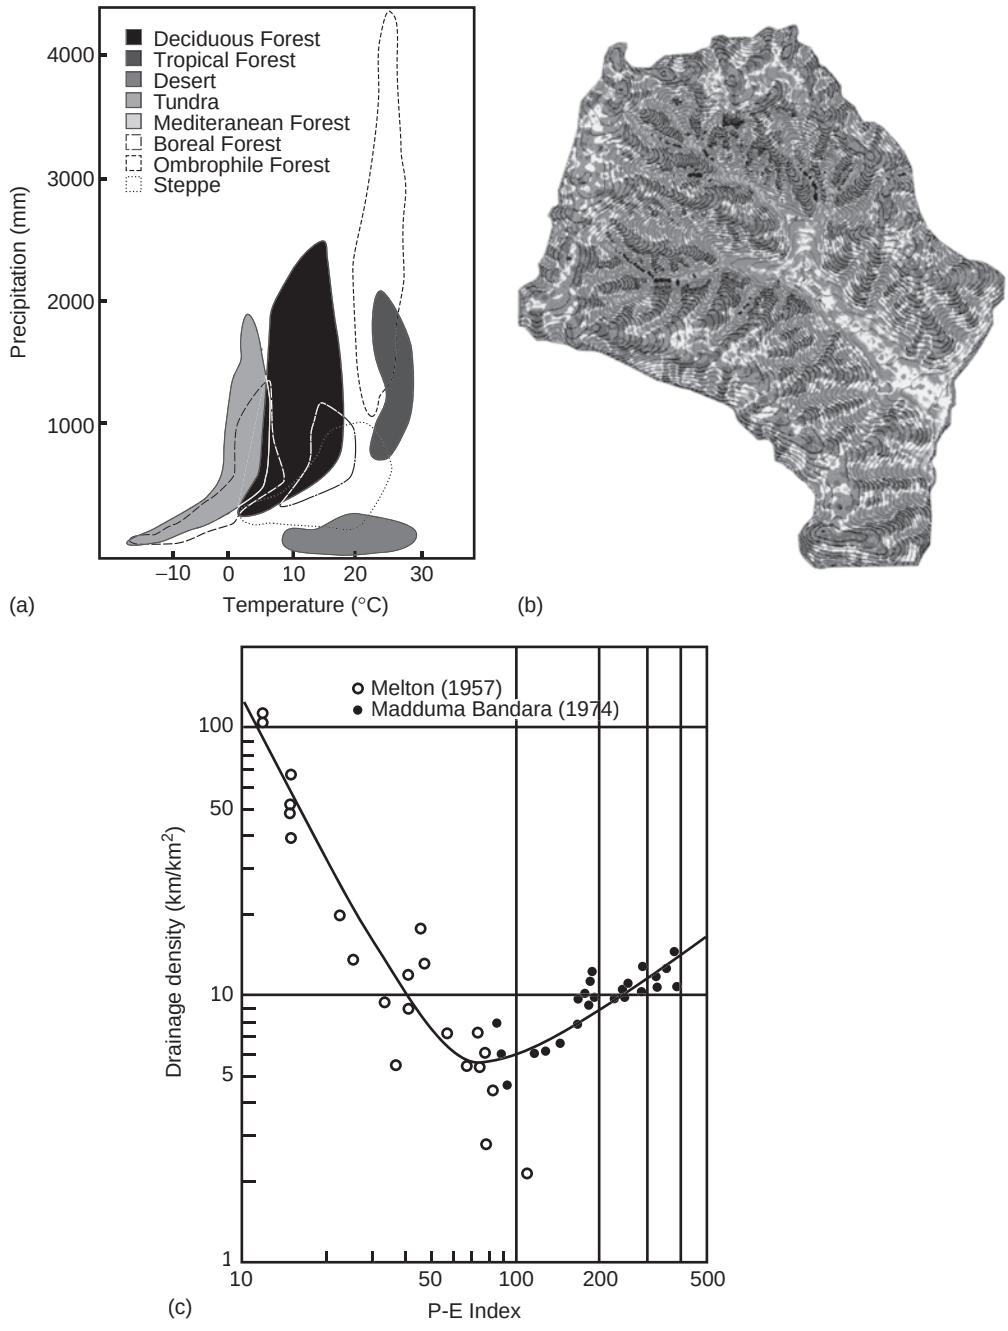

Figure 3 Patterns of landscape properties due to self-organization: (a) climatic influence on major vegetation zones of the world (from Shuttleworth, 1983); (b) soil catena – simulated patterns of soil depth within a catchment (from Dietrich *et al.,* 1995); (c) global relationship between drainage density of landforms against the precipitation–evaporation (P-E) index (Reproduced from Abrahams, 1984 by permission of American Geophysical Union)

synoptic areas, and so on as they develop, mature, move, and dissipate. Rivers carve the landscape into intricate shapes called *river networks*, which appear to embody a deep sense of symmetry (Rodriguez-Iturbe and Rinaldo, 2000). Soils tend to develop in response to state controls such as topography, with different parts of a basin (nose, slope, hollow) being formed by different processes and having different functions (e.g. concentration, storage, and evapotranspiration of water). The resulting soil patterns (soil catena) exhibit a common form of organization and symmetry, with water movement clearly being an active agent in their formation (Figure 3b, Dietrich *et al.*, 1995). Drainage densities observed around the world in different hydroclimatic regions demonstrate a robust relationship with the so-called precipitation–evaporation (P–E) index, the difference between annual precipitation and evaporation (Abrahams, 1984), the particular U-shape of this relation, and its minima (Figure 3c) being caused by the armoring imparted to the soil by the presence of vegetation roots.

The interactions between climate, soils, vegetation, and topography thus contribute to the generation of the interesting patterns that we see in natural catchments, which must contain valuable information about the way they function. Therefore, a fundamental aim of theoretical hydrology must be to recognize these patterns, decipher the underlying order or symmetry occurring over a wide range of scales, and explore the mechanisms that may have generated them. The field of hydrogeomorphology is attempting to discover the mechanisms underlying the order or symmetry in terms of quantitative measures of drainage network composition (Rodriguez-Iturbe and Rinaldo, 2000). In a similar vein, theories and associated models of soil formation, shallow landsliding, and erosion have been pursued in order to explain the observed patterns in soil properties (Jenny, 1941; Willgoose *et al.*, 1991; Dietrich *et al.*, 1995). On the other hand, the field of ecohydrology is attempting to discover rules or organizing principles governing spatial patterns of vegetation density and type, linking these to underlying water and energy balances, consistent with a Darwinian natural selection process that is optimal for growth and reproduction within the prevailing climate and geology (Rodriguez-Iturbe *et al.*, 1999; Eagleson, 2002). However, to complete the development of a theory of catchment hydrology, current understanding of self-organized patterns in landscape properties must be extended to produce insights into the interactions and feedbacks between hydrological processes at the catchment scale. Progress would be made, for example, when such natural self-organization in landscape properties could be confirmed to be the cause of simple process descriptions or closure relations extracted from observations at the catchment scale (Savenije, 2001).

The most that has been done to accommodate the natural self-organization has been with respect to the choice of model structure, that is, the way the various components of the landscape are organized and interconnected, that underlies many current hydrological models. For example, a typical model structure may consider a catchment to consist of a population of hillslopes, of different sizes, shapes and steepnesses, wrapped around the stream network, which is its most distinctive element (Troch *et al.*, 2003). The channel hydraulic properties, collectively known as *hydraulic geometry* (*HG*), may be allowed to vary systematically with flow at a single site, as well as in the downstream direction. In the vertical direction, the catchment (and the associated hillslopes) is assumed to consist of the land surface, and the soil and bedrock beneath it, including any vegetation that is contained within it. The subsurface is further characterized by an unsaturated zone, underlain by one or more saturated zones, underlain by bedrock. In larger catchments, to account for large-scale spatial variations of climatic and landscape properties, the catchment may be divided into a number of subcatchments which are hierarchically organized around the stream network, before being further divided into hillslopes (Gupta and Waymire, 1998; Reggiani *et al.*, 1998). Recent work has suggested that the treatment of hillslopes as monolithic entities suppresses important functional variations that may occur within them, and has advocated their partitioning into upland and riparian zones (McGlynn and McDonnell, 2003). Other studies have advocated the introduction of a hyporheic zone between the riparian and the stream zones.

However, this kind of representation is essentially a static stratification of the landscape, and does not necessarily recognize or incorporate the dynamic mechanisms that sustain those subsystems. In particular, the processes that occur within these subsystems continue to be described in terms of small-scale process theories. The effects of the natural self-organization of soil properties, vegetation, and topography have not been embedded in the process conceptualizations that appear in most current hydrological models. Notable exceptions to this are the body of work that led to the development of TOPMODEL (Beven and Kirkby, 1979; Sivapalan *et al.*, 1987) and the related TOPOG model (O'Loughlin, 1986). In this case, the two models captured the effects of topographic convergence through the use of a topographic wetness index, along with assumptions made to characterize in a simple way the interactions between upslope and downslope regions of hillslopes, including the accumulation of water near the stream zone and the generation of dynamic saturation areas generating saturation excess runoff. The kind of spatial organization of soil moisture assumed in TOPMODEL has since been supported, to some extent, through a number of field studies at the small catchment scale (e.g. Western *et al.*, 1999), although spatial patterns have also been observed which are not consistent with TOPMODEL predictions. Another example of the use of organization in developing appropriate process

conceptualization is the now popular Xinanjiang or variable infiltration capacity model (Zhao *et al.*, 1980; Wood *et al.*, 1992; Liang *et al.*, 1994; Sivapalan *et al.*, 1997). In this case, the self-organization present within the catchment is expressed in terms of a statistical distribution of soil depths or infiltration capacity, which implicitly also accounts for the position on the hillslope. A third and final example is the development of the geomorphological instantaneous unit hydrograph (GIUH) of catchments on the basis of the organization present within the stream network in the form of, for example, Horton's order ratios (Rodriguez-Iturbe and Valdes, 1979; Rinaldo *et al.*, 1991; Snell and Sivapalan, 1994; Saco and Kumar, 2002). In this case, the dispersion imparted to the incoming rainfall by the stream network is quantified in terms of measures of the drainage network structure.

Status of Theories of Catchment Hydrology: Impasse!

The paradigm underpinning current hydrological theories at the catchment scale is shown in Figure 4, and is essentially *reductionist*. In this framework, the natural organization present within catchments is partly embraced through model structures that may reflect the presence of a stream network, a set of hillslopes or subcatchments organized around this network, distinct saturated and unsaturated zones, and a further possible partitioning of the hillslopes into upland, riparian, and hyporheic zones. However, the conceptualizations of hydrological processes are still dominated by small-scale process theories, unrelated and unconnected to the nature of self-organization present within the catchment. A set of balance equations at the scale of a representative catchment, and respecting the natural organization that is present within catchments has been presented recently (Reggiani *et al.*, 1998, 1999); the lack of appropriate catchment-scale closure relations to close this set of equations is hampering efforts to turn these into a new blueprint for distributed modeling at the catchment scale (Lee *et al.*, 2005; Zehe *et al.*, 2005). Even the best models based on current process theories are found to be inadequate to predict catchment responses since they demand complete knowledge of climatic inputs and landscape (soils and vegetation) characteristics, which is not routinely available. In fact, due to the strong heterogeneities of climatic landscape and climate properties, hydrology is replete with examples of highly complex behavior, including strong nonlinearities and threshold behavior, and paradoxes that defy causal explanation by models based on small-scale theories.

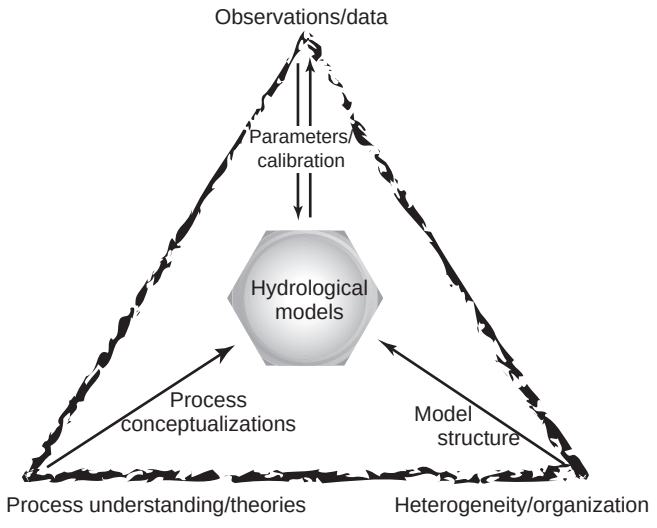

Figure 4 Current state of theory in catchment hydrology – reductionist with a reliance on calibration

Catchments being "poorly defined systems with some degree of organization", predictions of catchment responses must be conditioned or founded on empirical observations. Yet, in the current framework, the main role of observations and data appears to be, with a few exceptions, to assist in the calibration of models that are based on small-scale process theories, and *a priori* model structures, that is, "grist to the calibration mill" (Sivapalan, 1997). Indeed, hydrologists have not demonstrated the collective will, skill in experimental design, and the required clarity in posing scientific hypotheses and testing them on comprehensive datasets. The lack of holistic process theories and the inadequacies of current small-scale process theories, have meant that data collection to formulate alternative hypotheses has been limited and the analyses of existing datasets have not been so revealing. We do not yet have a sound quantitative framework, for example, a classification system, based on a set of predictor variables and governed by the understanding of underlying process controls, that can help us recognize interesting patterns in the data.

Because of the overparameterization in relation to the meagre datasets against which they are calibrated, current models suffer from the problem of equifinality (Beven, 1989a, 2001, 2002; Savenije, 2001), which expresses the fact that infinite combinations of parameters can give rise to model predictions that provide a good match to the observations. The lack of a holistic theory at the catchment scale has led to a plethora of alternative models that are overly complex, overparameterized, and uncertain. The end result is confusion not clarity, and stagnation and not real progress, in spite of the explosion of new knowledge related to various individual hydrological processes.

It is clear that catchment hydrology is trapped in a dead-end track, a theoretical impasse! We urgently require a new holistic and unified theory that overcomes the limitations of the current theories in dealing with processes, organization, and data analysis.

TOWARD A NEW UNIFIED HYDROLOGICAL THEORY AT THE CATCHMENT SCALE

Scope of a Unified Theory of Catchment Hydrology

In the discussions that follow, we will adopt a simple, but overarching definition of *theory* as the set of ideas or concepts that is best able to describe or explain the system of interest, the catchment, its presence in the landscape, its behavior, and its function in relation to other systems. In this context, theory is seen as more than the sum total of all knowledge, but as *distilled* knowledge, and, as knowledge that is causally interlinked, that is, every piece of knowledge must make sense with regard to all other pieces. Theory helps to connect the specific to the general, the local to the global, and the past to the future. Theory provides a framework to assess what we know and what we do not know. Theory provides the avenues to seek the knowledge that we do not possess.

Given the ubiquitous nature of hydrological variabilities at multiple space – time scales, the main role or purpose of a coherent hydrological theory is then to:

- help explain observed patterns of hydrological behavior over multiple space-timescales in terms of the underlying climate, soil, vegetation, and topography interactions, in this way providing a robust framework for a dialogue with nature;
- guide us to make appropriate measurements to further improve our understanding and our ability to generalize or extrapolate in space and time, and assist with the design of observational networks and/or focused field experiments; and
- guide us to make better predictions, into the future or to other points in space, that are based on *a priori* understanding and not just calibration, and in this way help establish the practice of hydrology on firm scientific foundations.

Given the nature and basis of hydrological science and its place at the center of a number of earth science disciplines, the desired hydrological theory at the catchment scale will combine ideas and concepts from:

- natural sciences such as physics, chemistry, and biology: examples include Newton's laws of motion, the 2nd law of thermodynamics, biological laws including theories of evolution, chemical laws of reaction and transformation;
- earth sciences, because of the overlap and interactions with other branches of earth system science: examples include theories of soil physics, micrometeorology, open channel hydraulics, geomorphology, ecology;
- empirical science: hydrology is fundamentally an empirical science, and depends crucially on inferences made from observations at all scales, all the way from laboratory to global;
- applied science: hydrology is also an applied science and elements of hydrological theory may derive from the sharing of experiences from its applications, for example, in agricultural hydrology, engineering hydrology, forest hydrology, and so on.

Hydrological theory will thus derive from the actual practice of the science, as natural science, empirical science, earth system science, and as applied science. Hydrological theory will not arise through mere speculation of the human mind, or, as Klemeŝ (1986) put it, "... the logic of hydrological processes cannot be deduced from algebra". By the same token, we cannot postpone the practice of the science of hydrology until a theory is ready.

Approaches to a New Unified Theory of Hydrology at the Catchment Scale

The observed patterns of variability of hydrological behavior at the catchment scale arise out of interactions between space-time variability of climatic inputs, for example, precipitation, solar radiation, atmospheric humidity, wind, and so on, the natural multiscale heterogeneity of landscape properties, such as the soils, vegetation, topography, and so on, and any alterations to these due to human impacts. The natural heterogeneities of the landscape properties, in turn, themselves arise through geomorphic (i.e. landforming), and ecological processes that occur over a much longer period of time, compared to the typical timescales of hydrological processes.

The new unified hydrological theory must ultimately consist of a set of organizing principles or natural laws governing:

- the ways that catchments are organized in space and time, in terms of their constituent landscape elements, including the geomorphic and ecological processes that may have led to them;
- the ways that catchments respond to climatic inputs and the nature of the interactions between the heterogeneities in the climatic inputs and the landscape properties;
- the resulting fundamental hydrological processes, their space-time variabilities, including the pathways, fluxes and stores of water, energy and other constituents, and the interactions between them;
- the way that the different constituent parts of the catchments, and the catchments as a whole, function, interact with, and feedback on each other; and
- the way that catchments respond to human-induced changes in the climate inputs and the landscape properties, in terms of both their form and function (e.g. storage of water, primary production etc.), in the short-term and in the long-term.

Considering the self-organized aspect of catchments, their constituent landscape elements, the processes that generated them in the first place, the way they interact and feedback on each other, and the resulting impact on hydrological processes at all scales, it is clear that feedbacks between pattern and process, must be the defining feature of any new, unified theory of catchment hydrology. It is also clear that the feedbacks between pattern and process are highly relevant in different contexts also, due to the critical role played by water in climatological, ecological, geomorphological, and pedological processes. Therefore, the ecological, geomorphological, and other "function" of the feedbacks between hydrological patterns and processes is essential for a deeper understanding of hydrological variability. For this reason, it is argued that pattern, process, and function must be the key elements of a new theory of hydrology at the catchment scale.

Pattern: instead of using observations and data for calibration of *a priori* constructed models, seek and identify patterns (both within-catchment and between-catchment) in the data or observations, to formulate and test hypotheses about processes, process interactions and feedbacks, including the mechanisms that contribute to natural self-organization;

Process: discover or explore new processes, process interactions, and feedbacks at all scales, and descriptions that embrace or embed within them explicitly or implicitly the effects of landscape and climatic heterogeneities, including any simplification that comes about due to the feedbacks and self-organization underlying these heterogeneities;

Function: investigate the processes that lead to the heterogeneities and self-organization exhibited by landscape properties, and explore the laws or organizing principles governing their ecological, geomorphological, or pedological "function", with the idea that these laws could act as constraints to both the process descriptions (within-catchment), and broad-scale patterns of behavior (between-catchment, regional etc.).

An example of an ecological function is the provision of physical habitat, or of food supply. The geomorphological function of watercourses may be the efficient movement of water and sediment. This function entails both conveyance and storage, which are critical to the healthy functioning of the stream. A stream may attain a shape, form, or pattern that permits the necessary movement of water and sediment with the energy available (i.e. slope). The landscape functioning may be related to maintaining the stability of the landscape, it may develop pipe flow as a mechanism for fast release of water to prevent too frequent landslides. It may develop a vegetation-soil association to keep erosion to a minimum.

By combining pattern, process, and function, the new theory will lead to process descriptions that respect patterns of observed behavior, it will lead to more parsimonious models with much-reduced parameterizations, it will encourage a scientific culture of learning from observations, instead of using them for calibration, and it will encourage the formulation of rigorous hypotheses to underpin future experimental campaigns and data collection exercises. By branching out to embrace organizing principles or natural laws from neighboring disciplines such as geomorphology, pedology, and ecology, it will also broaden and enrich the hydrological perspective.

Downward and Upward Approaches to Theory Development

Klemeš (1983) proposed two alternative approaches for pursuing the organizing principles or laws that might constitute the theory of hydrology at the catchment scale: the "upward or bottom-up approach" and the "downward or top-down approach", and the eventual reconciliation of the outcomes of these two approaches. Dooge (1986), in a similar vein, proposed parameterization of microscale effects (upward), and the search for general laws at the macroscale (downward) as alternative approaches to the discovery of hydrological laws at the catchment scale. Acknowledging the need for a reconciliation of these two approaches and considering the importance of scale and the adaptive or self-organized character of catchments, Dooge argued for the discovery and exploration of scaling laws in hydrological behavior as a third, alternative method that helps to find links across catchments of different sizes.

These ideas also resonate with recent developments in other related fields, as exemplified by the theoretical vision for earth system science proposed by Harte (2002). Harte considered systems having characteristics that apply equally well to catchments: poorly defined, unique, and continuously evolving; self-organized, characterized by strong feedbacks and interdependencies; requirement not just to characterize but also to generalize and extrapolate, so that the behavior in response to climate changes and/or land use changes can be predicted. Similar to Dooge, Harte proposed a theoretical framework that involves a combination of (i) simple falsifiable models, (ii) a search for patterns and laws, and (iii) the science of the place. Harte (2002) characterizes this theoretical framework as a synthesis of the Newtonian and Darwinian worldviews, combining "particularity and contingency, which characterize the ecological sciences, and generality and simplicity, which characterize the physical sciences".

Figure 5 illustrates the application of the downward and upward approaches, seeking connections between patterns and processes. Within-catchment investigations deal with specific catchments, and attempt to explain the temporal patterns of variability in terms of the underlying process

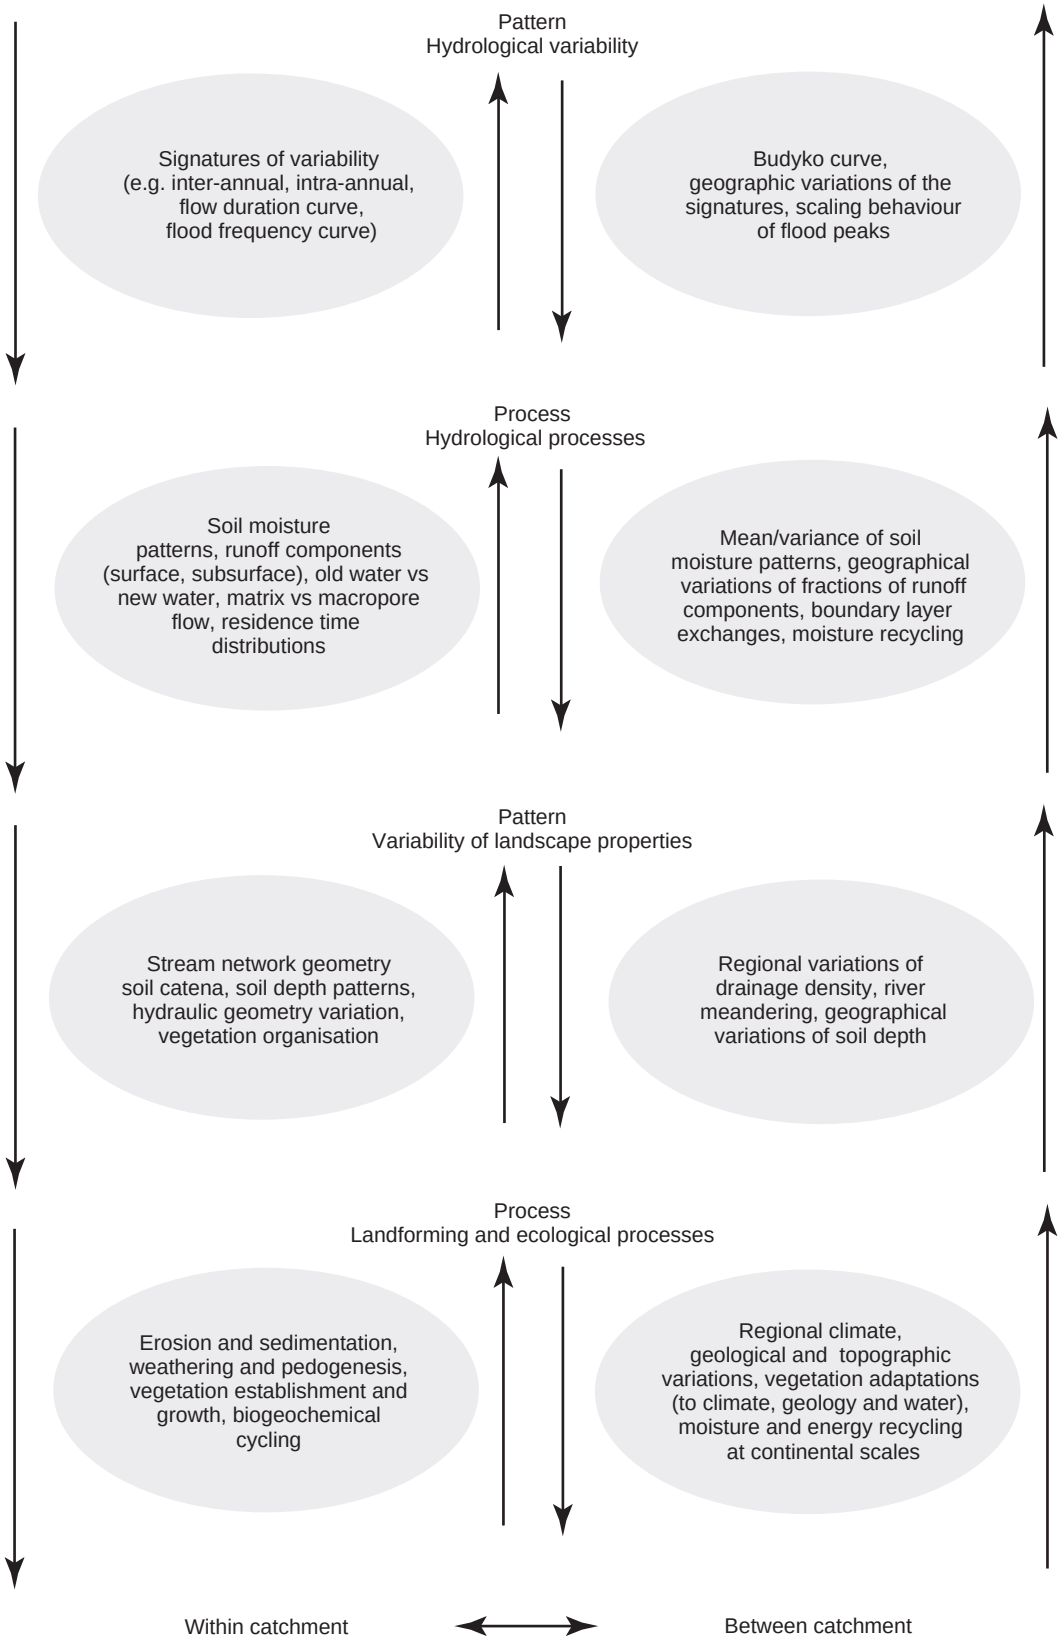

Figure 5 Downward and upward approaches to theory development in catchment hydrology – exchanges of knowledge and understanding at multiple levels

controls, and *vice versa*. In an analogous manner, between-catchment studies deal with spatial patterns, that is, differences between catchments located in the same region, or in different regions. Particular attention must be paid to scaling behavior exhibited by hydrological variables, both in the space and time domains.

Klemeš (1983) defines the downward approach as the "route that starts with trying to find a distinct conceptual node directly at the level of interest (or higher) and then looks for the steps that could have led to it from a lower level" (*see* also Sivapalan *et al.*, 2003a; and *see* **Chapter 134, Downward Approach to Hydrological Model Development, Volume 3**). Along this downward path, we start at the patterns of observed hydrological variability at the catchment scale, and characterize these using appropriate measures of variability, as outlined before. The role of hydrological theory then is to explore the underlying process controls behind these patterns. At the next level, the approach will first involve observing hydrological processes at multiple space scales, not just the catchment scale, but both smaller and larger scales, and characterizing their variability through appropriate measures. The next step is to interpret the observed process variabilities in terms of the underlying heterogeneities in landscape properties, for example, soils, vegetation, topography, network geomorphology, HG and so on, and climate inputs. At the final, deeper level, the approach is to first characterize the natural spatial heterogeneities in the landscape properties, and quantify the heterogeneities through appropriate quantitative measures. The role of hydrological theory then is to explore the underlying, that is, hydrological, landforming, and ecological, process controls.

On the other hand, Klemeš (1983) defines the upward approach as "the route that attempts to combine, by mathematical synthesis, the empirical facts and theoretical knowledge available at a lower level of scale, into theories capable of predicting events to be expected at a higher, in our case hydrological, level". Along the upward path, we start at the deeper level, utilize existing knowledge about hydrological, landforming, and ecological processes toward development of process-based models capable of generating realistic patterns of landscape heterogeneities and validate these against observed patterns. At the next higher level, the approach will characterize the spatial heterogeneities in the landscape and climate properties, for example, soils, vegetation, topography, HG, network geomorphology and rainfall, and combine these with available small-scale process theories. Theory development will proceed by testing the predictions of the models against any observations of hydrological processes at the catchment scale. At the final level, the approach will observe and characterize hydrological processes at a wide range of scales, and aggregate these to generate patterns of hydrological variability at the catchment scale. The hydrological theory will evolve through testing or matching these predictions against patterns of behavior observed in the field.

Reconciliation Between the Upward and Downward Approaches

It is clear that the development of the catchment-scale theory will involve, at each level, almost symmetrical exchanges, upward in scale as well as downward, of both knowledge and understanding between observed patterns and the underlying process controls on the one hand, and between observed processes and the underlying patterns, on the other. As indicated previously in Figure 5, in the downward direction, theory development involves:

1. knowing the observed patterns, testing hypotheses about alternative processes that may have led to them, and
2. knowing the observed processes, testing hypotheses about alternative patterns that may have contributed to them.

In the upward direction, theory development involves:

1. knowing the processes, learning through constraining the patterns that they produce to match observed patterns, and
2. knowing the patterns, constraining the processes that they generate to match those that are observed.

The methodologies associated with the application of the downward and upward approaches, and the role of data, are presented in Figure 6. The upward approach starts with complex process descriptions and patterns, and whittles away the complexity and/or heterogeneity by constraining the model predictions using observed patterns and processes (Dooge, 1986; Sivapalan, 2003b). When the upward approach is repeated in different catchments, the descriptions will therefore evolve from specific to general catchment behavior. The downward approach involves identifying patterns of behavior or global relationships at the larger scale, for example, catchment scale, and looking for the processes that may have produced them, trying to connect the identified patterns or global relationships ultimately to such factors as soils, vegetation, drainage networks, and rainfall patterns (Dooge, 1986). Typically, the downward approach will start with simple process descriptions or patterns, and gradually adds complexities, through learning from observed patterns and/or process complexities. As we add more details in this way, the resulting models and process descriptions will evolve from the general or universal behavior toward behavior of specific catchments.

These objectives of the upward and downward approaches to the development of a new theory of catchment hydrology bear remarkable resemblance to equivalent themes reflected in the fields of ecology. In a recent review, Levin (1992), an ecologist, suggested, *inter alia*, that:

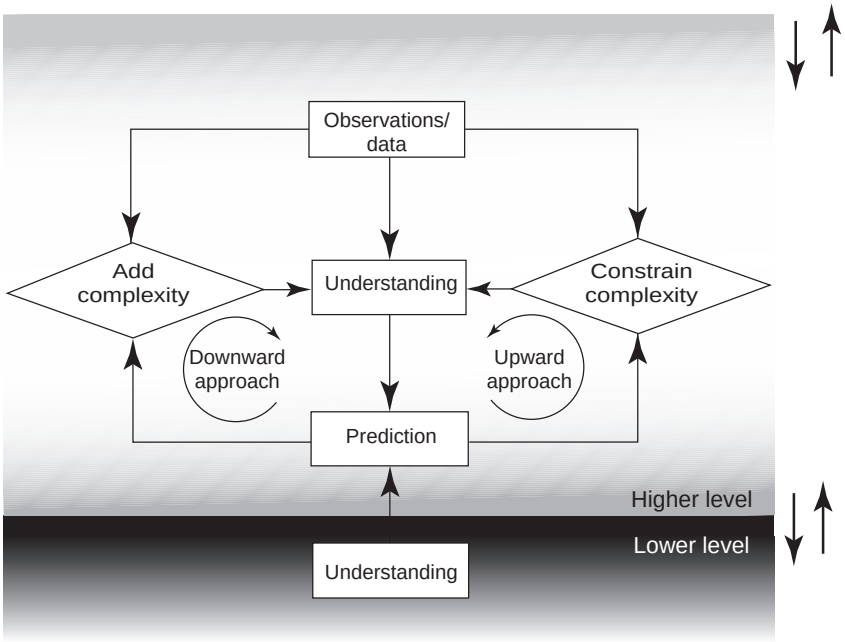

Figure 6 Methodologies of the downward and upward approaches to theory development. Adapted from Dooge (1986)

> "To scale from the leaf to the ecosystem to the landscape and beyond ... we must understand how information is transferred from fine scales, and vice versa. We must learn how to aggregate and simplify, retaining essential information without getting bogged down in unnecessary detail. The essence of modeling is, in fact, to facilitate the acquisition of this understanding, by abstracting and incorporating just enough detail to produce observed patterns... the objective of a model should be to ask how much detail can be ignored without producing results that contradict specific sets of observations, on particular scales of interest".

Clearly, there is much to learn from neighboring disciplines such as ecology, geomorphology, and pedology; the issues and the challenges are remarkably similar across the disciplines.

In fact, there is no reason for us not to use both the upward and downward approaches to generate and test *analogous* hypotheses regarding hydrological behavior at catchment scale. Independent application of the upward and downward approaches may, however, throw up conflicting outcomes, as illustrated schematically in Figure 7, which might still require reconciliation. One possibility is to altogether abandon any pretence to smaller scale process theories, and look for laws that may be sufficient to explain processes and/or patterns at the larger scale (Hatton *et al.*, 1997). Another possibility is that such conflicts or paradoxes might trigger further investigations leading to discoveries of new concepts or laws underpinning hydrological mechanisms that transcend multiple space-timescales, such as laws governing the ecological or geomorphological or pedological *function* of the catchment or parts of it, and in this way bring about the needed

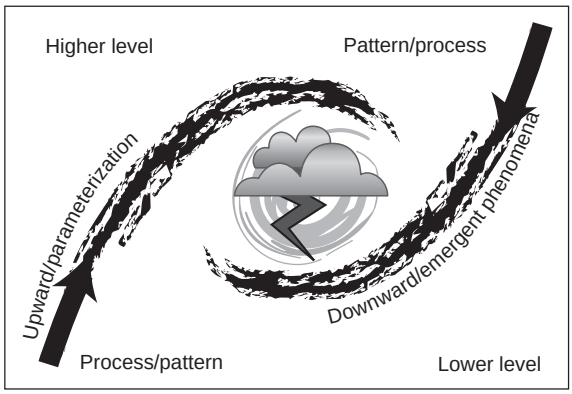

Figure 7 Reconciliation of downward and upward approaches – break or transition from a reliance on averaging and parameterization of lower level features to a culture of discovery and explanation of emergent phenomena at the higher level. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

reconciliation. Examples of organizing principles or natural laws that are currently debated in earth system science include, principle of minimum energy expenditure in geomorphological systems (Rodriguez-Iturbe and Rinaldo, 2000), ecological optimality in vegetation systems (Eagleson, 1978a,c,g, 1982, 2002; Cowan and Farquhar, 1977; Cowan, 1982; *see* **Chapter 12, Co-evolution of Climate, Soil and Vegetation, Volume 1**), maximum entropy production in climate change and climate-vegetation feedbacks (Ozawa *et al.*, 2003; Kleidon, 2004; Bejan, 2000), and

self-organized criticality in general complex systems (Bak, 1996; Rodriguez-Iturbe and Rinaldo, 2000; Hallet, 1990; De Boer, 2001). Any discoveries of this type can only come about through a broadening of the hydrological perspective to include multidisciplinary perspectives. These will also require or could be triggered through radically new observations that throw light on hitherto unknown mechanisms. Clearly, there is a lot of room for innovation and creativity; while the necessary conditions for breakthrough can be thus prescribed, success itself is *a priori* not predictable or guaranteed.

LEARNING FROM PATTERNS – METHODOLOGY OF THE DOWNWARD APPROACH, AND EXAMPLES

The methodology of the downward approach (Figure 6) may include the following steps: (i) identify an interesting pattern of behavior or an aspect of process observable at the catchment scale; (ii) devise alternative hypotheses, which may be potential explanations, or organizing principle, for the observed pattern or process characteristic; (iii) build the simplest possible predictive model based on this explanation or organizing principle; (iv) devise a numerical experiment (or several of them) with the simple numerical model, make a prediction of the pattern or process, and compare the predictions against data available at the higher scale; (v) on the basis of this test, either confirm or falsify the organizing principle or explanation as being correct or not; (vi) recycle the above steps, depending on the outcomes, making alternative hypotheses, or making further subhypotheses or sequential hypotheses to help resolve the possibilities that remain, developing a new numerical model and experiment to reflect the alternative hypothesis, or add more complexity to the previous model to reflect the subhypothesis or sequential hypothesis, and testing their predictions against the same data or additional data at the higher scale. Two examples are presented below as illustrations of the downward approach.

Pattern to Process: Spatial Scaling Behavior of Flood Frequency

The quantity of interest here is the annual maximum flood peak, and its dependence on catchment area. Empirical studies around the world have revealed that the annual flood peaks of a given return period T, Q_T, scale with catchment area, A, in terms of a relationship of the type $Q_T = cA^{\theta}$, with an exponent θ in the range between -0.10 and -0.40 (Jothityangkoon and Sivapalan, 2001). The power function relationship, and the exponent θ, can be seen as emergent behavior, that integrates information about complex rainfall–runoff–flood processes operating within a given region, how these change with increasing catchment size (Gupta and Dawdy, 1995; Robinson and Sivapalan, 1997a; Jothityangkoon and Sivapalan, 2001; Gupta, 2004), and about how the underlying process controls differ between different regions.

A number of studies have attempted to explore the physical basis of this scaling relationship, through the use of simple models that nevertheless captured the dominant process controls. Robinson and Sivapalan (1997a) approached this problem with the use of a simple rainfall-runoff model based on the unit hydrograph concept, with rainfall inputs that were scale-dependent, a mean catchment residence time also dependent on catchment area. With the use of this model, they showed that the interactions between two timescales, namely, rainfall duration and catchment response time, lay at the heart of the observed scaling relationship. Subsequent work by Robinson and Sivapalan (1997b) found that the observed apparent log–log linearity of the relationship between annual maximum flood peaks and catchment area is in fact caused by more complex interactions. At small catchment scales, within-storm patterns of rainfall variability interacted with the associated small mean resident times to increase the flow peaks. At large catchment scales, within-storm patterns were not important; instead, longer timescales in the rainfall field such as seasonality and the carry-over of storage between storms interacted with the longer residence times and again increased the magnitude of the flood peaks. Thus, the observed log–log linearity of the $E[Q_p]$ versus A relationship is a result of a "resonance" between the increasing catchment response time and the changing timescales associated with rainfall variability. Figure 8, adapted from Robinson and Sivapalan (1997b) illustrates this phenomenon. On the other hand, the spatial scaling of the rainfall intensities had a small but nevertheless significant contribution at all scales.

This then gives rise to a phenomenon which can be described as representing a *space to time connection* – an apparently simple spatial scaling behavior, an emergent property, being generated by complex interactions and feedbacks in the time domain between rainfall and runoff processes (Jothityangkoon and Sivapalan, 2001). The situation is further complicated when the relationship of the catchment response time to A depends on the relative dominance of hillslope and channel network in controlling the response time (Robinson *et al.*, 1995; Jothityangkoon and Sivapalan, 2001). Where the hillslope response time is dominant, θ approached zero, whereas in catchments where hillslope residence time is small, θ approached -0.40, an exponent in the relationship between channel length and A. Jothityangkoon and Sivapalan (2001) also demonstrated that the space-time connection and θ were also affected by the underlying long-term water balance regime, through its control of the antecedent soil moisture. Blöschl and Sivapalan (1997) found that the effects of resonance and the space-time connection, while important in a given hydrological setting, tend to be swamped by the other factors in larger, nonhomogeneous regions. They classified the

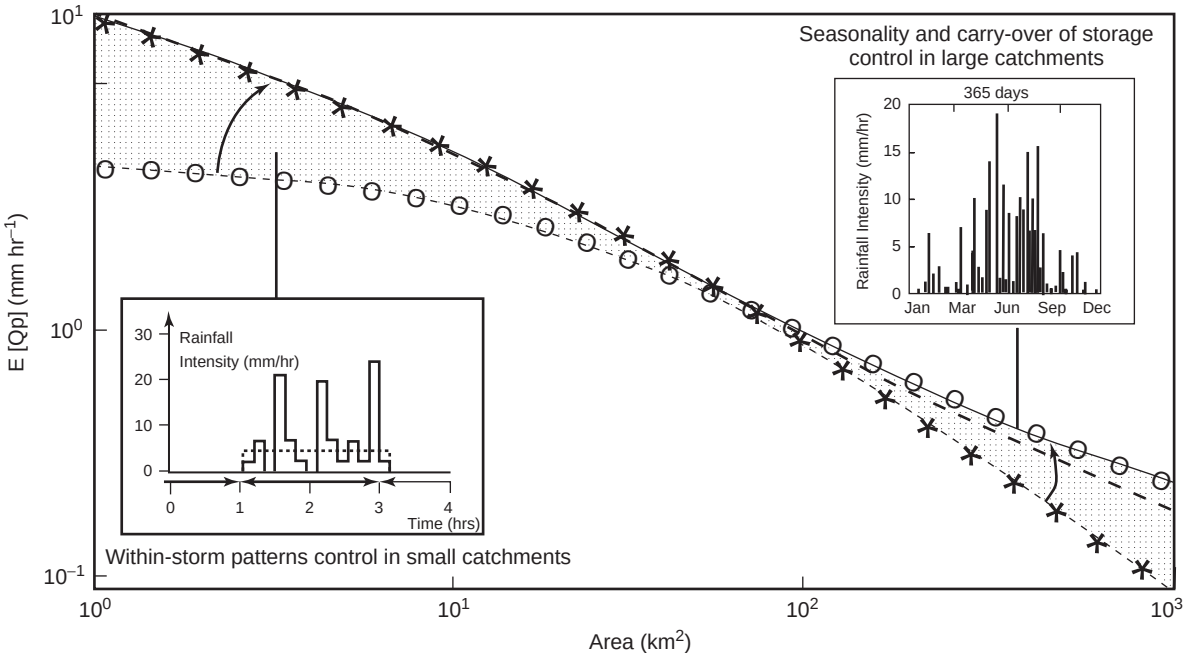

Figure 8 Process controls on scaling behavior of flood frequency. Power law relationship of mean annual flood with catchment area as an emergent property – complex interactions in the time domain leading to apparently simple pattern of behavior at the catchment scale

scaling behavior in Austria in terms of the differences in the underlying hydrological regime, which encapsulates the long-term water balance in a region.

A downward route for explaining the change of the flood frequency curve with catchment scale has also been taken by Merz and Blöschl (2003). They classified 12 000 flood peaks in Austria into long-rain floods, short-rain floods, flash-floods, rain-on-snow floods and snowmelt floods and then examined the flood statistics separately for each of the groups. They found that the coefficient of variation (CV) of the snowmelt flood type exhibited the flattest decrease with catchment area, which is consistent with the usually large extent of snowmelt. The CV of the flash-flood process type, however, tended to increase with catchment area, which was interpreted as being related to the nonlinearity of runoff generation associated with fast hillslope response.

These studies have demonstrated: (i) that apparently simple behavior may come about due to complex process interactions, and therefore the critical importance of these interactions; (ii) the power of simple models to elucidate the underlying process controls; and (iii) the use of these simple models to decipher broad-scale patterns and explain them in term of the underlying process controls.

Pattern to Process: Scaling of Hydraulic Geometry and Links to River Meandering

The dependence of channel hydraulic properties on streamflows have been known for a long time, and empirically described by the notion of HG introduced by Leopold and Maddock (1953). HG refers to the power law relationships relating the channel width, mean flow depth, and mean velocity to streamflow (discharge). These power law relationships have been observed to hold either for different discharges at a single cross section (called *at-a-station HG*), or for different downstream locations related through characteristic discharges having a constant frequency of occurrence (denoted as downstream *HG*). In their original work, Leopold and Maddock (1953) looked at HG in an *average* sense, ignoring the scattering around the proposed power laws.

Recently, Dodov and Foufoula-Georgiou (2004a) carried out extensive work on the *HG* relationships, paying particular attention to the scatter in the observed power laws. Through careful analysis, they showed that the exponents of the at-a-station *HG* systematically depended on catchment area, and that the exponents of downstream *HG* depended on the frequency. To quantify this empirical finding, they presented a lognormal multiscaling model, which was used to derive revised at-station HG whose coefficients are now explicit functions of catchment area. This generalized HG model was fitted to 85 gaging stations in Oklahoma and Kansas, and shown to reproduce the empirical trends extremely well. These revised HG relationships, being caused by streamflows in a self-organizing manner, therefore, represent an example of an emergent property, a phenomenon that only emerges at the catchment

scale, possibly due to complex process interactions and feedbacks.

Subsequent work by Dodov and Foufoula-Georgiou (2004b) set out to explore the underlying process controls of the empirically determined and statistically described scale-dependence of at-site *HG*. They presented an analysis of fluvial instability (Parker, 1976) as a function of catchment area, and showed that channel planform geometry (e.g. sinuosity, curvature, and wavelength) and, particularly, the transition between straight and meandering channels, are scale-dependent. To relate channel planform geometry and channel shape, they used the numerical river model of Johannesson and Parker (1989) to calculate the bed topography of representative meander bends of a given Strahler order, and subsequently the *HG* of these bends. In this way, Dodov and Foufoula-Georgiou (2004b) showed that the at-site *HG* that emerges from this physical model is scale-dependent, and agrees with the empirical trends and the proposed multiscaling statistical model. On the basis of these findings, they concluded that the scale-dependent *HG* is caused by the systematic increase of channel asymmetry downstream, induced by scale-dependent fluvial instability; an example of an apparently simple and useful relationship being brought out by complex process interactions at smaller scales.

LEARNING FROM MODELS – METHODOLOGY OF THE UPWARD APPROACH, AND AN EXAMPLE

The upward approach starts with the most complex model based on the most current or appropriate process descriptions. The objective then is to discover natural rules or organizing principles that may act to constrain the combinations of parameters or process interactions, into permissible ranges that are consistent with observed patterns in real catchments. The methodology of the upward approach, as presented in Figure 6, may include the following steps: (i) choose or identify the most detailed or appropriate process model for the problem and catchment of interest; (ii) devise alternative hypotheses regarding parameter combinations or process interactions; (iii) devise a numerical experiment (or several of them) with the chosen model, constrain the combination of model parameters or process interactions; (iv) compare the resulting model predictions against observations available at the higher scale; (v) on the basis of the above, confirm, or falsify the organizing principle as being correct or not; (vi) recycle the above steps, depending on the outcomes, making alternative hypotheses, or making further subhypotheses or sequential hypotheses to help define the possibilities that remain.

The use of models in this manner renders them "virtual reality models" (Weiler and McDonnell, 2004; Wood *et al.*, 2005), used to gain insights and generate hypotheses that can be tested with observations, and thus lead to gains in understanding. This is quite different from traditional calibration exercises aimed at choosing the parameter combination that produces the best match to observations, which are not meant to generate understanding. One example involving the upward approach is presented in the next section as an illustration of the method.

Process to Patterns: Climate-soil-vegetation Interactions and Ecological Optimality

The interactions between climate, soils, and vegetation in controlling a catchment's water balance and subsequently the drainage characteristics have been highlighted earlier through the Budyko (1974) curve (*see* Figure 2b), which suggests that in spite of differences in geology, soils, and vegetation, the annual water balance is governed, to a large extent, by climate, indicating that the soils and the vegetation that develop in a catchment are already adapted to the climate. Figure 3(c) from Abrahams (1984) was equally suggestive of the role of vegetation in controlling drainage density, through the role of soil armoring through vegetation roots. In other words, there are strong feedbacks between climate, soil and vegetation, through both the water balance and erosional stability.

Eagleson (1978a,b,c,d,e,f,g) carried out a pioneering study of climate-soil-vegetation controls on annual water balance, and feedbacks that develop between climate, soil and vegetation; his work represents the best example of the upward approach. For this, Eagleson utilized a comprehensive hydrological (water balance) model consisting of physically-based conservation equations governing each of the constituent processes: infiltration, exfiltration, transpiration, percolation to groundwater, and capillary rise from the water table. The climate inputs were intermittent rainfall events, separated by interstorm periods. Because all of the surface and subsurface fluxes depend on soil moisture content, which is time variable in response to the climatic inputs, an equilibrium soil moisture concentration s_0, which represents the spatially and temporally averaged state of the soil, was chosen as the state variable, and all fluxes were estimated in terms of the assumed equilibrium moisture content. By solving the resulting annual water balance equation, the unknown equilibrium moisture content s_0 was estimated as a function of the climatic variables and the soil and vegetation characteristics. The problem was cast within a statistical-dynamic framework by introducing the probability density functions of the climatic inputs, and Eagleson derived probability distribution functions of the annual water balance components: surface runoff, evaporation, and groundwater runoff.

These distribution functions expressed the mean water balance partitioning in terms of the independent climatic variables (rainfall intensity, duration, and interstorm period), and the soil hydraulic properties (mainly

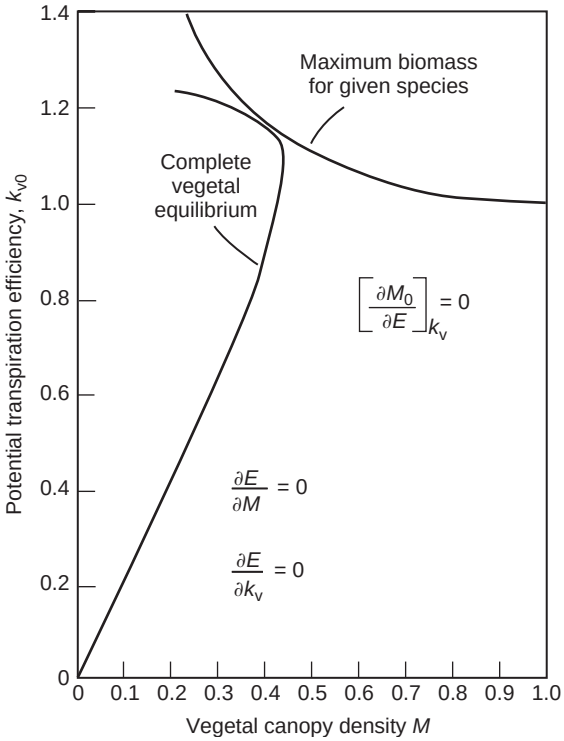

Figure 9 Ecological optimality constraints on climate-soil-vegetation interactions and the resulting water balance, and thus narrow down the space within which vegetation and soil parameters of a complex process-based model can vary (adapted from Eagleson, 1982)

the saturated hydraulic conductivity) and vegetation characteristics (density M, and species type k_v). In principle, according to the model, any combination of climate, soils, and vegetation is possible; apart from the climate inputs and process constraints, no constraints apply as yet to the soil-vegetation combinations that can be included in the model. In line with the methodology of the upward approach, Eagleson (1978d,e,f) invoked three constraints regarding the expected state of vegetation in a natural undisturbed ecosystem in an equilibrium state, which he called *the ecological optimality hypotheses* (*see* Figure 9).

Hypothesis 1: Over short timescales the vegetation canopy density, M, will equilibrate with the climate and soil parameters to minimize the water stress of the component plants, which is equivalent to a maximization of the equilibrium soil moisture, s_0.

Hypothesis 2: Over long timescales, species will be selected whose transpiration efficiency, k_v, maximizes the equilibrium soil moisture, s_0, which is equivalent to minimizing the total evapotranspiration, E.

Hypothesis 3: Over much longer timescales, vegetation will alter soil properties (saturated hydraulic conductivity, K_s, and the pore disconnectedness index, c, to maximize the optimal canopy density, M_0, derived from Hypothesis 1.

The invoking of these ecological constraints effectively limits the set of climate-soil-vegetation combinations to a small subset of the entire set of climate-soil-vegetation combinations that are possible in principle. Furthermore, through the invoking of the ecological optimality constraints, the theory can now be inverted; given the observed water balance in a given climate, the properties of the soil-vegetation system can be derived through an inversion procedure. Eagleson's ecological optimality hypotheses thus represent a predictive and testable theory (Hatton *et al.*, 1997; Kerkhoff *et al.*, 2004). Eagleson successfully tested his theory using observed data from catchments in different climates. In subsequent work, Eagleson (1982) argued that, with time, vegetation modifies (moderates) the hydraulic characteristics of parent material toward values which maximize vegetation production, that is, sandy soils become richer and more water-retentive; clayey soils become more porous and conductive. His ecological optimality hypotheses are capable of reproducing these observed features.

When confirmed on a wide variety of catchments, the ecological optimality hypotheses could constitute the elements of the new theory of hydrology. While recent analysis of the theory have cast doubts on the three

ecological optimality hypotheses (Kerkhoff *et al.*, 2004) based on ecological considerations, they do not invalidate the approach adopted.

SUMMARY AND FUTURE PERSPECTIVES

The foregoing review has highlighted the difficulties with the reductionist paradigm that underpins the current theory of hydrology at the catchment scale. Current process theories using the derivatives of mass, momentum and energy balances, along with empirically derived closure relations, such as Darcy's law and Manning's equation, are sufficient to capture only a small fraction of all the hydrological variability that occurs within catchments. Due to the uniformity assumption underlying the small-scale process theories, the resulting distributed models are highly complex, data hungry, and overparameterized compared to the meagre observations on which they can be calibrated. This reductionist framework and the focus on calibration leads hydrologists to study specific catchments in ever more detail, instead of exploring, and learning from, differences between catchments. In spite of the high level of model complexity and the inputs of enormous amounts of data on climatic variables and landscape properties, the models based on current theories still cannot reproduce some key or defining aspects of observed behavior; the old water paradox is just one example. Paradoxes like this abound in hydrology, and in the absence of a new theory of hydrology that can unify the different perspectives, different experiences, and observations made in different contexts, models are being made more and more complex to accommodate these differences. Current textbooks on hydrology propagate the same fragmented vision of hydrology, organized by process, and written in the form of recipes, for example, 10 different formulas for estimating infiltration, potential evaporation, and so on. The situation is literally analogous to "a cacophony of noises ... not a harmonious melody" (Sivapalan, 1997; Sivapalan *et al.*, 2003b). There is a clear and urgent need to develop a new, unified, and holistic theory of hydrology at the catchment scale that overcomes these limitations.

Elements of the New Unified Theory of Hydrology

On the basis of this review, it is clear that feedbacks will play a central, defining role in the new theory of hydrology at the catchment scale. These include feedbacks between different processes, between patterns and processes, between different parts of catchments, and feedbacks in time (through memory effects). With that focus on feedbacks, the new theory will include the following basic elements:

Pattern: The new theory will seek and identify patterns (both within-catchment and between-catchment) in the data or observations as part of the learning process, to formulate and test hypotheses about underlying processes, process interactions and feedbacks, including the mechanisms that contribute to natural self-organization. Increased attention will be given to structured learning from observations and data.

Process: The new theory will seek to discover or explore new processes, process interactions, or mechanisms at all scales that embed within them either explicitly or implicitly the effects of landscape and climatic heterogeneities, including any simplification that might come about due to natural self-organization that may underlie these heterogeneities.

Function: The new theory will investigate the processes that lead to heterogeneities and the natural self-organization exhibited by landscape properties, and explore the laws or organizing principles governing their ecological function, with the idea that these laws will act as constraints on both the process descriptions (within-catchment), and broad-scale patterns of behavior (between-catchment, regional etc.).

Holistic: The new theory will be holistic, treating pattern, process, and function as parts of a whole continuum – processes lead to patterns, which in turn lead to other processes, with the interactions and feedbacks between pattern and process being mediated by "function", a seemless transition between these three elements, as illustrated schematically in Figure 10.

Multiscale: The new theory will accommodate heterogeneities and variabilities of the catchment system and its responses over multiple space and timescales. It is not limited to making connections between just two scales, a small scale (microscale) and a larger scale (macroscale), but to

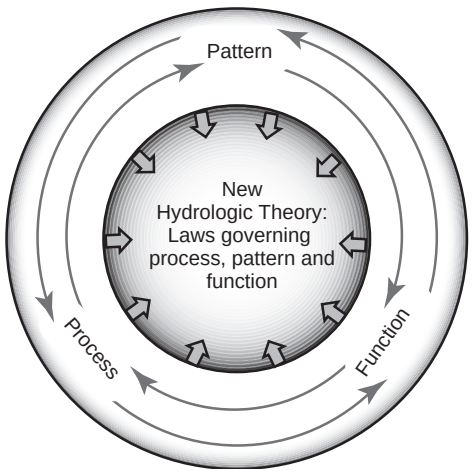

Figure 10 Pattern, process and function, feeding back on each other – elements of a new holistic theory of hydrology at the catchment scale

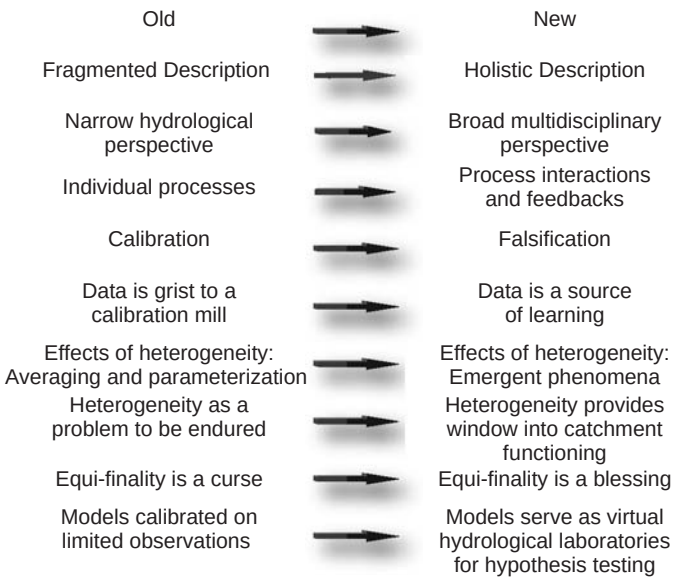

Figure 11 Paradigm shifts accompanying new theory of hydrology at the catchment scale

identifying and quantifying patterns that span a wide range of scales, and to exploring mechanistic explanations for and the common concepts behind these patterns.

Multidisciplinary: By broadening the nature of scientific inquiry to deal with "function", the new theory will necessarily deal with issues and questions that are at the interface between hydrology and neighboring disciplines such as geomorphology, ecology, pedology, and climatology. In this way, it will necessarily involve a broadening of the hydrologic perspective to include multidisciplinary perspectives.

Combination of "place-based" and comparative studies: Most studies exploring processes must be conducted in actual catchments, in real places. Studies of pattern require observations in many catchments, in the same region, and/or in different regions. Exploration of function underlying pattern and process will therefore require a combination of both place-based and comparative studies.

The development of a new theory of hydrology will therefore require nothing short of fundamental or paradigmatic shifts in both research and practice, as illustrated in Figure 11.

Process of Theory Development and Needed Infrastructure

Exploration of Puzzles and Paradoxes

A new theory will come about through answering specific questions regarding catchment behavior in real places, and solving what appear to be puzzles or paradoxes, that is, through a "dialogue with nature". Hydrologists have become very proficient at solving the "what" and "how" questions, but a new theory requires the answering of broader "why" type of questions related to "function". Examples of some unsolved puzzles or paradoxes include, but are by no means limited to the following questions.

- The old water paradox (Kirchner, 2003): How do catchments store "old" water for long periods, but then release it rapidly during storm events, and vary its chemistry according to the flow regime?
- Nature is replete with preferential flow at many scales, ranging from fingering, macropores, fractures, rills and gullies, all the way to the river network. What is the ecological or landscape function of these preferred pathways? Can we predict their occurrence and their spatial densities in terms of the underlying climate and geology alone?
- Why do landscapes evolve under the movement of water into intricate shapes, for example, river networks, soil catena, a signature of which is also present in vegetation and soil moisture patterns? What are the rules underlying their natural symmetry? What is their function?
- How does natural vegetation evolve and adapt itself to limitations of water, energy, and nutrients? What are the underlying organizing principles? Can the natural vegetation pattern and its functioning be predicted on the basis of climate, soils, and the water balance? Can the observed vegetation pattern in space and time give us clues to the underlying water balance?
- How does vegetation and other biotic elements generate and modify the soils to maximize their own ecological functioning? What are the underlying organizing principles?

Hydrological Infrastructure

Explorations of these puzzles and paradoxes will require sustained, painstaking work by individual hydrologists, perhaps working in small groups (but not in committees!). Nevertheless, this kind work will benefit from the presence of a supportive infrastructure, which helps to multiply and link the work of individual hydrologists. Infrastructure and organization focused on observations, new measurement technologies, and advances in modeling capability, all aimed at predictions in ungauged catchments worldwide will help advance fundamental theory development, as illustrated schematically in Figure 12.

Hydrological observatories: A number of highly focused, and detailed field experiments must be carefully designed and carried out in different regions of the world, in *nested* fashion, in order to observe the multiscale hydrological processes at the plot, hillslope and basin scales, assemble the necessary internal and surrogate data needed to make inferences about the underlying mechanisms over a wide range of scales, and their connections to landscape and climatic heterogeneities. By definition, these have to be established, and maintained over of long periods of time; this can only be done at the regional, national, or international level.

New measurement technologies: One of the difficulties that has hampered the development of a unified theory of hydrology has been the inability to observe processes over a wide range of scales, and at the same time, monitor internal variables such as soil moisture storage, groundwater levels, saturation areas, and so on, so that catchment water balance can be closed with confidence. Inadequate data resolution leads to incomplete or even wrong theories, and partly explains the stagnation in the development of a unified theory. There is a crying need for breakthroughs in measurement technology, on the ground as well as through remote sensing (e.g. radar, satellite, geophysical instruments, tracers). Along with new sources and types of data, we also need a revolution in techniques for data processing, and for identifying patterns in the data, extending beyond the present standard methods, such as cluster or principal component analysis, fractal analysis, artificial neural networks, and so on.

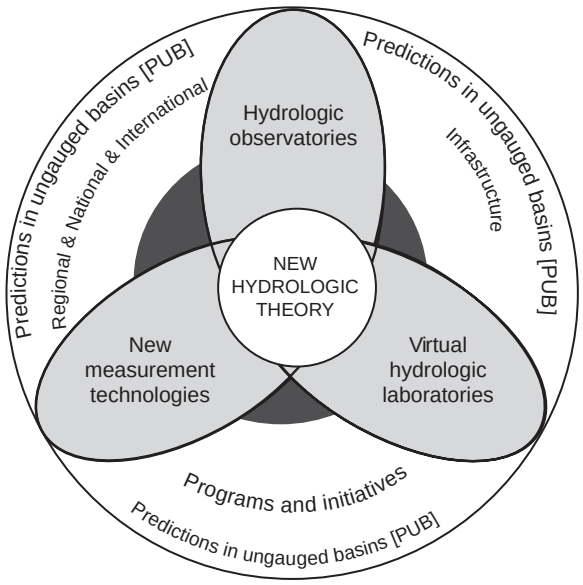

Figure 12 National and international initiatives provide the motivation and urgency toward theoretical advances in catchment hydrology

Virtual hydrological laboratories: In hydrology, we already have access to some of the most detailed, distributed, physically-based hydrological, hydrometeorological, eco-hydrological and landform evolution models, containing within them the most up-to-date process descriptions currently available. There is much to gain from their use as "virtual reality models", by implementing them to test alternative hypotheses about the constraints that need to be imposed on the underlying heterogeneities of landscape properties to match observed patterns of behavior. This kind of intellectual activity can play a critical role in the development of a new theory of hydrology, and along the way it will lead to improvements of the models for predictive purposes because of the possibility that such constraints will lead to a simplification of the models.

Methodological Framework

Two approaches, upward and downward, and their reconciliation, were outlined for the development of a new theory. Along the downward route, we begin with observed patterns at the catchment scale and explore the underlying process controls. Along the upward route, we combine existing knowledge about hydrological, landforming, and ecological processes in complex hydrological models, and explore their ability to reproduce observed patterns. Both methods, systematic data analysis and modeling investigations, require organization and a commonality of purpose. In this respect, we include three community level activities that are crucial to the success of the theory development effort.

Catchment classification: The downward approach involves, essentially, making inferences from patterns in the observations. To make progress, in order to decipher meaningful patterns in the observations, hydrology requires a globally agreed classification system capable of predicting, to first order, the dominant controls on water fluxes and pathways from amongst the entire range of mechanisms that are possible. The classification system, a prerequisite for any attempt at theory development, must be established urgently as part of a broad community effort, even though it will evolve with time as the field matures (Dooge, 1986).

Such a classification system would itself provide an important organizing principle, complementing the concept of the hydrological cycle and the principle of mass conservation (McDonnell and Woods, 2004; Woods, 2002). To provide meaningful distinctions between catchments, the classification scheme should be based on characteristic measures of fluxes, storages, and response times: a measure of climate dryness such as the ratio of mean annual potential evaporation to rainfall, E_p/P; the average volumes of water stored in different compartments, that is, snow and glaciers, pore water (in soils, and rocks), and in open water (lakes, wetlands, river channels); and characteristic response times of these catchment stores (Skøien *et al.*, 2003).

New balance equations for nested river basins: To make progress along the upward route to conceptualization, the new theory of hydrology must embrace a quantitative framework that is able to connect components of the hydrological cycle and the catchment system across multiple space-timescales. A primary requirement of this framework is that it be distributed, explicitly respecting the self-organized river network structure that connects different parts of the catchment, including the organized and random heterogeneities that develop within it (e.g. topography, soil catena, vegetation). This quantitative framework should be in the form of a set of coupled balance equations for mass (water), momentum and energy, that is consistent with the organized heterogeneities that are present within the catchment. The most obvious natural building blocks for the derivation of the balance laws are a nested set of subcatchments associated with individual stream links, although other building blocks may also be considered (Troch *et al.*, 2003). Gupta and Waymire (1998) presented a coupled set of mass balance equations for flow within a stream network, and for runoff processes within associated subcatchments, all expressed in the form of a set of hierarchical (nested) difference equations. Reggiani *et al.* (1998, 1999) derived a more complete set of coupled mass, momentum, and energy balance equations for the stream network and associated subcatchments, which they called *the representative elementary watersheds* (*REWs*). These are indeed significant advances toward a consistent quantitative framework that is required for catchment hydrology. Nevertheless, the balance equations derived in these studies must still be supplemented with numerous closure relations for various exchange fluxes (Lee *et al.*, 2005). The determination of such closure relations, reflecting the natural self-organization that is present within catchments, is a significant and as yet incomplete element of the new theory of hydrology (Zehe *et al.*, 2005).

Scaling laws in hydrological behavior: Observed patterns of heterogeneity of climatic inputs landscape elements and hydrological behavior are based on information from disparate sources: experimental plots, field surveys, weather radar reflectivities, and satellite data. Increasingly, much information relevant to hydrology is able to be extracted from satellite remote sensing, including aspects such as soil moisture and vegetation patterns. Coarser, larger-scale field surveys may reflect processes occurring over longer timescales. For example, tree rings and paleobiological and paleohydrological data may unearth information about past changes over very long timescales (Harte, 2002). If simple, robust scaling patterns exist among these variabilities, they will let us connect and extend insights between different scales. Fractals, multifractals, and random cascades are modern stochastic techniques, which exploit concepts such as geometric and statistical self-similarity to quantify the relationship between the variabilities present at different scales, and have the power to describe apparently complex forms of heterogeneity occurring over a wide range of scales with a small number of parameters (Lovejoy and Schertzer, 1995). Multifractal concepts have already been used successfully to characterize space-time variability of rainfall fields and the structure of stream networks, and are already beginning to be used to describe spatial patterns of soils and vegetation, soil moisture, and a number of other geophysical and biophysical phenomena. The search for scaling laws is a key component of the development of a new theory of hydrology (Dooge, 1986; Levin, 1992; Harte, 2002; West and Brown, 2004), and must happen independently of the other two approaches.

Predictions in Ungauged Basins (PUB)

The development of a new theory of hydrology receives additional impetus due to the urgent need to predict catchment behavior, for the sustainable management of water resources and water quality, and the prevention and amelioration of water-related natural hazards such as floods and droughts. The International Association of Hydrological Sciences (IAHS) has launched the IAHS Decade on Predictions in Ungauged Basins (2003–2012), or prediction of ungauged basins (PUB), a new global initiative, aimed at formulating and implementing appropriate science programs to engage and energize the scientific community toward achieving major advances in the capacity to make predictions in ungauged basins (Sivapalan *et al.*, 2003b). PUB emphasizes (i) improved understanding of multiscale variabilities of hydrological behavior at catchment scale, (ii) increased use of advanced technologies, and (iii) development and application of sophisticated numerical models that depend less on calibration and more on understanding. The urgency engendered by PUB forces us to challenge and critically evaluate existing approaches to making hydrological predictions. In addition, a number of other ongoing national and international initiatives act as strong catalysts toward triggering significant theoretical breakthroughs (*see* **Chapter 203, A Guide to International Hydrologic Science Programs, Volume 5**). Parallel national programs

are needed in many individual countries and in regions to provide the necessary infrastructure and funding for the associated research activities.

Current Intellectual Environment Surrounding Hydrology

Three contemporary scientific movements are providing a supportive environment for the theoretical advances in catchment hydrology, providing coherence and respectability to the efforts in this direction, as depicted schematically in Figure 13: (i) global change science, which provides support toward comparative hydrology on a global scale, helping to monitor large-scale patterns and understand the causes of these patterns; (ii) ecohydrology and earth system science, which help broaden the nature of hydrological inquiry, through exploration of process interactions and feedbacks, including interactions between hydrological, ecological, geomorphological, pedological, and climatological processes; and, (iii) complex systems science, an emerging interdisciplinary field spanning many fields, including mathematics, statistics, physics, ecology, and earth system science, which helps to generate new mathematical or analytical tools to deal with pattern dynamics and emergent phenomena that arise from nonlinear interactions and feedbacks in complex systems.

Apart from these scientific trends, the thrust toward a new theory of hydrology is also considerably aided by advances in technology: (i) vast improvements in our ability to measure and monitor hydrological parameters and state variables (and even fluxes through indirect methods) at large scales over the whole earth: these include satellite remote sensing, geophysical, and electronic measurements of increasing capability to plumb the subsurface hydrological condition, increasing sophistication of environmental isotope and chemical tracers to measure and monitor fluxes and state variables at the catchment scale; and (ii) increasing speed and storage capacity of digital computers that will enable hydrologists to run massively complex numerical models, in virtual reality mode, and improved methods of communication and sharing of data and results through the Internet which allows scientists to more easily cooperate and interact amongst large groups.

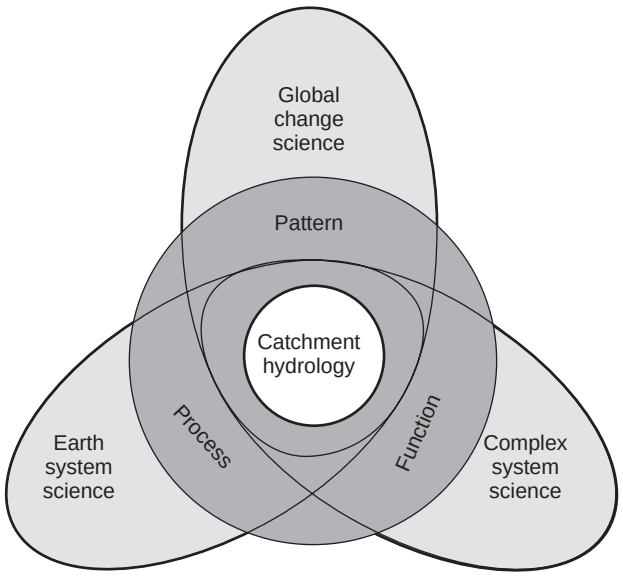

Figure 13 Current global scientific and intellectual environment providing a strong catalyst toward development of a new and holistic theory of hydrology at the catchment scale

Concluding Remarks

The urgency for a new, unified theory of catchment hydrology arises partly from the increasing frustration with the difficulties faced with existing hydrological models based on current theories, including the inability to satisfactorily resolve observed paradoxes. The urgent need to make satisfactory predictions of water quantity and water quality in ungauged basins, including the effects of climatic changes and human impacts requires a sound theory of hydrology that is solidly based on understanding and not calibration (Sivapalan *et al.*, 2003b). Therefore, the time is ripe for fundamental research that will set the stage for major advances in our predictive capabilities. Many national programs, and international initiatives such as PUB, are beginning to provide the necessary infrastructure, leadership, and coordination for groups of scientists to work together to address some of the most fundamental questions related to the development of a new theory. The increasing focus on earth system science, global change science, and complex system science is providing the necessary intellectual framework for a cross-fertilization of ideas across diverse disciplines, which can only benefit hydrology. For these reasons, there is real hope and excitement that catchment hydrology will leave behind the empiricism and fragmentation that has bedeviled it for so long, move forward toward a more unified and holistic theory that is fully accommodative of broad multidisciplinary perspectives, and will evolve from the "cacophony of noises to a harmonious melody" as anticipated in Figure 14. Hydrologists should rise up to these challenges and make use of the exciting opportunities that the pursuit of a new unified theory will generate.

Acknowledgments

Many of the ideas presented in this article are the result of discussions I have had with numerous colleagues and students over the past few years. As such, they are not just personal views and, to a large extent, they reflect the emerging views of many in the hydrology community. In particular, I am indebted to Günter Blöschl, Christoph Hinz,

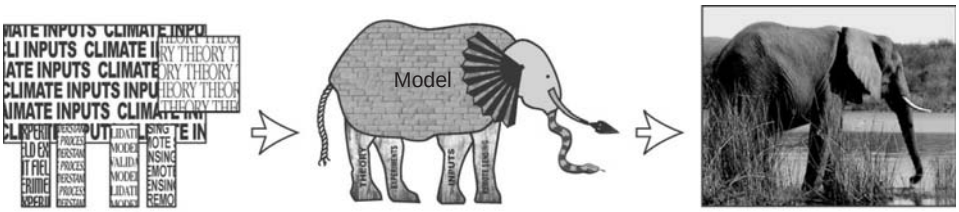

Figure 14 From a fragmented to a holistic view of catchment hydrology, as an integral part of earth system science (Reproduced from Sivapalan *et al.*, 2003b by permission of IAHS. Illustration of elephant reproduced with permission from Jason Hunt © 1999)

Gavan McGrath, Jeff McDonnell, Hubert Savenije, Stan Schymanski, Ross Woods, Matthias Boer, Greg Hancock, and Patricia Saco, for freely sharing their ideas with me, and for offering advice and many constructive criticisms, which have helped to substantially improve the article.

PART 2

Hydroinformatics

14: Hydroinformatics and its Contributions to Hydrology: From Computation to Communication

MICHAEL B ABBOTT[1], ARTHUR E MYNETT[2] AND J PHILIP O'KANE[3]

[1] *Knowledge Engineering B.V. Belgium and UNESCO-IHE Delft, Delft, The Netherlands*
[2] *WL Delft Hydraulics & UNESCO-IHE and Delft University of Technology, Delft, The Netherlands*
[3] *Environment Institute, National University of Ireland, Cork, Ireland*

Hydroinformatics is concerned with the application of information and communication technologies for the planning, management, and conservation of the aquatic environment. With the rapidly increasing capabilities of computer-based systems, considerable advances were made during the past decade or more. Some historic developments are outlined in this article and the development of hydroinformatics as a sociotechnology is explained. The transition from computation to communication is illustrated by examples from present day flood simulation and flood early warning systems; emerging applications of data-mining and evolutionary computing are demonstrated for the fields of ecohydraulics and ecohydrology. The impact of hydroinformatics on the future role of hydrology in a multiuser environment is discussed. The contours of a next (fifth) generation software systems making use of agent-based communication over a network of computers and developers are outlined. The scope and content of all subsequent articles within this chapter are presented; these can be broadly grouped into areas of (i) physics-based numerical modeling; (ii) data-driven modeling and evolutionary computing; and (iii) design and decision support systems.

INTRODUCTION

Hydroinformatics is quite often identified as "the application of information, computation, and communication technologies in the various fields of hydroscience and engineering". With the advent of computer-based modeling and stimulating the development of the SHE system (as will be elaborated later), hydroinformatics has been involved with hydrology already for quite some time. However, according to Abbott (1992):

> *"No theory of science – let alone a theory of sciences – can itself be constituted as a scientific theory. Similarly, that which serves a technology need not necessarily be a technology – and indeed it is most commonly not a technology. Hydrology, quite consentaneously, is itself not a science, and neither is it itself a technology, even though it deals in the productions of many sciences and serves many technologies. Accordingly, when viewed scientifically or technologically, it appears to be bereft of a body of theory and so lacking all intentionality. It appears to be without an own form and without an own direction. But if it is not a science and it is not a technology, what is the status of hydrology? It is now the time and the place to state, provocatively but with serious intent, that hydrology is a rhetoric waiting for a grammar."* (Abbott, 1992).

So much has happened in computer-based modeling in the years since this was written, and yet so little seems to have happened in the field of hydrology as a whole. Since that time, *hydroinformatics* has taken wing to become an indispensable adjunct and support to most major construction works in the aquatic environment, to have its own major biannual conferences, its own Journal of Hydroinformatics affiliated with all three international water associations, and to have been accepted generally as a major discipline in its own right, to be taught in many universities

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

around the world. Hydroinformatics started off as a technology by expanding the field of computational hydraulics in river, urban, and coastal engineering. However, hydroinformatics was also concerned with the field of computational hydrology through its involvement in the development of distributed physically based model codes, as represented by the European Hydrologic System/Système Européen Hydrologique (SHE – see Figure 1), which constituted a "quantum jump" in complexity as compared with any other code so far known in hydrology, as discussed by Abbott and Refsgaard (1996).

The ethos of the physics-based hydrological modeling systems that follow this tradition can be described as *essentialist*, while the regressions to devices that disregard many, if not all, of the productions of the physical, including biological, sciences, such as are still very actively propagated even today, can continue to be described as *intrumentalist*, in that they are only concerned to reproduce some observed results and even then only for particular combinations of processes occurring in specific places at specific times, and often further only under specific anterior conditions. As regressions to an earlier era, preceding that of modern science, they have the same concerns as had the ancient Greek astronomers, of saving the appearances ($\sigma\acute{\omega}\zeta\varepsilon\iota\nu\ \tau\acute{\alpha}\ \phi\alpha\iota\nu\acute{o}\mu\varepsilon\nu\alpha$) of certain observed phenomena, while disregarding all, or almost all, concern with understanding. It has been one of the disappointments of hydroinformatics that much excellent work that has been done, for example, in the area of data mining technologies, has been misused in this way and not least in the area of hydrology. Indeed, it is still apposite to repeat the observations of Klemes (1986; see also Abbott, 1992) on this unfortunate habit of misappropriating techniques borrowed from other disciplines:

> *"Hydrology, having no solid foundation of its own and moving clumsily along on an assortment of crutches borrowed from different disciplines, has always been an easy victim of this practice. Every mathematical tool has left behind a legacy of misconceptions invariably heralded as scientific breakthroughs. The Fourier analysis, as was pointed out by Yevjevich (in 1968), had seduced the older generation of hydrologists into decomposing hydrologic records into innumerable harmonics in the vain hope that their reconstruction would facilitate prediction of future hydrologic fluctuations (fortunately few computers were available at the time, so that the Fourier fever did not become an epidemic); various statistical methods developed for evaluation of differences in repeatable experiments have been misused to create a scientific analysis of unrepeatable hydrologic events; linear algebra has been used to transform the idea of a unit hydrograph from a crude but useful approximation of a soundly based concept into a pretentious masquerade of spurious rigour now exercised in the modelling of flood events;*

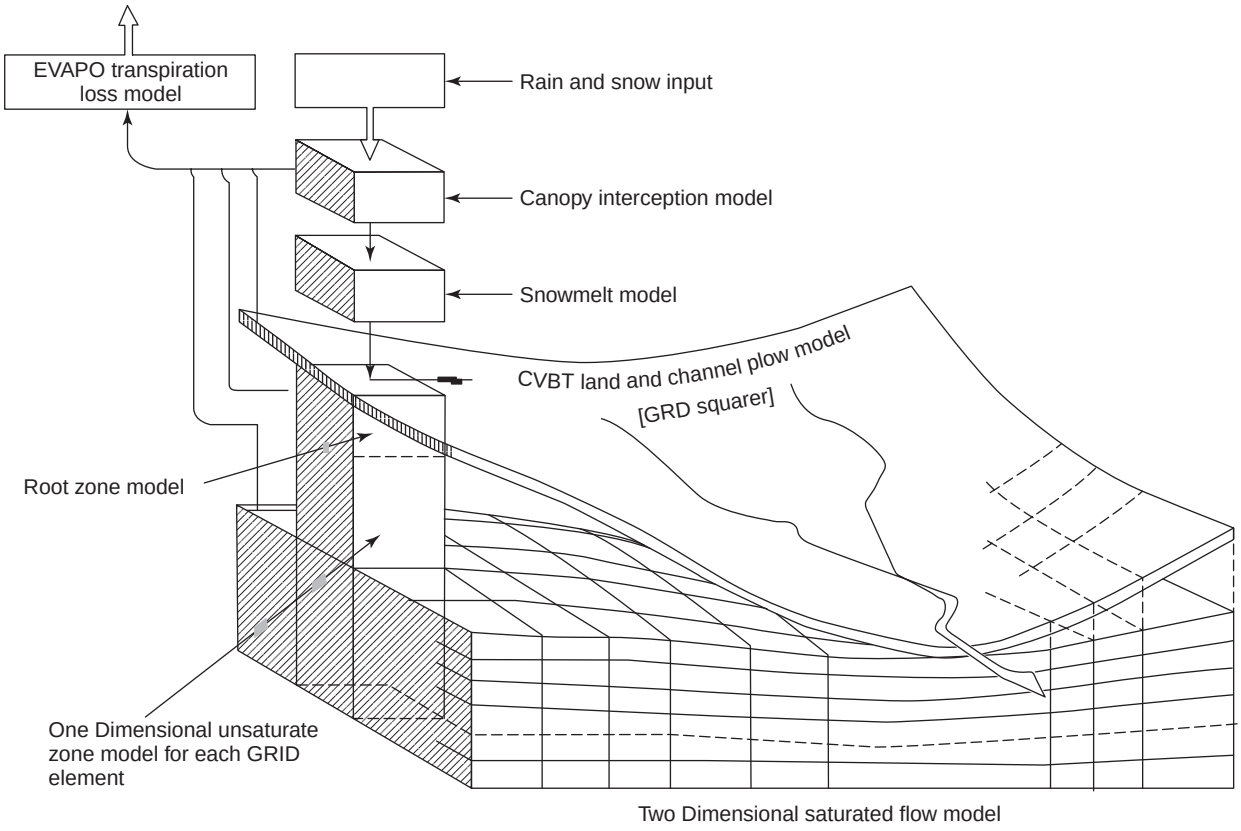

Figure 1 Schematic presentation of MIKE SHE (Courtesy DHI Water & Environment)

time series analysis has been used to remake inadequate 20-year stream flow records into 'adequate' 1,000-year records, or even more 'adequate' 10 000-year records; and the illusion of pattern recognition is now being courted in the vain hope that it will lend legitimacy to the unscientific concept of mindless fitting that dominates contemporary hydrologic modelling. In all these cases, mathematics has been used to redefine a hydrologic problem rather than to solve it". [Klemes, 1986]

Clearly, those who are concerned with modeling for engineering practice do not want to waste too much of their time on refuting these, as they see it, regressions to primitive forms of prescientific instrumentalism: they much prefer to persevere further along the path of modern science as this now comes to presence in an era of such greatly extended possibilities for communication. And, indeed, as will shortly be explained, it is in just this era that a modern-scientific hydrology can attain to its full potential.

HYDROINFORMATICS DEVELOPING INTO A SOCIOTECHNOLOGY

Hydroinformatics, being in essence "market-driven", so far has had relatively few dealings with the individual sciences that are linked together through hydrology and that constitute its scientific-hydrological foundation. Abbott and Refsgaard (1996) considered the marked discrepancies between developments in hydrology that could, in principle, be catalyzed by developments in hydroinformatics and developments in fields like river and coastal engineering, river basin, and coastal zone management, where already at that time hydroinformatics had triggered major advances.

It had by then become clear that only distributed physically based models like the SHE systems could make use of the rapid advances in instrumentation, supervisory control and data acquisition (SCADA) systems with real-time data transmission, data assimilation techniques, remotely sensed data and its interpretation systems, seamless geographical information systems (GIS) interfacing, advances in geodetic surveying incorporating GPS-based position-fixing equipment, cartographic transformation packages, intranetted and extranetted communication systems, and the many other developments that hydroinformatics had already woven together to obtain important synergies in areas like river basin and coastal zone management. By way of explanation of this situation, Abbott and Refsgaard (1996) identified the following four areas of difficulty in the application of such physics-based systems in hydrology:

"1. Data Availability

A prerequisite for making full use of the distributed physically-based models is the existence and easy accessibility of large amounts of data, including detailed spatial information on natural parameters such as geology, soil and vegetation and man-made impacts such as water abstractions, agricultural practices and discharges of pollutants. In most cases, all such relevant data does not exist and even the existing data is most often not easily accessible due to lack of suitably computerised data bases.

A further complication in this regard is the administrative problem created by the fact that these models, in addition to the traditional hydrometeorological data, require and can make use of many other data sources, such as those arising from agricultural, soil science, and geological investigations. Another important development gradually improving the availability of data is the application of GIS technology, which is particularly suitable for couplings with distributed hydrological models.

2. Lack of Scientific-Hydrological Understanding

With the introduction of a new modelling paradigm and concurrent research in process descriptions, new shortcomings in the scientific-hydrological understanding have emerged, especially with regard to flow, transport, and water quality processes at small scales and their up-scaling to describe larger areas. [Some of the key scientific problems were highlighted in several chapters of Abbott and Refsgaard (1996)]. These scientific shortcomings have, on the one hand, constrained the practical applications of distributed hydrological models and, on the other hand, the existence and application of such models have put a new focus on some of these problems, thus contributing to advances in the scientific-hydrological understanding.

3. Traditions in Hydrology and Water Resources Understanding

The distributed physically-based model codes, as represented by the European Hydrologic System/Système Européen Hydrologique (SHE), constituted a 'quantum jump' in complexity as compared with any other code so far known in hydrology. Moreover it used technologies, such as had been developed in computational hydraulics, with which few hydrologists were familiar. Although the numerical algorithmic problems could be largely overcome through the development of the codes into user-friendly fourth generation modelling systems with well proven algorithms, such as the MIKE SHE, the problem was then only shifted back to one of comprehending the fully integrated complexity of the physical system that was being modelled together with the constraints that were inherent in the modelling procedures.

Very few professional engineers and managers were, and still are, educated and trained with the necessary integrated view of hydrological processes in anything like their real-world physical complexity. This difficulty is exacerbated by the very nature of hydrology itself, whereby most professionals possess only a limited view of the physical processes involved. Soil physicists, plant physiologists, hydrogeologists and others usually have only a very partial view on the whole system, while there are few organisations that have available both the full range of such specialists and the more broader-ranging professionals that are needed in many situations to exploit the potential of distributed physically-based codes to such a degree that this exploitation is economically justified.

4. Technological Constraints

In order to achieve a wide dissemination of a new modelling technology to a considerable part of the professional community (and not only to experienced hydrological modellers) experience from hydraulic engineering shows that fourth generation (i.e. user-friendly software products) are required. Furthermore, it is believed that fifth generation systems are required to realise their full potential in terms of practical applications. The fifth generation systems [will be] hydroinformatics based." [Abbott and Refsgaard, 1996].

Thus, although already one decade ago the further development of physically realistic computer-based hydrological

modeling systems was seen to evolve from developments in hydroinformatics, the formidable institutional problems that could be blocking these developments in many areas were also foreseen already at the time. These institutional problems have become increasingly serious since then and have now, in their turn, led to serious problems within the hydrologic community itself. These problems appear as a divergence within the community concerning the very nature of hydrologic modeling and practice, and with this the role that hydrology has to play, or indeed can play, in society as a whole. Such divisions strike at the heart of the scientific foundations of hydrology, raising questions concerning its very nature as a discipline based upon the results of modern science.

In the years that have elapsed since the above evaluation was written, hydroinformatics has passed through two major transformations that have in turn been quite closely related. The first of these was the realization that hydroinformatics was something more again than a technology connecting together other technologies and sciences to provide applications. As the environmental movement grew ever more vociferous and exercised ever more power at the level of government, hydroinformatics was drawn increasingly into the public debates of the matters that it treated. It had then necessarily to develop new systems, both to provide means for governments to satisfy the engaged populace and to represent the interests of this populace at the level of government.

Hydroinformatics became increasingly involved in drafting legislation that would empower the concerned populace as genuine stakeholders in water resources, and this necessitated the development of information and knowledge systems for transforming this legislated empowerment into real-time, on-line operational realities. Hydroinformatics not only explored ongoing technical developments, such as those associated with rapidly expanding technologies like the Internet, mobile telephony, applications of Java, and other communication-enhancing technologies, but it also became inseparably involved in the so-called "technologies of persuasion" and other, previously separated, social aspects. It entered into a field where social and technical aspects were so closely interwoven that no development within the one could proceed at all without a corresponding development in the other – thus hydroinformatics increasingly became a *sociotechnology*.

FROM COMPUTATION TO COMMUNICATION

This chain of development was, of course, in all cases inseparable from the second major development: a change in emphasis in hydroinformatics *from computation to communication*. The computational development continued, of course, but its products were communicated in new forms directed to satisfy the needs for instantaneous information and supporting knowledge to a totally new kind of nonprofessional, but highly engaged, public, commonly represented by influential nongovernment organizations (NGOs). This public, whether as individuals or NGOs, needed to know the precise movements of water, sediments, and other materials not only at the very moment that these were occurring, but also as these would occur in the

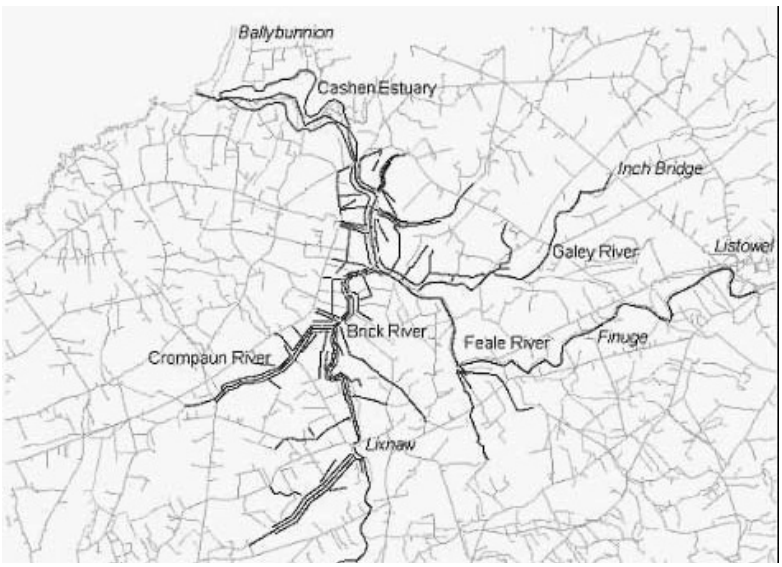

Figure 2 Lower Feale river network, Ireland. The Feale debouches through the short Cashen estuary into the outer Shannon at Ballybunnion. The Upper Feale enters the 250 km^2 Feale polders (15) at Listowel where it forms a torrent at high flows. foreseeable future under existing plans. Only under these circumstances could this public, through its NGOs, be responsibly empowered by legislation to modify, or even stop, the ongoing works if these posed threats to its perceived interests. Hydroinformatics thus entered into an ongoing process of ever increasing interaction between long-established representative democratic forms of government and certain new forms of participative democracy, as catalyzed by rapidly ongoing developments in communication technologies. It is only recently that the consequences of this development for hydrology have become clear.

If we define a science conventionally as a"totality established through an interconnection of true propositions", then each science can be regarded as the body of knowledge that is expressed by, or encapsulated in, this totality. When we speak about the physically and biologically based sciences upon which hydrology draws for its sustenance, we speak in the spirit of modern science. The development of modern science from Buridan's recognition of the law of conservation of momentum – of impetus – onwards, has been recorded so extensively that no further commentary will be given here. Similarly, the introduction of empirical, but carefully measured, coefficients into these universal laws in such a way that these coefficients also apply to all processes of a specific kind in all places and at all times, has been greatly advanced over the centuries: see Cunge (2003) as an example from hydraulics with an obvious relevance to hydrology.

O'Kane *et al.* (2004) followed this approach to explore the hydrology and hydraulics of a pumped polder in North Kerry, Ireland, by setting up a distributed physics-based modeling system for the lower Feale catchment in southwest Ireland – see Figure 2 – that is subject to annual flooding. Two of the 15 hydraulically independent polders making up the catchment were instrumented as part of a pump experiment. Several state-of-the-art, high frequency instruments monitor the pump experiment and provide input data for a very detailed hydrologic-hydraulic model. An electrical resistivity investigation and a ground-penetrating radar survey were carried out to collect subterranean data and a number of deep boreholes were drilled to calibrate these two surveys. A dynamic geographical database, built in ArcGIS (ESRI), was set up to store the wide range of data collected and the results of the different surveys carried out (see Figure 3).

An integrated hydrological-hydraulic model of the sub-catchment that includes the two polders was developed to

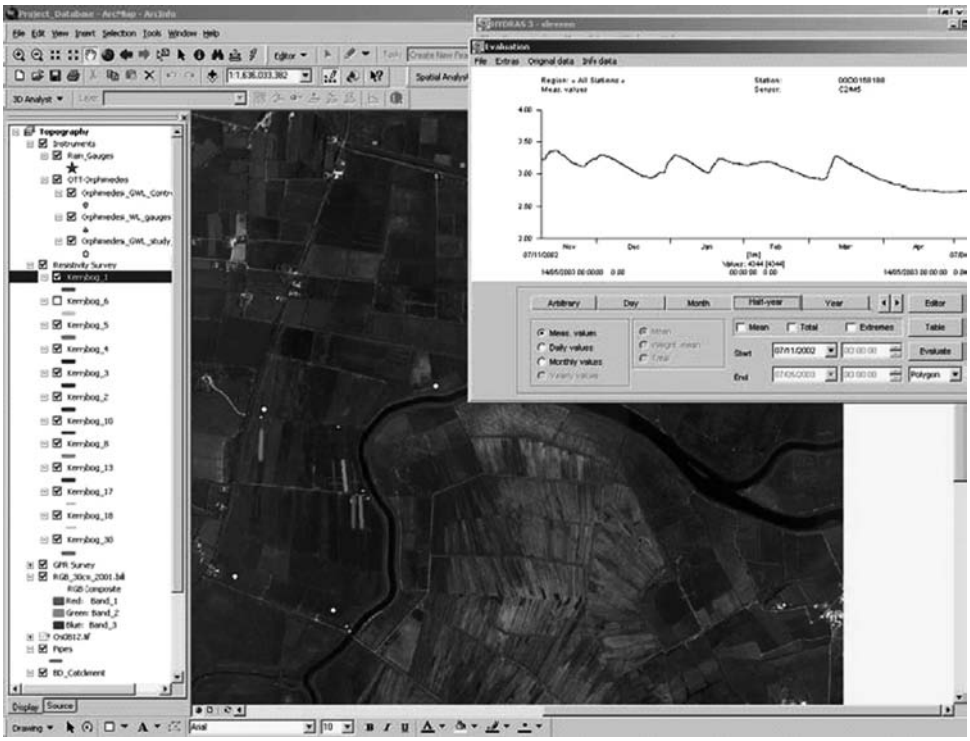

Figure 3 ArcGIS database and ArcMap layout of the centre of the Lower Feale – see figure 2. The window on the right shows the measurements of groundwater level during winter at a gauge in the pumped polder to the west of the Brick tributary. evaluate the effectiveness of pumping, for eventual implementation in a flood mitigation strategy in the remaining polders. The model of the study site was implemented using the combined Mike SHE/Mike11 modeling system of DHI Water and Environment. It simulates the surface drainage network, saturated and unsaturated groundwater zones, all hydraulic structures, and incorporates a high-resolution digital elevation model.

The main objective of the study was to properly understand the arterial drainage infrastructure, and, in particular, the performance of the sluiced culverts system and its relationship with flooding. A detailed evaluation of various degrees of engineering interventions for the alleviation of flooding (dredging, pumping, etc.) was carried out with the computer simulation model. A network of pumps was found to be the most effective solution from both engineering and economical point of view. On the basis of the graphical display capabilities of the (sociotechnical) hydroinformatics system, the results could easily be communicated with the public and provided useful support to the decision makers involved.

Yet another example of the combined use of high-resolution digital elevation (DEM) data, advanced numerical simulation systems, and the powerful visualization capabilities of GIS is demonstrated by McGrath *et al.* (2003), exploring the implications of sea level rise on the flood risk assessment for the city center of Cork, Ireland. With access to high-resolution DEM data produced by the German Aerospace Agency (DLR), the visualization of likely natural flooding behavior becomes much more achievable. Using the High Resolution Stereo Camera Airborne (HRSC-A) equipment originally intended for use in the Mission to Mars space program, the National University of Ireland, Cork, applied it to remote sensing problems on the surface of the Earth. In May 2001, an aerial survey using this camera was conducted over Cork City and the Lower River Lee. The resultant elevation datasets cover an area of 325 km^2, coregistered and geo-referenced to the Irish National Grid, having a −1 m spatial resolution and a −10 cm vertical resolution.

At present, the River Lee regularly reaches the level of the city center quays and occasionally overwhelms its banks and floods the central island and adjacent areas including the Central Business District. The usual scenario leading to such events is the joint occurrence of a spring tide with a low pressure weather system to the southwest of Ireland, which usually results in precipitation and Southerly winds driving the water up from the harbor. Such effects are presently mitigated by the controlled release of water into the river system by the Electricity Supply Board at the Inishcarra and Carrigadrohid dams to the west. It should be noted, however, that the elevation of the docklands regions is even lower than that of the city center. These docklands are in fact built in an urban polder and risk being completely inundated in the event of a general sea level rise due to global warming. This will be particularly worrying as The Cork Docklands Development Strategy foresees an investment of €38 000 0000 on infrastructure to facilitate high-density housing as well as improved transport facilities.

Because of this, detailed investigations into the hydrological and hydraulic implications were carried out using DEM and GIS in combination with advanced numerical simulation tools, presenting the results by easy-to-grasp visualizations of the likely flooding effects due to sea level rise, as presented in Figures 4a and 4b. These "hydroinformatics systems" offer powerful instruments for decision support on the development of any flood defence scheme and on the efficacy of potential mitigation measures. More details on these various aspects are provided in subsequent articles by

Moglen and Maidment (*see* **Chapter 15, Digital Elevation Model Analysis and Geographic Information Systems, Volume 1**), Stelling and Verwey (*see* **Chapter 16, Numerical Flood Simulation, Volume 1**), Lin and Falconer (*see* **Chapter 17, Hydrological and Environmental Modeling of Transport Processes in Rivers and Estuaries, Volume 1**), as well as Guinot (*see* **Chapter 18, Shallow Water Models with Porosity for Urban Flood Modeling, Volume 1**). A recent and ongoing application of flood early warning system (FEWS) development in the United Kingdom is elaborated in the article by Werner *et al.* (*see* **Chapter 23, Flood Early Warning Systems for Hydrological (sub) Catchments, Volume 1**).

FLOW RESISTANCE DUE TO VEGETATION OBTAINED FROM GENETIC PROGRAMMING

Since hydroinformatics is much concerned with planning, management, and conservation of the aquatic environment, applications in the area of ecohydraulics and ecohydrology arise quite naturally. The scope and techniques of environmental hydroinformatics were outlined by Mynett (1999, 2002) and some practical applications of hydroinformatics tools in eco-compatible adaptive water resources management were indeed a topic of discussion during the Virtual Water Forum at the WWF3 in Japan (Mynett, 2003a) as well as during the latest Hydroinformatics Conference in Singapore (Mynett, 2004a). Also, within the ecohydraulics community, it is recognized that eco-compatible adaptive water management strategies can only be developed and implemented by making full use of advances in hydroinformatics system development as demonstrated by Jorde (2004) and Hardy *et al.* (2004). For the design of river restoration measures and adaptive river basin management procedures, evolutionary algorithms and fuzzy rule-based systems prove extremely valuable (Chen, 2004a).

Since considerable emphasis is being put on flood simulation, proper modeling of overland flows in wetlands and vegetated floodplains is of great practical importance both in flood early warning and in river restoration. Many research initiatives have been undertaken in order to improve on the description of the relationship between flow resistance and the temporal and spatial distribution of vegetation. Both analytical and experimental studies of vegetation-related resistance to flow and the equivalent resistance coefficients have shown that the resistance coefficients are very much waterdepth- (and hence solution) dependent. Consequently, the traditional approach of using a single resistance coefficient fails to describe correctly the (nonlinear) physical behavior of this phenomenon. One way of improving the description is updating the equivalent resistance coefficient on the basis of the computed water depth. However, in order to do so, a relation between the vegetation characteristics, bed resistance, water depth, and equivalent resistance coefficient is needed. Genetic programming (GP) was used by Rodriguez (2004) following up from Babovic and Keijzer (1999, 2000) to derive such relation.

When refining a model of a physical process, a scientist focuses on the agreement of theoretically predicted and experimentally observed behavior. If these agree in some accepted sense, then the model is considered "correct" within that context. Here, the inverse problem to verification of theoretical models is considered: (how) can we obtain the governing equations directly from measurements? To do this, Babovic and Keijzer (2000) extended the notion of qualitative information contained in a sequence of observations to consider directly the underlying mechanisms. They showed that, using this information, one can deduce the effective governing equations directly from the data. In this way, the deterministic component of the observed behavior can be obtained to an *a priori* specified level of correctness or accuracy.

One way of obtaining a detailed account of resistance description of flow through and above vegetation is to perform detailed numerical simulations on the basis of a one-dimensional turbulence model for the vertical (1DV) direction (Uittenbogaard, 2003). The 1DV model assumes that the flow is locally uniform in the horizontal directions and calculates the orthogonal horizontal velocities $u(z)$ and $v(z)$ as a function of the vertical coordinate z. The 1DV model is a simplification of the full 3D Navier–Stokes equations by decoupling the vertical from the horizontal flow conditions. By including the effects of plants into the commonly used k-ε model for turbulence closure, the following equation of motion arises:

$$\rho_0 \frac{\partial u}{\partial t} + \frac{\partial p}{\partial x} = \frac{\rho_0}{1 - A_\mathrm{p}} \frac{\partial}{\partial z} \left((\nu + \nu_\mathrm{T}) \frac{\partial u}{\partial z} \right) - F \qquad (1)$$

where $(1 - A_\mathrm{p})$ denotes the specific area occupied by the fluid and F is the drag force exerted by the plants. The k-equation in the k-ε model can be formulated to account for the effect of plants, as described in detail by Uittenbogaard (2003). The results of the 1DV k-ε model can be used to obtain the detailed roughness description of resistance to the flow caused by vegetation and to obtain the commonly used roughness values like the Manning (n), Chézy (C), or Nikuradse (k_s) coefficients. Water-depth-dependent roughness relationship as well as the water-level slope are plotted in Figure 5 against the ratio of plant height (k) and water depth (h). Two different conditions can be identified: (i) unsubmerged vegetation, when the plants height exceeds the water depth and (ii) submerged vegetation, when the water depth exceeds the plants height.

Clearly, for unsubmerged flow conditions, the water-level slope is much higher than for submerged conditions implying that the resistance of the vegetation is higher.

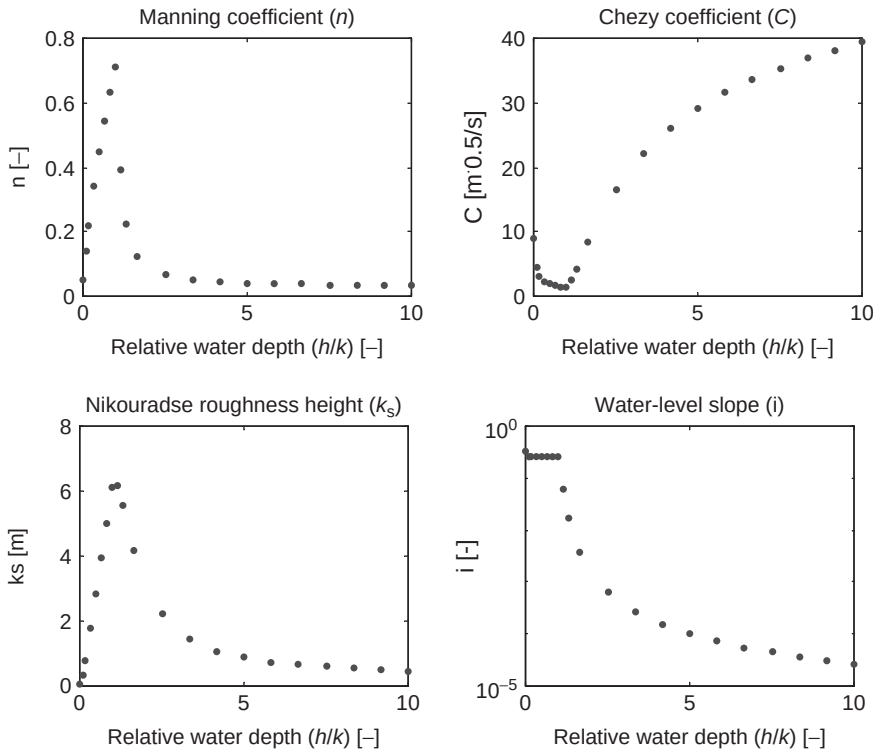

Figure 5 Vegetation-related resistance coefficients and water-level slope versus water depth. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Unsubmerged flow conditions can be successfully treated analytically (Rodriguez, 2004). If the water level is high enough, flow through the vegetation is negligible compared to the flow above, as can be seen from Figure 5; in the transition zone, both the flow through the vegetation as well as above it are both relevant and, consequently, all resistance coefficients are depth-dependent.

Genetic algorithms, evolution strategies, evolutionary programming as well as differential evolution represent just few examples of evolutionary algorithms that have been explored by a number of scientists during the past decades. However, it was rather recently that Koza (1992) of Stanford University proposed a special kind of evolutionary algorithm: GP, which involves symbolic expressions. Applications of GP in hydrosciences were introduced by (Babovic and Abbott, 1997) and (Babovic and Keijzer, 2000). Also, (Keijzer and Babovic, 1999) developed the *dimensionally aware GP* algorithm, using the observations together with their units of measurement. By requiring dimensional correctness as constraints – in what can be called a *weakly typed* or *implicit casting* approach – dimensional correctness is promoted rather than enforced.

The role of the (expert) user is then to choose his most suitable formulation to further analyze the proposed relationships. The user can exploit background knowledge or implement some belief about the problem domain. The final step lies in examining the selected equation(s) in order to interpret them. When a reasonable explanation for the apparent goodness-of-fit of such an equation is produced, the user's belief in the correctness of the equation is enhanced. The equation then no longer functions as a black box for making accurate predictions but as a genuine empirical equation that can be used with more confidence than mere statistical accuracy: the equation and its interpretation are amenable for review by experts and peers.

The dimensionally aware GP approach was applied to a set of 990 calculations carried out with the 1DV numerical model for submerged vegetation, using the input variables as presented in the table below (Rodriguez, 2004). For dimensional consistency, a slightly adapted Chézy's coefficient was used by virtue of which time-related units of measurements can be avoided and the resistance coefficient becomes solely a function of the geometry of the system. GP was then employed in a multiobjective sense, simultaneously optimizing the following three objectives:

1. root mean square error (RMSE) (RMSE – measure of the overall accuracy of the formula)
2. coefficient of determination (CoD) – measure of the goodness of shape of the formula and
3. dimensional error – measure of the dimensional consistency of the formulae.

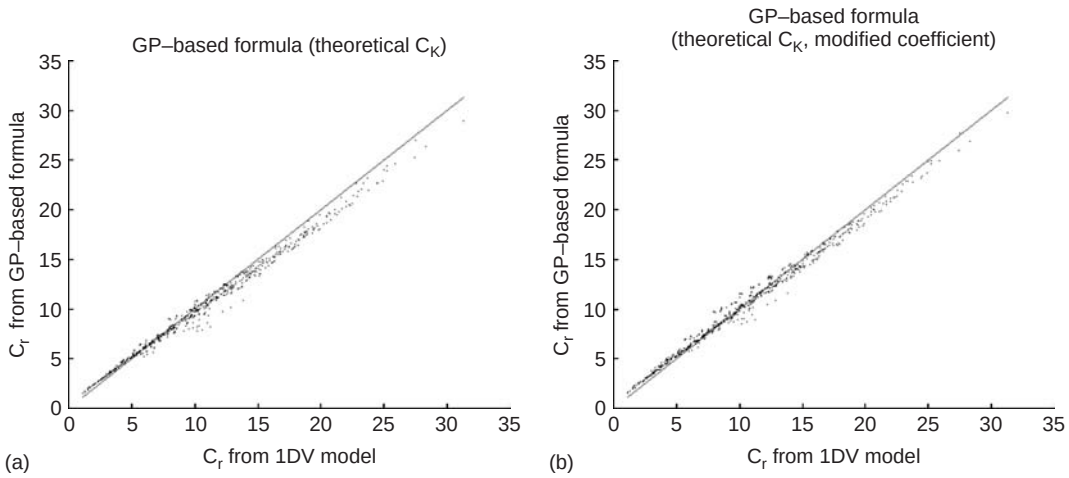

Figure 6 Scatter plots for C_r (GP-based formula with theoretical C_k for different coefficients). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

The results presented in Figure 6 indicate that quite a good agreement was achieved.

HARMFUL ALGAL BLOOM PREDICTION USING FUZZY LOGIC AND CELLULAR AUTOMATA

In case of flooding over large areas and/or prolonged periods of time, pollution is likely to become an issue. Algal blooms may develop that can significantly affect water quality and cause ecosystem deterioration or even threaten human health. Predicting algal blooms is an ambitious and difficult topic because of the complexity of the aquatic ecosystem behavior, the insufficient knowledge available on the detailed processes and mechanisms involved, and the shortage of high quality data. However, artificial intelligence and machine learning techniques like fuzzy logic (FL) have the ability to deal with imprecise, uncertain or ambiguous data or relationships among data, and, hence, have the potential to be a useful and practical method in algal bloom modeling.

In order to explore this, a robust fuzzy logic approach was developed by Chen and Mynett (2004b) deriving (inter) relationships directly from measurements, using expert knowledge as a reference. This allows the combination of partial knowledge on processes with partially available data from observations. In collaboration with the European Commission project Harmful Algal Bloom Expert System (EU-HABES), this approach was applied to the North Sea for modeling Chlorophyll-a (Chl-a) concentrations, which provide a good indication of the likely expectance of algal bloom events.

In Dutch coastal waters, spring algal blooms, in particular, *Phaeocystis globosa* occur almost every year. The blooms cause great adverse impacts on shellfish farming and recreation. In order to predict the possible occurrence of spring algal blooms, Chen and Mynett (2004b) developed an integrated numerical and fuzzy cellular automata model combining information on irradiance, nutrients availability, and neighborhood conditions. The model was developed to predict phytoplankton biomass – a very good indicator for the potential occurrence of algal blooms in the Dutch coastal waters. The numerical Delft3D-WAQ (water quality) model was used to simulate the flow conditions, water column irradiance, nitrogen and phosphorus concentrations discharged from the River Rhine.

Membership functions are constructed by: (i) collecting available heuristic knowledge and setting up a reference rule base; (ii) clustering input and output data into characteristic clusters or subsets using, for example, self-organizing feature map (SOFM) techniques; (iii) defining membership functions for each variable by selecting proper function types and mean values for each cluster; (iv) inducing fuzzy rules by either *feature reasoning* or *case-based reasoning* (Chen and Mynett, 2004b). Sample membership functions for total inorganic nitrogen (TIN) and Chlorophyll-a for conditions along the Dutch North Sea coast are presented below in Figure 8.

The fuzzy logic module developed for the Dutch coast was used to predict algal biomass using the computed abiotic factors from the numerical Delft3D model. In order to take into account the spatial heterogeneity and local behavior, and to capture patchiness dynamics, a cellular automata paradigm was implemented using the available model grid configuration. The simulation results for the year 1995 as presented in Figure 7 were found to exhibit similar features as obtained from satellite images (Mynett, 2003b). As to the temporal evolution of bloom events, the modeled and observed increase in Chl-a concentration are seen to correspond quite well (Figure 9), given the complexity of the processes involved.

The overall conclusion is that hydroinformatics is seen to play an increasingly important role in water quality and ecosystem modeling by providing tools and technologies (often in terms of software systems) that can integrate expert knowledge with measurement data and numerical simulation packages, as elaborated by Mynett *et al.* (2004c).

THE "HOLY GRAIL" OF THE FIFTH GENERATION SOFTWARE SYSTEM

It may be recalled that the first generation software was confined to the programming of methods originally intended for human computation, so that these methods were "people friendly" and often not at all suited to solutions using digital

machines. The second generation, from 1955 onwards, was consequently directed to more machine-friendly methods that were, correspondingly, not particularly "people friendly". These methods then necessitated the construction of a theoretical apparatus to enable the programmer to translate from people-friendly methods (e.g. partial differential equations) to computer-friendly methods (e.g. finite-difference, finite-element, finite-volume methods etc.). The second generation restricted itself almost exclusively to physics-based models that were distributed in space and time but each of which was specialized to a particular, domain-specific, physical object (a particular river, a particular coast, particular settling tank, etc.). The third generation, from 1970 onwards, took the methods developed for the second generation but encapsulated them into devices that could themselves construct any domain-specific model from a prescribed formatted description of the particular domain of interest.

The first three generations of software in this area were all restricted to models of movements of water and all that this moving water transported. The business area that was built up around this technology was correspondingly a business that was restricted to supplying the *results* obtained from running these models and was not a business in supplying the models themselves. It was only with the introduction of fourth-generation modeling systems, from 1985 onwards, that a part of the business passed over to selling models to end-users, so that at least a part of the business organizations involved passed from being "performers of projects" to being "providers of products". The project departments themselves grew as the products became more widely diffused and as the possibilities as well as the difficulties of modeling became more clearly delineated: "the projects followed the products" as sources of revenue to the tool-making/tool-using organizations. Also, the development of fourth-generation modeling introduced a new business model in this field: products had to be marketed and sold, training had to be provided, and service had to be available locally, in the local language. This in turn led to agent-network arrangements of considerable proportions, so that even at these early stages, activities in this area took on a *socio*technical complexion.

Almost simultaneously, with the development of fourth-generation modeling was the rise of hydroinformatics: the much more general application of information, and subsequently also communication, technologies to water problems. An increasing variety of data acquisition, data transmission, data processing, and data storage systems were elaborated; geographical information system (GIS) were ever more closely integrated with numerical simulation algorithms through "seamless interfaces"; these integrations greatly facilitated the incorporation of remotely sensed data into the domain description; global positioning systems (GPS) were integrated into hydraulic-geographic-photogrammetric systems; software for transformations between different cartographic coordinate systems and rapid advances in geodetic surveying were further incorporated; complex information management systems were installed to make the resulting information applicable to a wide range of end-users; elementary knowledge management systems appeared as means to accommodate the stream, growing to a flood, of information; and so on.

This complex of developments was the birthplace and the nursery of hydroinformatics. It quickly became clear (typically from 1995 onwards), however, that few, and ever fewer, of the problems with which hydroinformatics was confronted would be usefully treated as purely technical problems, but the greater number, and an ever greater number, were essentially *socio*technical. Whether this was in the area of self-management systems that allowed two or more contractors to work simultaneously in the same space under design-and-build contractual arrangements, or for enabling work schedules to be synchronized accurately with determinant hydraulic and environmental events, or for such operations as bathing, fishing, and mussel farming to be sustained in the vicinity of disturbances due to large constructions, which could extend over 100 km or more, or – most important of all – for gaining and retaining public tolerance, acceptance, and even support for interventions in nature that affected the interests of this public, the sociotechnical came ever more to the fore.

The introduction of *communication* (and primarily Internet-enabled) systems that made it possible for the general public to participate actively in all the activities that concerned this public became the *conditio sine qua non* for the practice of such activities. The duties and rights to exercise this participation were then anchored in the enabling legislation itself. It thereby became increasingly apparent that the communication processes were becoming ever more prominent as compared with the purely computational processes. Correspondingly, ever more persons were employed on enabling the communicative processes than were employed on the computational processes.

AGENT-BASED COMMUNICATION

These developments have led some hydroinformaticians to turn their attention increasingly towards communication processes, all of which are in their essence sociotechnical processes. They have done this from the two sides, both from the social side and from the technical side, even while understanding how the processes studied on these sides conjoin, merge or are "woven together" in the center of the sociotechnical complex. One part of the resulting study has been directed to societies that are themselves composed of those artifacts, commonly described as "agents", that

have been introduced above. These agents interact so as to form societies rather like "human agents" do, and these interactions are inevitably realized through processes of communication. It was long ago recognized that as models, for example, become taxonomically more extended, the communication aspects increasingly take precedence over the computational processes (Abbott, 1992, 1993). These studies have now resulted in the identification of a new approach to software applications in the water sector, and one that is in no way restricted to stand-alone numerical modeling but is much broader in its scope.

The fifth generation paradigm starts out from the observation that the communication aspects of software systems have now become the predominant ones in future developments. This is not to say, of course, that the computational aspects can now be ignored – that is far from being the case – but that the strategic developments must now proceed primarily through communication paradigms. Thus, to take the most familiar example of the numerical model, the main thrust of developments resides in allowing the various computational elements in this model to communicate with one another and with the world outside the model in much more efficient ways. For the sake of simplicity, it is possible to think of the fifth generation paradigm as being one in which software systems generally, with models as just one example, are composed of numerical components, regarded as "agents". These communicate with one another through what can be regarded as a kind of intranet and which, correspondingly, communicate with other, and normally very different, "agents" in their outer world through what can be regarded as a kind of extranet. Since all the "agents" involved then communicate and thereby cooperate by passing messages between them, the resulting architecture is commonly described as a "multiagent, message-passing" architecture.

This communication architecture can also be applied to the elaboration of new hydrologic modeling tools and new hydrologic modeling practices where this approach to modeling is most obviously beneficial. However, this approach may be hampered by the restrictive communication architectures of existing distributed physics-based hydrological systems. The reason for this is simple: once having accepted that the communications within every model generated by the new system should use the same technology as the communications between this model and its environment, the use of a common communication technology is almost mandatory. However, the communication processes occurring in, for example, MIKE SHE are, so to say, "hard wired", being largely fixed for all models, with only limited facilities for customization to specific modeled conditions. Although advanced for its time (1977–1978), it achieved its reliability at a cost in inflexibility that is not warranted by recent developments in communication technologies.

Despite its antiquity, the integration provided by the MIKE SHE modeling system is still judged higher than in any other hydrological modeling system currently available (e.g. Kaiser-Hill, 2001). With the various add-ons now available, it remains a powerful tool for modeling many water and environmental problems. Moreover, developments are already under way to extend the integrated modeling capacity even more, by interfacing with other models that were previously designed for modeling entirely separated water-related problems. For example, work continues on interfacing MIKE SHE with the MIKE MOUSE modeling system, used for urban drainage and sewer systems (where leakages into ground water commonly occur). This demonstrates the increasing demand for integrated modeling.

However, by the same token, since this system can currently be operated only through its graphical user interface, having no facilities to communicate with its outside world in any other way, it has no capacity to communicate over the Internet: in a word, it is not web-enabled. Thus, although the MIKE SHE remains a formidable instrument, it belongs to a paradigm that is rapidly becoming too restricted to remain competitive with future generation communication-based systems.

HYDROLOGY AS A CONJUNCTIVE KNOWLEDGE IN A MULTIKNOWLEDGE ENVIRONMENT

Multiknowledge environments are those in which two or more different knowledges have to function simultaneously and interactively in supporting one and the same activity. For this purpose, the participating knowledges alone cannot suffice, but a quite other knowledge is required to connect and coordinate their interactions. Such a knowledge is called *a conjunctive knowledge* (Abbott, 1993). Thus, for example, *sociotechnology* is a conjunctive knowledge that connects and coordinates (or *conjoins*) interacting social and technical processes, weaving these together to provide knowledge products that are not accessible from the social and technical domains independently. In such cases, the one knowledge is said to be *implected in*, or *implexively contained within*, the other through the intercession of the conjunctive knowledge. Clearly, hydrology is also a conjunctive knowledge, weaving together the strands of meteorology, plant physiology, soil physics, and other such sciences within its multiknowledge environment with its intention always directed towards the world of practice, of technology. The structure within a professional space implies the relevance of a specific architecture, which is called most generally an *agent-orientated architecture*. Then, in the words of Jonoski (2002, p203):

> *"What then is the essence of the new approach to conceptualization that is based on agent-orientation? As a first step, the new*

approach 'expands' the traditional conceptualization of knowledge domains beyond their descriptions in terms of different objects, with their properties and relations. In fact it 'replaces' the basic notion of 'knowledge domain' with a much broader notion of an 'environment', where the basic conceptualization units are not objects, but new kinds of entities called agents. The fundamental property of the agents is that they are embedded in their environment and are able to perceive and affect the environment. In addition to that, in their interaction with the environment they express goal-like behaviour. This is in fact very close to a general definition of an agent provided by Russel and Norvig (1995) who define an agent as any entity which operates in some environment (physical, virtual, cyberspace), which possess sensors to perceive this environment, effectors to act on this environment, and goals of its own which may or may not be explicitly represented in the agent itself. In general terms, an agent can be envisaged as a "creator of objects" within a fluctuating content."

"One of the radical changes that this shift in the mode of conceptualisation brings about is that it allows the agents to have their own representation of knowledge domains, which may or may not be part of their own environment. An agent's environment is therefore not to be confused with a knowledge domain. In some sense, the exclusive role of the (human) observer in the traditional, purely rationalistic, approach, of conceptualising and representing domains in terms of objects, has now been attributed to these new kinds of entities called agents. This is certainly one of the most fundamental changes brought about with the new approach, primarily because it allows for different perspectives (or points of view) between the human observer and the agent, and/or between the different agents themselves."

Thus, instead of the crude *positivism* associated with an object orientation, one has a much more flexible and subtle *phenomenology* associated with an agent orientation. In this approach, an agent can be attributed to, for example, the unsaturated zone in the soil, and this will then be interrogating its environment of precipitation, infiltration, evaporation, transpiration, and root water uptake as defined by its position in the professional space in order to decide upon *its own most appropriate physical and biological behavior*. Other domain agents will have other "concerns" again, and each agent will be monitoring *its own environment* within the professional space from *its own point of view*, corresponding to *its own perceptions*, as colored by *its own intentions*. It is the interaction between these *agents with different perceptions corresponding to different intentions* that generates an *active cooperation between the agents* in the representation of the physical system, as each of these does, so to say, "what it most wants to do" within the constraints of its physical and biological environment. Thus, whereas an object-oriented approach leads to totally managed, fixed hierarchical structures, *which correspond to exostructure*s, an agent-oriented approach has the potential to provide emergent, self-managing structures *that constitute endostructures*.

The future (fifth generation) software systems can be characterized as "network centered" as opposed to the previous "desktop-centered" or even earlier "host-centered" systems. This means that the platform for its development and deployment will not be a single machine, but a *network of computers* and developers. Initially, the primary focus will be the utilization of the internal network of computers that functions as the central, or kernel, organization's intranet. In due time, but most likely sooner than most are expecting – and hydrologists better take active part in these developments or they will find themselves overtaken by developments in the combined areas of meteorology and hydraulics – these new approaches will lead to an entirely new generation of computer-based hydrological modeling in practice.

OUTLINE AND SCOPE OF SUBSEQUENT ARTICLES CONTAINED IN THE REMAINDER OF THIS CHAPTER

Maidment and Moglen (*see* **Chapter 15, Digital Elevation Model Analysis and Geographic Information Systems, Volume 1**) elaborate on the powerful capabilities of the use of digital elevation data (DEM) and geographic information systems (GIS), already introduced above for some practical applications. The basic properties of all DEMs are introduced as well as the basic concepts of GIS technology. The use of GIS and DEM in a hydrologic context is demonstrated; the principles of flow direction, flow accumulation, watershed delineation, flow lengths, slopes, and travel times as derived from DEM data within a GIS are presented.

Stelling and Verwey (*see* **Chapter 16, Numerical Flood Simulation, Volume 1**) describe the state-of-the-art of numerical flood simulation, in particular, of hydraulic models based upon the laws of physics. The concepts of kinematic and diffusive wave approximations are discussed in order to provide better ways of understanding the physical behavior of flood wave propagation and to demonstrate the link between hydraulics and hydrology. This contribution briefly introduces the impact of new data collection techniques on numerical flood model schematization.

Lin and Falconer (*see* **Chapter 17, Hydrological and Environmental Modeling of Transport Processes in Rivers and Estuaries, Volume 1**) focus on the hydrological and environmental modeling of transport processes in rivers and estuaries. Numerical solutions of the governing hydrodynamic, solute, and sediment transport equations form the basis of a number of software tools. Details are given of three-, two-, and one-dimensional flow-field formulations and the transport of water quality indicators as well as sediment transport processes within the water column. The implications are discussed for hydrological models used to specify the pollutant discharge loads from land use models.

Guinot (*see* **Chapter 18, Shallow Water Models with Porosity for Urban Flood Modeling, Volume 1**) introduces the concept of porosity in combination with hydrodynamic flow modeling in order to model urban flooding where one has to deal with highly variable geometries and flow parameters. Since the application of distributed, physically based models to refined urban flood modeling is not yet feasible, an alternative approach could be to use two-dimensional macroscopic models on the basis of a modified version of the classical shallow water equations, where the fraction of the land surface occupied by buildings is accounted for via porosity. Such models provide a practical alternative to classical semidistributed models, as illustrated by a computational example on a small-sized urban area.

Solomatine (*see* **Chapter 19, Data-driven Modeling and Computational Intelligence Methods in Hydrology, Volume 1**) elaborates on the use of data-driven modeling and computational intelligence methods in hydrology. With the advent of rapidly increasing data volumes, there is a strong emphasis in the field of Hydroinformatics already for a decade or more, on exploring so-called *data-driven modeling paradigms*. These are based on methods from artificial intelligence, computational intelligence, and machine learning that are becoming more and more feasible for practical application when increasing amounts of data are available that describe the phenomenon of interest. Various aspects of data-driven modeling are discussed, including data preparation and a brief overview of popular techniques – neural networks, regression and model trees, instance-based learning, nonlinear dynamics.

Minns and Hall (*see* **Chapter 20, Artificial Neural Network Concepts in Hydrology, Volume 1**) elaborate in more detail the use of Artificial Neural Network (ANN) concepts in hydrology. The solution of many applied hydrological problems, such as the forecasting of floods, has for several decades been based upon the concepts of linear systems analysis. However, the introduction of informatics tools, such as ANNs, with their origins in cognitive sciences and pattern recognition, has made available new lines of investigation. Provided proper attention is paid by the expert modeler, ANNs invariably seem to provide a model whose goodness-of-fit to an independent testing data set is superior to that of parameter-based hydrological modeling systems.

Babovic and Keijzer (*see* **Chapter 21, Rainfall-runoff Modeling Based on Genetic Programming, Volume 1**) demonstrate the use of GP, yet another technique from computational intelligence, for modeling rainfall-runoff processes that are often highly nonlinear, time-varying, spatially distributed, and hence not easily described by simple models. By using data-driven models such as GP, one can attempt to model runoff on the basis of available hydrometeorological data. The capabilities of GP are discussed for creating rainfall-runoff models on the basis of data alone, as well as in combination with conceptual models (i.e. taking advantage of knowledge about the problem domain).

Savic and Khu (*see* **Chapter 22, Evolutionary Computing in Hydrological Sciences, Volume 1**) provide an extensive overview of applications of Evolutionary Computing (EC) in the Hydrological Sciences. These applications range from the use of EC to assist in the understanding of hydrological processes, to improve the performance of simulation models and, most recently, to quantify risk and uncertainty with the aim of providing decision support. Examples are drawn from hydrologic processes research, rainfall-runoff modeling, reservoir operations and control, groundwater systems, urban water systems, and water quality modeling.

Werner *et al.* (*see* **Chapter 23, Flood Early Warning Systems for Hydrological (sub) Catchments, Volume 1**) demonstrate the impact of hydroinformatics on the increasingly relevant practical (sociotechnical) issue of providing early warning as an effective strategy in reducing flood damage and loss of life. By combining computer-based simulation techniques, computer-based data processing capabilities, and computer-based communication facilities, they show the present state-of-the-art capabilities of setting up FEWS for hydrological (sub) catchments.

Jonoski (*see* **Chapter 24, Network Distributed Decision Support Systems and the Role of Hydrological Knowledge, Volume 1**) outlines a next generation Network Distributed Decision Support environment for decision-making processes in the fields of water and environment. These (NDDSS) systems are designed to enable active participation of large numbers of interested stakeholders, including the general public, using electronic networks such as the Internet and wireless mobile telephony. Core components of such systems are instantiated hydrological models, open for wider integration with, for example, ecological or socioeconomic models.

15: Digital Elevation Model Analysis and Geographic Information Systems

GLENN E MOGLEN[1] AND DAVID R MAIDMENT[2]

[1]Department of Civil and Environmental Engineering, University of Maryland, College Park, MD, US
[2]Department of Civil Engineering, University of Texas, Austin, TX, US

This article presents the technology of Geographic Information Systems (GIS) applied to a particular form of representation of topography, the digital elevation model (DEM). It first defines what a DEM is and introduces the basic properties of all DEMs, as well as several common sources of DEM data. Then the basic concepts of GIS technology are presented, defining what a GIS is, what fundamental data types it can store, and what kind of manipulations it can perform. Some of the most common GIS software packages are discussed. The remainder of the article focuses on the use of GIS technology for the interpretation of DEM in a hydrologic context. The principles of flow direction, flow accumulation, watershed delineation, flow lengths, slopes, and travel times as derived from DEM data within a GIS are presented. A brief case study is presented illustrating a number of the concepts presented in this article.

INTRODUCTION

The hydrologic sciences depend on quantifying the characteristics of watersheds as derived from topographic maps. Such maps reveal both the horizontal extent of the watersheds as well as their relief and drainage structure. This article focuses on two relatively recent technological innovations that allow the interpretation of topography to be performed quickly, systematically, and at a very detailed level. In a sense, this article does not contribute any new ideas to the hydrological sciences. Rather, the focus here is on cutting edge software and data products that work together to provide the hydrologist the information necessary to apply fundamental hydrologic concepts at a high spatial resolution and over a large spatial extent. Present-day technology allows these concepts to be applied quickly and uniformly so that the hydrologist can focus on the physical system, while the drudgery of the mechanics of the analysis is taken care of by the computer.

The first innovation in technologies that has emerged over the recent decade or so, the development of digital elevation models or DEMs, is in essence nothing more than a digital representation of a topographic map. Scientists and engineers have worked with paper forms of topographic maps for a long time. Digital representations of topography are even more powerful because algorithms allow for the automated interpretation of the topography, rendering results reproducible between different individuals.

The second innovation is the technological advance brought on by the advent of the geographic information system or GIS. This software technology provides a common structure within which spatial data can be stored, displayed, and analyzed. It is not necessary to use a GIS to handle DEM data, but most GIS packages provide standard algorithms for the hydrologic interpretation of DEMs. These algorithms automate the determination of flow directions, drainage areas, watershed delineation, channel slopes, and travel distances and time. The GIS also includes visualization tools allowing the hydrologist to see the spatial distribution and organization of all of the above quantities. This visual component aids in the development of an intuitive understanding of the systems being studied, and in the presentation of information to others.

This article gives a broad overview of the basics of DEMs. The focus is on the standard characteristics of all DEMs and on sources for obtaining this type of data. A

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

very natural way to interact with DEM data is through the use of GIS technology; so this article will also provide a brief introduction to this technology focusing on the central concepts common to all geographic information systems. The main body of this article will provide a detailed description of how DEM data is interpreted in a hydrologic context within the GIS. A case study illustrating a packaged system that integrated DEM data within a GIS environment is demonstrated in the final section of this article, briefly illustrating the kind of the DEM-based analysis that can be automated within a GIS. Relevant software links are also provided in the article.

DIGITAL ELEVATION MODELS

A digital elevation model (DEM) is a raster-based presentation of topography. Each cell of the DEM contains a representative value of the elevation related to the areal extent of the cell.

DEM Data Sources and Products

In the United States, the standard digital elevation model is the National Elevation Dataset (NED) (USGS, 2003a). This is a seamless 1-arc second (30 m) grid whose elevation values are expressed in floating point meter units. It was compiled by converting to a grid the topographic contours from standard 1 : 24 000 maps sheets covering the nation, and merging the resulting grids and filling in small gaps in coverage between the map sheets. NED data can be obtained for any user-selected area from a seamless data server (**`http://seamless.usgs.gov/`**).

A series of hydrologic data products called the *Elevation Derivatives for National Application* (EDNA) have been derived from the National Elevation Dataset (**`http://edna.usgs.gov/`**) (USGS, 2003b). These include the flow direction and flow accumulation grids, a stream network defined for cells with more than 5000 cells upstream, and a catchment set with one catchment for each stream reach. The average size of these catchments is approximately 8 km^2, and they form with the stream network a dendritic representation of the drainage network of the nation.

In a similar manner to the National Elevation Dataset, Figure 1 shows the United States Geological Survey's (USGS) EROS Data Center has created a 30 arc-second (1 km) digital elevation model of the earth called *GTOPO30* (**`http://edcdaac.usgs.gov/gtopo30/gtopo30.html`**) (USGS, 2003c). This dataset was produced by converting the topographic information from the 1 : 1 000 000 scale Digital Chart of the World, and supplemented with other data sources.

The EROS Data Center has compiled a series of hydrologic derivative products called *HYDRO1K* for GTOPO30, using the same process as for the Elevation Derivatives

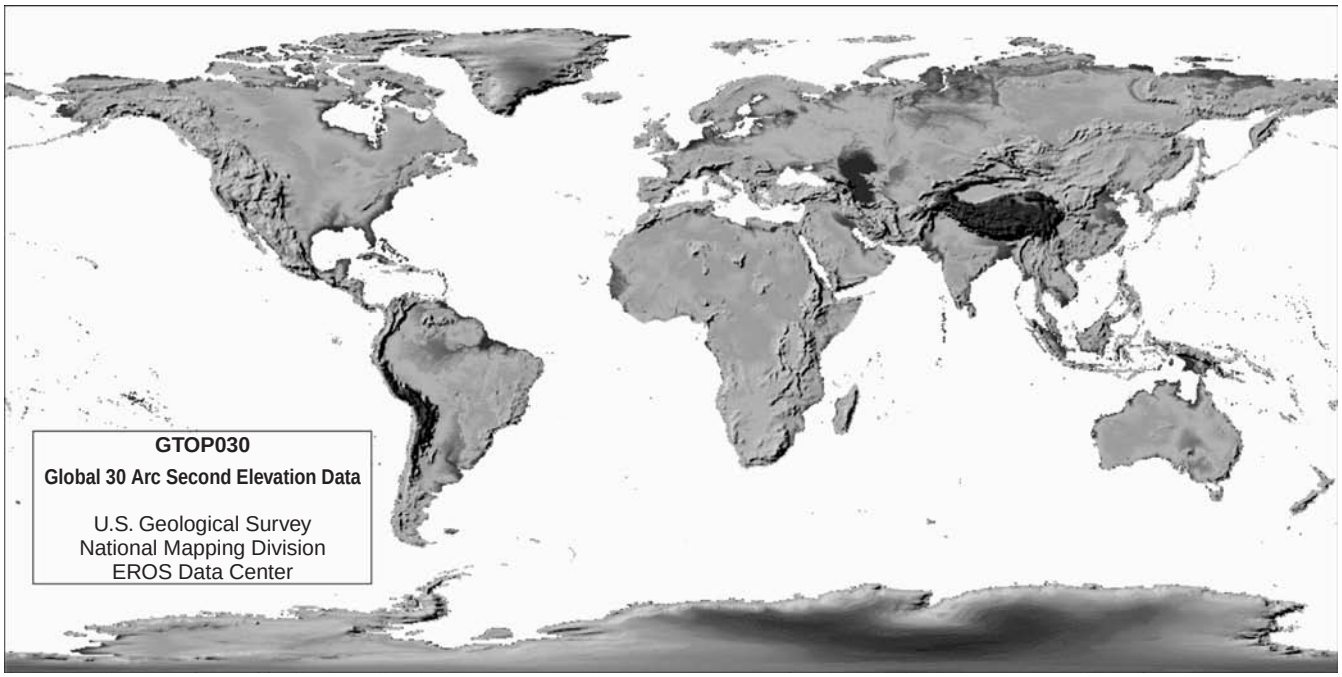

Figure 1 The GTOPO30 elevation dataset produced globally by the United States Geological Survey (Data available from United States Geological Survey, EROS Data Center, Sioux Falls, SD; source: http://edcdaac.usgs.gov/gtopo30/dem_img.html). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

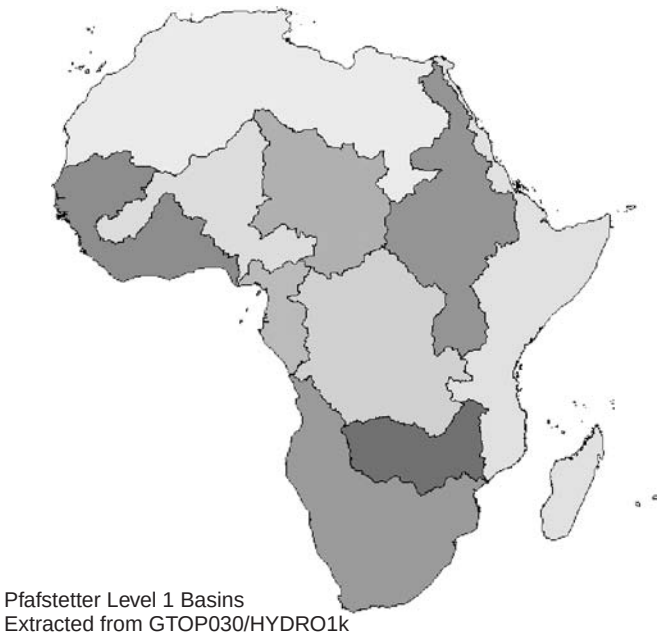

Figure 2 Level 1 drainage basins in Africa determined from GTOPO30 elevation dataset (Data available from United States Geological Survey, EROS Data Center, Sioux Falls, SD; source: http://edcdaac.usgs.gov/gtopo30/hydro/af_basins.html). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

for National Application (see Figure 2). Thus, DEM-based hydrology can be applied at a coarse resolution anywhere in the world.

The level of accuracy of global terrain information was dramatically increased by the Shuttle Radar Topography Mission (SRTM) (NASA, 2003), which took place from February 11–22 in the year 2000 (**http://www.jpl.nasa.gov/srtm/**). Figure 3 shows an image from this SRTM dataset.

Earth surface terrain was sensed by using two radar emitters mounted at a distance from one another on the space shuttle, where each sent out radar waves and received reflected waves from the land surface. By using radar interferometry, a principle similar to the human eyes being able to determine depth by coordinating two parallel images, the radar images are converted into terrain grids, at 30 m resolution for the United States and 90 m for the rest of the earth, although for scientific purposes 30 m data can be obtained for regions outside the United States.

DEMs are useful for hydrologic analysis through the many automated procedures commonly incorporated in GIS software. These procedures allow the hydrologist to, among other tasks, interpret flow paths, delineate watersheds, derive channel networks, and measure slopes.

GEOGRAPHIC INFORMATION SYSTEMS

A geographic information system (GIS) is an assembly of geospatial data and functions by operating on those data whose purpose is to describe the landscape and facilitate its analysis. Geospatial data describe the earth using a geographically referenced set of spatial coordinates. When the term "hydrologic data" is used, hydrologists have long understood this term to mean data on hydrologic observations, such as rainfall or streamflow. As the use of GIS in hydrology has matured, the term hydrologic data has broadened to include geospatial data describing the hydrologic environment, including land surface terrain, soils, land use, river networks, water body hydrography, and the like. Of these geospatial data, terrain information in the form of digital elevation models has had the greatest impact because it enabled for the first time an automated delineation of an interrelated set of watersheds and stream networks, and thus created the basis for a greater degree of detail and spatial scope of hydrologic modeling than had been possible previously.

Geospatial data can describe the earth in either continuous or discrete space. Digital elevation models are an example of a continuous spatial representation, in which the spatial domain is covered by a regular grid or raster of square cells, in each cell of which is stored a value, in this case the land surface elevation. This representation is also appropriate for other continuous spatial variables

in hydrology, such as rainfall or evaporation. A discrete space or vector representation is used where the landscape is subdivided into distinct spatial units, such as watersheds, where each unit has a boundary that divides it from its neighbors. The boundary is represented by a connected set of lines that close to form an area or polygon feature. Similarly, stream networks are defined by connected sets of line features, where a line is formed as a sequence of points. Gauging stations are represented as point features defined by a single pair of (x, y) coordinates. The term vector data arises from the fact that a vector can be drawn from the origin (0,0) to any (x, y) point, and thus from one point to the next in a line, and so on. A comprehensive hydrologic database of a region contains both raster and vector data. Conversions between these two different data formats can be made (see Figure 4), such that a single raster cell corresponds to a point, and a set or zone of raster cells corresponds to a line or an area. Thus, watersheds and stream networks can be defined by raster DEM analysis and then converted to vector format for further analysis.

GIS databases are built using layers of data representing different types of information (see Figure 5). This concept is derived from the traditional process of map printing in which the "blue lines" represent hydrography, the "brown lines" represent topography, and so on. Each of these layers of information is prepared on a separate sheet and maps are printed by repeatedly running the map sheet through a press and applying the different colors in succession. By extension, each data "theme" in a GIS database is represented as a separate layer in which all the geographic features in the landscape of that type are gathered.

However, GIS is more than just a digital map – the features also have data or "attributes" associated with them. Thus, the name of the watershed, its drainage area, average slope, and rainfall can be attached as attributes of a watershed data layer (see Figure 6). Attributes are collected in rectangular tables, in which each row represents one spatial feature, and each column or field represents an attribute. These tables can in turn be related to other tables containing more details where necessary. Thus, a GIS integrates both geospatial and tabular information about hydrologic features of the landscape.

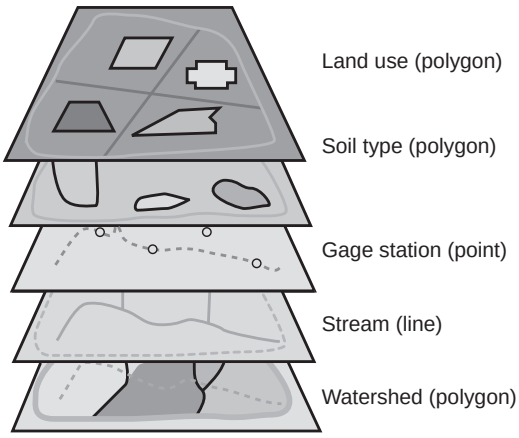

Figure 5 Illustration of multiple GIS layers at a given location depicting various forms of hydrologically relevant data. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

The most widely used GIS products are the ArcView and ArcInfo systems produced by the Environmental Systems Research Institute (ESRI) (**http://www.esri.com**) of Redlands, California (ESRI, 2003). These systems have recently been merged into a new form called *ArcGIS*, and a customization of this system for water resources has been developed called *Arc Hydro* (Maidment, 2002) (**http://gis.esri.com/esripress/display/index.cfm?fuseaction=display&websiteID=56&moduleID=0**). Arc Hydro integrates the various data layers together using database relationships, and also integrates geospatial and temporal water resources information into a single database for the first time in a GIS setting. This lays the foundation for the development of hydrologic information systems, which synthesize water resources data and hydrologic models to describe the functioning of hydrologic processes.

Map Projections

The earth is spherical in shape but maps are flat, so to relate locations on the earth in latitude and longitude coordinates to locations on a map in (x, y) coordinates, a coordinate transformation is needed. This involves first a reduction in scale from the earth to a globe (a map scale of 1 : 100 000 means that 1 mm on the map corresponds to 100 000 mm or

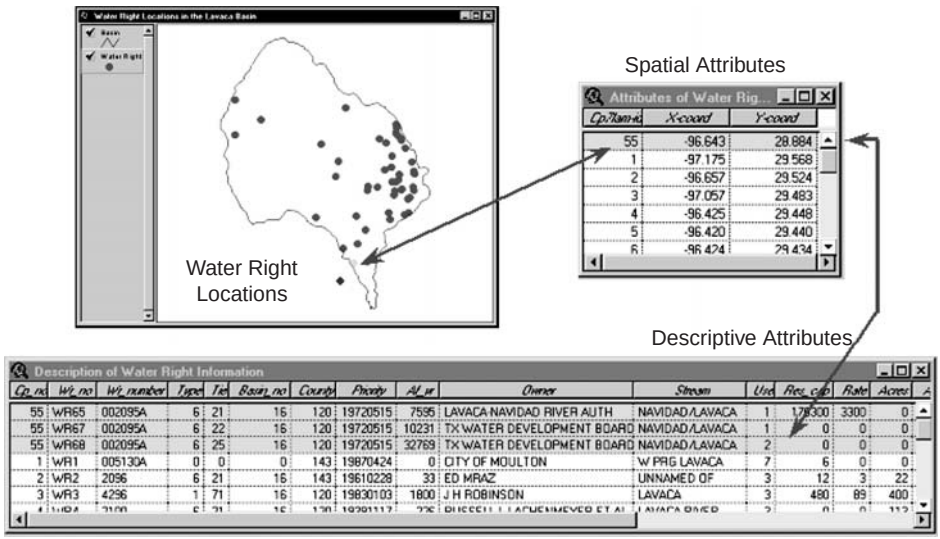

Figure 6 Illustration of the relationship between geospatial and tabular data as managed within a GIS environment. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

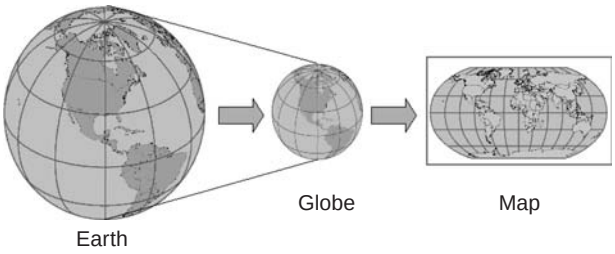

Figure 7 Illustration of concept of map projections. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

100 m on the earth's surface), and then a projection from a curved globe to a flat map (see Figure 7). Hydrologic analysis of digital elevation models requires map projection because its computations depend on the slope between cells, and thus the (x, y, z) coordinates must all be expressed in length units. For hydrologic analysis of digital elevation models, the most common map projection is the Albers Equal Area projection, which preserves true earth surface area on the projected map.

A good freeware program that illustrates the concepts of map projections and coordinate systems is produced by the United States Army Corps of Engineers – Topographic Engineering Center. The program, called *CORPSCON*, may be obtained at `http://crunch.tec.army.mil/software/corpscon/corpscon.html` (USACE, 2003a). Although this is not, strictly speaking, GIS software, this program is useful in gaining an appreciation for the concepts of map projections and may be used to project a point or a series of points from one projection/coordinate system to another.

HYDROLOGIC INTERPRETATION OF A DEM

DEMs may be employed in many different contexts depending on the user's intended application. Interpretation of the DEM varies naturally along with this application. For instance, a road designer or land developer would tend to interpret the elevations reported by the DEM at face value, and compare these predevelopment DEM elevations against the desired postdevelopment elevations to determine "cut and fill" requirements. In contrast, the hydrologist views the DEM as a surface that naturally sheds water and directs its flow to channels located at relatively low points in the topography.

Flow Direction

There are numerous algorithms employed to interpret DEMs. Probably, the most common algorithm is the "D8" algorithm, where the flow direction for every cell within the watershed is determined by considering the surrounding eight neighboring cells. The local slope in each of the eight directions of these neighboring cells is calculated by taking the difference in elevation indicated by the DEM value at each of these eight neighboring locations and the value at the cell being examined. This difference in elevation is then divided by the center-to-center distance between these cells (this distance will be the cell size in the cardinal directions and the cell size $\cdot\sqrt{2}$ in each of the diagonal directions). The direction that yields the steepest downhill slope is the inferred direction of water flow. The concept of flow direction is very important because it allows for the inference of drainage areas, flow lengths, and the automated delineation of watersheds as will be illustrated later in this article.

Figure 8 Small sample 3 × 3 DEM to illustrate calculation of flow direction

Consider the 3 × 3 DEM in Figure 8 with a horizontal resolution of 30 m and reported in vertical units of meters.

Notice that in general, the elevations decrease from the top row to the bottom row so the general sense of flow that we anticipate is from the top to the bottom of Figure 8. Let us calculate the slope in each of the eight directions from the central cell:

Due East:

$$\text{Slope} = \frac{(10-11)}{30} = -0.0333 \tag{1}$$

Northeast:

$$\text{Slope} = \frac{(10-12)}{30}\sqrt{2} = -0.0471 \tag{2}$$

Due North:

$$\text{Slope} = \frac{(10-11)}{30} = -0.0333 \tag{3}$$

Northwest:

$$\text{Slope} = \frac{(10-13)}{30}\sqrt{2} = -0.0707 \tag{4}$$

Due West:

$$\text{Slope} = \frac{(10-9)}{30} = 0.0333 \tag{5}$$

Southwest

$$\text{Slope} = \frac{(10-6)}{30}\sqrt{2} = 0.0943 \tag{6}$$

Due South:

$$\text{Slope} = \frac{(10-6)}{30} = 0.1333 \tag{7}$$

Southeast:

$$\text{Slope} = \frac{(10-8)}{30}\sqrt{2} = 0.0471 \tag{8}$$

10	10	12	11	9
8	9	11	8	10

Figure 9 Sample 5 × 5 DEM used to illustrate hydrologic interpretation methods throughout article

Notice that the slopes in the east, northeast, north, and northwest directions are negative (indicating that the flow directions are uphill) from the center cell. These flow directions can be immediately discarded as possible directions for this particular cell. The largest positive slope is in the due south direction with a value of 0.1333. This is the inferred flow direction for the center cell. The reader will notice that the elevation in the southwest direction is the same as in the due south direction, however, because of the greater center-to-center distance, the slope in southwest direction is slightly less steep. Owing to the $\sqrt{2}$ factor, it is even possible in some cases for the elevation in one of the cardinal directions to be slightly higher than in a diagonal direction and yet, the steepest slope may still correspond to the cardinal direction. Let us examine a slightly larger example shown in Figure 9.

Consider the 5 × 5 DEM in Figure 9 where we add the additional stipulation that the flow cannot leave the boundaries of the 5 × 5 grid (i.e. it is as if there are vertical walls bounding the overall grid). Before solving for the flow directions, the following observations can be made concerning this grid:

- As in the 3 × 3 grid, there is a general trend of decreasing elevations as we scan from the top rows to the bottom rows (therefore we would expect that most of the drainage directions will have a southerly component: south, southeast, or southwest).
- The middle column has relatively higher elevations than those in adjacent columns (therefore we would expect that this column will act as a divide between the right and left sides of the grid).
- There is a tie for the lowest elevations in the grid with a value of "8". We will expect these two locations to act as "sinks" for this system.

The reader should be able to verify that the flow directions are as those shown in Figure 10.

Notice that each cell has only one flow direction. However, some cells, for example, cell $C4$, receive flow from cells $B3$, $B4$, and $C3$. Cells $E1$ and $E4$ were the locations of a tie for the lowest elevation. The flow directions here

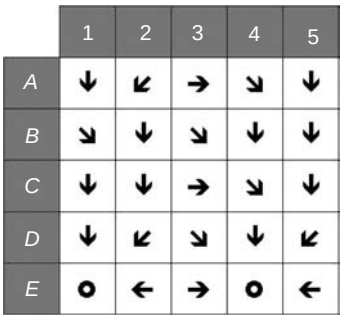

Figure 10 Arrows indicate visually the flow directions throughout the 5 × 5 sample DEM

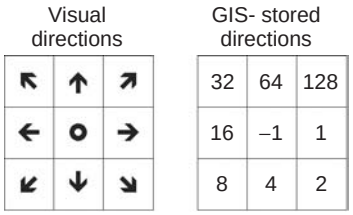

Figure 11 An illustration of the transformation of visually meaningful flow direction to GIS-stored information

are undefined (or these cells can be considered to be sinks). Here, we indicate their flow direction (or lack of one) by the "○" symbol. The reader should notice that the other observations made before determining flow directions have been borne out. There is a general tendency for southerly flow and there are no arrows (flow directions) that cross through the plane separating columns 2 and 3, confirming the existence of a drainage divide between these columns.

The arrows indicating flow directions are useful for the human eye to interpret, but unfortunately, the GIS needs some other method to "understand" which way the flow is going at a given cell. The method used to denote these flow directions is arbitrary. The ArcView GIS uses powers of 2 increasing clockwise from due east: 1, 2, 4, 8, 16, 32, 64, and 128. We add the numerical value, −1, to indicate the existence of a sink or undefined flow direction as shown in Figure 11.

Applying this GIS's nomenclature for flow directions, we obtain the flow direction matrix for the 5 × 5 DEM example shown in Figure 12.

It is worthwhile to briefly comment on some practical difficulties that must often be overcome in determining flow directions from a DEM. The D8 algorithm presented here assumes that flow directions always exist. In areas where the topography is flat or if the vertical resolution of the DEM is poor, it is not unusual to have many adjacent cells all with the same elevation. These are referred to as "flats" and secondary rules, beyond those illustrated above, must be incorporated in order to determine flow directions in

	1	2	3	4	5

D	4	8	2	4	8
E	–1	16	1	–1	16

Figure 12 GIS-stored flow directions for 5 × 5 sample DEM

these areas. These rules are somewhat arbitrary, but they generally work by taking a more broad-ranging view of the DEM and assign flow directions in flat areas consistent with these larger scale tendencies in the topography. A more severe problem in hydrologically interpreting DEMs is the presence of "pits" or local low points in the topography. In the case of pits, the assumption of the flow direction algorithm is that all flow drains off the edge of the DEM defined extent of the topography. Thus, any internal pits must somehow be removed. The typical algorithm is to fill these pits until the elevation within the pit is the same as that of the lowest neighboring cell that drains elsewhere. These pits then become flats that are resolved as described above. A by-product of the flow direction algorithm, not shown here, is usually an updated DEM in which the pits have been removed by this filling process.

Flow Accumulation

Once flow directions are determined, this information is used to determine the flow accumulation. Adjusted to proper units, the flow accumulation is synonymous with drainage area. We begin by defining a two-rule algorithm for determining flow accumulation at any cell:

1. If the cell has no neighboring cells draining to it, a value of "1" is assigned.
2. If the cell receives drainage from any of the eight immediate neighboring cells, it is assigned the value of "1" plus the sum of the flow accumulation draining from each of these neighbors.

Notice that Rule 2 amounts to a recursive definition. In practice, one must start determining flow accumulation at the upstream end of all flow paths and work downstream, otherwise the drainage area of all neighboring cells to the cell in question may not be known. Rules 1 and 2 are repeated across the entire DEM. Flow accumulation is a powerful GIS capability because calculating it as a spatially distributed quantity allows us to determine drainage area not at just one point, but at *any* point within the domain of the original DEM field.

	1	2	3	4	5
A	1	1	1	2	1
B	3	1	1	1	4
C	1	5	1	4	5
D	2	6	1	1	10
E	10	1	1	15	1

Figure 13 Flow accumulation for 5 × 5 sample DEM. Cells that have a flow accumulation of 5 cells or greater are shaded here to illustrate the hypothetical beginnings of the channel network. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Having determined the flow directions, we are now ready to determine the "flow accumulation" for the 5 × 5 sample DEM illustrated in the previous section. Applying Rules 1 and 2 to the 5 × 5 DEM results in the solution shown in Figure 13.

Let us examine several cells in the above example to see how they illustrate the flow accumulation algorithm rules. Note that cell $A1$ has no arrow (flow) going into it – therefore Rule 1 applies and this cell receives a value of "1". In contrast, cell $D5$ receives flow from cells $C4$ and $C5$, which carry flow accumulations of 4 and 5 cells respectively. Therefore, the flow accumulation for cell $D5$ is $4 + 5 + 1 = 10$. Notice that the values in our two sink cells, cells $E1$ and $E4$, are 10 and 15 respectively. The sum of these two values is 25, which is equal to the area (in cells) of our 5 × 5 DEM grid. Further, notice that the value at $E1$ (10) is the area of this 2 column by 5 row "watershed" (recall the divide between columns 2 and 3 noted earlier) and the value at $E4$ (15) is the area of this 3 column by 5 row "watershed". It is always the case that the flow accumulation at the outlet cell of a watershed is equal to the drainage area (in cells) of the watershed it is draining. If we know the resolution of the DEM being examined (e.g. 30 m cells), then the drainage area of the rightmost or eastern watershed in this 5 × 5 DEM is:

$$\mathrm{DA} = 15 \text{ cells} \times \frac{(30\mathrm{m})^2}{\text{cell}} = 13\,500\,\mathrm{m}^2 \qquad (9)$$

A simple way to infer the location of streams or rivers is to have the GIS indicate all cells with a flow accumulation in excess of a fixed value. This fixed value physically corresponds to a source area and is interpreted as the minimum source area needed to support the existence of a stream. This approach is illustrated for the 5 × 5 sample DEM. A hypothetical minimum source area of five cells was applied to this DEM, and those cells draining this area or greater are shown shaded in Figure 13. At this scale it is difficult to envision, but these two shaded lengths can be physically interpreted as the very beginnings of the channel network. In the examples and case study to follow where a drainage network is shown, this is the approach used to infer the location of the drainage network.

We should note that the above flow accumulation algorithm is premised on the D8 model of flow directions. If a more complicated flow direction algorithm is used such as those developed by Costa-Cabral and Burges (1994) or Tarboton (1997), then determining flow accumulation is also somewhat more complicated. The main difference in the outcomes from these other algorithms is that the resulting flow accumulation will no longer work out to be in integer counts of cells, but instead flow accumulation will generally be a real quantity. In any case, the physical interpretation remains the same that flow accumulation corresponds to drainage area.

Watershed Delineation

Flow accumulation and watershed delineation are closely related concepts. This idea was alluded too briefly in the 5 × 5 sample DEM illustration, but merits further discussion here. In the above section, a claim was made that the flow accumulation at the outlet cell of a watershed is equal to the drainage area (in cells) of the watershed it is draining. In other words, if we can identify all the cells that are draining to a common location or outlet, this set of cells represents the watershed associated with that outlet. In the days before GIS and the availability of DEM data, watershed delineation often required painstaking and time-consuming manual effort on the part of the hydrologist to determine watershed boundaries, hand-drawing curves emanating from the watershed outlet, and always traveling perpendicular to contour lines of elevation. Today's commonly available GIS-based tools have reduced the efforts of watershed delineation to a simple "mouse-click" at the location of the desired watershed outlet, as will be illustrated in the case study section to follow.

Flow Length

The flow length is the distance from any point in the watershed to the watershed outlet. This distance is measured along the flow paths determined from the topography not "as the crow flies". In GIS, the flow length of an arbitrary cell is determined by summing the incremental distances from center-to-center of each cell along the flow path from the selected cell to the outlet cell. The flow length assigned to the outlet cell is zero.

The concept of flow lengths is important to hydrologists. When it rains, a drop of water landing somewhere in the basin must first travel some distance before reaching the outlet. Assuming constant flow velocities (an assumption we will relax later), the cell with the greatest flow length to the outlet represents the hydrologically most remote cell.

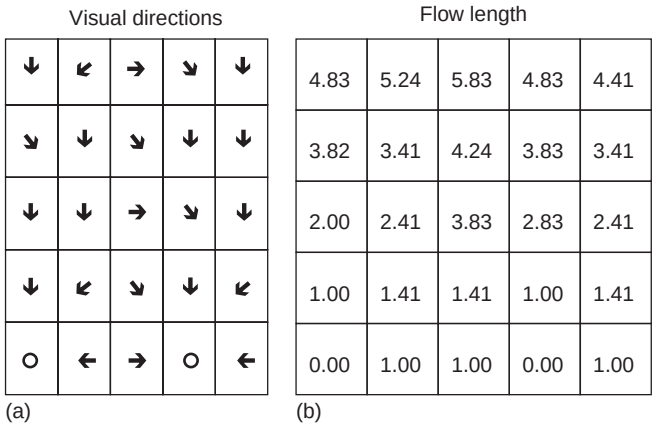

Figure 14 Visual flow directions and flow lengths for the 5 × 5 sample DEM

Its flow length divided by the flow velocity represents a representative lag time for the basin. The lag time quantifies how long before the entire basin is contributing to surface flow at the outlet, and is a representative timescale for the basin. Returning to the 5 × 5 DEM sample used earlier, let us examine this sample in terms of flow lengths.

The left grid in Figure 14 shows schematically the flow directions that were determined from the original DEM. If the resolution of the original DEM is 1 unit, then the right grid shows the downstream flow lengths from each cell to the grid outlets. (Recall that we have two outlets as shown by grid cells shown with a ○ symbol.) The flow lengths at the outlet cells themselves have been set to zero.

There are three ways that we might choose to look at travel times within the GIS environment:

1. As a mapped iso-distance ("contour" lines of travel length).
2. As a frequency distribution.
3. As the longest flow path within the watershed.

Considering the first perspective enumerated above, a map of shaded iso-distance lines is shown in Figure 15 for a small watershed near Washington DC, measured at 30 m resolution.

As would be expected, the smallest flow lengths occur in the proximity of the watershed outlet and generally increase away from the outlet. However, notice that the shaded areas do not radiate out in concentric circles from the watershed outlet, but instead have jagged edges and are organized along the drainage paths of main channels within the watershed as indicated by the dark lines within the figure. This perspective is useful for gaining insight into the overall spatial distribution of flow lengths within the watershed and how these flow lengths are organized along the principal channels within the watershed.

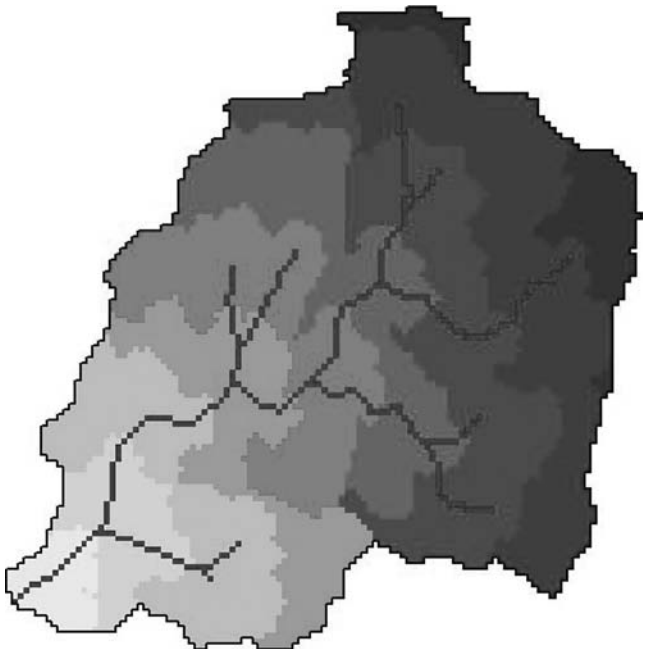

Figure 15 Shaded map of flow lengths in a small watershed. Darker shades correspond to longer flow lengths. The inferred drainage network is shown to help in visualizing the overall organization of flow paths. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

The second perspective to analyze flow lengths involves creating a frequency distribution of travel lengths with each cell within the watershed contributing a single travel length "observation". This distribution, first discussed by Surkan (1968) is referred to in the geomorphology literature as the width function. A coarse frequency plot corresponding to the flow lengths shown in Figure 15 is provided in Figure 16.

The overall shape and time base of this distribution is often strongly correlated with the unit hydrograph for the same watershed. We will return to this idea later as we examine travel times in contrast to the flow lengths we are considering here.

The third and final perspective we will consider is the location of the longest flow path within the watershed. This is the path that the flow from the cell that is located the greatest distance from the watershed outlet will take as it drains to this outlet. The length of this longest flow path is indicated by the upper-bound of the last bin of the frequency distribution and its location is hinted at by the contour lines of iso-distance. The actual path is determined readily using GIS techniques and can be likened to placing a drop of water on this most remote cell and then tracing its path as it flows towards the watershed outlet. Figure 17 shows this longest flow path for the watershed examined for the previous two perspectives.

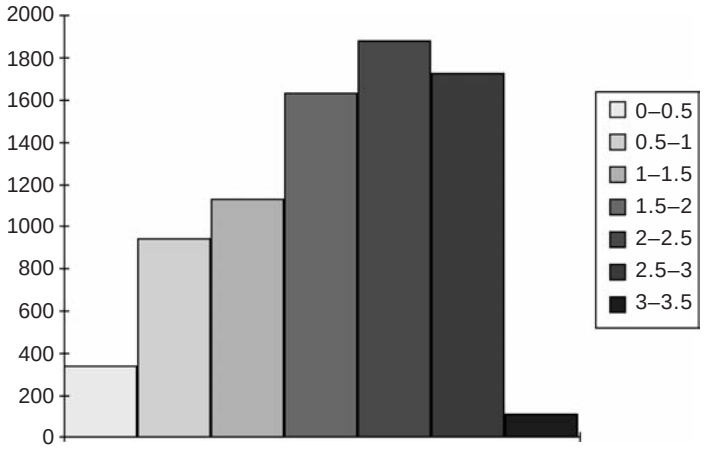

Figure 16 Frequency distribution of flow lengths for watershed pictured in Figure 15. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Figure 17 The longest flow path within the watershed pictured in Figure 15. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Velocity and Travel Times

In the previous section, we considered the frequency distribution of flow lengths within the watershed and noted that this is essentially the width function defined by Surkan (1968). The shape of the frequency distribution shown in Figure 16 bears some similarity to a hydrograph, although its negative skew is counter to the shape typically encountered by hydrologists.

Let us assume a uniform velocity throughout the watershed; another interpretation of this width function is that it is synonymous with the "Instantaneous Unit Hydrograph" or IUH. The IUH is defined as the hydrograph that would be observed at the watershed outlet if a unit pulse of water were instantaneously placed uniformly over the entire watershed at a given instant. With the travel lengths known and a single uniform velocity of flow observed throughout the watershed, the travel time ($t_{t,i}$) to the outlet for any randomly chosen cell, i, would be given by:

$$t_{t,i} = \frac{d_i}{v} \tag{10}$$

where d_i is the distance from the ith cell to the watershed outlet and v is the uniform watershed flow velocity. This is a powerful concept, because we have now used the DEM to discern the flow organization of the watershed and its unique hydrologic signal, the unit hydrograph, which is dependent on the watershed size, shape, and connectivity. In this way, we can determine a unique unit hydrograph for any watershed, being no longer bound by the dimensionless hydrographs offered by the Natural Resources Conservation Service (NRCS) (SCS, 1985), Clark (1943), or the Snyder (1938) model, to name a few.

We note that this uniform velocity assumption simply amounts to a scaling factor on the width function. We are apparently no closer to a typical hydrograph shape than we were before. What have we neglected? Immediately, the reader may recognize that we have assumed a uniform velocity everywhere throughout the watershed. In reality, we would expect much greater velocities in the channels than on the hillslopes. This velocity difference can either be conceptualized as a difference in the Manning's n roughness of the flow surface encountered on hillslopes versus channels, or as the difference between surface runoff in the channels and subsurface flow on the hillslopes. In any event, we expect the difference in velocities could easily be on the order of 10 to 100 times greater in the channels than on the hillslopes. Let us rewrite equation (10) now with this

Flow accumulation		
1	2	1
1	1	4
1	4	5
1	1	10
1	15	1

Travel time		
3.66	2.66	2.24
2.97	2.56	1.24
2.56	1.56	0.24
1.41	1.00	0.14
1.00	0.00	1.00

Figure 18 Flow accumulation and travel times for rightmost three columns of sample 5×5 DEM. Shaded cells are interpreted here to correspond to the very head of a channel. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

two-velocity model:

$$t_{t,i} = \frac{d_{\mathrm{H},i}}{v_{\mathrm{H}}} + \frac{d_{\mathrm{C},i}}{v_{\mathrm{C}}} \tag{11}$$

where $d_{\mathrm{H},i}$ and $d_{\mathrm{C},i}$ are the flow distances for cell i from along the hillslope and channel portions of the overall flow path, respectively. Let us return to the rightmost three columns of the 5×5 DEM analyzed earlier. We will define a channel as any cell with a cumulative area of five cells or greater. For simplicity, we will take each cell to have a side length of 1 unit and use a channel velocity (v_{C}) of 10 units-t^{-1}, and a hillslope velocity (v_{H}) of 1 unit-t^{-1}. The result is shown in Figure 18. The left side of Figure 18 repeats the flow accumulation grid for these columns and the right side of Figure 18 shows the distribution of travel times. Notice the very small travel times associated with the cells draining 5 and 10 cells towards the bottom right of the grid. These two cells, by virtue of equaling or exceeding the channel threshold of 5 cells, develop velocities that are 10 times greater than any other cells in the grid. The result is that the travel times to the outlet associated with these two cells are greatly diminished. It is instructive to compare these travel times to the flow lengths (which can be equated to travel times for a uniform velocity of 1 unit-t^{-1} throughout) shown previously in Figure 14. Notice the much smaller values in Figure 18 for the rightmost three columns compared to those in Figure 14. If we think of the watershed as a system whose objective is to drain water as quickly as possible, then the presence of channel cells with high travel velocities represents an efficiency within the system as indicated by the small travel times associated with these cells.

Figure 19 illustrates the distribution of travel times resulting from the application of equations (10) and (11) to a small watershed draining to Rock Creek immediately north of Washington DC.

The left image corresponds to either the single velocity model of equation (10) applied to the watershed, or to equation (11) with $v_{\mathrm{C}} = v_{\mathrm{H}}$. The right image corresponds to the case where the channel velocity, v_{C}, is 20 times greater than the hillslope velocity and the channels have been defined according to a minimum source area concept, requiring $250 - 30$ m cells to form a channel. The channel network is indicated by the dark cells in both images. The reader should note the strong tendency in the right image for small travel times to cluster around the drainage network. This tendency is absent in the left image where, because of the single velocity applied throughout, the channel network does not play an accentuated role in the spatial distribution of travel times. Figure 20 provides the frequency distributions of travel times for the two cases shown in Figure 19.

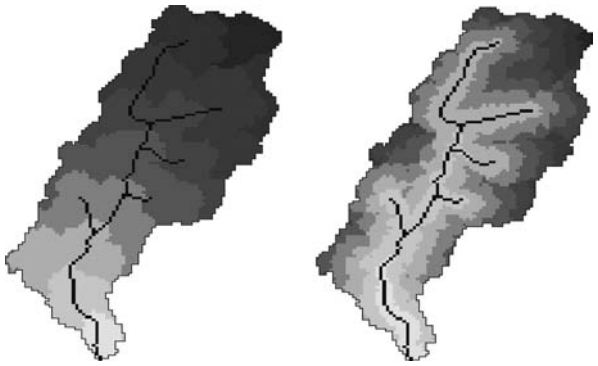

Figure 19 Isochrones of travel time for a small watershed draining to Rock Creek immediately north of Washington, DC. Image (a) corresponds to a single velocity applied uniformly across the entire watershed. Image (b) corresponds to the two-velocity model where channels flow faster than hillslopes. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

The use of the two-velocity model has had the effect of making the skew of the travel time distribution more positive. Notice also that since the single velocity model quantified in Figure 19(a) employed a large velocity throughout the watershed, the overall time base of this distribution is considerably shorter than in Figure 19(b) where the hillslope velocity was 20 times smaller than the channel velocity.

Watershed and Channel Slopes

The interpretation of the DEM to this point has largely focused on horizontal information contained in the DEM. Vertical information was used to determine flow directions, which have served to determine all subsequent information such as watershed boundaries, drainage areas, and flow paths. We return now to examining the vertical component of the watershed as described by the DEMs.

Hydrologists have historically quantified the vertical characteristics of the watershed in a number of ways. In the context of a GIS analysis, we will examine several such characterizations here: channel slope, watershed slope,

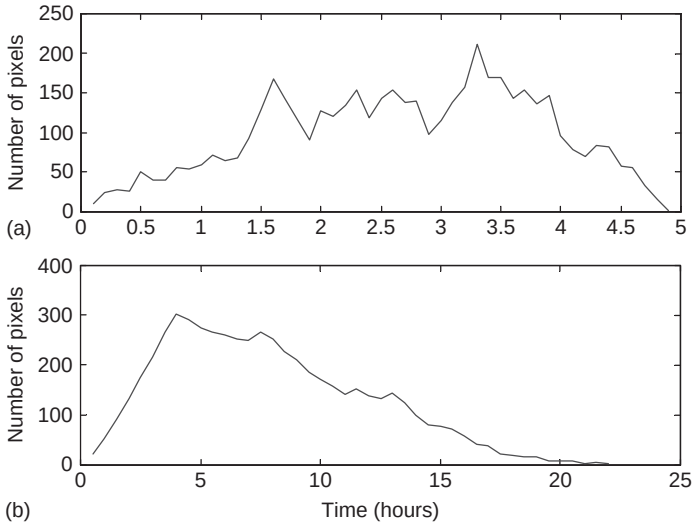

Figure 20 Frequency distribution of travel times for the two cases shown in Figure 19. Images (a) and (b) of Figure 19 result in the frequency distributions shown in (a) and (b), respectively. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

land slope, and basin relief. We start with the channel slope, which is defined as the difference in elevation from the upstream to the downstream end of the main channel divided by the length of the main channel:

$$S_c = \frac{\Delta E}{L_c} \tag{12}$$

where ΔE is the change in elevation from the upstream to downstream end of the main channel and L_c is the length of the main channel. From a hydrologic standpoint, the calculation of the channel slope as defined by equation (12) is straightforward. However, from a GIS perspective there is an ambiguity to consider. One may readily assume the outlet of the watershed to indicate the downstream extent of the channel, but where does the channel begin? This can be a matter of interpretation depending on the scale of the map or aerial photograph being used. Such information might easily differ with field observations of the same channel. The "blue lines", such as those defined by the USGS in the National Hydrography Dataset (USGS, 2003d), are often taken to indicate the upstream extent of a stream, however, these lines vary with map scale and are subject to the personal aesthetics of those digitizing the streams (Leopold, 1994). In the end, some objective, reproducible approach must be employed by the GIS user to define the upstream extent of a stream. For instance, the minimum source area described earlier and illustrated in Figure 13 for a value of 5 cells might be one way to define the upstream extent of a stream. (Please note that the 5 cell threshold used in the 5×5 DEM example is purely for illustrative purposes and is not intended to imply an appropriate value for 30 m DEMs or any other resolution.) Coupling whatever rule for defining the upstream end of the channel with the watershed's outlet location, the GIS can then readily determine the channel slope as given in equation (12).

The watershed slope is calculated in much the same way as the channel slope except that the upstream end of the "channel" is chosen to begin at the watershed divide. The flow path (and thus the flow length) is determined exactly as shown in Figure 17 describing the calculation of the "longest flow path". Such a definition removes the ambiguity of defining an upstream end of the "channel" and makes the determination of this slope more straightforward than the calculation of the channel slope.

The land slope is defined by the NRCS (SCS, 1985) as the average of all the individual slopes determined over the grid system placed over the watershed. This definition precedes the advent of GIS technology, but the grid is clearly analogous to a raster characterization of the watershed. The average slope is thus determined by using the GIS to calculate the local cell-to-cell slopes, as was illustrated earlier in the flow direction section. These local slopes are determined throughout the watershed and then averaged to derive the land slope.

Watershed relief is another measure of the vertical character of the watershed. It is defined as the average of all elevations within the watershed minus the elevation at the watershed outlet. Because this quantity is averaged over the watershed, it is a better indicator of the potential energy available to runoff than is the maximum basin relief that only considers the most extreme elevation within a watershed. The basin relief is readily calculated within the GIS using only the DEM and knowledge of the watershed boundaries.

Clearly DEM and GIS are extremely helpful tools to provide an indication, or a first approximation, of the real hydrological and hydraulic behavior of a watershed or river basin. Such approximation can prove quite adequate (and perhaps even suffice) if the interest is in the overall basin characteristics. However, if detailed simulations are required of dynamic processes (like in case of flood routing or flood early warning) then often a more physically based description is to be used, deriving flows from physical conservation principles of mass, momentum, and energy, as described in the articles by Verwey and Stelling (2005), Lin and Falconer (2005), Werner *et al.* (2005) and elaborated in more detail in **Chapter 13, Pattern, Process and Function: Elements of a Unified Theory of Hydrology at the Catchment Scale, Volume 1** of this Encyclopedia.

CASE STUDY – MARYLAND'S GISHYDRO2000

The users of GIS technology and DEM data for hydrologic analysis and modeling has steadily grown outward from academia into a community of practitioners that use these tools and data on a daily basis. Along these lines, specialized GIS-based environments have evolved that help streamline the types of hydrologic analyses that practitioners are performing. Such tools include HEC-GeoRAS (USACE, 2003b) and the Watershed Modeling System (WMS) (USACE, 2003c). These are GIS-based tools that serve as interactive "front-ends" to hydrologic or hydraulic models that depend heavily on topographic and other geographic data. These tools take advantage of GIS technology to aid the user in developing input data for computer models that might otherwise require time-consuming or repetitive manipulations before an analysis can be performed.

We focus here on a specialized environment, GISHydro2000, developed at the University of Maryland (Ragan, 1991; Moglen and Casey, 1998; Moglen and Kosicki, 2000; Moglen, 2003) for use in conducting hydrologic analyses anywhere in the State of Maryland. This tool runs within the ArcView GIS environment and depends critically on DEM data in order to function. GISHydro2000 is unique in that it contains both the data and software tools necessary to perform a hydrologic analysis all within a single interface. A brief sample analysis will be demonstrated here to illustrate the merger of a GIS-based tool with DEM data.

The first step of the analysis process is the selection of data to sufficiently cover the watershed being studied. In GISHydro2000, this step is performed either graphically or by textually selecting the areal extent of the analysis. This is shown in Figure 21 where the user specifies the analysis extent by selecting one or more USGS 7.5 minute

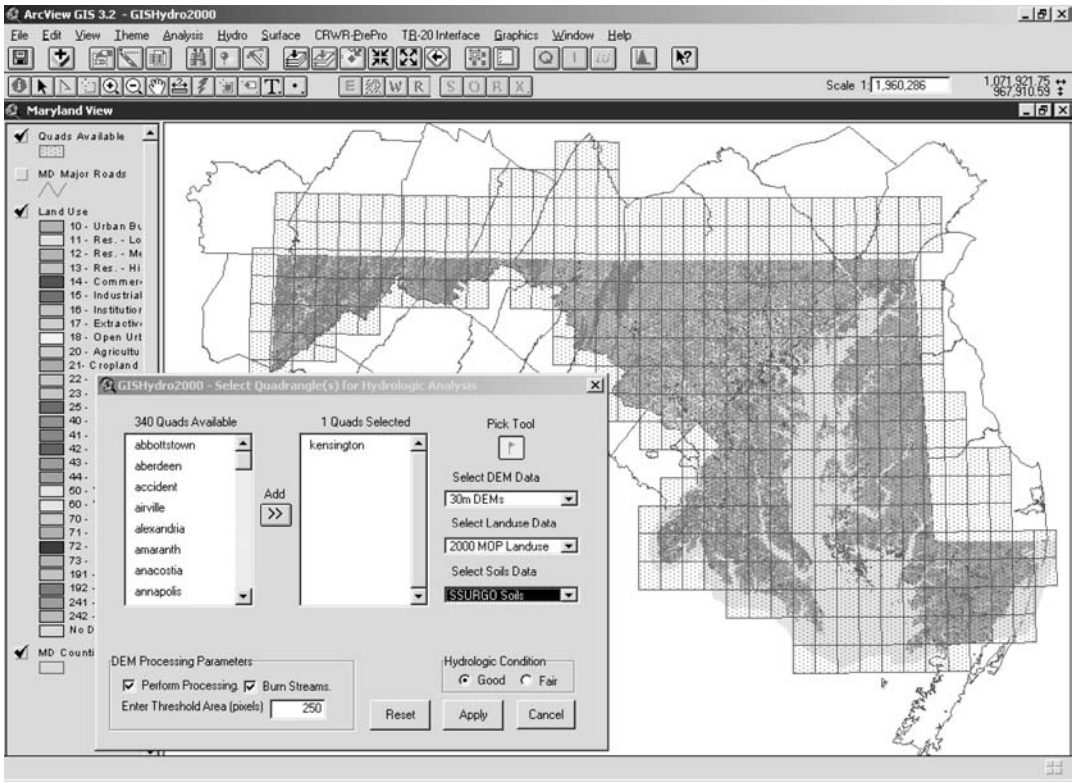

Figure 21 The data selection step in GISHydro2000. The dialogue box at lower right allows for graphical or textual selection of quadrangles. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

quadrangles (the Kensington quadrangle is shown selected in the dialogue box).

In addition to specifying the analysis extent, the user is able to specify different resolutions of DEMs (30 m, 90 m, or a mixture), different dates or sources of land use information, and different sources of soils information. Finally, the user indicates whether only these raw data are desired or if the DEM is to be interpreted hydrologically for flow directions and flow accumulation as described earlier in this article. When all the above information is specified, the user presses the "Apply" button which then extracts the requested data and performs the hydrologic interpretation of the DEM if indicated. For a single 7.5-min quadrangle, the entire process of determining flow directions and flow accumulation may take on the order of 30 – 60 s depending on the hardware that is being used.

The next step, delineation of the watershed, requires the user to indicate the watershed outlet. The GIS then delineates the watershed draining to that outlet with a typical result shown in Figure 22.

Notice in this figure the concept of overlapping information described earlier. The shaded background surrounding the watershed is the DEM with darker shades corresponding to higher elevations. The solid region superimposed on this layer is the watershed itself. Within the watershed, the inferred stream network is indicated. This network was inferred by having the GIS indicate all cells that have a flow accumulation in excess of a fixed amount that is typical of the source area needed to form a stream in this region. (Please note that these cells are not the same information as the "blue lines" that are part of the National Hydrography Dataset (NHD) USGS, 2003d). Blue lines are a vector quantity that are manually digitized by cartographers. These inferred channel cells are a raster quantity that is automatically derived from the DEM as described earlier in this article.) Finally, the major road network is shown as a set of black vector lines spanning the entire area of interest.

The outcome of the selection of a menu choice is the next illustrated step that produces the dialogue box shown in Figure 23.

The upper portion of this dialogue reflects back to the user the data and parameters that were used for the analysis. (For instance, the reader here can confirm that the data are for a watershed in the Kensington, MD quadrangle with an outlet at the indicated location in the Maryland state plane coordinate system.) Under "Findings", a suite of GIS-based calculations have been performed, many of which have been described earlier in this article. The drainage area has been determined (2.8 $mile^2$, 7.3 km^2), the channel slope (62.8 ft $mile^{-1}$, 11.9 m km^{-1}) and land

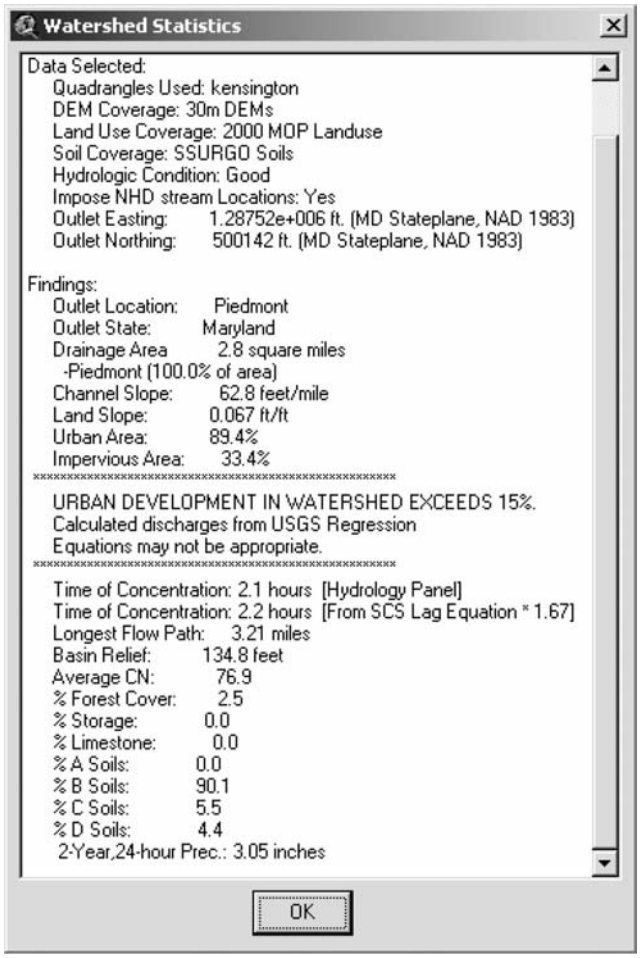

Figure 23 The watershed statistics dialogue in GISHydro2000 corresponding to the watershed delineated in Figure 22. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

slopes have been calculated (0.067 ft ft^{-1}, 0.067 m m^{-1}), the longest flow path is 3.21 miles (5.77 km), and the basin relief is 134.8 ft (41.1 m). By virtue of the land use and soils data also used in the analysis, the reader should note that the statistics include information about the land use and soils distributions in the watershed. The NRCS (SCS, 1985) curve number can also be determined readily from land use and soils information with the average value for the watershed shown here (76.9). This information is all quickly determined within the GIS by using the watershed boundary as a "cookie-cutter" or mask to include only those data that are located within the watershed in any reported calculation. Note that the NRCS lag-based time of concentration is easily calculated. This value is calculated defined as (SCS, 1973)

$$t_c = \frac{L^{0.8}[(1000/CN) - 9]^{0.7}}{441 \cdot S^{0.5}} \tag{13}$$

where t_c is the time of concentration in hours, L is the length of the longest flow path (in meters), CN is the basin-averaged curve number, and S is the land slope in percent. The calculation of several of these quantities was described earlier in this article. The reader should verify that the resulting time of concentration, t_c, is approximately 2.2 h for the data reported in the dialogue box shown in Figure 23. The automation of exactly these types of calculations is easily performed within the GIS.

Although GISHydro2000 also serves as a front-end to the NRCS TR-20 (SCS, 1984) rainfall-runoff model, we will end our case study illustration here with a second dialogue box, shown in Figure 24, that shows the peak flow estimates based on the USGS regression equations applied to this case study watershed.

The current USGS peak flow regression equations (Dillow, 1996) estimate the 2- through 500-year peak flows at ungauged rural sites on the basis of the watershed characteristics shown in Figure 23. For instance, the 2-year peak discharge in the Maryland Piedmont province is calculated as:

$$Q_2 = 6.979A^{0.635}(F + 10)^{-0.266} \tag{14}$$

where Q_2 is the 2-year peak discharge in m^3 s^{-1}, A is the drainage area in km^2, and F is the percent forest cover. In this case, the drainage area is 7.25 km^2 (2.8 mile^2) and the forest cover is 2.5%. The reader can confirm that the discharge is essentially 12.5 m^3 s^{-1} (442 ft^3 s^{-1}) (to within truncation error in the reporting of both inputs to equation (14) and the resulting discharge estimate output). In Figure 24, the GIS has simply been used as a tool to quickly apply these regression equations to the case study watershed. To learn more about this particular analysis and

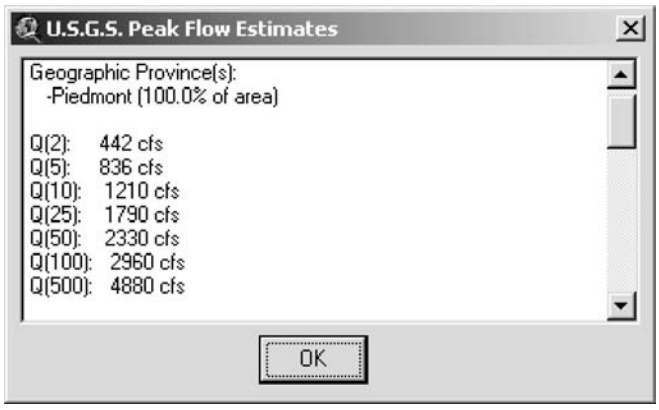

Figure 24 The USGS rural regression equations peak discharge dialogue in GISHydro2000 corresponding to the watershed delineated in Figure 22. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

modeling tool and to download a copy of this program, please visit **http://www.gishydro.umd.edu**.

We should emphasize that none of the results presented here are profound or novel. Rather, the novelty lies in the means used to arrive at these results. By virtue of GIS technology and being driven heavily by DEM data, the illustrative case study could be performed very rapidly (less than 2 min) with the user only needing to specify an analysis extent, the location of the watershed outlet, and then selecting two menu choices to request the watershed characteristics and peak flow estimates. A similar analysis done entirely by hand using the older technologies of a planimeter or a light table and graph paper could easily take an hour or longer just for this small watershed. If the watershed were more substantial in area, the time necessary to do a similar analysis within the GIS would still remain negligible while the old technology analysis time might stretch to weeks or even months. Furthermore, the results from the GIS are objective and reproducible where hand analyses are probably not.

Hence, DEM and GIS prove to be powerful tools when it comes to a rapid assessment of overall watershed/river basin characteristics. This may often already be quite adequate for hydrological analysis purposes. However, if more detailed processes are to be derived from sufficiently available hydrological data (e.g. rainfall-runoff relations), then other technologies are available based on, for example, data-driven modeling, as described by Solomatine (2005) and Artificial Neural Network concepts in hydrology, as elaborated by Minns and Hall (2005).

SUMMARY AND CONCLUSIONS

In this article, the DEM data and GIS technologies have been presented with a specific emphasis on their relevance to hydrologic analysis. DEMs were defined and several sources for these data were provided. GIS technology was introduced with a basic description of both raster and vector data models. The database-map presentation linkage of GIS was illustrated and a brief discussion of map projections was provided. The majority of this article focused on the hydrologic interpretation of DEMs. Flow directions, flow accumulation, watershed delineation, flow lengths, travel times, and measures of slopes were discussed and illustrated through several GIS-based examples. This article concluded with a brief illustration of a GIS-based computer environment developed for the State of Maryland that uses DEM and other spatial data to automate hydrologic analysis. A sample watershed was delineated, its main physical characteristics were quantified, and its peak flow behavior was estimated using rural peak discharges provided by the USGS. The purpose of this illustration was to show how DEM data and the GIS environment can be integrated to streamline hydrologic analyses and rapidly provide both visual and textual information about any watershed the hydrologist wishes to study. Moreover, these computer-based methodologies allow analyses to be performed in a fraction of the time spent by traditional hand methods, with greater consistency and reproducibility. DEM and GIS are typical examples of the importance and capability of hydroinformatics tools and technologies in the field of hydrology.

16: Numerical Flood Simulation

GUUS S STELLING[1] AND ADRI VERWEY[2]

[1]Department of Civil Engineering, Technical University of Delft, Delft, The Netherlands
[2]WL Delft Hydraulics, Delft, The Netherlands

This contribution describes the state of the art of numerical flood simulation, in particular, the models based upon hydraulic laws. Both theory and practical aspects are discussed. In the introduction, various types of applications of these models are listed with their requirements in terms of robustness, accuracy, speed of operation, and engineering staff time. After introducing the 1D Saint Venant unsteady flow equations and describing the meaning of their terms, the concepts of kinematic and diffusive wave approximations are discussed. These provide better ways of understanding the physical behavior of flood waves and demonstrate the link between hydraulic and hydrologic flood propagation models. Numerical discretization of the unsteady flow equations is introduced with special attention given to the correct and robust modeling of rapidly varying flow, as occurring around hydraulic structures, discontinuities in channel beds, and flood-generating breaches of river embankments and reservoir dams. Proceeding with the 2D flow description and its numerical discretization principles, the emergence of hybrid 1D/2D models is discussed with their different options of linking model components of flood-prone areas. The quality of models also relies very much on the availability of detailed and correct data. This contribution briefly introduces the impact of new data collection techniques on numerical flood model schematization.

INTRODUCTION

The risk and impact of floods have always challenged scientists and engineers to master the knowledge on this phenomenon. Over the past decades, for a number of reasons, considerable energy has been spent towards achieving this end. In the first place, there was the challenge of protecting a rapidly increasing world population with a strong drive to settle in flood-prone coastal zones and river flood plains. In addition, there was the increasing awareness about climate changes, which appear to bring more and more precipitation to river catchments. There also are numerous intellectual challenges, as scientific and technological developments in a wide range of fields open up many new ways of supporting flood related studies.

In this contribution, we are limiting ourselves to physically based hydrodynamic or hydraulic models. The underlying principles are conservation of volume, momentum, and energy. The equations were already developed some centuries ago by Newton (1687), who introduced clear mathematical formulations based on physical conservation principles, and De Saint Venant (1871), who formulated the mathematical equations for modern day river flow simulations. However, it required the development of powerful computer equipment to obtain suitable numerical techniques to solve these equations for practical applications. This has led to a large number of modeling systems for the simulation of unsteady channel flow. In the area of numerical flood simulation, the frequently used tools currently available in the market are: the integrated 1D/2D modeling system SOBEK of Delft Hydraulics (**www.wldelft.nl** and **www.sobek.nl**), the Mike11 (1D) and Mike21 (2D) modeling systems of the Danish Hydraulics Institute (**www.dhi.dk**), ISIS of Wallingford Software (**www.wallingfordsoftware.com**), and HEC-RAS of the US Army Corps of Engineers (**www.hec.usace.army.mil/software/hec-ras**).

Although numerical methods for solving unsteady flow equations were developed already half a century ago, for example, by Arakawa (1966), it was only recently that numerical techniques behind flood simulation models reached an acceptable level of perfection. Hydrologists are now able to model flow in channels and over flood plains, irrespective of their bathymetric or topographic

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

complexity, the number and location of embankments for flood protection, roads and railways, and the number and complexity of hydraulic structures and the way we control these.

Depending on their objective, flood simulation models may differ in their requirements. Criteria for the selection of the appropriate tool are often based on the required engineering staff time for model development, overall consultancy time for product delivery, speed of computation, completion time for a simulation, accuracy level of results, data requirements, numerical robustness, user-friendliness of the software, and possibly others, depending on the objective of the model. These objectives may be related to flood risk analysis, flood forecasting, and flood control and may be based upon a variety of causes, such as storms, dam or dike breaks, hurricanes, typhoons, or similar low atmospheric pressure phenomena. Recently (2004) attention has also been drawn once again to the devastating effects of tsunamis. All these application areas of numerical models have their own requirements, as will be discussed briefly in the sequel.

In many countries, insurance companies are using flood risk maps, sometimes based upon relatively simple and quick estimates obtained via simple rules in GIS. Generally, this does not justify the more complex laws defining the flow of water. For this reason, a first improvement is found by applying 1D (one-dimensional) steady flow models with GIS postprocessing to develop topography based flood frequency contour lines (e.g. FEMA procedures: `www.floodmaps.fema.gov/fhm/`). However, there is a tendency now to base flood risk analysis on more detailed 1D and 2D unsteady flow models for flood-prone areas with valuable assets and a complex infrastructure. Federal and local governments have also become more aware of the potential of using such models for evacuation planning. In The Netherlands, for example, more than 60% of the country is subject to flood risk and for most of these areas, combined 1D and 2D hydrodynamic models have been developed to study the effects of potential dike breaks to provide guidelines to authorities in setting up evacuation plans. Besides generating flood depths, these models have to be capable of providing accurate estimates of flood wave propagation celerities over dry beds.

Flood forecasting sets quite different requirements. The speed of producing a forecast is one of the most important criteria, especially in areas where flash floods occur. For this reason, numerical models behind a river–catchment flood forecasting system are usually 1D hydrodynamic models, gradually replacing the simpler hydrological routing techniques. There is a tendency to include partly 2D hydrodynamic models, which is already common practice in flood forecasting systems for coastal areas and seas. Numerical models for flood forecasting are usually embedded in a flood forecasting platform, such as the Delft FEWS system (Werner *et al.*, 2004), which has recently been installed in the UK to provide flood forecasts for nearly all river basins in the country.

Important criteria for numerical models supporting flood control are accuracy, flexible schematization options, numerical robustness, and consultancy time for model development and use. Currently, state of the art for flood control is the use of combined 1D and 2D models (e.g. Hesselink *et al.*, 2003). The former use of flood cells has been replaced by complete 2D flow descriptions, whereas subgrid channel flow is still better described in 1D. Flood control models should be based upon reliable physical descriptions and schematizations, as part of their use is in extrapolation of calibrated models to extreme situations that have never occurred. One of the reasons to build models for flood control is the study of downstream impacts, especially cross-border effects. Downstream impacts of flood control are changed flood wave celerity and changed flood peak attenuation. Higher flood wave celerities result from deepening of the river and the construction of embankments. This, in turn, leads to increased peak floods downstream. The construction of flood retention areas has opposite impacts and may be used to compensate the negative impacts. Model selection criteria then follow from the detail in which potential economic, environmental, and social impacts have to be studied.

The analysis of floods caused by dam- and dike breaks requires extremely robust numerical methods, especially for the description of flooding of dry areas and the correct propagation of the wave front. Moreover, model accuracy, partly based upon the ability to describe the full hydrodynamic equations, is important, as will be discussed in the section on software and model validation. As dam- and dike break simulations are nearly always made for the prediction of their potential effects, data for model calibration is rarely available. The quality of the model fully depends on its descriptive capabilities of the physical system in terms of topographic and roughness data, the representativeness of the equations, and the numerical methods applied. However, it has to be kept in mind that the overall model accuracy also follows from the quality of the description of the dam failure mechanism and the assumptions made here.

Floods generated by the passage of low atmospheric pressure zones such as hurricanes, typhoons, and the geologically induced tsunamis require the modeling of 2D flow in coastal zones, seas, and oceans and may set requirements such as the description of Coriolis forces, the use of spherical coordinates and curvilinear grids, the specification of moving atmospheric pressure fields, special ways of handling initial data, and so on. A possible integrated use of 1D, 2D and 3D models may provide advantages here.

In addition to numerical method developments, new technologies for the collection of data have recently led to complete changes in the selection of the type of numerical models. In particular, the development of global positioning system (GPS) and differential GPS (DGPS) technology has led to far cheaper methods of collecting bathymetric and topographic data (Moglen and Maidment, **Chapter 15, Digital Elevation Model Analysis and Geographic Information Systems, Volume 1**). In turn, this has led to the gradual replacement of the hydrograph-based hydrologic models by the bathymetric- and topographic-based hydrodynamic or hydraulic models. Similarly, the collection of detailed digital terrain data in river and coastal flood plains has led to the replacement of 1D models by 2D models.

Let us first consider the impact of LIDAR (Light Detection And Ranging). The use of this laser technology, scanning the earth's surface with laser beams from airplanes or helicopters, has provided the means to generate highly accurate digital elevation models at a relatively low cost. As an example, the whole area of The Netherlands has been remapped over the past years, with an accuracy of approximately 10 cm in the vertical at a density of 1 point per 16 m^2. Total cost of this project was approximately 10 million euros, or approximately 250 euros per km^2 (Verwey, 2001). This new topographic information has been essential for the flood risk analyses and the evacuation planning studies mentioned earlier.

Also river bathymetries are obtained at a relatively low cost now by boats equipped with multibeam echo sounders. Here also, the position of the boat is recorded via DGPS, while the spatial sound signals record bottom depths relative to the boat at an accuracy of approximately 10 cm in the vertical. At a typical boat speed of 4 m s^{-1} and a swat width of the order of magnitude of the river depth, the bathymetry of quite large riverbeds can be obtained in a few days. Experiments are also being made with laser beams in the green range, as these are able to pass through clean water and enable the application of LIDAR technology for river bathymetries also.

In similar ways, other technologies are advancing rapidly, enabling large amounts of data to be collected at relatively low cost. Worth mentioning are the Acoustic Doppler Current Profiler (ADCP) technology for tidal discharge measurements and the increased precision of spatially distributed precipitation measurements with radar.

ONE-DIMENSIONAL FLOW

By using one-dimensional models (1D) in flood simulation, it is assumed that the phenomenon can be described satisfactorily as unsteady flow in one spatial dimension. In this approach, the flood is assumed to be correctly defined by the state variables or dependent variables, discharge Q and water level h, as a function of the independent variables t for time and x for space.

Basic assumptions and/or limiting conditions are:

- the discharge is sufficiently well defined as the integral of the velocities through a cross section, perpendicular to the x-axis and perpendicular to the flow velocity vectors in the flood plain;
- the water level is constant along the cross section. This implies that at any time the water level at all points along a given cross section should rise or fall at the same rate. This assumption is generally justified when the widths of river and flood plain are of the same scale and free of obstacles such as natural levees or embankments;
- the water level slope or gradient in the x-direction is constant along the cross section. However, it should be noted that in case this condition is not satisfied, correction factors may be applied to reduce significantly errors in the model parameters, as discussed in this contribution.

Quantitative analysis of the two state variables requires two independent equations. Usually, the following equations are used:

- the continuity equation, based upon volume conservation in a control volume defined between two successive points along the channel axis;
- the momentum equation, based upon the conservation of momentum, including the effect of impulses generated by forces acting upon the water contained in the control volume.

Making, furthermore, the following assumptions that

- the pressure distribution in the vertical is hydrostatic;
- the resistance relationship for steady flow is also applicable for unsteady flow; and
- the bed slope is moderately steep so that the cosine of the slope can be replaced by unity,

De Saint Venant (1871) derived the following equations (presented in a slightly adapted form here):

$$\frac{\partial A_t}{\partial t} + \frac{\partial Q}{\partial x} = q_{\text{lat}} \tag{1}$$

$$\frac{1}{gA}\left\{\frac{\partial Q}{\partial t} + \frac{\partial}{\partial x}\left(\frac{Q^2}{A}\right)\right\} + \frac{\partial \zeta}{\partial x} + \frac{Q|Q|}{K^2} = 0 \tag{2}$$

where A_t is the cross-sectional area representative of storage over a control volume (m^2), t is the time (s), Q is the discharge (m^3 s^{-1}), x is the position along the channel axis (m), q_{lat} is the lateral discharge per unit length of channel (m^2 s^{-1}), A the flow-conveying cross-sectional area

(m^2), ζ the water level above a selected horizontal reference plane (m) and K the channel conveyance ($m^3\ s^{-1}$).

The first term of equation (1) accounts for the rate of change in volume stored over a unit length of channel. The second term represents the rate at which the discharge changes along the channel per unit time. The term at the right-hand side represents the effect of lateral flow per unit time and length into the channel.

Equation 2 is the momentum equation which has been simplified by dividing all terms by a density, assumed to be constant. In its original form, the first term represents the change of momentum in a control volume of unit length of channel and reflects the inertia of the water mass present in that control volume. The second term is called the *convective momentum term* and reflects the balance of momentum flowing through the control volumes' upstream and downstream cross section. The third term combines the effect of the impulses generated by differences in upstream and downstream hydrostatic forces (*hydrostatic pressure term*) and the gravity acting on the mass in the control volume (*gravity term*). Finally, the last so-called *friction term* represents the effect of channel wall friction.

It is readily observed that all terms in the momentum equation are written in dimensionless form and represent a gradient of a certain quantity along the channel axis. In its simplest form, equation (2) may be reduced to the familiar steady flow conveyance relationship

$$Q = K\sqrt{I} \tag{3}$$

with the conveyance K expressed, as

$$K = CA\sqrt{R} \quad \text{or} \quad K = \frac{1}{n}AR^{2/3} \tag{4}$$

by equivalence with the Chezy equation and with the Manning equation, respectively, where I is the channel bed slope (−), C the Chezy resistance coefficient ($m^{1/2}\ s^{-1}$), R the hydraulic radius (m); and n the Manning friction coefficient ($s\,m^{-1/3}$).

The set of equations (1) and (3) forms the so-called *kinematic wave approximation* for flood propagation, which, after substitution of (3) into (1) and neglecting the lateral flow term, can be further simplified to the form

$$\frac{\partial Q}{\partial t} + c\frac{\partial Q}{\partial x} = 0 \tag{5}$$

with a flood wave celerity c ($m\,s^{-1}$) expressed as

$$c = \frac{1}{b_s}\frac{dQ}{dh} \tag{6}$$

It is important to realize that, as an essential assumption in the derivation of this kinematic waveform, the *channel bed slope* has been used in the conveyance relationship. Equation (5) has the form of an advection equation, which expresses that flood waves propagate with a celerity c which is inversely proportional to the available channel storage width b_s (m) and a linear function of the derivative of the local flow *rating curve*. The characteristic celerity of this kinematic wave is lower than that of the dynamic wave characteristic in the same direction. As discussed by Abbott (1979) it is this mechanism that leads to roll waves at flood wave fronts, limiting their propagation speed (*see also* Stoker, 1957).

The first-order partial differential equation (5) also expresses that along its characteristic celerity c the discharge remains constant, and so does the peak of the flood wave. In other words, there is no dampening effect of the flood peak. Though this is approximately true for rivers with steep slopes, the stretches with milder slopes require a lesser simplification of the Saint Venant equations. Following, for example, Chaudhry (1993) and defining I of equation (3) as the *water level slope* $\partial\zeta/\partial z$, substitution of the full last two terms of equation (2) into equation (1) gives the so-called *diffusive wave approximation*

$$\frac{\partial Q}{\partial t} + c\frac{\partial Q}{\partial x} = D\frac{\partial^2 Q}{\partial x^2} \tag{7}$$

with a flood wave diffusion coefficient D ($m^2\ s^{-1}$) derived as

$$D = \frac{K}{2b_s\sqrt{I}} \tag{8}$$

Including the lateral flow term, the diffusive wave approximation reads

$$\frac{\partial Q}{\partial t} + c\frac{\partial Q}{\partial x} = D\frac{\partial^2 Q}{\partial x^2} + cq \tag{9}$$

Returning to equation (3) again, the variable I represents the bed slope in the case of the kinematic wave approximation and the water level slope in the case of the diffusive wave approximation. The description based upon the full set of equations (1) and (2) is defined as the *full dynamic wave description*.

Equation (9) shows that along the characteristic line $c = dx/dt$ the flood peaks are dampened by the integral of the diffusion term, whereas they are increased by the integral of the lateral flow term. Although equations (5) and (9) are rarely used in discretized form anymore, they are useful for the flood modeler to provide insight into the physical nature of flood wave propagation. Moreover, it links hydrologic and hydraulic flood routing techniques. By applying a Taylor's series expansion to the Muskingum equation, Cunge (1969) has demonstrated that the well-known hydrological Muskingum flood routing technique emulates the solution

of the advection–diffusion equation (7). This insight provides guidelines for a suitable choice of the Muskingum parameters on the basis of the expressions for c and D (equations (6) and (8) respectively).

The numerical Muskingum method belongs to the class of hydrological routing techniques. These methods are based upon the notion that flood wave propagation characteristics can be derived from measured flood hydrographs along the river, rather than from detailed topographic information, as discussed in the World Meteorological Organization (WMO) report on flood forecasting models by Serban *et al.* (2005). The basis of these methods is that flood wave propagation and diffusion behavior can be represented by a limited number of parameters that can be calibrated from observed hydrographs. Usually there are only two parameters, as in the case of the Muskingum routing method. The limitation of this assumption is clearly shown by analyzing the stage-dependent expressions for celerity and diffusion given by equations (6) and (8). Although the current methods for flood routing are far more precise, there are still many situations where the use of hydrological flood routing techniques is still justified. In many river catchments, and especially in tributaries, the collection of detailed information on river bathymetry and floodplain topography is economically not always justified, despite the emergence of relatively cheap, new technologies.

An alternative to hydrological forecasting methods is provided by newly developed artificial neural network (ANN) concepts (Minns & Hall, **Chapter 20, Artificial Neural Network Concepts in Hydrology, Volume 1**). This technology also relies on measured hydrographs to derive relationships between inflowing and out flowing hydrographs, though in practice ANNs are mostly applied to the development of relationships between rainfall and river catchment runoff.

Both hydrological routing and ANN techniques provide limited reliability for the range of events outside those used for calibration. However, this is exactly the range one is interested in when dealing with extreme flood events, which rarely occur and for which measurements are even more rarely available. So, even though ANNs and other data-driven modeling techniques may prove quite valuable in, for example, determining rainfall-runoff relations (Solomatine, **Chapter 19, Data-driven Modeling and Computational Intelligence Methods in Hydrology, Volume 1**), physically based descriptions, such as those provided by hydraulic routing techniques and based upon the full use of equations (1) and (2), offer better extrapolation possibilities than hydrological routing methods or ANN-based models. For this reason, we will focus on hydraulic modeling techniques in the sequel. However, it should be realized that simplified equations, such as equation (7), remain useful, as these offer us a good insight into the physical nature of flood propagation, in particular, the concepts of flood peak arrival time and the attenuation of peak discharges.

NUMERICAL SOLUTIONS

Hydraulic modeling techniques for 1D are currently based upon the numerical solution of the Saint Venant equations, including the full convective momentum term. These numerical solutions are nearly exclusively based upon implicit finite difference methods. These offer the advantage of unconditional numerical stability, while the various robustness problems of the past, relating to nonlinear effects and flooding and drying of channels and flood plains, have been solved satisfactorily. The application of finite elements and finite volume techniques does not provide specific advantages as, in 1D modeling, most of these techniques lead to equivalent forms derived through finite difference formulations.

Numerical methods for the Saint Venant equations may be based upon so-called *staggered* and *nonstaggered schemes*. The first category represents formulations where the dependent variables Q and ζ are defined alternately at successive grid points along the x-axis. For nonstaggered schemes, however, the variables Q and ζ are defined at the same grid points. At first sight, this last definition offers advantages through the availability of the state variables discharge and water level at the same points along the channel axis. It has been shown, however, that the staggered grid approach offers distinct advantages over nonstaggered grids by guaranteeing the convergence of numerical solutions and the better ability to handle flooding and drying of grid sections, as shown by Stelling *et al.* (1998).

For the numerical solution of the Saint Venant equations (1) and (2), we will consider their Eulerian form per unit width of channel by first neglecting the lateral flow and further simplifying the equations to

$$\frac{\partial \zeta}{\partial t} + \frac{\partial (uh)}{\partial x} = 0 \tag{10}$$

and

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + g\frac{\partial \zeta}{\partial x} + c_f \frac{u|u|}{h} = 0 \tag{11}$$

where ζ is the water level defined as $\zeta = h + z_b$ with h defined as the local water depth (m) and z_b as the local bottom level (m), u the flow velocity ($\mathrm{m\,s^{-1}}$), and c_f the dimensionless bottom friction coefficient.

Referring to Figure 1 and to Stelling and Duinmeijer (2003) for further details, the staggered grid approach requires that alternately at ζ- and u-points, equations (10) and (11) are transformed into finite difference form (*see also* Abbott, 1979; Cunge *et al.*, 1986; Hirsch, 1990; Toro, 1999). Taking a ζ-point as the only feasible choice for

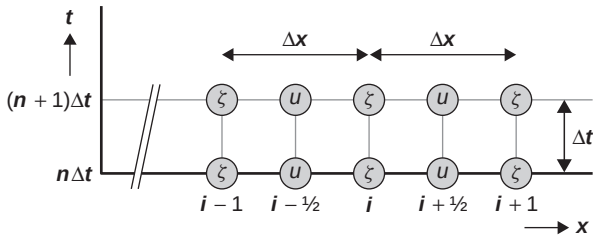

Figure 1 Staggered grid for unsteady channel flow

the transformation of the continuity equation, the finite difference form relates three successive unknowns $u_{i-1/2}^{n+1}$, ς_i^{n+1} and $u_{i+1/2}^{n+1}$ defined at the time level $(n+1)\ \Delta t$ to known values at time level $n\Delta t$ as

$$\frac{\varsigma_i^{n+1} - \varsigma_i^n}{\Delta t} + \frac{{}^*h_{i+1/2}^n\, u_{i+1/2}^{n+\theta} - {}^*h_{i-1/2}^n\, u_{i-1/2}^{n+\theta}}{\Delta x} = 0 \quad (12)$$

where

$$u^{n+\theta} = (1-\theta)u^n + \theta u^{n+1} \quad (13)$$

and

Δt = the time step along the t-axis (s)
Δx = the space step along the x-axis (m)
n = a superscript denoting the time-step number along t
i = a subscript denoting the space step number along x
θ = the time-step weighting coefficient.

The symbol * in equation (12) indicates that the value of h at this grid point has to be approximated by its nearest available upstream value along the grid. For a positive flow direction, for example, this means that $h_{i+1/2}$ is approximated by the value of h_i.

Equation (12) can be reformulated as

$$\alpha 1_i u_{i-1/2}^{n+1} + \beta 1_i \varsigma_i^{n+1} + \gamma 1_i u_{i+1/2}^{n+1} = \delta 1_i \quad (14)$$

where $\alpha 1_i$, $\beta 1_i$, $\gamma 1_i$, and $\delta 1_i$ are the coefficients of the linearized implicit finite difference scheme.

Equation (12) can also be rewritten to provide a choice of time step that guarantees the computation of positive water depths, as:

$$h_i^{n+1} = \left(1 - u_{i+1/2}^{n+\theta}\frac{\Delta t}{\Delta x}\right) h_i^n + u_{i-1/2}^{n+\theta}\frac{\Delta t}{\Delta x} h_{i-1}^n \quad (15)$$

for

$$u_{i-1/2}^{n+\theta} \geq 0 \quad \text{and} \quad u_{i+1/2}^{n+\theta} \geq 0 \quad (16)$$

Equation (15) shows that for positive water velocities and for positive water depths, the *velocity Courant number* condition

$$u_{i+1/2}^{n+\theta}\frac{\Delta t}{\Delta x} \leq 1; \text{ or } \Delta t \leq \frac{\Delta x}{u_{i+1/2}^{n+\theta}} \quad (17)$$

can be applied to provide a sufficient condition for obtaining positive water depths at the new time level. This implies that for the time-step limitation of equation (17), newly computed water levels can never fall below the bottom of the channel. As a consequence, no artificial bottom slots or other arrangements are required to avoid numerical robustness problems for small water depths. A similar condition can be derived for negative flow directions.

Following the same procedure as applied to the continuity equation, the momentum equation (11) can now be defined at a velocity point, by the finite difference form

$$\frac{u_{i+1/2}^{n+1} - u_{i+1/2}^n}{\Delta t} + a(u^n, u^n) + g\frac{\varsigma_{i+1}^{n+\theta} - \varsigma_i^{n+\theta}}{\Delta x} + c_f \frac{\left|u_{i+1/2}^n\right| u_{i+1/2}^{n+1}}{{}^*h_{i+1/2}^n} = 0 \quad (18)$$

where the symbol * has the same meaning as in equation (12) and $a(u^n, u^n)$ is a generalization of the discretization of the convective momentum term.

Appropriate formulations for $a(u^n, u^n)$ follow from the physical conditions, as detailed by Stelling and Duinmeijer (2003). In that paper, it is shown that the correct formulation of the convective momentum term depends on the way in which the convective speed of momentum is interpolated on the grid. As a rule, the discretization is based upon a transformation of the convective momentum term to

$$u\frac{\partial u}{\partial x} = \frac{1}{h}\left\{\frac{\partial (uq)}{\partial x} - u\frac{\partial q}{\partial x}\right\} \quad (19)$$

and its discretization

$$u\frac{\partial u}{\partial x} \simeq \frac{1}{\overline{h}_{i+1/2}}\left(\frac{{}^*u_{i+1}\overline{q}_{i+1} - {}^*u_i\overline{q}_i}{\Delta x} - u_{i+1/2}\frac{\overline{q}_{i+1} - \overline{q}_i}{\Delta x}\right) \quad (20)$$

where

$$\overline{h}_{i+1/2} = \frac{h_i + h_{i+1}}{2}; \quad \overline{q}_i = \frac{q_{i-1/2} + q_{i+1/2}}{2}$$

and $\quad q_{i+1/2} = {}^*h_{i+1/2}u_{i+1/2}$

Also here the value of $^*h$ has the same meaning as in equation (12). The values of $^*u_i$ are missing at ζ-points on the grid and are approximated by first-order unwinding as

$$^*u_i = u_{i-1/2}, \text{ if } \frac{q_{i-1/2} + q_{i+1/2}}{2} \geq 0$$

$$\text{and} \quad ^*u_i = u_{i+1/2}, \text{ if } \frac{q_{i-1/2} + q_{i+1/2}}{2} < 0 \quad (21)$$

For positive flow direction, this yields the simple expression

$$u\frac{\partial u}{\partial x} \simeq \frac{\bar{q}_i}{\bar{h}_{i+1/2}}\left(\frac{u_{i+1/2} - u_{i-1/2}}{\Delta x}\right) \quad (22)$$

This momentum conservative approximation is applied in cases of gradually varying flow or in flow expansions. Referring to Stelling and Duinmeijer (2003) again, this formulation should not be used in strong flow contractions, as this will breed energy. Instead, the energy head conservation formulation should be used, given by

$$u\frac{\partial u}{\partial x} + g\frac{\partial \varsigma}{\partial x} = g\frac{\partial}{\partial x}\left(\frac{u^2}{2g} + \varsigma\right) \tag{23}$$

and, for positive values of u, the energy head conservative upwind discretization

$$u\frac{\partial u}{\partial x} \simeq \frac{u_{i+1/2}^2 - u_{i-1/2}^2}{2\Delta x} = \frac{1}{2}(u_{i-1/2} + u_{i+1/2})\left(\frac{u_{i+1/2} - u_{i-1/2}}{\Delta x}\right) \tag{24}$$

For negative flow velocity, this complete expression is shifted one grid point in the positive x-direction. Comparison of equations (22) and (24) leads to the conclusion that the difference in obtaining momentum or energy conservation lies in the way in which the convective velocity of momentum is interpolated from the flow field.

Terms in equation (18), including (20) or (24) can be collected to give the generalized relation

$$\alpha 2_i \varsigma_i^{n+1} + \beta 2_i u_{i+1/2}^{n+1} + \gamma 2_i \ \varsigma_{i+1}^{n+1} = \delta 2_i \tag{25}$$

By successive elimination of all equations at u-points, the remaining set is given by

$$\alpha_i \varsigma_{i-1}^{n+1} + \beta_i \varsigma_i^{n+1} + \gamma_i \ \varsigma_{i+1}^{n+1} = \delta_i \tag{26}$$

and is solved by applying elimination or conjugate gradient techniques, as discussed further down in this contribution.

The numerical discretization is second-order accurate for all terms of the Saint Venant equations, except for the convective momentum term, which is first-order accurate. For many practical applications, the convective momentum term is of lesser importance and this lower discretization accuracy is quite acceptable then. However, near second-order accuracy can be achieved by up-winded second-order extrapolation of u-values, combined with slope limiters, as described by Stelling and Duinmeijer (2003), again.

In rapidly varying flow, the convective momentum term becomes locally dominant. Modeling these types of flow requires an appropriate implementation of the convective momentum term. By doing so, Delft Hydraulics' SOBEK package has enabled the highly accurate and robust modeling of phenomena such as supercritical flow in steep channels and moving hydraulic jumps.

The numerical scheme given by equations (14) and (25) only provides linear equations at internal grid points. At channel boundaries, additional equations are required. As the Saint Venant equations are of second-order hyperbolic type, one boundary condition is required for each of its characteristic lines entering the computational domain. Boundary condition requirements for 1D river models were discussed extensively by Cunge *et al.* (1986). Here we will limit ourselves by stating that in most practical applications, inflowing discharges are specified at the upstream ends of channels entering the flood model domain and water levels or rating curves at channels leaving the model domain. At internal boundaries, such as channel junctions, usually a modified continuity equation is applied, jointly with water level compatibility at all channel boundaries at that junction.

HYDRAULIC STRUCTURES

Nearly all flood simulation models deal with hydraulic structures, such as dams, weirs, bridges, and so on. The length of the hydraulic structure along the x-axis is usually supposed to be negligible on the scale of the river or channel, and therefore the structure can be seen as one single point along x, where both water- and energy levels are discontinuous and the Saint Venant equations do not apply. At this point a relation is established between the upstream water level, the discharge through the structure, and the downstream water level. In this relation, it is assumed that the upstream water level is taken at the nearest point just upstream of the structure, where vertical accelerations can still be neglected. Similarly, the downstream water level is taken at the nearest location just downstream of the structure, where the flow can be seen as nearly horizontal and the structure flow no longer contributes to the energy dissipation. Usually, it is also assumed that storage of water around the structure is negligible, so the relationship is applicable at any point in time. On this basis, there is a variety of ways in which the flow through hydraulic structures can be formulated:

- in most cases, hydraulic structure descriptions are based upon empirical laws relating the discharge through the structure to the upstream and downstream water level. The relation has the general form,

$$Q_{\text{crest}} = Q(\varsigma_{\text{up}}, \varsigma_{\text{down}}) \tag{27}$$

  where ζ_{up} is the water level upstream of the structure (m), Q_{crest} the discharge through the structure ($\text{m}^3\ \text{s}^{-1}$), and ζ_{down} the water level downstream of the structure (m). This formulation includes the possibility of using energy levels instead of water levels. Equation (27) may be linearized to

$$\alpha \varsigma_{\text{up}} + \beta Q_{\text{crest}} + \gamma \varsigma_{\text{down}} = \delta \tag{28}$$

where α, β, γ, and δ are the local values of nonlinear coefficients at a given state of the flow. A wide variety of structure descriptions is available from literature, for example, the classic books of Chow (1959), Henderson (1966) and, more recently, of Chanson (1999);

- as an alternative, the state of the flow in the section just upstream of the structure, where the flow is contracted and vertical accelerations occur, can be described by an energy conservation principle. Similarly, the state of the flow just downstream of the structure, where the flow expands with energy losses associated to it, can be described by a momentum and impulse balance relationship. By internal elimination of unknowns in these relationships, the water level at the structure crest or at its most contracted section can be eliminated, and a relation similar to equation (28) is obtained;
- in cases where it is difficult to define the state of the flow in terms of equations, laboratory experiments may be set up to define a matrix relating upstream and downstream water levels to the structure discharge. As an alternative, the structure may be modeled in detail by a 3D numerical code, leading to a similar set of matrix coefficients. Conditions are that a fine grid is used, and that the code is based upon an appropriate numerical description of convective momentum terms and the effect of turbulence.

In all cases discussed previously, the structure equations could be based upon energy levels, instead of water levels. Through suitable transformations, these relations can be reworked to the form of equation (28). Similar descriptions can be made for local energy loss descriptions along a channel.

Appropriate linearization of equation (27), or of the other structure flow descriptions, leads to a numerical scheme of the form of equation (25). In the total set of equations for channel flow, this structure relationship replaces the momentum equation that is generally applied between successive ζ-points.

In the case of a closed structure or a discharge specified by a pump, the coefficients α and γ of equation (25) are both zero, and the structure presents itself as an internal boundary condition with a discharge given. In the case of free flow in the positive x-direction, only the coefficient γ equals zero, showing also in the numerical relationship that the structure discharge is only dependent on the upstream water level.

In the literature, an abundant number of structure equations can be found (Chow, 1959; Henderson, 1966; and more recently, Chanson, 1999). Implementing these in a numerical code requires attention for discharge compatibility among the various flow states, especially at the transition between free and submerged flow. Incompatibility in the definition of the discharge may lead to oscillations in the computed flow, in particular, at the moment of flow reversal. Problems may be suppressed by defining some inertia to the structure flow. This is implemented by adding a small term to the coefficients β and δ. The numerical structure behavior is generally better when applying an energy relationship in the accelerating flow section upstream of the structure combined with a momentum–impulse relationship for the section downstream of the structure. Where appropriate, energy losses may be added to the description of flow in the contracted section. Internal elimination of local variables leads, again, to a relationship as given by equation (25). In all cases, the different flow states only affect the computation of the coefficients α, β, γ, and δ and have no bearing on the solution algorithm of the resulting system of equations.

TWO-DIMENSIONAL MODELING

Following the same principles as those leading to the 1D flow equations, the two-dimensional (2D), shallow-water equations read

$$\frac{\partial h}{\partial t} + \frac{\partial (uh)}{\partial x} + \frac{\partial (vh)}{\partial y} = 0 \tag{29}$$

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} + g\frac{\partial (h + z_b)}{\partial x} + c_f \frac{u\sqrt{u^2 + v^2}}{h} = 0 \tag{30}$$

$$\frac{\partial v}{\partial t} + u\frac{\partial v}{\partial x} + v\frac{\partial v}{\partial y} + g\frac{\partial (h + z_b)}{\partial y} + c_f \frac{v\sqrt{u^2 + v^2}}{h} = 0 \tag{31}$$

where we now also introduce the y-axis, orthogonal to the x-axis, with its flow velocity v ($\mathrm{m\,s^{-1}}$) associated to it. Basic assumptions are similar to those given for the 1D equations, as far as applicable in this form of schematization.

Referring to the 2D grid shown in Figure 2, a volume conservative finite difference form of the continuity equation is given by:

$$\frac{\zeta_{i,j}^{n+1} - \zeta_{i,j}^{n}}{\Delta t} + \frac{{}^{*}h_{i+1/2,j}^{n} u_{i+1/2,j}^{n+\theta} - {}^{*}h_{i-1/2,j}^{n} u_{i-1/2,j}^{n+\theta}}{\Delta x} + \frac{{}^{*}h_{i,j+1/2}^{n} v_{i,j+1/2}^{n+\theta} - {}^{*}h_{i,j-1/2}^{n} v_{i,j-1/2}^{n+\theta}}{\Delta y} = 0 \tag{32}$$

$$\frac{u_{i+1/2,j}^{n+1} - u_{i+1/2,j}^{n}}{\Delta t} + a_{11}(u^n, u^n) + a_{12}(v^n, u^n) + g\frac{\zeta_{i+1,j}^{n+\theta} - \zeta_{i,j}^{n+\theta}}{\Delta x} + c_f \frac{u_{i+1/2,j}^{n+1}\sqrt{\left(u_{i+1/2,j}^{n}\right)^2 + \left(\overline{\overline{v_{i+1/2,j}^{n}}}\right)^2}}{{}^{*}h_{i+1/2,j}^{n}} = 0 \tag{33}$$

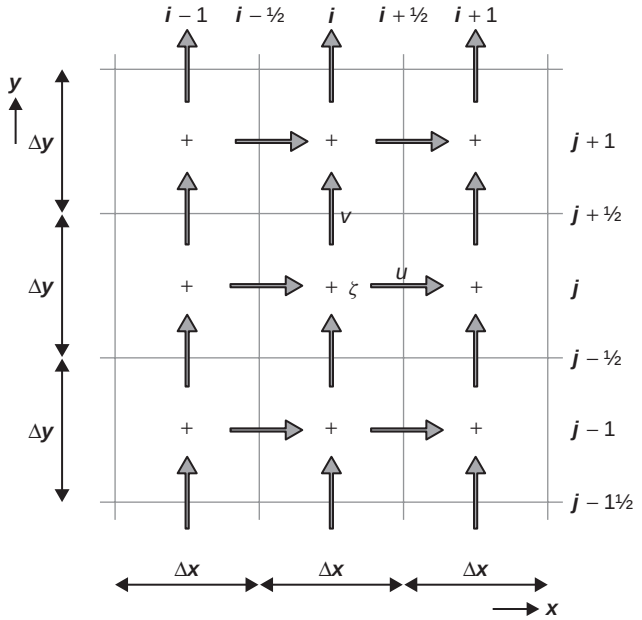

Figure 2 Staggered grid for 2D flow simulations

$$\frac{v_{i,j+1/2}^{n+1} - v_{i,j+1/2}^{n}}{\Delta t} + a_{21}(u^n, v^n) + a_{22}(v^n, v^n) + g\frac{\varsigma_{i,j+1}^{n+\theta} - \varsigma_{i,j}^{n+\theta}}{\Delta y} + c_f \frac{v_{i,j+1/2}^{n+1}\sqrt{\left(\overline{\overline{u_{i,j+1/2}^{n}}}\right)^2 + \left(v_{i,j+1/2}^{n}\right)^2}}{{}^{*}h_{i,j+1/2}^{n}} = 0 \quad (34)$$

where the symbol * has the same meaning as in equation (12) again and $a_{11}(u^n, u^n)$, $a_{12}(v^n, u^n)$, $a_{21}(u^n, v^n)$, and $a_{22}(v^n, v^n)$ are generalizations of the discretization of the convective momentum term. The long double bar over the velocity in the friction term means that this velocity is obtained by averaging over values at four surrounding grid points. The friction term requires special treatment in case of flooding of dry terrain. At the wave front the water velocity rapidly accelerates from zero. Overshoot of velocities can be prevented by a predictor–corrector approach.

The convective momentum terms are subject to the same principles as discussed for the 1D approximations. For example, for positive flow velocities the momentum conservative discretization of the term $a_{12}(u^n, v^n)$ is given by

$$a_{12}(v^n, u^n) \simeq \frac{\overline{{}_{v}q}^{x}_{i+1/2,j-1/2}}{\overline{h}^{x}_{i+1/2,j}} \left(\frac{u_{i+1/2,j} - u_{i+1/2,j-1}}{\Delta y}\right) \quad (35)$$

whereas, it is given by

$$a_{12}(v^n, u^n) \simeq \overline{v}^{x}_{i+1/2,j-1/2} \left(\frac{u_{i+1/2,j} - u_{i+1/2,j-1}}{\Delta y}\right) \quad (36)$$

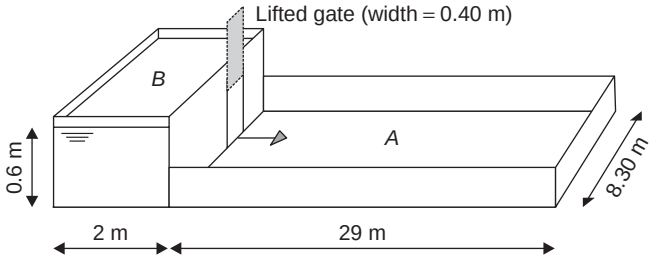

Figure 3 Layout of the instantaneous dam break experiment

for the energy conservative discretization. In the first expression $\overline{{}_{v}q}^{x}$ means the specific discharge in y-direction averaged over two surrounding points along the local x-axis. In the last expression $\overline{v}^{x}$ has the same meaning in relation to the velocity v.

The treatment of the convective momentum terms shown in the preceding text is numerically very robust and allows for the correct description of the effects of sudden expansions and contractions and similar changes in the topography, such as steps in the bed level. Moreover, it allows for the 2D simulation of supercritical flows and the propagation of hydraulic jumps.

As described by Stelling and Duinmeijer (2003), the correct modeling of these phenomena has been demonstrated in a software validation study, where results of the numerical scheme of equations (32), (33) and (34) were compared with video monitored measurements in a physical model (Figure 3). The setup consists of two reservoirs with different water levels, separated by a wall. The wall contains a gate which can be lifted. The width of both reservoirs is 8.30 m, the length of the upper reservoir 2 m, and the length of the lower reservoir 29 m. The gate has a width of 0.4 m and has been placed at the middle of the wall.

The numerical experiment was made on a grid of 0.1 × 0.1 m, giving a total of approximately 25 000 grid cells. The time step was set to 0.005 s. The gate was lifted at a speed of 0.16 m s^{-1}, to produce a flow spreading out into a two-dimensional plain. Initial data were set at a depth of 0.60 m for the upstream reservoir and a depth of 0.05 m for the downstream reservoir.

Figure 4 shows the results of this simulation. Figure 4(a) presents a video recorded view from above. Figure 4(b) presents the computed results. It is clearly seen that the front propagation, the propagation of the hydraulic jump, and the side-spreading of the wave are represented reasonably well. Figure 5 shows a comparison of the measured and computed position of the wave front at various times.

Simulations were made with various Manning roughness coefficients and both for an initially wet and a dry downstream reservoir. For the propagation of the flood on the dry bed, the Manning roughness turned out to be a sensitive parameter. If, for dam break models, a reliable

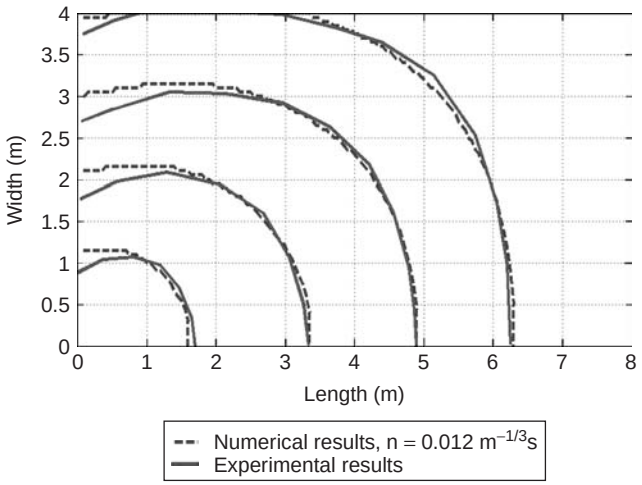

Figure 5 Comparison of measured and computed wave front position at various times (see case Figure 4). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

topography is available, the roughness parameter remains the only parameter to be estimated. Currently, researchers are focusing on better descriptions of roughness parameters by deriving depth-dependent relationships on the basis of vegetation characteristics; see for example, Uittenbogaard (2003), Rodriguez Uthurburu (2004) and Baptist (2005).

INTEGRATED 1D/2D MODELING

In flood modeling, there are numerous practical examples where flows are best described by combinations of 1D and 2D schematizations. An obvious example is the flooding of delta areas, often characterized by a flat topography with complex networks of natural levees, polder dikes, drainage channels, elevated roads and railways, and a large variety of hydraulic structures. Flow over the terrain is best described by the 2D equations, whereas channel flow and the role of hydraulic structures are satisfactorily described in 1D. Flow over higher elevated line elements, such as roads and embankments, can be reasonably modeled in 2D by raising the bottom of computational cells to embankment level. However, for a higher accuracy of the numerical description, adapted formulations have to be applied, such as energy conservation upstream of overtopped embankments.

Another example is the flood propagation in a meandering river, with shortcuts via the flood plain when over-bank flow occurs. In large-scale models, the flow between the riverbanks is satisfactorily described by the Saint Venant equations, solved with 1D grid steps several times the width of the channel. An equivalent accuracy of description in 2D would require a large number of grid cells with step sizes of a fraction of the channel width. However, flow in the flood plain may be better described in 2D and may allow for 2D grid steps often exceeding the width of the river, as made plausible for the flood plain shown in Figure 6.

For this reason, hybrid 1D and 2D schematizations are often used. Basically there are two approaches: one with

Figure 6 Small river with a large flat flood plain in the south of The Netherlands. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

interfaces defined between 1D and 2D along vertical planes and the other with schematization interfaces in almost horizontal planes.

Coupling along vertical planes gives a full separation in the horizontal space of the 1D and 2D modeled domains. In the 1D domain, the flow is modeled with the Saint Venant equations applied over the full water depth. The direction of flow in the 1D domain is assumed to follow the channel x-axis and in the model, it carries its momentum in this direction, also above bank level. Without special provisions, there is no momentum transfer accounting applied between the 1D and 2D domains. Momentum and volume entering or leaving the 2D domain at these interfaces are generated by the compatibility condition applied. As a result, the coupling cannot be expected to be momentum-conservative. Depending on the numerical solution applied, the linkage may either be on water level or on discharge compatibility. Particular care has to be taken in applying this form of schematization if water quality processes are to be included in the model.

In a model coupled along an almost horizontal plane, 2D grid cells are placed above the 1D domain, as shown in Figure 7. In this schematization, the Saint Venant equations are applied only up to bank level. Above this level, the flow description in the 2D cell takes over. For relatively small channel widths compared to the 2D cell size, errors in neglecting the effect of momentum transfer at the interface are minor. This would be the case for a 1D/2D model built for the situation shown in Figure 6. For wider channels, it is recommended to modify each 2D cell depth used in the momentum equation by adding a layer defined by the local hydraulic radius for that part of the 1D cross section which underlies a 2D cell. Further refinements are possible, including terms describing the momentum transfer between the 1D and 2D domains.

Numerical solutions are obtained by discretizing separately the 1D and 2D domains. Assuming that for both

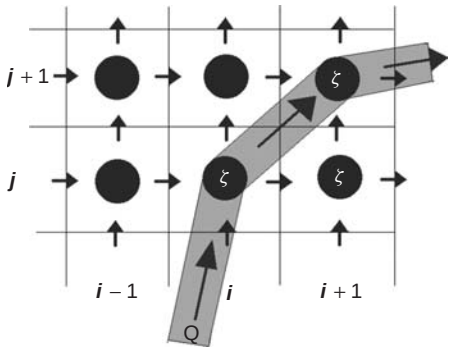

Figure 7 Coupling of 1D and 2D domains in SOBEK. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

domains implicit numerical schemes are applied, the interface compatibility conditions can be modeled either as an explicit or an implicit link. Applying explicit links, first the solutions for the 1D and 2D domains are generated sequentially. Subsequently, exchange flows are computed and added as lateral flows at the next time step. Implicit links are based upon water level compatibility. These equations are then added to the complete sets of equations generated separately for the 1D and 2D domains. There are many approaches to solving the complete set of equations. With the current state of the art, it is no longer necessary to apply for the 1D domain different solvers for so-called *simply-* or *multiply connected channel networks*. Similarly, in 2D there is no real need anymore for alternating direction algorithms, as the efficiency of the conjugate gradient solvers has increased significantly over the past years.

As an example, Delft Hydraulics has developed its combined 1D/2D package SOBEK for the modeling of integrated freshwater systems. The 1D part of hybrid models is based upon the numerical scheme of equations (12) and (18). The 2D part is described by the single step 2D scheme given by equations (32), (33), and (34). For efficiency reasons, the continuity equations for the 1D and 2D domains are combined into one single equation at points where 1D grid sections underlie a 2D cell. As a first step in reducing the total number of equations, SOBEK eliminates all equations at velocity grid points. The second step in the solution algorithm is the elimination of a large number of unknowns by applying a minimum connection search between unknown water levels. As a rule, this leads to an efficient elimination of nearly all unknowns of the 1D domain and a substantial number of unknowns in the 2D domain. This direct solver carries its elimination on, until nearly every second equation in the 2D domain has been eliminated. Beyond this point, it is more economical to apply the conjugate gradient solver to solve the remaining set of equations.

Apart from its efficiency, an additional advantage of eliminating nearly every second 2D equation is the improved conditioning of the resulting matrix. This follows from the fact that elimination of an unknown water level at a 2D grid point has the effect of increasing the spatial distance between the remaining adjacent points, where water levels are still unknown. This, in turn, reduces Courant numbers and as a consequence leads to changed coefficients at the main diagonal of the matrix, which is now more dominant in relation to the other diagonals; see for example, Verwey (1994).

An example of a combined 1D/2D model is shown in Figure 8. It represents the schematization of a model of the Eem Valley area in The Netherlands applied in a study of the potential effects of a River Rhine dike breach. This model has been used to provide information on warning lead times and flood depths for evacuation planning. The

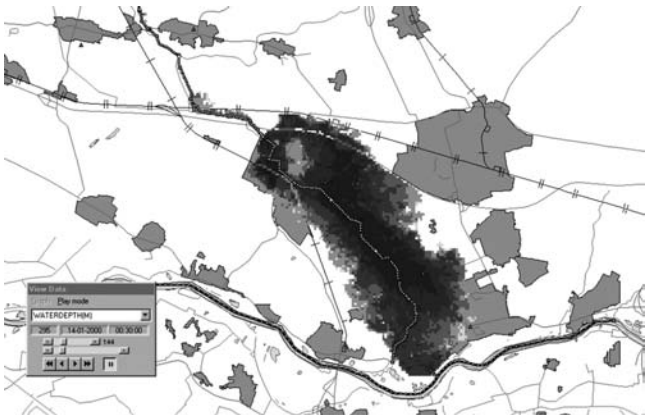

Figure 8 Flood modeling of the Vallei and Eem area, The Netherlands. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Rhine branch upstream of the breach has been modeled in 1D. At its upstream end a design hydrograph was specified, whereas the downstream boundary condition of this relatively short branch is given by a rating curve. Such a short downstream reach is permissible as the rating curve automatically corrects for most of the effects of flow deviated through the breach at this boundary. The breach itself has been described in 1D as a structure with a velocity dependent breach growth. North of the dike, the 1D link discharges into the 2D domain, given by a 100×100 m grid with bottom levels derived from a digital elevation model and resistance coefficients derived from land use maps. Elevated roads and railways are presented as flow barriers by raising the underlying cell bottom levels up to the levels of these embankments. The resulting flood depths presented in Figure 8 clearly show the effect of the 1D channel in the schematization. Because of their greater depth, flood waves propagate faster in these channels than over land. Further downstream, this leads to first signs of the progressing flood wave already one or two days before the main flood arrives.

CONCLUDING REMARKS

The state of the art of numerical flood simulation has progressed significantly over the last decades of the twentieth century and has come to the point where a quite realistic picture of potential flood threats can be produced at very reasonable costs. On the one hand, new data collection techniques have emerged which alleviate the traditional problem of lack of data for model construction. On the other, numerical techniques have matured, providing robustness and efficiency in model simulation.

Such simulation models have proven to be of great value for flood forecasting, flood control, dam break analysis, and flood damage assessment. In flood forecasting, the numerical flood simulation models, or hydraulic models, gradually replace the traditional hydrologic modeling methods such as Muskingum. In flood control, dam break analysis, and flood damage assessment, there is a much longer tradition of using hydraulic models. In these areas we see a gradual replacement of 1D models by integrated 1D/2D models. Typical applications are design of flood protection works, both in rural and urban areas, design and operation of flood retention basins, studies of the effect of climate change, evacuation planning, and GIS-based postprocessing of model results for damage assessment and flood insurance support.

Over the past decades significant progress has been made in the numerical solution of the unsteady flow equations, both in 1D and in 2D. On the basis of bathymetric and topographic information, robust and efficient simulations of flood wave propagation can be produced. Numerical models are now able to model without problems, flooding and drying of floodplains and all sorts of sudden variations in river or channel bathymetry or floodplain topography. Also, there is no longer a problem in modeling sudden transitions between sub- and supercritical flow states, such as frequently encountered in dam break analyses.

Robustness of numerical flood simulation models is not only based upon the use of unconditionally stable numerical schemes. Because of the highly nonlinear nature of the unsteady flow equations, additional conditions have to be imposed, such as the velocity Courant number condition, to avoid negative water depths. Sudden variations in channel cross-sections are modeled better now by applying energy conservation principles in strong flow contractions and correct momentum principles in sudden flow expansions. In addition, other time-step limiters or artificial inertia may be necessary to avoid problems, such as nonconvergence of numerical solutions, mass balance problems, oscillating hydraulic structure flow, and so on. Currently, the nature of most of these problems is well understood.

The construction of numerical flood models has been facilitated much by the development of new data collection equipment, such as LIDAR, ADCPs, multibeam echo sounders, and advanced radar technology. The use of these technologies, jointly with the increased speed of computers, has led to the gradual replacement of 1D models by 2D models for floodplain, wetland, and shallow lagoon modeling. As some water bodies, such as rivers and canals are, for large-scale flood routing problems, still modeled better in 1D, the use of hybrid 1D/2D models has emerged. Coupling of these models may be along vertical planes or along a nearly horizontal plane. This last option provides the most realistic representation of physical processes.

The speed of computers is still increasing continuously. Currently we are able to run a model in one single minute, where this took one hour one decade ago. This has a

strong impact on the practical applications of models. In the coming years, much of this additional speed will be mobilized for simulations on finer grids, to make better use of the details provided by digital elevation models and the use of more refined roughness descriptors, such as those based upon vegetation characteristics. This area still leaves much space for further research. Much research also is needed on improved flood generating breach development descriptions, based upon the physical description of soil–water interactions.

Over the past decade the emerging field of hydroinformatics has provided many new technologies supporting data acquisition, processing, and mining leading to the development of new knowledge, such as more correct empirical relationships, improved optimization methods, and new simulation techniques (*see* **Chapter 21, Rainfall-runoff Modeling Based on Genetic Programming, Volume 1**; **Chapter 20, Artificial Neural Network Concepts in Hydrology, Volume 1**; **Chapter 19, Data-driven Modeling and Computational Intelligence Methods in Hydrology, Volume 1**; **Chapter 23, Flood Early Warning Systems for Hydrological (sub) Catchments, Volume 1**; **Chapter 15, Digital Elevation Model Analysis and Geographic Information Systems, Volume 1**; **Chapter 60, Estimation of River and Water-Body Stage, Width and Gradients Using Radar Altimetry, Interferometric SAR and Laser Altimetry, Volume 2**; **Chapter 61, Estimation of River Discharge, Volume 2**; **Chapter 138, Unsteady Flow, Volume 4**; **Chapter 139, Numerical Modeling of Unsteady Flows in Rivers, Volume 4**; **Chapter 141, Computer Modeling of Overbank Flows, Volume 4** and in particular, abbott and mynett, **Chapter 14, Hydroinformatics and its Contributions to Hydrology: From Computation to Communication, Volume 1**). These developments are likely to have further great impact on the way hydrologists are composing their tool boxes in the years to come.

17: Hydrological and Environmental Modeling of Transport Processes in Rivers and Estuaries

BINLIANG LIN AND ROGER A FALCONER

Cardiff School of Engineering, Cardiff University, Cardiff, UK

Hydroinformatics tools are increasingly being used for predicting hydrodynamic, hydrological, and water quality processes in river and estuarine waters. The numerical solutions of the governing hydrodynamic and solute and sediment transport equations form the basis of these software tools. Details are given herein of the governing equations for three-, two- and one-dimensional flow-field predictions and the transport of water quality indicators and sediment transport processes within the water column. Two case studies are then discussed. In the first of these studies linked 1-D and 2-D models are used to predict the velocity and fecal coliform distributions for a relatively large river and estuarine system, including the Ribble Estuary, its tributaries, and the Fylde coast. In the second of these studies, the velocity, suspended sediment, and heavy metal concentration distributions are predicted along the Humber Estuary using 2-D and 3-D models, with dynamic partitioning coefficients being used to link the metal concentrations and sediments. Details are also given of the hydrological models used to specify the pollutant discharge loads from land used models.

INTRODUCTION

In recent years there has been growing public concern about the quality of water within many river and estuarine systems, particularly in those parts of the world where rivers and estuaries have become increasingly used as receiving water bodies for the discharges of domestic effluents, industrial by-products, agricultural waste, and urban drainage. Clearly this has been an important driver for computer-based modeling paradigms in hydrology, as described by Abbott *et al.* (2005; *see* **Chapter 14, Hydroinformatics and its Contributions to Hydrology: From Computation to Communication, Volume 1**). Human and aquatic life is often threatened by the transport of pollutants through riverine systems to coastal waters, and it is therefore not surprising to find that from a water quality point of view, rivers have been studied more extensively and for longer periods of time than any other bodies of water (Thomann and Mueller, 1987). This is partly due to the fact that many people live close to, or interact with, rivers and streams.

An estuary is a semienclosed coastal body of water that has a free connection with the open sea and within which seawater is measurably diluted with freshwater derived from land drainage and so on (Dyer, 1997). It includes a mixing zone that moves in position according to factors such as tide, wind, and freshwater flow. Consequently, water quality in estuaries usually exhibits marked spatial and temporal variations and involves a range of abiotic as well as biotic processes, as outlined by Mynett (2002). Salinity levels increase from zero at the upstream tidal limit to approximately the same value as that of the open sea. For a well-mixed estuary, these variations produce a water quality gradient along the estuary (Wallingford, 1996). The high, suspended sediment load in most rivers and estuaries provides a large surface area for the attachment of chemical and biological species, including heavy metals arising from industrial waste discharges and bacterial microorganisms arising from urban domestic wastewater discharges.

With increasing awareness of all aspects of hydroinformatics and hydroecological pollution, there has been a marked increase in recent years in the development and application of numerical models to predict river and estuarine water quality characteristics. One of the main reasons for this increase is that numerical models offer powerful tools for investigating the complex interactions between velocities, sediment fluxes, and water quality indicators

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

(Falconer *et al.*, 2001). Water quality modeling originally focused on river and stream pollution, with one-dimensional numerical models often being used for modeling river flow and transport processes (Stelling and Verwey, 2005; *see* **Chapter 16, Numerical Flood Simulation, Volume 1**) as well as water quality assessment. Because of the spatial variation in the distributions of flow velocities and solute concentration distributions, two- and three-dimensional (2-D and 3-D) models are often used for estuarine problems.

The primary processes occurring in rivers and estuaries are usually classified separately as hydrodynamic and transport processes, thus these two processes are also often numerically treated separately. The main objectives of this chapter are to present the governing differential equations and parameters describing the hydrodynamic, water quality, and sediment transport processes occurring in rivers and estuaries and to review recent applications of hydroinformatics tools for modeling water quality indicators. Details are given of 1-D, 2-D and 3-D modeling approaches, with examples being given on the capabilities of such tools.

HYDRODYNAMIC MODELING

Three-dimensional Flows

The numerical models used by water and environmental engineers and managers to predict the flow, water quality, and sediment and contaminant transport processes in rivers and estuaries are based on first solving the governing hydrodynamic equations. For a Cartesian coordinate system, with the main body of the flow in the x-direction, the corresponding 3-D Reynolds equations for mass and momentum conservation can be written in a general conservative form as (Falconer, 1993; Falconer *et al.*, 2001):

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0 \tag{1}$$

$$\underbrace{\frac{\partial u}{\partial t}}_{1} + \underbrace{\frac{\partial u^2}{\partial x} + \frac{\partial uv}{\partial y} + \frac{\partial uw}{\partial z}}_{2} = \underbrace{X}_{3} - \underbrace{\frac{1}{\rho}\frac{\partial P}{\partial x}}_{4} - \underbrace{\frac{\partial \overline{u'u'}}{\partial x} + \frac{\partial \overline{u'v'}}{\partial y} + \frac{\partial \overline{u'w'}}{\partial z}}_{5} \tag{2}$$

where u, v, w, are the velocity components in x, y, z coordinate directions respectively, t = time, X = body force in x-direction, ρ = fluid density, P = fluid pressure, and $\overline{u'u'}, \overline{u'v'}, \overline{u'w'}$ = Reynolds stresses in x-direction on x, y, z planes respectively.

Equations similar to (2) can be written to evaluate the velocity components v and w in the y and z directions respectively. The numbered terms in equation (2) refer to: local acceleration (term 1), advective acceleration (2), body force (3), pressure gradient (4) and turbulent shear stresses (5).

In modeling estuarine flows in two and three dimensions, the effects of the earth's rotation need to be included, giving for the body force components

$$\left.\begin{aligned} X &= 2v\varpi \sin\phi \\ Y &= -2u\varpi \sin\phi \\ Z &= -g \end{aligned}\right\} \tag{3}$$

where ϖ = speed of earth's rotation, ϕ = earth's latitude and g = gravitational acceleration. The main effects of the earth's rotation, give rise to the Coriolis acceleration, which can set up transverse water surface slopes across an estuary and enhance the effects of secondary currents and meandering.

For three-dimensional flow predictions, either the full three-dimensional governing equations are solved, which leads to a complex numerical formulation to evaluate the pressure P, or, more usually, a hydrostatic pressure distribution is assumed to occur in the vertical (z) direction, which leads to an expression for P of the following form:

$$P(z) = \rho g(\zeta - z) + P_a \tag{4}$$

where ζ = water surface elevation above (positive) datum and P_a = atmospheric pressure. The corresponding derivative of equation (4), for inclusion in equation (2), gives:

$$\frac{\partial P}{\partial x} = \rho g \frac{\partial \zeta}{\partial x} + \frac{\partial P_a}{\partial x} \tag{5}$$

A similar representation can be written for the pressure gradient in the y-direction. The effects of the atmospheric pressure gradient are generally small in riverine and estuarine flows and are neglected.

As a consequence, the only unknown terms remaining in equation (2) are the Reynolds stresses, which need to be related to the 3-D velocity field before solving for the water levels and the three-dimensional velocity components. In solving for these stresses, Boussinesq (Goldstein, 1938) proposed that they could be represented in a diffusive manner, giving:

$$\left.\begin{aligned} -\overline{u'u'} &= \nu_t \left[\frac{\partial u}{\partial x} + \frac{\partial u}{\partial x}\right] \\ -\overline{u'v'} &= \nu_t \left[\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right] \\ -\overline{u'w'} &= \nu_t \left[\frac{\partial u}{\partial z} + \frac{\partial w}{\partial x}\right] \end{aligned}\right\} \tag{6}$$

where ν_t = kinematic eddy viscosity.

The eddy viscosity coefficient can be obtained in several ways (Falconer and Chen, 1996). The simplest approach is to assume a constant value based on field data. However,

whilst this approach may be adequate for predicting velocity distributions in large water bodies, such as coastal basins, lakes, or reservoirs, it is not particularly accurate for 3-D model simulations in rivers and estuaries, where such models are generally only used for predicting complex velocity field distributions in the vicinity of structures (such as bridge piers) and short river reaches. Another approach is to apply a zero-equation turbulence model, similar to that prescribed by Prandtl's mixing length hypothesis (Goldstein, 1938), wherein:

$$\nu_t = \ell^2 J \tag{7}$$

where $\ell =$ a characteristic mixing length and $J =$ magnitude of local velocity gradients in x, y, z directions. Using this approach, the mixing length can readily be determined for a typical logarithmic type velocity profile, but for the more complex flow fields where 3-D models are appropriate, the velocity distribution is unlikely to be primarily logarithmic in form, and strong secondary currents often lead to a more complex and less well-defined mixing length.

Hence, for most practical problems, where 3-D models are appropriate for river and estuarine simulations, the turbulent stresses given in equation (2) need to be solved using either a two-equation turbulence model of the k-ε type, or an algebraic stress type model wherein the Reynolds stress terms are solved directly (Lin and Shiono, 1995). For the more usual approach, using either the linear or nonlinear k-ε model, the eddy viscosity is defined as:

$$\nu_t = \frac{C_\mu k^2}{\varepsilon} \tag{8}$$

where $C_\mu =$ turbulent model coefficient, $k =$ turbulent kinetic energy and $\varepsilon =$ dissipation rate of turbulent kinetic energy. Transport equations are derived for k and ε (Rodi, 1984), which, in general, include: transport by advection, production, and dissipation.

Two-dimensional Flows

For many practical problems where there are significant variations across the streamwise flow direction, it is commonplace for the velocity field to be determined using a 2-D depth-integrated numerical model. To determine the hydrodynamic velocity field using a 2-D model, the governing three-dimensional equations are integrated over the depth, giving for equations (1) and (2) respectively:

$$\frac{\partial \zeta}{\partial t} + \frac{\partial q_x}{\partial x} + \frac{\partial q_y}{\partial y} = 0 \tag{9}$$

$$\frac{\partial q_x}{\partial t} + \beta\left[\frac{\partial U q_x}{\partial x} + \frac{\partial V q_x}{\partial y}\right] = f q_y - gH\frac{\partial \zeta}{\partial x} + \frac{\tau_{xw}}{\rho} - \frac{\tau_{xb}}{\rho} + 2\frac{\partial}{\partial x}\left[\bar{\nu}_t \frac{\partial q_x}{\partial x}\right] + \frac{\partial}{\partial y}\left[\bar{\nu}_t\left(\frac{\partial q_x}{\partial y} + \frac{\partial q_y}{\partial x}\right)\right] \tag{10}$$

where q_x, $q_y =$ discharges per unit width in x, y directions, U, V are the depth-averaged velocities in x, y directions; $\beta =$ momentum correction factor for nonuniform vertical velocity profile; τ_{xw}, τ_{xb} are surface and bed shear stress components respectively in x-direction; and $\bar{\nu}_t =$ depth-averaged eddy viscosity.

The momentum correction factor can be estimated either from field data, which is preferable, or alternatively by assuming a velocity profile, such as a logarithmic distribution, to give:

$$\beta = \left[1 + \frac{g}{C^2\kappa^2}\right] \tag{11}$$

where $C =$ Chezy bed roughness coefficient and $\kappa =$ von Karman's constant ($= 0.41$).

For the surface wind stress a quadratic friction law is generally assumed (Wu, 1969), giving:

$$\tau_{xw} = C_s \rho_a W_x W_s \tag{12}$$

where $C_s =$ air-water resistance coefficient, $\rho_a =$ air density, $W_x =$ wind velocity component in x-direction and $W_s =$ wind speed $(= \sqrt{W_x{}^2 + W_y{}^2})$, where $W_y =$ wind velocity component in y-direction.

Bed friction is also generally represented in the form of a quadratic friction law, as given by:

$$\tau_{xb} = \rho g q_x \frac{V_s}{C^2 H} \tag{13}$$

where $V_s =$ depth-average fluid speed $(= \sqrt{U^2 + V^2})$, and $H =$ total depth of water.

To determine the Chezy value for the bed roughness, most of the widely used models tend to use the Manning formula, which expresses C in terms of the local depth as follows:

$$C = \frac{H^{1/6}}{n} \tag{14}$$

where $n =$ Manning roughness coefficient with typical values of n being in the range from 0.012 for smooth lined channelized rivers to 0.04 or more for meandering rivers with vegetation and so on. Although the Manning coefficient is primarily measured in practice for 1-D river reaches, this parameter has been widely used in 2-D flow fields with high levels of accuracy often being obtained for relatively complex flow fields.

Although this approach is appropriate for most rivers and estuaries, the Manning representation assumes that the

flow is rough turbulent flow and that the local head-loss is dependent only on the size and characteristics of the bed roughness, that is, form drag dominates. However, for low velocity flows on shallow floodplains and wetlands, Reynolds number effects may be significant, reflecting the increased influence of skin friction. This complex hydrodynamic phenomenon can be represented using the more comprehensive friction formulation given by the Colebrook–White equation (Henderson, 1966), given as:

$$C = -17.715 \log_{10}\left[\frac{k_s}{12H} + \frac{0.282C}{R_e}\right] \tag{15}$$

where k_s = Nikuradse equivalent sand grain roughness and R_e = Reynolds number for estuaries $= 4V_s/\nu$, where ν = kinematic laminar viscosity. The other advantage in using the Colebrook–White formulation to represent the bed roughness, rather than the Manning formulation, is that the physical roughness parameter k_s can be directly related to the height of bed features, such as ripples or dunes, rather than being based on a descriptive representation of the bed characteristics as for the Manning formulation.

Finally, for the depth-averaged eddy viscosity $\bar{\nu}_t$, this parameter can preferably be estimated from field data of the vertical velocity profile or assuming bed-generated turbulence dominates over free shear layer turbulence, then a logarithmic velocity profile can be assumed giving (Elder, 1959):

$$\bar{\nu}_t = 0.167\kappa U_* H \tag{16}$$

where U_* = shear velocity ($\sqrt{g}V_s/C$). However, field data by Fischer (1973) showed that the turbulent diffusion coefficient in straight, fairly uniform rivers is generally much higher and is more accurately represented by:

$$\bar{\nu}_t = 0.15U_* H \tag{17}$$

For most practical estuaries, even this value can be low compared with the measured data recorded in rivers, with values for $\bar{\nu}_t/U_*H$ typically ranging from 0.42 to 1.61 (Fischer *et al.*, 1979). Recent results of using data-mining techniques for deriving formulations for variable (viz. water depth dependent) roughness coefficients are described by Babovic (2005) (*see* **Chapter 21, Rainfall-runoff Modeling Based on Genetic Programming, Volume 1**) who used Genetic Programming techniques to obtain a formulation of the variable roughness that can be elegantly incorporated in the numerical formulation, as demonstrated by Stelling and Verwey (2005) (*see* **Chapter 16, Numerical Flood Simulation, Volume 1**).

One-dimensional Flows

In simulating flows within rivers and narrow estuaries, one-dimensional models may be used where the longitudinal flow features dominate the system. The governing St. Venant equations of motion are obtained by integrating the 3-D equations of motion (i.e. equations (1) and (2)) over the area of flow to give:

$$T\frac{\partial \zeta}{\partial t} + \frac{\partial Q}{\partial x} = q \tag{18}$$

$$\frac{\partial Q}{\partial t} + \beta\frac{\partial (Q^2/A)}{\partial x} = -gA\frac{\partial \zeta}{\partial x} - gAS_f \tag{19}$$

where T = surface width of flow, Q = discharge, q = lateral inflow or outflow per unit length of river, A = area of flow, and S_f = friction slope, or slope of total energy line, which is given by the following representation:

$$S_f = \frac{Q|Q|}{C^2A^2R} \tag{20}$$

where R = hydraulic radius for conveyance segment and C (i.e. the Chezy coefficient) may be estimated from either equations (14) or (15). More details can be found in the accompanying article by Stelling and Verwey (2005) (*see* **Chapter 16, Numerical Flood Simulation, Volume 1**).

WATER QUALITY MODELING

Three-dimensional Flow Fields

In modeling numerically the flux of water quality indicators, sediments, or contaminants within a river or estuary, the conservation of mass equation can first be written in general terms for a three-dimensional flow field as given by (Harleman, 1966):

$$\underbrace{\frac{\partial \varphi}{\partial t}}_{1} + \underbrace{\frac{\partial \varphi u}{\partial x} + \frac{\partial \varphi v}{\partial y} + \frac{\partial \varphi w}{\partial z}}_{2} + \underbrace{\frac{\partial}{\partial x}\overline{u'\varphi'} + \frac{\partial}{\partial y}\overline{v'\varphi'} + \frac{\partial}{\partial z}\overline{w'\varphi'}}_{3} = \underbrace{\varphi_S + \varphi_d + \varphi_k}_{4} \tag{21}$$

where φ = solute concentration, φ_S = source or sink solute input (e.g. an outfall), φ_d = solute decay or growth term, and φ_k = kinetic transformation rate for solute. The individual terms in equation (21), generally referred to as *the advection-diffusion equation*, refer to: local effects (term 1), transport by advection (2), turbulence effects (3), and source (or sink), decay (or growth), and kinetic transformation effects (4).

The cross-produced terms $\overline{u'\varphi'}$ and so on represent the mass flux of solute due to the turbulent fluctuations and, by analogy with Fick's law of diffusion, it can be assumed that

this flux is proportional to the mean concentration gradient and is in the direction of decreasing concentration. Hence, the third terms can be written as:

$$\left.\begin{aligned}\overline{u'\varphi'} &= -D_{tx}\frac{\partial\varphi}{\partial x}\\ \overline{v'\varphi'} &= -D_{ty}\frac{\partial\varphi}{\partial y}\\ \overline{w'\varphi'} &= -D_{tz}\frac{\partial\varphi}{\partial z}\end{aligned}\right\} \tag{22}$$

where D_{tx}, D_{ty}, D_{tz} = turbulent diffusion coefficients in x, y, z directions. These coefficients are often associated with the eddy viscosity ν_t and a Schmidt number, with its value found to vary between 0.5 and 1.0 (Lin and Shiono, 1995). For estuarine flows it is common to assume isotropic turbulence and to approximate the horizontal diffusion terms to the depth mean coefficients as given by Fischer (1973), whereby, in the absence of field data, these terms are often equated to:

$$D_{tx} = D_{ty} = 0.15U_*H \tag{23}$$

Likewise, for the vertical diffusion coefficient, in the absence of stratification and field data, it is common to assume a linear shear stress distribution and a logarithmic velocity profile giving (Vieira, 1993):

$$D_{tz} = U_*\kappa z\left(1 - \frac{z}{H}\right) \tag{24}$$

However, as indicated for hydrodynamic modeling, 3-D models only tend to be used for simulating water quality processes in which the vertical variations of a water quality indicator, such as density, are significant.

Two-dimensional Flow Fields

For practical problems where there are significant variations in the velocity field across the river or estuary, such as over floodplains or mangrove forests, a 2-D numerical model solution is more commonly used, together with the depth-integrated advective-diffusion equation (Falconer, 1991) given as:

$$\begin{aligned}\frac{\partial\phi H}{\partial t} + \frac{\partial\phi q_x}{\partial x} + \frac{\partial\phi q_y}{\partial y} - \frac{\partial}{\partial x}\left[HD_{xx}\frac{\partial\phi}{\partial x} + HD_{xy}\frac{\partial\phi}{\partial y}\right]\\ - \frac{\partial}{\partial y}\left[HD_{yx}\frac{\partial\phi}{\partial x} + HD_{yy}\frac{\partial\phi}{\partial y}\right]\\ = H[\phi_s + \phi_d + \phi_k]\end{aligned} \tag{25}$$

where ϕ = depth-average solute concentration, k = decay rate constant and so on, ϕ_s, ϕ_d, ϕ_k are the depth-average concentrates corresponding to φ_s, φ_d, φ_k, in equation (21) and D_{xx}, D_{xy}, D_{yx}, D_{yy} are the depth-average longitudinal dispersion and turbulent diffusion coefficients in x, y directions.

For the dispersion-diffusion terms, these coefficients can be shown to be of the following form (Preston, 1985):

$$\left.\begin{aligned}D_{xx} &= \frac{(D_\ell U^2 + D_t V^2)H\sqrt{g}}{V_s C} + D_w\\ D_{yy} &= \frac{(D_\ell V^2 + D_t U^2)H\sqrt{g}}{V_s C} + D_w\\ D_{xy} = D_{yx} &= \frac{(D_\ell - D_t)UVH\sqrt{g}}{V_s C} + D_w\end{aligned}\right\} \tag{26}$$

where D_ℓ = depth-average longitudinal dispersion constant, D_t = depth-average turbulent diffusion constant, and D_w = wind-induced dispersion coefficient. For values of D_ℓ and D_t, these dimensionless constants can be preferably obtained from field data, or alternatively minimum values can be obtained by assuming a logarithmic velocity profile, wherein $D_\ell = 5.93$ (Elder, 1959) and $D_t = 0.15$ (Fischer, 1973). However, in practical studies these values tend to be rather low (Fischer *et al.*, 1979), with measured values for D_ℓ and D_t ranging from 8.6 to 7500 and 0.42 to 1.61 respectively. For present-day capabilities of data-driven modeling and data-mining techniques, reference is made to, for example, Solomatine (2005) (*see* **Chapter 19, Data-driven Modeling and Computational Intelligence Methods in Hydrology, Volume 1**), Babovic (2005) (*see* **Chapter 21, Rainfall-runoff Modeling Based on Genetic Programming, Volume 1**), and Savic and Khu (2005) (**Chapter 22, Evolutionary Computing in Hydrological Sciences, Volume 1**).

One-dimensional Flow Fields

As for hydrodynamic studies, water quality studies of rivers and narrow well-mixed estuaries are often based on a 1-D numerical model. For this purpose the 3-D advective-diffusion equation (21) is integrated over an arbitrary cross-sectional area A to give:

$$\frac{\partial\phi A}{\partial t} + \frac{\partial\phi Q}{\partial x} - \frac{\partial}{\partial x}\left[AD_l\frac{\partial\phi}{\partial x}\right] = S_s + S_d + qS_L \tag{27}$$

where ϕ = area-average solute concentration, S_s = area-average source term, S_d = area-average decay term and S_L = solute concentration of lateral input (or output) (see also equation (18)).

WATER QUALITY PROCESSES

In modeling water quality processes in rivers and estuaries, a range of water quality parameters are often modeled, including physical, chemical, and biological indicators

(Falconer *et al.*, 2001). General discussions on water quality processes can be found in Part 8 of this Encyclopedia: Water Quality & Biogeochemistry (McCutcheon, 2005) (*see* **Chapter 100, Water Quality Modeling, Volume 3**). In this article, details are given of the procedures used for modeling fecal coliform (FC) and heavy metals.

Fecal Coliform Modeling

Total coliform (TC) has been used for many years as the main indicator in evaluating bathing-water quality with respect to domestic waste. However, because of the difficulties associated with the occurrence of non-fecal bacteria in tests, the use of the TC test is being gradually replaced by FC and fecal streptococci as the main bacteriological indicators (Thomann and Mueller, 1987). The FC bacteria group are indicative of organisms from the intestinal tract of humans and other animals. In recent years, FC has been used by several researchers to assess the quality of bathing water and urban streams for both outfall and/or nonoutfall sources (Wyer *et al.*, 1997; Thackston and Murr, 1999; Young and Thackston, 1999).

In modeling FC, the decay terms in equations (25) and (27) are generally expressed as a first-order decay function and are typically included in 1-D and 2-D models respectively via the following equations:

$$S_d = -k_B \phi A \quad \text{and} \quad \phi_d = -k_B \phi \tag{28}$$

where k_B = coliform decay rate (day^{-1}). The response time, that is, the time required for the water body (i.e. river or estuary etc.) to complete a fixed percentage of its recovery, is also commonly used to represent the growth/decay of bacteria. This parameter can be easily derived from a first-order decay formulation of the form $\phi = \phi_0 e^{-kt}$, where ϕ_0 = initial concentration at $t = 0$. In practice, T_{90} is a commonly used parameter for this purpose and is defined as the time during which the original organism population would reduce by 90%. It can readily be shown that T_{90} can be calculated from (Chapra, 1997):

$$T_{90} = \frac{2.303}{k_B} \tag{29}$$

Several factors may influence the population of the organisms in a water body, and thus, in reporting the decay rate, sampling conditions are usually specified. These factors are mainly sunlight intensity and duration, temperature and salinity levels, suspended particulate matter, and concentrations of toxic substances. A wide range of decay rates for TCs and FCs and fecal streptococci have been reported in the literature. For example, TC and FC decay rate values have been reported from 0 to 2.4 day^{-1} for 2–18% salinity and dark conditions and 2.5 to 6.1 day^{-1} for 15% salinity and sunlight conditions. Likewise, a range of 37 to 110 day^{-1} has also been reported for FC decay rates in seawater under good sunlight conditions (see Thomann and Mueller, 1987, Table 9).

Sediment Transport Modeling

On the basis of the general advective-diffusion equation (21), the governing equation for suspended sediment transport processes is generally written as:

$$\frac{\partial S}{\partial t} + \frac{\partial}{\partial x}(uS) + \frac{\partial}{\partial y}(vS) + \frac{\partial}{\partial z}[(w - w_s)S] - \frac{\partial}{\partial x}\left(D_{tx}\frac{\partial S}{\partial x}\right) - \frac{\partial}{\partial y}\left(D_{ty}\frac{\partial S}{\partial y}\right) - \frac{\partial}{\partial z}\left(D_{tz}\frac{\partial S}{\partial z}\right) = S_T \tag{30}$$

where S = suspended sediment concentration and S_T = source or sink term. It should be noted that the source or sink term is introduced through the bed boundary conditions. For cohesive sediments, the following bed conditions have been used (Wu *et al.*, 1999):

$$-w_s S - D_{tz}\frac{\partial S}{\partial z} = q_{dep} \quad \text{when } \tau_b \le \tau_d \quad \text{(deposition)} \tag{31a}$$

$$-w_s S - D_{tz}\frac{\partial S}{\partial z} = q_{ero} \quad \text{when } \tau_b \ge \tau_e \quad \text{(erosion)} \tag{31b}$$

$$-w_s S - D_{tz}\frac{\partial S}{\partial z} = 0 \quad \text{when } \tau_d < \tau_b < \tau_e \quad \text{(equilibrium)} \tag{31c}$$

where τ_b = bed shear stress, τ_d = critical shear stress beyond which no further deposition occurs, τ_e = critical shear stress for erosion, and q_{dep}, q_{ero} are the deposition and erosion rates respectively at the bed.

Heavy Metal Modeling

As heavy metals can exist in both dissolved and adsorbed particulate phases in rivers and estuaries, the distribution between these two phases is usually described by a partitioning coefficient K_D. For transport of metals in the dissolved phase, the three-dimensional advective-diffusion equation is given as:

$$\frac{\partial C}{\partial t} + \frac{\partial}{\partial x}(uC) + \frac{\partial}{\partial y}(vC) + \frac{\partial}{\partial z}(wC) - \frac{\partial}{\partial x}\left[D_{tx}\frac{\partial C}{\partial x}\right] - \frac{\partial}{\partial y}\left[D_{ty}\frac{\partial C}{\partial y}\right] - \frac{\partial}{\partial z}\left[D_{tz}\frac{\partial C}{\partial z}\right] = (C_d + C_t) \tag{32}$$

where C = concentration of heavy metals dissolved in water column, C_d = source or sink of dissolved heavy metal, and C_t = transformation flux from, or to, adsorbed particulate phase onto the sediments. The adsorbed

particulate phase is transported with the sediments and this process may be described by the following equation:

$$\frac{\partial SP}{\partial t} + \frac{\partial}{\partial x}(uSP) + \frac{\partial}{\partial y}(vSP) + \frac{\partial}{\partial z}[(w - w_s)SP] - \frac{\partial}{\partial x}\left[D_{tx}\frac{\partial SP}{\partial x}\right] - \frac{\partial}{\partial y}\left[D_{ty}\frac{\partial SP}{\partial y}\right] - \frac{\partial}{\partial z}\left[D_{tz}\frac{\partial SP}{\partial z}\right] = (SP_d + SP_t) \quad (33)$$

where SP = concentration of heavy metal adsorbed on the suspended sediments, w_s = apparent sediment settling velocity, SP_d = source or sink of adsorbed particulate heavy metal, SP_t = transformation flux from, or to, dissolved phase in water column. The transformation processes between the dissolved and adsorbed particulate phases are very complex.

Millward and Turner (1995) have established that the partitioning of heavy metals between the particulate and dissolved phase is dependent upon salinity. They established from field data an empirical relationship linking the partitioning coefficient with salinity of the following form:

$$\log_e(K_D) = b\log_e(S + 1) + \log_e(K_D^0) \quad (34)$$

where K_D = partitioning coefficient, S = salinity and K_D^0 = partition coefficient in freshwater.

MODELING APPLICATIONS

In this section, details are given of two modeling studies undertaken by the authors in applying the above governing equations for predicting the hydrodynamic, water quality, and sediment transport processes in river and estuarine waters in two UK basins. Some other recently published studies that are related to the modeling of riverine and estuarine processes are also highlighted.

Modeling Bathing Water Quality in the Ribble Estuary

A numerical model study was undertaken to establish the water quality of the EU-designated bathing waters located near the mouth of the Ribble Estuary, located along the northwest coast of England (Kashefipour *et al.*, 2002). The numerical model domain included three tidal rivers, namely, the Ribble, Darwen and Douglas rivers, and the Ribble Estuary, with the upstream boundaries being at the tidal limits of these three rivers and with the downstream boundary being located around the 25-m depth contour in the Irish Sea (see Figure 1). The length of the seaward boundary was 41.2 km, with the width of the river boundaries being generally less than 10 m. Thus, in this study a 1-D model was dynamically linked to a 2-D model to create a single model in which the computations for the hydrodynamic and water quality variables were undertaken simultaneously across the entire model domain.

Six sets of hydrodynamic and water quality data were collected during the winter of 1998 and summer of 1999, thereby including different weather and tide conditions.

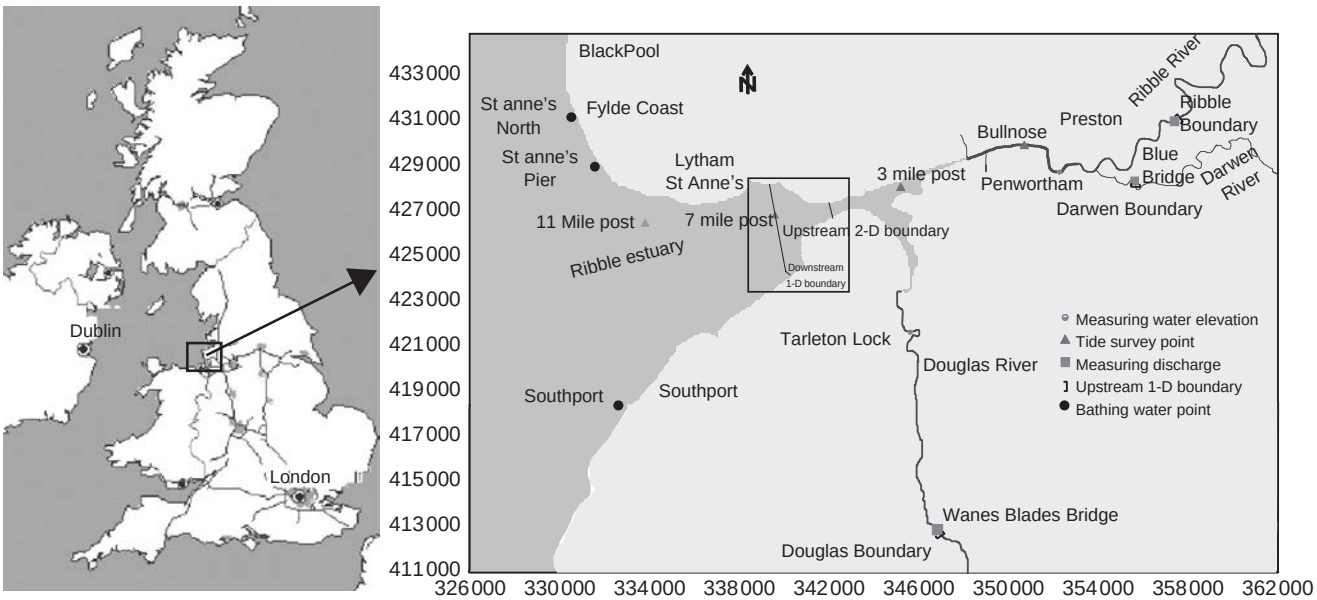

Figure 1 Fylde Coast, Ribble Estuary and its tributaries. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Comprehensive data were collected, including water depths, current speeds and directions, salinity levels, and concentrations of suspended solids, fecal and total coliforms, and fecal streptococci.

Fecal indicator organisms in river and estuarine waters could derive from human and/or animal sources. The former could be effluents discharged to rivers and estuaries and spills from combined sewer overflows (CSOs). The latter could be diffuse sources in riverine catchments related to agriculture activities (Loague, 2005) (*see* **Chapter 94, Point and NonPoint Source Pollution, Volume 3**). Field mapping of land use was undertaken over the catchments using a classification scheme (Fewtrell *et al.*, 1998) that divided the land use into 25 classes, including improved pasture, rough grazing, arable, woodland and built-up land and so on. A stepwise multiple regression analysis was used to model relationships between geometric mean indicator concentrations and land use types for base and high flows.

As an example, the results obtained for the survey on 3 June 1999 are discussed herein. This survey was carried out during a wet period for a mean tidal range. Figures 2 (a–c) show comparisons at a calibration point, that is, 7 milepost (see Figure 1), between predicted water elevations and current speeds and directions respectively. Figure 2 (a) shows that good agreement was achieved between the predicted and measured water levels at this site, with an average error of 0.11 m when compared with the measured tidal range. Figures 2 (b, c) illustrate relatively good agreement between the predicted current speeds and directions with the corresponding measured data, with an average error of 0.13 m s^{-1} and 8.1° respectively.

In this study, FC was used as the main water quality indicator organism. To reflect all of the environmental conditions affecting the fate of microorganisms, different decay rates were used for (i) day and night times (ii) dry and wet weather conditions, and (iii) sea and river waters. FC inputs during the 3 June 1999 survey along the rivers and estuary were categorized into four groups, including open boundaries, wastewater treatment works (WwTWs), CSOs, and the other inputs. As can be seen from Figure 3 the most significant FC load came from the river inputs. Statistical analysis showed similar results for the other surveys, both for wet and dry events.

Predicted and measured FC concentrations at 7 milepost for the survey on 3 June 1999 are compared in Figure 4. Relatively good agreement between both sets of data can be seen from this figure, with an average error of 30.5%. Figure 5 shows another example for the linked model application to the Ribble Estuary and compares the predicted and measured FC concentrations at 3 milepost for the 19 May 1999 survey, which was carried out for a dry event and a spring tidal range. As can be seen from this figure, both sets of data agreed well, with an average error of 27.6%.

Model Application to Humber Estuary

The Humber Basin is a well-mixed estuarine system located along the east coast of northern England and providing an outlet to the North Sea for the rivers Trent and Ouse and shipping access to a number of ports, including Hull, Immingham, and Grimsby (see Figure 6). The management and monitoring of water quality in the Humber Basin is coordinated by the UK Environment Agency (Edwards *et al.*, 1987). Field measurements of water elevations,

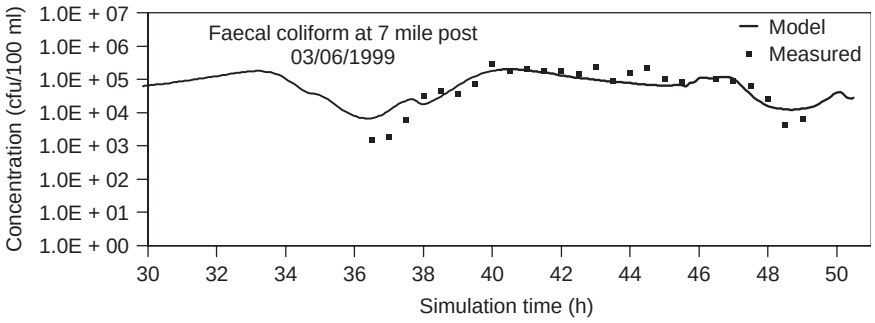

Figure 4 Comparison of predicted and measured fecal coliform concentrations at 7 milepost, on 3 June, 1999

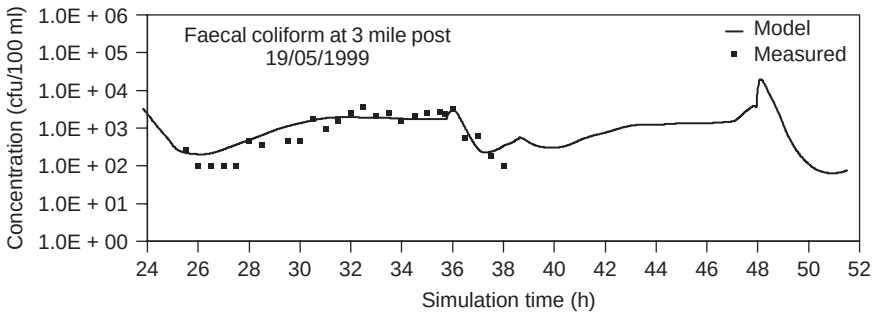

Figure 5 Comparison of predicted and measured fecal coliform concentrations at 3 milepost, on 19 May 1999

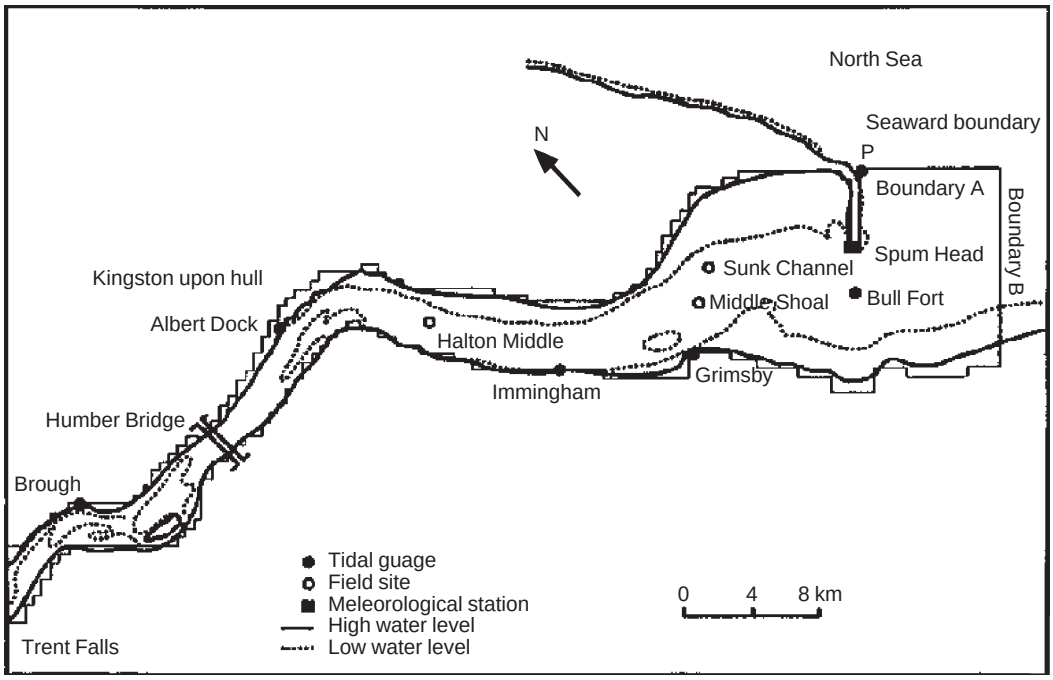

Figure 6 Plan of Humber Estuary

velocities, and various water quality constituents were also available at several sites in between the two open boundaries. Data were available for different tidal ranges at each site, with a complete tidal cycle being monitored at quarter hour intervals. For the water quality constituent inputs from the rivers Wharfe, Aire, Don, Trent, and Ouse, the boundary values used were obtained by summing up the individual components. For the loadings from the various

sewage treatment works at Hull and others, corresponding values were obtained from Yorkshire Water plc.

In general, it is always necessary to be able to check the water levels and velocity field predictions obtained from a numerical model with field data before proceeding with any analysis of the predictive results obtained, with the same being true for a laboratory model investigation. For the model studies undertaken for this basin, comparisons were first made using 3-D and 2-D models of the water level, and velocity predictions and measurements were taken at several sites along the estuary. For the 3-D model predictions, a typical set of results are shown in Figure 7, for comparison, at Halton Middle. As can be seen, the corresponding typical comparison shows good agreement between both sets of results. Predictions were made using the water quality formulations cited previously, and comparisons between measured and predicted results along the estuary are shown for salinity and dissolved oxygen in Figures 8 and 9 respectively. As can be seen from these results, the agreement between the measured and predicted concentration levels was encouraging for all of the individual constituents considered.

Finally, the sediment transport and water quality models were extended to predict trace metal contaminant levels, including the sorption and desorption between dissolved and particulate forms in the water column and the sediments. The 2-D model was applied to simulate the distribution, behavior, and characteristics of the dissolved and particulate metal phases in the Humber for different partition coefficients. These scenarios included (i) no partitioning of contaminants between the dissolved and adsorbed phases, (ii) partitioning of contaminants with no salinity dependence, and (iii) partitioning with salinity dependence.

A series of numerical experiments were undertaken to study the impact of sediment transport on the fate of heavy metals. Figure 10 shows a typical dissolved metal concentration distribution predicted by the numerical model, 496 h after an outfall spill (Gunapala, 2002). The period of spill was assumed to be 12.4 h, with the discharge, and metal concentrations being $2.75\,m^3\ s^{-1}$ and $1.32\,\mu g\,l^{-1}$,

respectively. As the sediment suspends and deposits from the bed in a cyclical manner with tidal movement, suspension and deposition occurs at high and low velocities respectively. However, because the residual velocity is towards the lower boundary, this suspension, deposition, and resuspension of the sediments results in slowly transporting the metals seawards. From Figure 11 it can be seen that heavy metals adsorbed onto the bed sediments have moved seawards, but at a much slower pace when compared with the dissolved metals.

Discussion

Details are given of two modeling studies to illustrate how integrated hydroinformatics tools can be used in the assessment of river and estuarine water quality. However, it is worthwhile noting that water quality models are now widely used in river and estuarine environmental impact assessment studies, and, in particular, three-dimensional numerical models are increasingly being refined for this purpose.

In a separate, but related, modeling study of the Humber Estuary, Naden *et al.* (2002) used three types of models to

estimate these input fluxes, including (i) a diffuse source model, (ii) a point source model, and (iii) an in-stream model. A catchment delivery model was used to predict the diffuse input of water, sediment, and selected nutrients and other contaminants. The delivery model was spatially distributed to represent the regional variation in contaminant loss. The simulated fluxes from diffuse sources were delivered into a one-dimensional river model simulating transfer and transformation processes in the river network.

Huang and Spaulding (1995) developed a three-dimensional model to predict tidal circulation and mixing processes induced by surface discharges in estuarine and coastal waters. The model consists of a hydrodynamic, pollutant water quality and turbulence modules. Model simulations were compared with analytical solutions and laboratory experiments, and good comparisons were obtained for tidal, wind, and density forcing, as well as salinity intrusion.

In recent years, more effort has also been focused on developing full 3-D hydrodynamic models that do not use the assumption of a hydrostatic pressure distribution in the vertical direction (Casulli and Stelling, 1996). These types of models have been shown to be able to simulate flows with large vertical accelerations and are particularly useful for density stratified estuarine flows.

A 3-D numerical model developed by Chau and Jiang (2002) was used to predict the hydrodynamic and pollutant transport processes in the Pearl River Estuary, China. The model is based on an orthogonal coordinate system in the horizontal direction and a sigma coordinate system in the vertical direction. The model was used to predict salinity and Chemical Oxygen Demand (COD) concentrations along the estuary.

For predicting heavy metal transport processes in riverine systems, Ji *et al.* (2002) applied coupled hydrodynamic, sediment transport, and contaminant transport models to the Blackstone River in the United States. The model was used to predict five types of metals during storm events to clarify the impact of contaminant sources and sediment resuspension processes on the river water quality.

CONCLUSIONS

As a result of the rapid advances in both computer power and numerical solution techniques, numerical models are increasingly used to predict hydrodynamic, hydrological, and water quality processes in river and estuarine waters. Details are given in this article of the governing hydrodynamic equations for flow-field predictions and the corresponding advective-diffusion equation for the transport of water quality indicators, suspend sediments, and contaminant solutes. Emphasis has been focused on the equations that are widely used for unsteady river and estuarine flow conditions. In applying the advective-diffusion equation to solute transport processes, details are given of the kinetic reactions and decay rates for FC. For simulating heavy metal fluxes, details are given of the procedures for modeling both sediment erosion and deposition, and metal adsorption and desorption processes.

In detailing the modeling of FC concentrations for the Ribble Estuary, UK, it has been shown that dynamically linked 1-D and 2-D models can provide accurate predictions of the transport processes of FCs along complex river basins. This conclusion is consistent with that obtained by Stelling and Verwey (2005) (*see* **Chapter 16, Numerical Flood Simulation, Volume 1**) on numerical flood modeling. It has also been shown that field surveys and hydrological models are both important for accurately specifying bacterial loads from boundaries, outfalls, and diffuse sources associated with the manner in which the catchment land is being used. In modeling the concentration distributions of water quality indicators and sediments in the Humber Estuary, UK, it has been shown that the model predictions generally agree well with field-measured data. In modeling the fate of heavy metals, it has been shown that the tidal environment, because of the adsorption and desorption of metals onto the sediments, and the erosion and deposition processes play a critical role in the retention time of contaminants within the estuary. Finally, some related 3-D modeling studies were briefly described to highlight that 3-D models are increasingly applied to predict river and estuarine water quality characteristics.

Acknowledgments

The research studies reported herein were mainly funded by the Natural Environment Research Council and the Engineering and Physical Sciences Research Council. The authors are grateful to North West Water Ltd (NWW) and the Environmental Agency for funding one of the projects and for the provision of data for the Ribble basin. They are also grateful to Dr Seyed Kashefipour and Ms Emma Harris and Professor David Kay and Dr Carl Stapleton (University of Wales, Aberystwyth) for their contribution to this study.

18: Shallow Water Models with Porosity for Urban Flood Modeling

VINCENT GUINOT

Hydrosciences Montpellier, Université Montpellier 2, Montpellier Cedex 5, France

The modeling of urban floods has to cope with highly variable geometries and flow parameters. Among the various types of models available, distributed, physically based models offer the best insight into the processes. However, the application of such models to refined urban flood modeling is not foreseeable in the near future. An alternative approach could be to use two-dimensional macroscopic models based on a modified version of the classical shallow–water equations, in which the fraction of the land surface occupied by the buildings is accounted for via a porosity. In such models, a cell covers part or totality of a house block. Such models provide a viable alternative to classical semidistributed models, as illustrated by a computational example on a small-sized urban area.

INTRODUCTION

With about 60% of the world total population expected to live in urban areas by the year 2030 (United Nations, 2002), urban floods may be seen as a very good illustration of the gradual shift "from nature-dominated to human-dominated" (Messerli *et al.*, 2000) environmental hazards. Hydraulic/hydrological modeling has proved its usefulness in the assessment of urban flood-related risk. However, it is hampered with a number of difficulties.

1. The meteorological forcing and its impact on urban runoff production (hence on the flood) has been observed to be highly variable in time and space (Ragab *et al.*, 2003). The typical temporal and spatial resolutions needed for efficient monitoring of urban meteorological forcing were identified (Schilling, 1991; Berne *et al.*, 2004) to be 1 to 5 min and 1 km^2 respectively. Radar-based rainfall measurement and its coupling with distributed hydrological models is currently being seen as a promising research path (Einfalt *et al.*, 2004).
2. Owing to the artificial nature of the urban geometry, the flow is highly variable in space and time and the role of inertial effects is nonnegligible, especially in the neighborhood of junctions (crossroads, roundabouts, etc.). The topographical features are identified as a major source of uncertainty in the modeling output of urban floods using distributed hydraulic models (Paquier and Mignot, 2003).
3. The variability of the flow is often related to variations in the hydraulic regime (such as transcritical flow or hydraulic jumps), which are not handled equally well by all existing modeling software packages. Besides the possible limited validity of the assumptions and equations attached to the various types of models, significant differences may be found between the outputs of models solving the same set of equations when different solution techniques are used, as shown by the results of the IMPACT benchmarking tests (see e.g. IMPACT, 2001).

Three main types of urban flood modeling approaches can be identified.

The first type of approach aims to determine a reduced set of specific flow variables (such as a peak discharge or a total flood hydrograph for a specifically delimited urban zone). The simulation results may then be interpreted in the light of the local topographical features in order to produce risk maps. Empirical models such as the unit hydrograph method (Nash, 1957) are often used because of their simplicity and rapidity. Gremillion *et al.*

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

(2000) investigated runoff production over an urbanizing catchment in Florida using a hydrograph separation method. Calabro (2001) applied a unit hydrograph method to the prediction of urban runoff over catchments in Italy and Yugoslavia. The use of reservoir models is also reported in the literature (e.g. Kang *et al.*, 1998; Cheng and Wang, 2002).

In a second approach, a conceptual distinction is made between runoff production and flood routing. In semidistributed, conceptual models the urban area is decomposed into subcatchments that contribute individually to runoff production. The runoff at the outlet of the various subcatchments is routed to the catchment outlet by means of a reservoir-based method (Boyd *et al.*, 1996; Hsieh and Wang, 1999) or a kinematic wave-based approach (Aronica and Cannarozzo, 2000). This approach has the advantage over the former in that the flow distribution (and consequently the distribution of the estimated risk) can be spatialized in greater detail. However the parameters of the routing methods used in such models do not often bear a physical meaning (Hsieh and Wang, 1999), which makes the analysis of urban development scenarios rather difficult.

The third category is that of physically based, distributed modeling. Physically based models have the advantage that the embedded flow parameters have a direct physical meaning and that scenario-based analyses thus become possible. Such models may be one-dimensional (Mark *et al.*, 2004), two-dimensional (Haider *et al.*, 2003; Turner-Gillespie *et al.*, 2003), or a combination of both (Hsu *et al.*, 2000). The use of three-dimensional Computational Fluid Dynamics (CFD) models in urban areas is also reported for the detailed investigation of the local features of the flow (Ma *et al.*, 2002). More integrated attempts focus on the coupling between the dynamics of surface water and the other compartments of the hydrological cycle (Valeo and Moin, 2000a,b; Jia *et al.*, 2001).

The strong variability of the urban geometry has a direct consequence on the variability of the flow patterns. In most cases, the flow characteristics cannot be considered to be uniform and the classical one-dimensional approach is not valid any more and the usual assumptions of equality of levels or heads at junctions (Cunge *et al.*, 1980) does not hold. Conversely, the refined simulation of the flow patterns in urban areas (e.g. using two-dimensional models) require an amount of data and a computational power that is hardly compatible with the constraints associated with classical engineering studies. This is illustrated by an example of a refined, two-dimensional urban flood simulation over a 290 m × 280 m area in the center of Nice, France (Gourbesville *et al.*, 2004). The cell size of the Digital Elevation Model (DEM) is 1 m × 1 m (Figure 1). The effect of the injection of a hypothetical hydrograph with a peak value 100 m^3 s^{-1} along a main street is simulated using the Shallow Water 2D (SW2D) computational code (Guinot, 2004) that solves the two-dimensional shallow-water equations using Godunov-type algorithms.

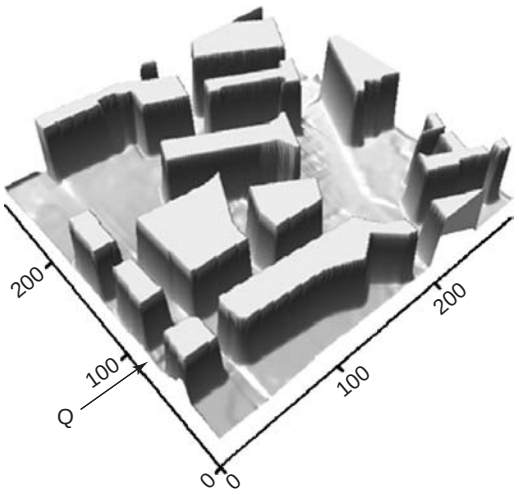

Figure 1 Perspective view of the DEM used for the refined simulation; distances in meters (By courtesy of Philippe Gourbesville, University of Nice, France)

Figure 2 shows the water depths computed at intervals of 60 s. The resolution of the DEM and the refinement of the computational grid allow the flow patterns to be investigated in detail (note the multiple front reflection across the street in the N-E part of the model at $t =$ 2 min). However the typical ratio of CPU to simulated time for the 80 000 cell model is about 6 on a 3.2 GHz Pentium 4 processor with 1 GB RAM. Clearly, the refined simulation of flow transients over entire urban areas cannot be foreseen to become a daily engineering practice in the near future.

Shallow Water Models with Porosity

A reasonable alternative to refined two-dimensional modeling consists in using large-scale, or so-called macroscopic flow models, in which a computational cell covers part or the totality of a house block. Such models may be used to represent the broad characteristics of the flow and its distribution between the various districts of a given urban area. The computational results can be used as boundary conditions for smaller-scale, nested models with a more refined grid, in which all the details of the urban geometry are represented. The formulation of large-scale urban hydrodynamics differs from the classical free-surface flow formulation in that part of the land surface is occupied by buildings or structures and is therefore not available to the flow. This is accounted for by introducing a so-called porosity. The shallow-water equations with porosity

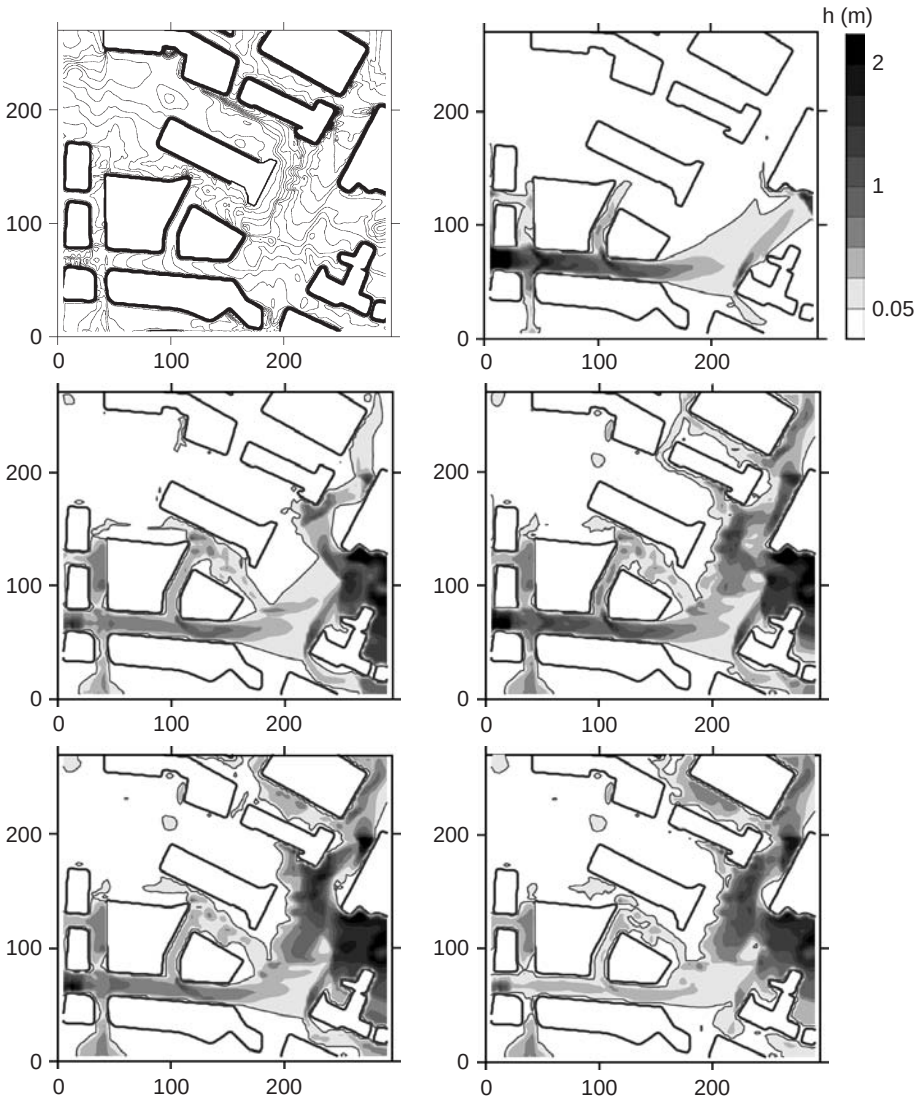

Figure 2 Model topography and water depths simulated using the SW2D computational code. Time interval between the plots: 60 s. Topographical contour line spacing: 0.25 m

were introduced in the mid-1990s (Defina *et al.*, 1994; Hervouet *et al.*, 2000). They can be written in conservation form as

$$\frac{\partial \mathbf{U}}{\partial t} + \frac{\partial \mathbf{F}}{\partial x} + \frac{\partial \mathbf{G}}{\partial y} = \mathbf{S} \tag{1}$$

where the conserved vector variable **U**, the vector fluxes **F** and **G** and the source term **S** are defined as

$$\mathbf{U} = \begin{bmatrix} \phi h \\ \phi uh \\ \phi vh \end{bmatrix}, \qquad \mathbf{F} = \begin{bmatrix} \phi uh \\ (u^2 h + gh^2/2)\phi \\ \phi uvh \end{bmatrix},$$

$$\mathbf{G} = \begin{bmatrix} \phi vh \\ \phi uvh \\ (v^2 h + gh^2/2)\phi \end{bmatrix}, \quad \mathbf{S} = \begin{bmatrix} 0 \\ (S_{0,x} - S_{f,x})\phi gh \\ (S_{0,y} - S_{f,y})\phi gh \end{bmatrix} \tag{2}$$

where g is the gravitational acceleration, h is the water depth, u and v are the x- and y-velocities respectively, $S_{0,x}$ and $S_{0,y}$ are the source terms arising from the bottom slope and the porosity gradient in the x- and y-directions respectively, $S_{f,x}$ and $S_{f,y}$ are the friction slopes in the x- and y-directions respectively, and ϕ is the porosity. The porosity is defined as

$$\phi = \frac{V}{Ah} \tag{3}$$

where A is the total plan view area and V is the volume actually occupied by the water. Note that Ah is the total volume of water in the absence of structures or objects on the ground surface. The source terms $S_{0,x}$ and $S_{0,y}$ are

defined as

$$\left.\begin{aligned} S_{0,x} &= -\phi g h \frac{\partial z_b}{\partial x} + g\frac{h^2}{2}\frac{\partial \phi}{\partial x} \\ S_{0,y} &= -\phi g h \frac{\partial z_b}{\partial y} + g\frac{h^2}{2}\frac{\partial \phi}{\partial y} \end{aligned}\right\} \quad (4)$$

Equation (1) can also be written in characteristic form as

$$\frac{\partial \mathbf{U}}{\partial t} + \mathbf{A}\frac{\partial \mathbf{U}}{\partial x} + \mathbf{B}\frac{\partial \mathbf{U}}{\partial y} = \mathbf{S} \quad (5)$$

where $\mathbf{A}$ and $\mathbf{B}$ are the Jacobian matrices of $\mathbf{F}$ and $\mathbf{G}$ respectively with respect to $\mathbf{U}$. Equation (2) leads to the following expressions for $\mathbf{A}$ and $\mathbf{B}$:

$$\mathbf{A} = \begin{bmatrix} 0 & 1 & 0 \\ c^2 - u^2 & 2u & 0 \\ -uv & v & u \end{bmatrix}, \mathbf{B} = \begin{bmatrix} 0 & 1 & 0 \\ -uv & v & u \\ c^2 - v^2 & 0 & 2v \end{bmatrix} \quad (6)$$

These are the characteristic matrices for the classical, two-dimensional shallow-water equations (see e.g. Daubert and Graffe, 1967; Katopodes and Strelkoff, 1979; Gerritsen, 1982; Guinot, 2003a,b for the derivation of the equations and analysis of the solution properties). The wave celerities and the stability properties of explicit discretizations of the conservation form (1) are identical to those of the classical shallow-water equations. The problems induced by the discretization of (1) mainly arise from the discretization of the fluxes and source terms in the presence of strong variations in the bottom level and the porosity. These parameters can be expected to vary strongly in real-world applications. Inadequate discretization of the source terms may lead to the instability of the numerical solution. The most common available options for the discretization of source terms arising from bottom slope are the so-called well-balanced approach and associated techniques (Greenberg and Le Roux, 1997; Alcrudo and Benkhaldoun, 2001), the quasi-steady wave propagation algorithm (LeVeque, 1998) and source term upwinding (Bermudez and Vasquez-Cendon, 1994).

In the proposed approach, equation (1) is discretized using the finite-volume formalism (Figure 3). The computational domain is discretized into cells, over which the average value of the conserved variable $\mathbf{U}$ is known. Integrating equation (1) over a cell between two time levels n and $n+1$ yields the following formula

$$\left.\begin{aligned} \mathbf{U}_i^{n+1,h} &= \mathbf{U}_i^n - \frac{\Delta t}{A_i}\sum_{j\in \mathrm{N}(i)} (\mathbf{F}_{i,j}^{n+\frac{1}{2}} n_{i,j}^{(x)} + \mathbf{G}_{i,j}^{n+\frac{1}{2}} n_{i,j}^{(y)}) \\ &\qquad w_{i,j} + {\mathbf{S}_{0_i}}^{n+\frac{1}{2}} \Delta t \\ \mathbf{U}_i^{n+1} &= \mathbf{S}_f(\mathbf{U}_i^{n+1,h}) \end{aligned}\right\} \quad (7)$$

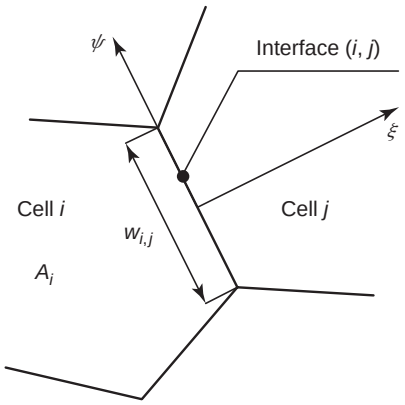

Figure 3 Definition sketch of the geometry

where A_i is the area of the cell i, $\mathrm{N}(i)$ is the set of neighbor cells of the cell i, $n_{i,j}^{(x)}$ and $n_{i,j}^{(y)}$ are the x- and y-components of the normal unit vector between the cells i and j (oriented from i to j), $w_{i,j}$ is the width of the interface (i, j) between the cells i and j, $\mathbf{U}_i^n$ is the average value of $\mathbf{U}$ over the cell i at the time level n, $\mathbf{F}_{i,j}^{n+1/2}$ and $\mathbf{G}_{i,j}^{n+1/2}$ are the average values of $\mathbf{F}$ and $\mathbf{G}$ respectively between the time levels n and $n+1$ over the interface (i, j), ${\mathbf{S}_{0_i}}^{n+1/2}$ and ${\mathbf{S}_{f_i}}^{n+1/2}$ are the average values of the source terms over the cell i between the time-steps n and $n+1$, and Δt is the computational time-step. The superscript h denotes the solution obtained at the time level $n+1$ after the solution of the hyperbolic terms only. Computing the values of $\mathbf{F}_{i,j}^{n+1/2}$ and $\mathbf{G}_{i,j}^{n+1/2}$ at all the cell interfaces allows $\mathbf{U}_i^{n+1,h}$ to be computed for all the cells. In the present approach, the fluxes and source terms are computed explicitly from the average values $\mathbf{U}_i^n$ at the time level n. Equation (6) is rewritten in the local coordinate system as

$$\frac{\partial \mathbf{U}}{\partial t} + \frac{\partial \mathbf{F}}{\partial \xi} = \mathbf{S}_0 \quad (8)$$

where ξ denotes the coordinate in the normal direction to the interface. The flux $\mathbf{F}$ is computed using a one-dimensional Riemann solver, namely, a procedure that solves the following initial-value problem, also called *Riemann problem*

$$\mathbf{U}(\eta, t=0) = \begin{cases} \mathbf{U}_\mathrm{L} & \text{for } \xi < 0 \\ \mathbf{U}_\mathrm{R} & \text{for } \xi > 0 \end{cases} \quad (9)$$

where $\mathbf{U}_\mathrm{L}$ and $\mathbf{U}_\mathrm{R}$ are the (constant, non necessarily equal) left and right states of the Riemann problem. The solution algorithm consists of the following steps:

1. For each interface (i, j), convert the variable $\mathbf{U}$ to the local coordinate system (ξ, ψ) formed by the normal and tangent unit vectors to the interface. Define

the Riemann problem in the direction normal to the interface (i, j).
2. Solve the Riemann problem using an exact or approximate Riemann solver such as Roe's solver (Roe, 1981), the HLLC solver (Toro *et al.*, 1994) or any approximate state solver (Glaister, 1988; Guinot, 2003a). This yields the constant value $\mathbf{F}_{i,j}^{n+1/2}$ at the location $\xi = 0$.
3. Carry out the mass balance on the cell i according to equation (6).
4. Add the effect of the source term in the ξ-direction using the source term upwinding approach (Bermudez and Vasquez-Cendon, 1994).
5. Use the solution obtained from the previous four steps as a starting point to incorporate the effects of friction.

The robustness of the porosity approach is illustrated by simulating the effects of a flash flood wave propagating into an initially dry plain, in the middle of which the extension of an existing urban area is planned. The site chosen for this application is the urban area of Saint Mathieu (South of France). The area under study is rectangular, with dimensions 2700 m × 2200 m (Figure 4). The ground levels range from 88 m to 120 m. The city is currently located on the right bank of the valley. The shallow-water model with porosity is used to simulate the propagation of a flash flood wave into the valley. Two simulations are presented hereafter. In the first simulation the valley is free from any buildings. In the second simulation the urban zone is extended into the valley, as indicated by the thick dashed line in Figure 5. The urban area is characterized by a porosity of 25%. The same input hydrograph is used in both simulations. The peak discharge is equal to $100\,m^3\ s^{-1}$. The DEM has a grid size of 25 m × 25 m. The effects of the urbanized area on the floodplain dynamics are clearly visible in Figure 5. The reduction in the cross-sectional area and in storage capacity results in a head loss that triggers a rise in the water levels upstream of the urban area and contributed to the retardation of the flood (see the maps at $t = 600$ s and $t = 1200$ s). As a result, the stream is partly diverted to the west and flows across a saddle to fill the western part of the area.

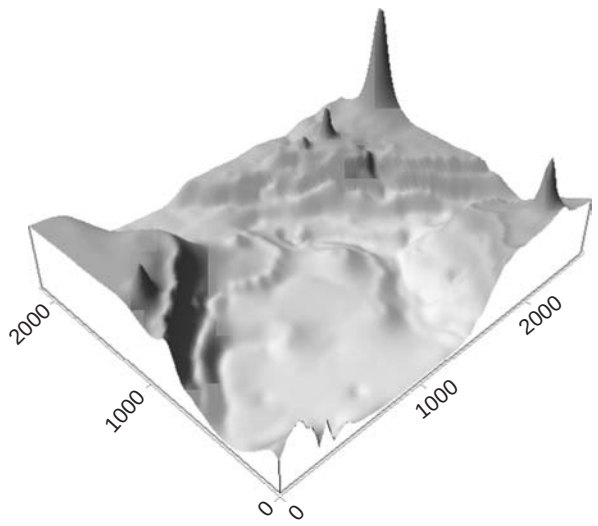

Figure 4 Perspective view of the DEM for the Saint Mathieu application. Ratio of vertical to horizontal scale 1 : 10

Table 1 Characteristics of the refined and large-scale simulations

	Refined model (Nice)	Large-scale model (Saint Mathieu)
Modeled area	7.6 ha	59 000 ha
Number of cells	75 600	9504
DEM grid size	1 m	25 m
Ratio CPU/real-time per unit area	8.5×10^{-1} ha^{-1}	1.9×10^{-7} ha^{-1}

The CPU time needed by the SW2D computational code to simulate the propagation of the 1 h hydrograph is approximately 40 s for both configurations. Note that the 3.2 GHz processor with 1.0 GB RAM used for these two simulations is the same as for the refined simulation in the center of Nice. Table 1 summarizes the characteristics of both models. Obviously, the geometries of the two test cases are not comparable. However, the differences between the CPU times show that the porosity approach is a viable alternative for the investigation of the flow patterns over urbanized areas.

CONCLUSIONS

Conceptual and semidistributed conceptual models probably represent the most widely used approaches in urban watershed modeling. Such models have the advantage that they do not require as much data as do distributed, physically based models. They are also simpler to operate and easier to tune. However, the parameters of such models do not bear the physical meaning that is attached to the more refined, and more computationally demanding, physically based approach. Therefore, conceptual and semidistributed models can hardly be operated in view of scenario-based analyses. Shallow water models with porosity appear as a viable compromise between refined CFD approaches and conceptual models for the investigation of surface water transients in urban areas. The outputs from such models may be used as inputs for local, refined physically based models in specific areas.

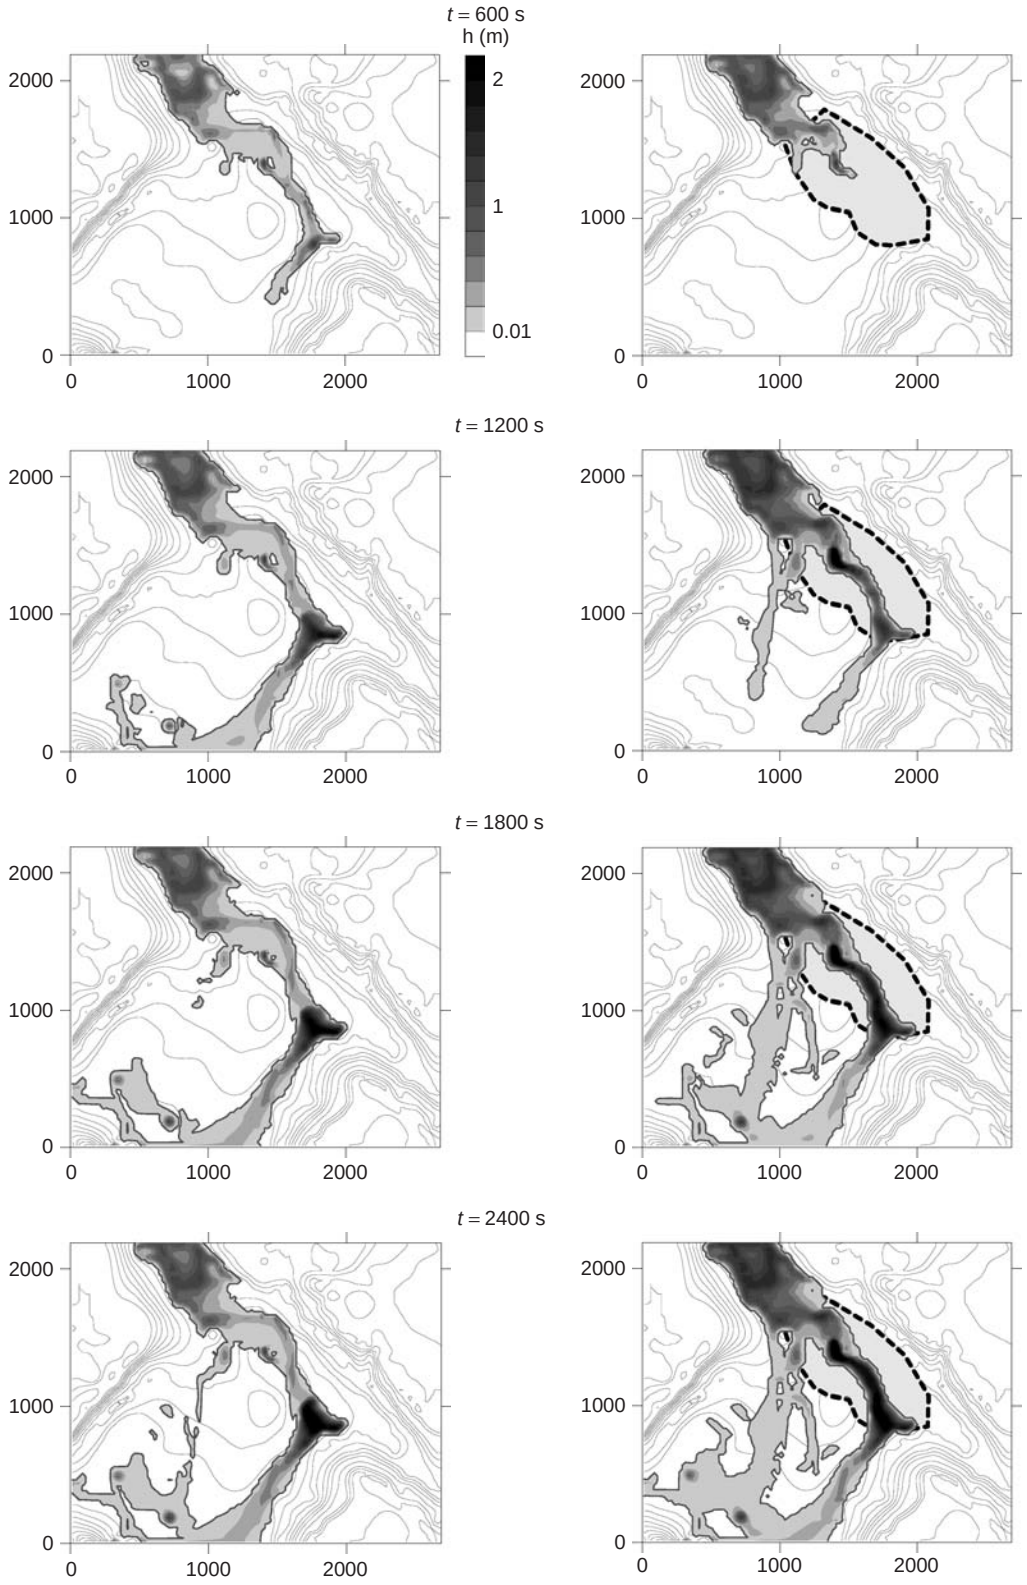

Figure 5 Influence of the urbanization of the plain of Saint Mathieu (south of France). Water depths simulated at various times using the shallow water with porosity without (a) and with (b) the hypothetical urbanized area. The planned urban extension is indicated by the thick dashed line in the maps on the right-hand side. Topographical contour line spacing 2.5 m; distances in meters

Acknowledgments

The DEM used for the refined flow simulation in Nice was kindly provided by Dr Philippe Gourbesville from the University of Nice-Sophia Antipolis (France).

19: Data-driven Modeling and Computational Intelligence Methods in Hydrology

DIMITRI P SOLOMATINE

UNESCO-IHE Institute for Water Education, Delft, The Netherlands

Along with the physically based (process) models based on mathematical descriptions of hydrological processes, the so-called data-driven models (DDM) are becoming popular. They are based on the use of methods of computational intelligence and machine learning and assume the presence of considerable amount of data describing the modeled phenomenon. The article covers various aspects of DDM, including the data preparation and a brief overview of the used techniques – neural networks, regression and model trees, instance-based learning, and nonlinear dynamics. A number of references to the successful application of data-driven methods are provided along with the links to the relevant web sites and software packages. An example where several data-driven methods were used in a hydrologic forecasting problem is provided.

INTRODUCTION

In the field of hydrology a range of modeling techniques can be applied. A *model* can be defined as a simplified representation of reality with the objective of explanation or prediction. Modeling includes studying the system, formulating its behavior, collecting and preparing data, building the model, testing it, using it, interpreting the results, and, possibly, iterating the entire procedure. In hydrology and hydraulics, the following types of models are commonly distinguished:

1. a *physical* or *scale* model (since it is usually smaller than the real system) built from material components or objects; in particular, in hydraulics these types of models have been well established;
2. a *mathematical* model based on the description of its behavior (often based on first-order principles from physics) of a phenomenon or system, referred to later as *process model* (also called *knowledge-driven, simulation, behavioral* or *physically based* model). In hydrology, the following simulation models are typically distinguished:
   (a) lumped conceptual models that operate with different but mutually interrelated storages representing physical elements in a catchment;
   (b) distributed physically based models that describe the natural system using the basic mathematical representations of the flows of mass, momentum, and various forms of energy;
3. an *empirical* model that involves mathematical equations that have been assessed not from the physical process in the catchment but from analysis of concurrent input and output time series. Typical examples here are the unit hydrograph method and various statistical models – for example, linear regression, multilinear, ARIMA, and so on. During the last decade, the area of empirical modeling received an important boost due to developments in the area of computational intelligence (CI), particularly, machine learning (ML). It can be said that it has now entered a new phase and deserves a special name – *data-driven modeling* (DDM).

DDM is based on the analysis of all the data characterizing the system under study. A model can then be defined on the basis of the connections between the system state variables (input, internal, and output variables) with only a limited number of assumptions about the "physical" behavior of the system. The methods used nowadays can go much further than the ones used in conventional empirical modeling: they allow for solving numerical prediction problems, reconstructing highly nonlinear functions, performing classification, grouping data, and building rule-based systems.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

CONTRIBUTORS TO DATA-DRIVEN MODELING

The following areas contributing to DDM can be mentioned: artificial intelligence (AI), data mining (DM), knowledge discovery in databases (KDD), CI, ML, intelligent data analysis (IDA), soft computing (SC), and pattern recognition – all these areas overlap, with often similar focus and application areas. Terminologies and research areas sometimes compete to name the same interdisciplinary area. It is difficult, if not impossible, to provide a formal definition of disparate areas with their own established individualities such as fuzzy logic, neural networks, pattern recognition, evolutionary computation, ML, Bayesian reasoning, and so on. It is really difficult to find clear-cut differences between them. Still certain definitions can be formulated:

- CI incorporates three large areas: neural networks, fuzzy systems, and evolutionary computing. CI tends to incorporate more and more areas that are also considered in AI (except perhaps symbolic methods) and ML.
- SC is an area that is very close to CI, but with a special focus on fuzzy rule-based systems (FRBS) induced from data.
- ML is an area of computer science, which was for a long time considered a subarea of AI and concentrates on the theoretical foundations used by CI and SC. Classification (pattern recognition) problems are addressed by ML more often than regression (numerical prediction) problems.
- DM and KDD are focused often at very large databases and are associated with applications in banking, financial services, and customer resources management. DM is seen as a part of a wider KDD. Methods used are mainly from statistics and ML.
- IDA is a relatively new term and seems to denote studies concentrating more on the data analysis in medicine and research. Methods used are also from statistics and ML.

In this connection we see DDM as an approach to modeling that focuses on using the CI (particularly ML) methods in building models (often of natural systems) that would complement or replace the "knowledge-driven" models describing behavior of physical systems. DDM uses methods developed in the fields mentioned earlier and tunes them to particular application areas. Examples of the most popular methods used in DDM of hydrological systems are: statistical methods, artificial neural networks (ANN) and FRBS. Among popular CI methods are also genetic algorithms (GA), evolutionary algorithms, and other global optimization algorithms; they are not, however, modeling paradigms or function approximation methods but constitute an approach to optimization that can be used in model calibration or model structure optimization. For more on evolutionary methods, *see* **Chapter 22, Evolutionary Computing in Hydrological Sciences, Volume 1**.

MACHINE LEARNING AS THE BASIS FOR DDM

One could see ML as the main source of method for DDM. An ML method (Figure 1) is an algorithm that estimates so-far-unknown mappings (or dependencies) between a system's inputs and its outputs from the available data (Mitchell, 1997). By data we understand known samples that are combinations of inputs and corresponding outputs. As such a dependency (*viz.* mapping, or "model") is discovered (induced), which can be used to predict (or effectively deduce) the future system's outputs from the known input values.

By data we usually understand a set K of examples (or instances) represented by tuples $\langle \mathbf{x}_k, \mathbf{y}_k \rangle$, where $k = 1, \ldots, K$, vector $\mathbf{x}_k = \{x_1, \ldots, x_n\}_k$, vector $\mathbf{y}_k = \{y_1, \ldots, y_m\}_k$, $n =$ number of inputs, $m =$ number of outputs. The process of building a function (or "mapping", or "model") $y = f(\mathbf{x})$ is called *training*. Very often only one output is considered, so $m = 1$ and the model to build takes the following form: $\mathbf{y} = f(\mathbf{x})$.

In statistics the following four types of data are considered: nominal (e.g. color, symbolic labels); ordinal (e.g. flood severity expressed as low, medium, or high); interval (e.g. temperature), and ratio (real-valued numeric, e.g. water level or flow). In ML there is a tendency to speak only of two data types: nominal (that includes also ordinal and sometimes integer numeric), and real-valued numeric.

There are four main styles of learning considered:

- classification – on the basis of classified examples, a way of assigning a class label to the unseen examples is to be found. In this case the output variable y takes nominal values;
- association – association between all variables characterizing the system is to be identified (typically based on finding combinations of values that are most frequent);

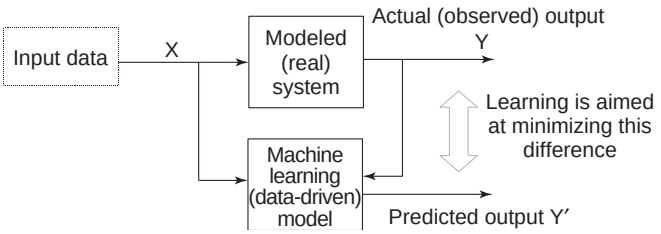

Figure 1 Learning in data-driven modeling. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

- numeric prediction (regression) – outcome is not a class, but a numeric real value or a vector ($\mathbf{y}_k \in \Re^m$). In engineering applications, inputs are often numeric as well, so $\mathbf{x}_k \in \Re^n$;
- clustering – groups of objects (examples) that are "close" in space of input variables are to be identified. In this case there is no explicit output variable.

Many numerical prediction methods can also be used for classification but the data should be rearranged. The number of outputs is made equal to the number of possible class labels, the nominal values of the output (class labels) in the training data should be replaced by a vector of real values with zeros for all outputs except the one that has the number corresponding to the original class label. When the model is trained, then it can predict the class label of a new example: the number of the output with the maximum value is taken as the class label number.

THE PROCESS OF DATA-DRIVEN MODELING

The following list of steps in model building is often distinguished (e.g. Pyle, 1999):

1. Select a clearly defined problem that the model will help to resolve.
2. Specify the type of solution to the problem.
3. Define how the solution delivered is going to be used in practice.
4. Learn the problem, collect the domain knowledge, and understand it. Clearly define assumptions, discuss them with the domain knowledge experts.
5. Let the problem drive the selection of modeling techniques.
6. Make the model as simple as possible, but no simpler. This rule is formulated sometimes in different ways – like KISS, for example ("Keep It Sufficiently Simple", or "Keep It Simple, Stupid!"). More generally, this idea is widely known as the *Occam's Razor principle* – formulated by William of Occam in 1320 in the following form: "shave all unneeded philosophy off the explanation".
7. Build (train) the model.
8. Refine the model iteratively (try different options until the model seems as good as it is going to get).
9. Test the model and evaluate the results.
10. Explore instabilities in the model (critical areas where small changes in inputs lead to large changes in output).
11. Define uncertainties in the model (critical areas and ranges in the data set where the model produces low confidence predictions).
12. Put the model into operation. Review it, if necessary, when experience is obtained.

TRAINING, CROSS-VALIDATION, VERIFICATION (TESTING)

In reality, the process of modeling is not linear but continuous with feedback loops. For example, the lack of particular data may lead to a change in the modeling method selected. Minimizing the difference between observed and predicted outputs actually has a double meaning. One should distinguish:

- minimizing the error during model training (calibration); and
- minimizing the error during model operation.

A model that has been trained may perform well (with low error) on the training data set, but when new instances, previously unseen by the model, are fed into the model, the error may be high. This means that it is necessary to have a separate data set (called *cross-validation* set), which does not contain instances from the training set and is used to judge the model error. A training set is sometimes called *in-sample data set.* Data that do not contain instances from the training set is often called *out-of-sample data set* (Figure 2).

As the model gradually improves as a result of the training process, the model error on the training (in-sample) set continuously decreases. However, the error on the out-of-sample set first decreases, but then starts to increase. This effect of "being trained too long" results in *overfitting* – the model tries to follow all data points (possibly noisy) too closely "forgetting" actually about the underlying trend in the data. It is said that the error on the out-of-sample set presents the *generalization accuracy* of a model – the accuracy with which it fits examples beyond the training data.

The presented example prompts for the necessity of using a cross-validation data set along with the training set. Training actually should stop when the error on cross-validation data set starts to increase – this is an indicator of the start of overfitting.

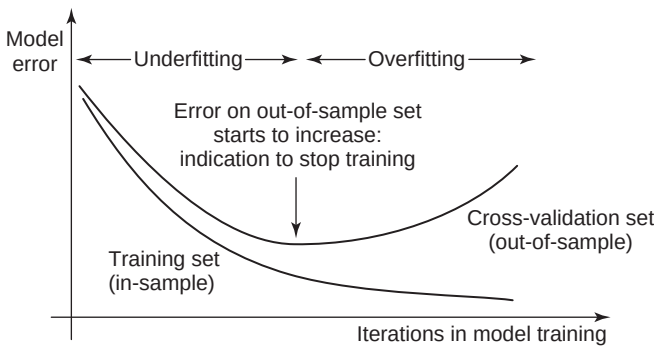

Figure 2 Use of cross-validation (out-of-sample testing) during training

When a model is put into operation, it will confront input instances that it never encountered before. In order to test its performance before the model is put into operation, it has to be verified (by some form of error measurement). For this purpose, yet another data set is used, called *verification (test) data set*. It allows to see how the model would perform if new data is fed into it.

Construction of these three data sets on the basis of available data, should follow the following principle: the three sets should be statistically similar, that is, they should have at least similar ranges and variability. This can be achieved by the careful selection of examples for each data set to ensure such statistical similarity, or for example, by random sampling of data from the whole data set.

The following summarizes the use of these three data sets: the training set is used to train the model; the cross-validation set is used to determine the moment of stopping the training process and possibly additional tuning of model parameters; the verification (test) set is used to measure the error of the trained model before the model is put into operation.

MODELS DRIVEN BY NOMINAL DATA: CLUSTERING AND CLASSIFICATION

Classification is often treated as attributing class labels to data points $\{x_k\} \in R^n$. Classes must be such that points in a class are close to each other in some sense, and classes are far from each other. *Clustering* is finding groups (subsets) of data without assigning them to particular classes. These types of models are in essence a mapping from the space of input data to classes or groups.

Popular methods for clustering are: partition-based clustering based on Euclidean distance, for example, k-means; fuzzy c-means; self-organizing feature maps (SOFM) also called *Kohonen networks* (Duda *et al.*, 2001). For classification, the following methods can be mentioned: k-nearest neighbors method, Bayesian classification, Decision trees (DTs) classification (Quinlan, 1992; Witten and Frank, 2000), support vector machines (SVM) classification (Vapnik, 1998), and ANN, (*see also* **Chapter 20, Artificial Neural Network Concepts in Hydrology, Volume 1**). These last two methods can be used both for classification and for prediction.

Examples of Applications

In hydrology, clustering and classification are used much less frequently than prediction algorithms. However, a number of successful examples of their use were reported:

- Frapporti *et al.* (1993) used the method of fuzzy c-means clustering in the problem of classifying shallow Dutch groundwater sites into homogeneous groups.
- Hall and Minns (1999) used SOFM for classifying catchments into groups based on their characteristics, and then applying ANN to model the regional flood frequency.
- Hannah *et al.* (2000) used clustering for finding groups of hydrographs on the basis of their shape and magnitude; clusters are then used for classification by experts.
- Harris *et al.* (2000) applied clustering to identify the classes of river regimes.
- Velickov *et al.* (2000) used SOFM (Kohonen networks) as clustering methods, and SVM as classification method in aerial photograph interpretation with the purpose of subsequent construction of flood severity maps.
- Solomatine and Maskey (2005) used DTs and k-NN in the classification of river flow levels according to their severity in a flood forecasting problem in Nepal.

In this last problem a medium-sized foothill-fed river in the Bagmati basin was considered, having an area of about $3700\,\mathrm{km}^2$. Time series data of rainfall at three stations within the basin with daily sampling over eight years (1988 to 1995) were collected. Daily flows were recorded at one station, so this precluded modeling the routing. Weight factors were calculated using the Thiessen polygon. The daily evapotranspiration was computed using the modified Penman method recommended by FAO. A dependency analysis of input and output variables was done by visual inspection and the interdependencies between variables and the lags τ were established using correlation and average mutual information analyses. The classification model predicting the flow class one day ahead on the basis of five variables was set to be of the form

$$Q_{t+1} = f(RE_{t-2}, RE_{t-1}, RE_t, Q_{t-1}, Q_t)$$

where RE_{t-k} and Q_{t-k}, are the lagged effective rainfall and runoff respectively.

Eight years of data sets (2919 records) were split as follows: the first 919 points (3 January 1988 to 7 July 1990) were used as testing data set, and the remaining points (8 July 1990 to 30 December 1995) as training data set. Each instance was represented by a vector in a five-dimensional space (since there are five inputs) accompanied by the associated value of its output variable.

The forecasting problem was formulated in two ways: as a classification problem and as a prediction problem. For classification, the runoff data was discretized on the basis of the statistical properties and the following five classes were distinguished: "very low" (flow $<50\,\mathrm{m}^3\,\mathrm{s}^{-1}$), "low" (flow $50-300\,\mathrm{m}^3\,\mathrm{s}^{-1}$), "medium" (flow $300-750\,\mathrm{m}^3\,\mathrm{s}^{-1}$), "medium high" (flow $750-1350\,\mathrm{m}^3\,\mathrm{s}^{-1}$), and "high" (flow $>1350\,\mathrm{m}^3\,\mathrm{s}^{-1}$). Decision tree (DT) and k-nearest neighbor classifiers were trained – their errors in testing error were found to be 89% and 96% respectively.

MODELS DRIVEN BY REAL-VALUED DATA: SIMPLE FUNCTIONS COMBINED

Most hydrologic modeling problems are formulated with the view of real-valued data. The problem of prediction of real-valued variables is also called a *regression problem*. Since ML aims at finding a function that would best approximate some given function, it can also be seen as a problem of function-fitting, and this prompts for the use of the corresponding methods already available like linear regression, polynomial functions like splines or orthogonal polynomial functions, for example, Chebyshev polynomials. Current trend in DDM, however, is in combining many simple functions. It has been mathematically proven that adding up simple functions allows for a universal approximation of more complex functions (Kolmogorov, 1957).

Radial basis functions (**RBF**) could be seen as a sensible alternative to the use of complex polynomials. The idea is to approximate some function $y = f(x)$ by a superposition of J functions $F(x, \sigma)$, where σ is a parameter characterizing the span, or "width" of the function in the input space (Figure 3).

Functions F are typically "bell-shaped" (e.g. a Gaussian function is often used) so that they are defined in the proximity to some "representative" locations (centers) w_j in n-dimensional input space, $j = 1, \ldots, J$ and their values are close to zero far from these centers. Then the approximation becomes

$$f(x) = \sum_{j=1}^{J} b_j \exp(-\delta_j^2/\sigma_j^2)$$

where δ is the distance from point x to center w_j understood in Euclidean sense:

$$\delta_j = \sqrt{\sum_{i=1}^{n}(x_i - w_{ij})^2}$$

Finding the positions of centers w_j and the parameter σ of the functions $f(x, \sigma)$ is the aim of learning and can be done by building a *RBF neural network*; its training allows to identify these unknown parameters. Ideologically, RBF networks are close to the modular models considered in the following text.

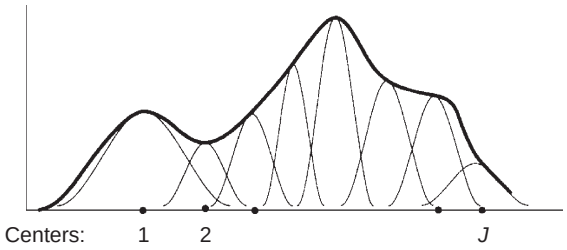

Figure 3 Using a number of radial basis functions (RBFs) as an approximation (an example for one input variable)

Multilayer perceptron (**MLP**) is a typical example of an ANN. It consists of several layers of connected nodes; each node calculates the weighted sum of its inputs and subjects the result to a nonlinear transformation (sigmoid of hyperbolic tangent function) which then serves as the input for all nodes in the next layer. Typically there are two layers. The weights are found by training, that is, by solving the problem of minimizing the model error in the space of weights (Haykin, 1999).

In the 1970–1980s the so-called backpropagation method for efficient training of MLPs was found and perfected, and this made this type of ANN the most popular ML tool of today. Various types of ANNs are widely used for prediction and classification.

A typical MLP network is presented in Figure 4.

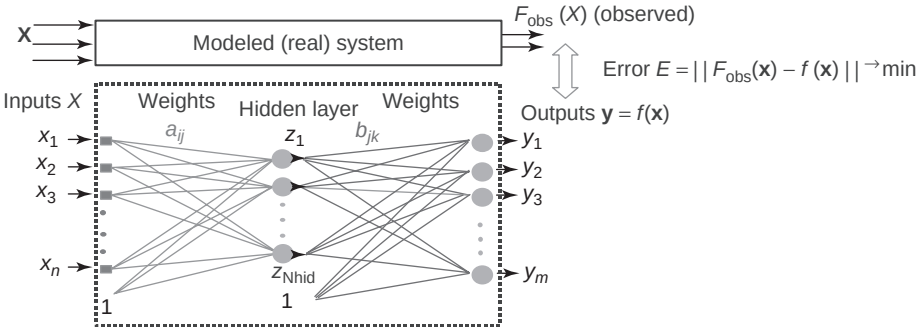

Figure 4 Structure of a multilayer perceptron (MLP) network. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Intermediate ("hidden") nodes calculate the weighted sum of the inputs and then perform a nonlinear transformation F of the form:

$$z_j = F\left(a_{oj} + \sum_{i=1}^{N_{inp}} a_{ij} x_i\right)$$
$$j = 1, \ldots, N_{hid}$$

The output nodes perform a similar transformation but use different weights:

$$y_k = F\left(b_{ok} + \sum_{i=1}^{N_{hid}} b_{jk} y_j\right)$$
$$k = 1, \ldots, m$$

The function F enables the presence of nonlinearity in the model and "squashes" the output signal. Often the so-called logistic function (Figure 5) is used:

$$F(u) = \frac{1}{1 + e^{-u}}$$

Training of MLP is in fact an optimization procedure aimed at finding such weight vectors $\boldsymbol{a}$ and $\boldsymbol{b}$ that minimize error E.

Examples of Applications

The use of ANNs is known to have several dozens of successful applications in hydrology and related problems:

- modeling rainfall-runoff processes: Hsu *et al.* (1995), Minns and Hall (1996), Dawson and Wilby (1998), Dibike *et al.* (1999), Abrahart and See (2000), Govindaraju and Ramachandra Rao (2001);
- replicating the behavior of hydrodynamic/hydrological models of a river basin where ANNs are used in model-based optimal control of a reservoir (Solomatine and Torres, 1996);
- building ANN-based intelligent controller for real-time control of water levels in a polder (Lobbrecht and Solomatine, 1999); and
- modeling stage-discharge relationships (Sudheer and Jain, 2003; Bhattacharya and Solomatine, 2005).

For more on the use of ANNs in hydrology, *see also* **Chapter 20, Artificial Neural Network Concepts in Hydrology, Volume 1**.

COMBINING MODELS: LOCAL MODELS, BOOSTING, COMMITTEE MACHINES, AND TREES

Hydrologic phenomena are multistationary and are composed of a number of processes, and their accurate modeling sometimes is not possible by building of one single ("global") model. In this case, the training set can be split into a number of subsets (possibly, statistically sampled) and separate models are trained on these subsets. It can also be said that the input space can be divided into a number of subspaces or regions for each of which a separate specialized model is built. These models are called *local*, or *expert models*, or *experts* (not to confuse with the human domain experts). Such modular model is often called a *committee machine* (CM) (Haykin, 1999).

When building, training and using a CM, two decisions have to be made: (A) which module should receive which training pattern (splitting problem); and (B) how the outputs of the modules should be combined to form the output of the final output of the system (combining problem). Accordingly, two decision units have to be built, or one unit performing both functions. Such a unit is called an *integrating unit*, or a *gating network* (a reference to a neural network often used for this purpose). It should be delivered to the user of the final model, along with the trained modules. Note that the functioning of units A and B could be different during training and operation. Figure 6 illustrates the principle.

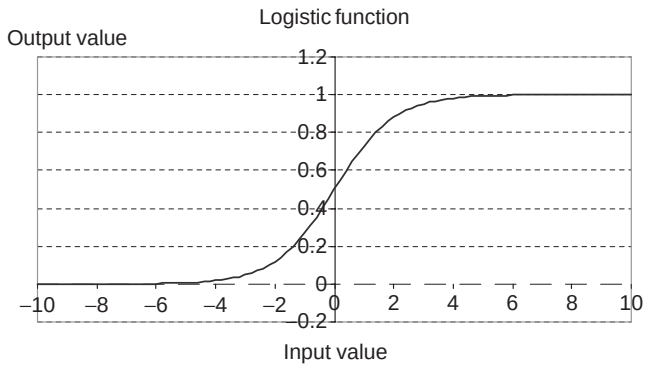

Figure 5 Logistic function A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

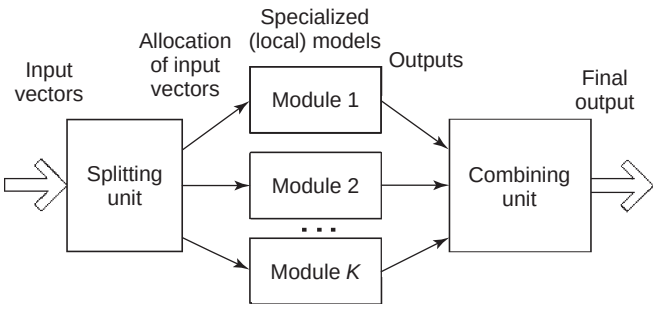

Figure 6 Splitting inputs, local models and combining outputs

Soft Splitting of the Training Set (Input Space)

The group of the statistically driven approaches with "soft" splits of input space are represented by *mixtures of experts* (Jordan and Jacobs, 1995), *bagging* (Breiman, 1996), and *boosting* (Freund and Schapire, 1997). Here we will briefly introduce boosting only.

Boosting (its advanced version, *AdaBoost*, is described by Freund and Schapire, 1997) can be seen as a method of building a series of modular models using soft splits. It was designed to improve the performance of the so-called *weak classifiers*, that is, the ones that are just marginally better than guessing; however, it has a more general applicability. In the first iteration, the basis model is trained (this will be the first module) on the whole data set and prediction error is calculated for each data point. The probabilities for each data vectors to be selected for the next iteration is adjusted: it is increased if prediction for this data vector was poor. Using this distribution, the new data set of the same size is sampled from the original data set. This process is repeated n times thus resulting in n modules, each trained on different (intersecting) subsets. Combining unit B uses the weighted sum of the modules, weight being dependent on the accuracy of the module. During training, splitting unit A arranges recalculation of the distribution and proper resampling, and during operation simply distributes each new input vector to all modules. Boosting was originally developed for binary classification problems and was later extended to solve multiclass classification problems (*AdaBoost.M2*) and regression problems (*AdaBoost.R*). Yet another version of boosting for regression is *AdaBoost.RT* by Solomatine and Shrestha (2004). They have demonstrated on two problems of rainfall-runoff modeling that this algorithm is more accurate than other data-driven methods.

Hard Splitting of the Training Set (Input Space)

A number of methods do not combine the outputs of different models but explicitly use only one of them, the most appropriate one (a particular case when the weights of other expert models are zero). Such methods use "hard" splits of input space into regions. Each individual local model is trained individually on subsets of instances contained in these regions, and finally the output of only one specialized expert is taken into consideration. This can be done manually by experts on the basis of domain knowledge. Another way is to use information theory to perform such splits and to perform splitting progressively; examples are: DTs, regression trees, MARS (Breiman *et al.*, 1984), and M5 model trees (MTs) (Quinlan, 1992).

Regression Trees and M5 Model Trees

These ML techniques use the following idea: split the parameter space into areas (subspaces) and build in each of them a separate regression model of zero or first order (Figure 7). If models in the leaves are of zero order (numeric constants) then this model is called a *regression tree* (Breiman *et al.*, 1984), if the models are of first order (linear regression models) then the model is referred to as a M5 MT (Quinlan, 1992). "M5" stands for "Model trees, version 5". Tree-based models are constructed by a divide-and-conquer method. The set T is either associated with a leaf, or some test is chosen that splits T into subsets corresponding to the test outcomes and the same process is applied recursively to the subsets. The splitting criterion for the M5 MT algorithm is based on treating the standard deviation of the output values that reach a node as a measure of the error at that node, and calculating the expected reduction in this error as a result of testing each attribute at that node.

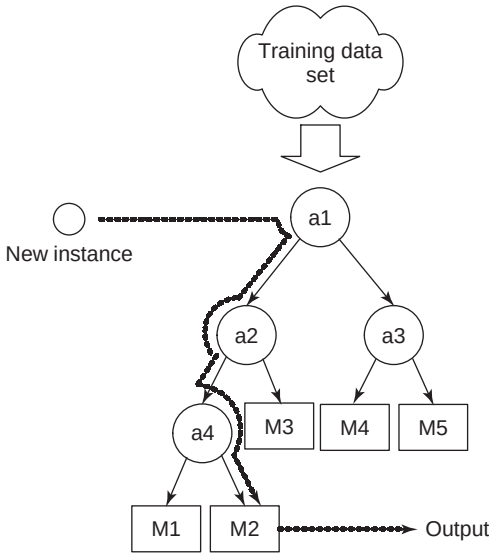

Figure 7 Building a tree-like modular model

In case of numeric inputs, the Boolean tests a_i used to split the data set have the form "$x_i < C$" where i and C are chosen to minimize the standard deviation in the subsets resulting from the split. *Mn* are local specialized models built for subsets filtered down to a given tree leaf. In fact, the resulting model can be seen as a committee of linear models being specialized on certain subsets of the training set belonging to particular regions of the input space.

This idea is not new; a combination of specialized models ("local" models) is used in modeling quite often. One can find a clear analogy between MTs and a combination of linear models used in dynamic hydrology already in the 1970s – a notable paper on multilinear models is by Becker and Kundzewicz (1987). However, the M5 MT approach – based on the principle of information theory – makes it possible to split the multidimensional parameter space and generate the models automatically according to the overall

quality criterion; it also allows for varying the number of models.

Each leaf in an MT represents a local model and, in principle, is (locally) more accurate than a global model (even a nonlinear one, e.g. a neural network) trained on the whole data set. The linear regression method is based on an assumption of linear dependencies between input and output. In an M5 MT a step toward nonlinearity is made by building a model that is locally linear, but overall is nonlinear. MTs may serve as an alternative to nonlinear models like ANNs (which are *global* models) and are often almost as accurate as ANNs but have some important advantages:

- training of MTs is much faster than ANNs, and it always converges;
- the results can be easily understood by decision makers;
- by applying *pruning* (that is making trees smaller by combining subtrees in one node) it is possible to generate a range of MTs – from an inaccurate but simple linear regression (one leaf only) to a much more accurate but complex combination of local models (many branches and leaves).

Probably the first application of M5 MTs in hydrologic forecasting was reported by Kompare *et al.* (1997). Solomatine and Dulal (2003) used M5 MT in rainfall-runoff modeling of a catchment in Italy (*see* the example at the end of this article).

Hybrid Models

Note that the models (modules) in Figure 6 may not be necessarily data-driven ones but rather have various nature, and may include expert judgments. If an overall model uses various types of models, it can be called a *hybrid model*. One of the important problems is incorporation of domain knowledge into the modeling process. A typical ML algorithm minimizes the training (cross-validation) error, seeing it as the ultimate indicator of the algorithm's performance, and so is purely data driven. Domain experts, however, may have other considerations in judging the quality of the model, and want to have certain control over the decisions (A) and (B) and over the choice of models used in each unit. These models could be not only data-driven ones based on ML but also physically based models based on the description of the underlying physical processes.

Xiong *et al.* (2001) combined several physically based forecasting models with the help of a fuzzy system. Solomatine and Maskey (2005) built a committee on the basis of several types of data-driven models including instance-based models, M5 MTs and neural networks.

In a study where flow predictions in the Huai river basin (China) were made on the basis of previous flows and precipitation, Solomatine and Xue (2004) built a committee hybrid model. The problem was to predict Q_{t+1} flow one day ahead. The following notations are used: flows on the previous and current day as Q_{t-1} and Q_t, respectively; precipitation on the previous day as P_{t-1}; moving average (two days) of the precipitation two days before as $P\text{mov}2_{t-2}$; moving average (three days) precipitation four days before as $P\text{mov}3_{t-4}$.

As a first step, domain experts were asked to identify several hydrological conditions (rules), used to split the input space into three regions:

1. $Q_{t-1} \geq 1000\,\text{m}^3\,\text{s}^{-1}$ (high flows)
2. $Q_{t-1} < 1000\,\text{m}^3\,\text{s}^{-1}$ and $Q_t \geq 200\,\text{m}^3\,\text{s}^{-1}$ (medium flows)
3. $P_{t-1} > 50$ and $P\text{mov}2_{t-2} < 5$ and $P\text{mov}3_{t-4} < 5$ (flood condition due to the short but intensive rainfall after a period of dry weather).

For each of these regions separate local models were built (M5 MTs and ANNs).

Addressing the problem of incorporating domain knowledge in DDM, Solomatine and Siek (2004) presented *M5flex* algorithm, an approach allowing for a more active role of an expert in building M5 trees, and demonstrated its accuracy in hydrologic modeling.

Complementary Models

Models can be combined not only to model the same process but also to complement each other. In such combined model a data-driven model can be used to correct errors of the primary model (this would be typically a physically based model, but can be a data-driven model as well), *see* Figure 8. Such an approach was employed in a number of hydrologic studies. Shamseldin and O'Connor (2001) used ANNs to update runoff forecasts; the simulated flows from a model and the current and previously observed flows were used as input, and the corresponding observed flow as the target output. Updates of daily flow forecasts for a lead-time of up to four days were made. It was reported that ANN models gave more accurate improvements than autoregressive models. Lekkas *et al.* (2001) showed that error forecasting provides improved real-time flow forecasting, especially when the forecasting model is poor. Abebe and Price (2004) used this approach to correct the errors of a routing model of the River Wye in UK by an ANN. Solomatine and Maskey (2005) built an ANN-based rainfall-runoff model where its outputs were corrected by an instance-based model.

NO EXPLICIT MODELS: INSTANCE-BASED LEARNING

In instance-based learning (IBL) (Mitchell, 1997) no model is built: classification or prediction is made directly by

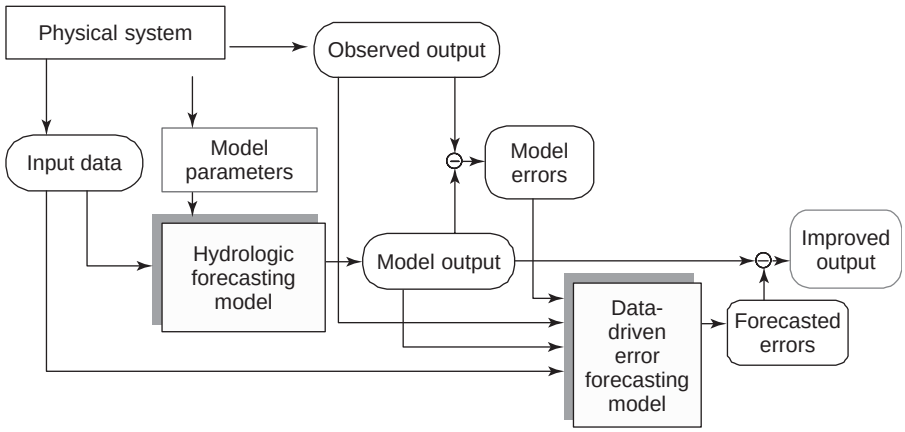

Figure 8 Complementary modeling. The output of the hydrologic forecasting model (physically based or data driven) is corrected by the data-driven model. (Adapted from Abebe and Price (2004).) A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

combining instances from the training data set that are close to the new vector $\mathbf{x}_q$ of inputs. In fact, IBL methods construct a local approximation to the modeled function that applies well in the immediate neighborhood of the new query instance encountered; IBL methods are never intended to construct an approximation designed to perform well over the entire instance space. Thus it describes a very complex target function as a collection of less complex local approximations. IBL often demonstrates competitive performance when compared with, for example, ANNs.

The nearest neighbor classifier approach is one of the simplest and oldest methods of classification. It classifies an unknown pattern $\mathbf{x}_q$ by choosing the class of the nearest example x in the training set as measured by some distance metric, typically Euclidean.

Generalization of this method is the k-nearest neighbor (k-NN) method. For a discrete valued target function, the estimate will just be the most common value among k training examples nearest to $\mathbf{x}_q$. For real-valued target functions, the estimate is the mean value of the k-nearest neighboring examples. The k-NN algorithm can be improved by weighting each of the k neighbors according to their distance to the query point $\mathbf{x}_q$.

Further extensions are known as *locally weighted regression* (LWR) when the regression model is built on k-nearest instances. The training instances are assigned weights according to their distance to the query instance and the regression equations are generated on the weighted data.

Applications of IBL in hydrology mainly refer to the simplest method, *viz.* k-NN. Karlsson and Yakowitz (1987) were probably the first to use this method in hydrology, focusing, however, only on (single-variate) time series forecasts. Galeati (1990) demonstrated the applicability of the k-NN method (with the vectors composed of the lagged rainfall and flow values) for daily discharge forecasting and favorably compared it to the statistical ARX model. Shamseldin and O'Connor (1996) used the k-NN method for adjusting the parameters of the linear perturbation model for river flow forecasting. Toth *et al.* (2000) compared the k-NN approach with other time series prediction methods in a problem of short-term rainfall forecasting. Solomatine and Maskey (2005) considered IBL on a wider context of ML and explored several methods, tested their applicability in short-term hydrologic forecasting and compared their performance to other methods on a number of case studies and benchmark data sets; the LWR with Gaussian kernels appeared to be the most accurate IBL method.

OTHER METHODS

Chaos theory and nonlinear dynamics appear to be excellent predictive tools for time series that are of sufficient length. A single-variate model uses only the time series itself, without any use of other related variables, so it is applicable when the time series carries enough information about the behavior of the system (Lorenz 1963; Abarbanel 1996). Let a time series $\{x_1, x_2, \ldots, x_t, \ldots, x_n\}$ be given (e.g. a sequence of river water levels). The main idea is to represent the state of the system at time t by a vector in m-dimensional state space:

$$\mathbf{y_t} = \{x_t, x_{t-\tau}, x_{t-2\tau}, \ldots, x_{t-(m-1)\tau}\} \quad (1)$$

where τ is the delay time. The whole time series can then be represented by a sequence of such vectors $\{\mathbf{y}_t\}$:

$$\{\boldsymbol{y}_m, \boldsymbol{y}_{\mathrm{m}+1}, \ldots, \boldsymbol{y}_n\}.$$

If the original time series exhibits so-called chaotic properties, then its equivalent trajectory in the phase space has properties allowing for accurate predictions of the future

values of $\boldsymbol{y}$, and hence x. In practical applications, the delay time τ and the dimension m need to be appropriately chosen in order to fully capture the dynamic structure of the time series. Multivariate models embody time series representing several variables.

The predictive capacity of chaos theory, based on an idea that the system behaves in the future in a similar manner as in the past, supersedes the class of linear models like ARIMA. Solomatine *et al.* (2000) and Velickov *et al.* (2003) used chaos theory to predict the surge water level in the North Sea close to Hook of Holland; the data set included measurements of surge for 5 years with a 10-min interval. For a two-hourly prediction, the error was as low as 10 cm and was at least on par with the accuracy of hydrodynamic models. Babovic *et al.* (2000) used a chaos theory-based approach for predicting water levels at the Venice lagoon, and Phoon *et al.* (2002) used it for forecasting hydrologic time series. These methods do not have universal applicability: they can be successfully applied only when time series (or their combination) exhibit properties of chaotic behavior and when time series are of adequate (considerable) length.

Fuzzy Rule-based Systems (FRBS)

After fuzzy logic (as opposed to the classical "crisp" logic) was introduced by Lotfi Zadeh(Zadeh 1965), it found multiple successful applications, mainly in control theory (*see* Kosko, 1997). FRBS can be built by interviewing human experts, or by processing historical data and thus forming a data-driven model. The basics of the latter approach and its use in a number of water-related applications can be found in Bárdossy and Duckstein (1995). FRBS were effectively used for drought assessment (Pesti *et al.*, 1996), prediction of precipitation events (Abebe *et al.*, 2000b), analysis of groundwater model uncertainty (Abebe *et al.*, 2000a), control of water levels in polder areas (Lobbrecht and Solomatine, 1999), and modeling rainfall-discharge dynamics (Vernieuwe *et al.*, 2005). One of the limitations of FRBS is that the demand for computer memory grows exponentially with an increasing number of input variables.

Genetic Programming (GP) and Evolutionary Regression

GP is a regression method where various elementary mathematical functions, constants, and arithmetic operations are combined in one function. Such combination is sought to form a tree structure that is optimized by a multiextremum nonderivative based optimization method – usually a genetic (evolutionary) algorithm. More on GP and its applications can be found in **Chapter 21, Rainfall-runoff Modeling Based on Genetic Programming, Volume 1**.

Evolutionary regression is a method similar to GP, but in which the elementary functions are chosen from a limited set, and the structure of the overall function is fixed. Typically, polynomial regression equation is used, and the coefficients are found by genetic (evolutionary) algorithm. Giustolisi and Savic (2005) used this method for modeling groundwater level and river temperature.

Support Vector Machines (SVM)

SVM is a relatively new important method based on the extension of the idea of identifying a line (or a plane or some surface) that separates two classes in classification. It is based on statistical learning theory initiated by V. Vapnik in the 1970s (Vapnik, 1998, Kecman, 2001). This classification method was also extended to solving prediction problems, and in this capacity was used in hydrology-related tasks. Dibike *et al.* (2001) and Liong and Sivapragasam (2002) reported using SVMs for flood management and in prediction of water flows and stages.

AN EXAMPLE OF APPLYING DATA-DRIVEN MODELING TO HYDROLOGIC FORECASTING

A problem of short-term flow forecasting was posed for the Sieve River – a tributary of Arno River located in the Central Italian Apennines, Italy. The basin covers mostly hills, forests and mountainous areas except in the valley, with an average elevation of 470 m above sea level. A total of 2160 records of hourly discharge downstream, precipitation, and potential evapotranspiration data were available (December 1969; January and February 1970), which represent various types of hydrological conditions. The discharge data were available only for one location. The Arno basin that includes the Sieve catchment was extensively studied and was used as a case study for various physically based hydrologic modeling exercises (Todini 1996; Marsigli *et al.*, 2002). Data-driven methods were used by Solomatine and Dulal (2003). The objective is to forecast the future flow 1 h and 3 h ahead (Q_{t+1} and Q_{t+3} respectively) on the basis of previous values of effective rainfalls $RE_{t-\tau}$ and flows Q_{t-k} (where τ and k are time lags).

One of the important steps of DDM in hydrologic forecasting is data preparation and selection of the relevant input variables and time lags τ and k. Visual inspection of a number of rainfall events makes it possible to identify the time lags between peak rainfall and runoff which is around 5 to 7 h for this particular catchment. The highest correlation between lagged rainfall and discharge is at a lag of 6 h. The autocorrelation value for the discharge is 0.989 for a lag of 1 h (and drops as the time lag increases). Additionally, average mutual information can be used for the same purpose. Such analysis allows for identification of the proper lags τ and k (Figure 9).

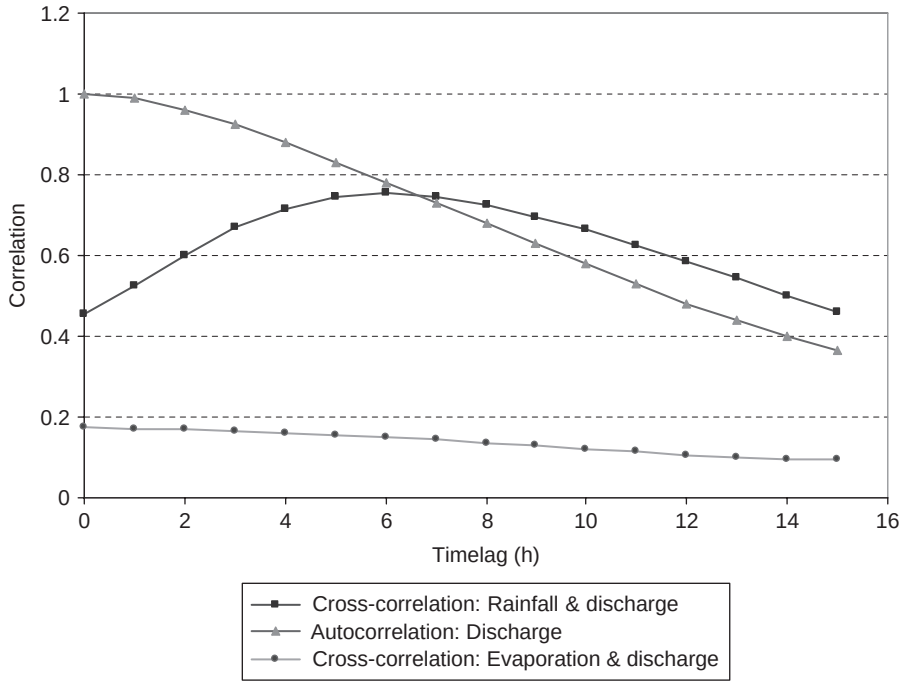

Figure 9 Correlation analysis used to assess the proper lags

The following models with eight and six input variables were built:

$$Q_{t+1} = f(RE_t, RE_{t-1}, RE_{t-2}, RE_{t-3}, RE_{t-4}, RE_{t-5}, Q_{t-1}, Q_t)$$

$$Q_{t+3} = f(RE_t, RE_{t-1}, RE_{t-2}, RE_{t-3}, Q_{t-1}, Q_t)$$

The first 300 examples were used as test data and the rest of data as training data set. The split was made in such a way that both sets have data of similar range and variability. The problem of classification, namely, predicting classes of flow rather than their numerical values was posed as well. The output was discretized into three levels: "low" (flow $<50\,m^3\,s^{-1}$), "medium" (flow $50-300\,m^3\,s^{-1}$), and "high" (flow $>300\,m^3\,s^{-1}$).

A number of DDM methods were applied: MLP ANN, RBF ANN, M5 MTs(Solomatine and Dulal, 2003; Solomatine and Siek 2004), IBL, LWR (Solomatine and Maskey, 2005). Software packages *NeuralMachine* [**http://www.data-machine.com**] and *NeuroSolutions* [**http://www.nd.com**] were used for the ANN modeling; MLP architecture was used. A nonlinear activation function, the hyperbolic tangent function (bounded between -1 and $+1$) was used in the hidden layer. A linear activation function was used in the output layer because it is unbounded and is able, to a certain extent, to extrapolate beyond the range of the training data. The number of hidden nodes was determined by trial-and-error optimization (performed automatically by the software). For training, the back propagation algorithm was used with momentum rule and stopping after 5000 epochs or when the mean squared error (MSE) reached 0.0001.

For M5 MT construction, *Weka* software was used (Witten and Frank, 2000). An example of a pruned (reduced) MT (to 3 rules) from the total of 16 rules is shown in the following:

```
if Q(t) <= 59.4 then
   if Q(t) <= 32.5 then LM1 (1011 examples)
                   else LM2 ( 396 examples)
if Q(t) > 59.4     then LM3 ( 447 examples)

LM1: Q(t+1) = 0.0388 + 0.0108RE(t)
              + 0.0535RE(t-1) + 0.0173RE(t-2)
              + 0.0346RE(t-3) + 1.01Q(t)
              - 0.0127Q(t-1) + 0.00311Q(t-2)
LM2: Q(t+1) = -0.221 + 0.0108RE(t)
              + 1.68RE(t-1) + 0.0626RE(t-2)
              + 7.3RE(t-3) + 1Q(t)
              - 0.0127Q(t-1) + 0.00311Q(t-2)
LM3: Q(t+1) = 3.04 + 2.46RE(t)
              + 4.97RE(t-1) - 0.04RE(t-2)
              + 1.75Q(t) - 1.08Q(t-1)
              + 0.265Q(t-2)
```

It can be seen that actually a mixture of three linear models was built; each of the models is trained on nonintersecting data sets corresponding to low- (below $32.5\,m^3\,s^{-1}$), medium- (between 32.5 and $59.4\,m^3\,s^{-1}$), and high (above $59.4\,m^3\,s^{-1}$) flows. The simple structure of the

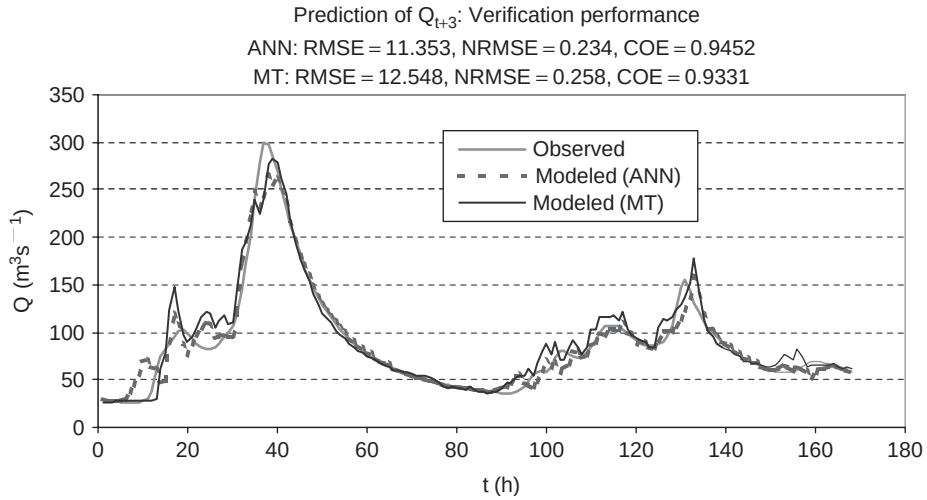

Figure 10 Flow forecasting using ANN and M5 MT

resulting individual models makes it possible to easily see the relative influence of all input variables and perform sensitivity analyses. The equations can be simplified even more by removing the terms with small coefficients. A similar model was generated for predicting Q_{t+3}.

One of the resulting plots comparing the performance of ANN and M5 MT in forecasting Q_{t+3} is shown in Figure 10. In solving the problem of classifying the conditions leading to a particular flow level (low, medium, and high), DTs and SVMs were used. The experiments show the applicability and high accuracy of DDM in short-term hydrologic forecasting.

CONCLUSIONS

DDM and CI methods have proven their applicability to various hydrologic problems: modeling, short-term forecasting, classification of hydrology-related data, building flood severity maps based on aerial or satellite photos, and so on. Normally, any particular (scientific) domain area will benefit from DDM if: (i) there is a considerable amount of data available; (ii) there are no considerable changes to the system during the period covered by the model; (iii) it is difficult to build knowledge-driven simulation models (e.g. due to lack of understanding of the underlying processes); or (iv) in particular cases, when available models are not adequate enough; and (v) there is a necessity to validate the simulation results of physically based models with other types of models.

It is always advisable to apply various types of DDMs and to compare and/or combine the results. For example, M5 MTs, combining local and global properties, could very well complement ANNs, and be more easily accepted by decision makers because of their reliance on simple linear models.

The future is seen in using the hybrid models-combining models of different types and following different modeling paradigms, including the combination with physically based models. It can be foreseen that computational intelligence (machine learning) will be used not only for building data-driven models, but also for building optimal and adaptive *model structures* of such hybrid models.

20: Artificial Neural Network Concepts in Hydrology

ANTHONY W MINNS[1] AND MICHAEL J HALL[2]

[1]*Marine & Coastal Management, WL Delft Hydraulics, Delft, The Netherlands*
[2]*Department of Water Engineering, UNESCO-IHE, Delft, The Netherlands*

The solution of many applied hydrological problems, such as the forecasting of floods, has for several decades been based upon the concepts of linear systems analysis. However, the introduction of informatics tools, such as Artificial Neural Networks (ANNs), with their origins in cognitive sciences and pattern recognition, has made available new lines of investigation. Nevertheless, despite their apparent structural simplicity, the use of ANNs to encapsulate the transformation of rainfall over a catchment into streamflow at its outlet requires at least as much hydrological insight as a conventional physical/conceptual hydrological model. Of particular importance are: the choice of the input data streams; and the maintenance of the ability of the ANN to generalize and extrapolate beyond its training data set. Attention to these aspects invariably provides a model whose goodness-of-fit to an independent testing data set is superior to that of parameter-based hydrological modeling systems.

INTRODUCTION

Hydrology has always suffered from the dichotomy of being a geophysical science on the one hand, and an applied science for the solution of engineering problems on the other. In its latter guise, hydrology is essentially data dependent, with the optimal use being made of whatever information is available at the time of the investigation. The application of linear systems theory (e.g. Dooge, 1973; Domenico, 1972), developed during the 1950s and 1960s, provides a ready example of an approach that is still widely applied. However, the last decade has seen the gradual introduction of informatics tools, such as artificial neural networks (ANNs), into hydrology, hydrogeology, and water resources planning and management. An ANN is also often referred to as a *data-driven method* (*see* **Chapter 19, Data-driven Modeling and Computational Intelligence Methods in Hydrology, Volume 1**), and, taken at face value, should be similar in utility to linear systems analysis, but with less onerous constraints in application.

Unfortunately, despite the many and various applications of data-driven methods that have appeared over the last decade, a broad appreciation of their potential has been slow to develop. This apparent reluctance to consider such approaches could be partly ascribed to unfamiliarity with the concept of devices such as ANNs, a circumstance that has not been assisted by the somewhat esoteric nomenclature associated with neural networks, stemming from their origins as computational devices for pattern recognition and classification in artificial intelligence and cognitive sciences. However, there is indeed a growing awareness of these techniques as most clearly demonstrated by the very existence of the ASCE Task Committee on Application of Artificial Neural Networks in Hydrology (ASCE-TCANNH, 2000a,b) and the recent publication of several textbooks dedicated solely to this subject (e.g. Abrahart *et al.*, 2004; Govindaraju and Rao, 2000).

The parallel processing architecture and multiple interconnections of processing elements that make up the structure of an ANN have an obvious analogy with biological systems, as explained in any introductory textbook on the subject (e.g. Aleksander and Morton, 1990; Beale and Jackson, 1990; Hertz *et al.*, 1991; Haykin, 1999). The discomfort of the potential user tends to be increased by the many different types of neural networks that are available. However, the emphasis of this review is on *applications*, although inevitably some reference has to be made to the available architectures and calibration methods. In this

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

context, a cursory review of the literature is sufficient to reveal the wide variety of hydrological problems to which ANNs have been applied successfully. The following listing, expanded from Minns and Hall (2004), is intended to be illustrative rather than exhaustive:

- as submodels of complex processes within a larger physically based framework; the estimation of daily solar radiation from daily maximum and minimum air temperatures and precipitation (Elizondo *et al.*, 1994), and the modeling of drying water retention curves for sandy soils by Schaap and Bouten (1996) provide ready examples of this approach;
- as a replacement for, or for modeling the results obtained from, more complex, physically based computer models that impose heavy demands on computing resources (often referred to as *emulating* complex systems); examples include the river salinity forecasting model of Maier and Dandy (1996), and the determination of optimum pumping scenarios for groundwater remediation schemes by Rogers and Dowla (1994), Rogers *et al.* (1995), and Aly and Peralta (1999);
- as models of analytically intractable relationships, such as the approximation for the confidence limits to the quantiles from a flood frequency distribution derived by Whitley and Hromadka (1999);
- as a method of avoiding the constraints associated with standard techniques, such as multiple linear regression analysis, in deriving relationships between the parameters of a regional flood-frequency distribution and catchment characteristics (Muttiah *et al.*, 1997; Hall and Minns, 1998; Hall *et al.*, 2002);
- as a screening model, for example, for the identification of critical realizations of log conductivity fields for a single realization groundwater remediation management model (Ranjithan *et al.*, 1993);
- for the modeling of water table fluctuations (Coulibaly *et al.*, 2001) and the migration of pollutant plumes in groundwater (Hassan and Khaled, 2001);
- as a method of pattern completion, for example, the neural kriging method of Rizzo and Dougherty (1994) and spatial (Lin and Chen, 2004a) and temporal infilling (Khalil *et al.*, 2001);
- as a classification tool for spatial variation and severity of droughts (Shin and Salas, 2000);
- as models of various aspects of sediment transport (Abrahart and White, 2001; Tayfur, 2002);
- as a model of the preferences of decision-makers in multiobjective optimization (see Wen and Lee, 1998, for an example);
- as a forecasting device, such as that for predicting rainfall fields proposed by French *et al.* (1992) and Luk *et al.* (1998, 2000), and for integrating radar images (Hessami *et al.*, 2003) or radiosonde and satellite information (Kim and Barros, 2001) with rainfall gauge measurements;
- for the classification and interpretation of remote sensing data (Islam and Kothari, 2000; Matheussen and Thorolfsson, 2003);
- as an alternative to parameter-intensive physical/conceptual models in applications that do not require a detailed understanding of the system dynamics.

The last category is typified by the problem of modeling the relationship between rainfall and runoff (*see* **Chapter 122, Rainfall-runoff Modeling: Introduction, Volume 3**). However, as the following review is intended to demonstrate, the application of ANNs to the development of a rainfall-runoff model demands as much, if not more, hydrological insight than the calibration of a standard physical/conceptual model (see also Maier and Dandy, 1999).

The details of 18 studies in which ANNs have been employed to develop rainfall-runoff models are presented in Table 1, adapted from Minns and Hall (2004). A similar tabulation has also been provided by Dawson and Wilby (2001). The approach that has been overwhelmingly favored has been the multilayer perceptron (MLP) network with the error back-propagation learning algorithm. Several authors reported favorable results using radial basis function (RBF) networks, largely because the training time of RBF networks was usually significantly less than that for equivalent MLP networks. Furthermore, the RBF networks appear to provide a superior performance over MLPs when dealing with only small numbers of input data sets. However, Dibike *et al.* (1999b) reported that the generalization properties of the RBF networks deteriorated as the number of input data sets was increased and the RBF networks were subsequently out-performed by the MLP networks in this case.

ARTIFICIAL NEURAL NETWORKS

In brief, an ANN consists of layers of processing units (representing biological neurons – see Hopfield, 1994) where each processing unit in each layer is connected to all processing units in the adjacent layers (representing biological synapses and dendrites). The architecture of the various types of ANNs have been well described elsewhere (for example, Beale and Jackson, 1990; Aleksander and Morton, 1990; Hertz *et al.*, 1991; Haykin, 1999). The selection of an appropriate architecture for an ANN depends upon both the problem to be solved and the type of learning algorithm to be applied. For example, the use of Kohonen networks (Kohonen, 1997) for unsupervised classification of patterns, and the use of Hopfield networks for recalling previously learned patterns are two approaches commonly used in pattern recognition.

Table 1 Summary of previous studies in which ANNs have been employed to model rainfall-runoff relationships

Note: MLP – multilayer perceptron; BP – error back-propagation; RBF – radial basis function; OLS – ordinary least squares; LLSSIM – linear least squares with multistart simplex operation; CG – conjugate gradient; KN – Kohonen network; CC – cascade correlation.

However, when applied more generally to systems identification, the purpose is to train an ANN to provide a correct output response to a given input stimulus. In particular, for rainfall-runoff modeling, the input stimulus corresponds to the measured rainfall and the output response to the measured runoff from a catchment. A multilayer, feed-forward, perceptron-type ANN is one of the most suitable types of ANN for learning the stimulus-response relationship for a given set of measured data. Figure 1 shows a general schematization of a three-layer, feed-forward ANN.

The working of an ANN can best be described with the aid of Figure 1 by following the operations involved during training and computation. An input signal, consisting of an array of numbers x_i is introduced to the input layer of processing units or nodes.

The signals are carried along connections to each of the nodes in the adjacent layer, and can be either amplified or inhibited through weights, w_i, associated with each connection. The nodes in the adjacent layer act as summation devices for the incoming (weighted) signals (see Figure 2).

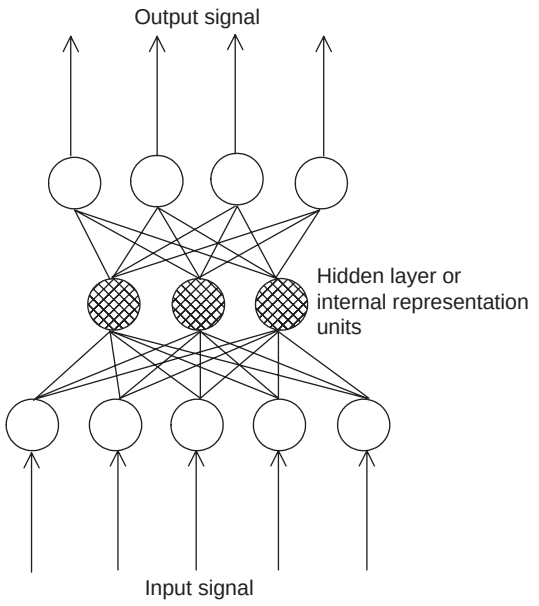

Figure 1 Representation of a multilayer, feed-forward artificial neural network (ANN)

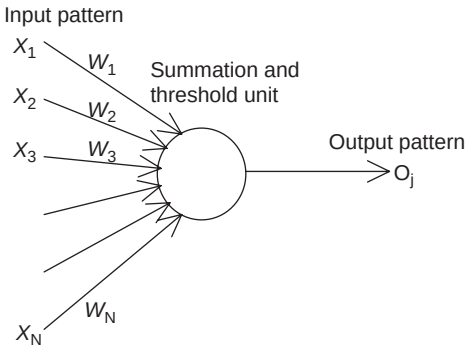

Figure 2 A typical ANN node

The incoming signal is transformed into an output signal, O_j, within the processing units by passing it through a threshold function. A common threshold function for the ANN depicted in Figure 1 is the sigmoid function defined as:

$$f(x) = \frac{1}{1 + e^{-x}} \tag{1}$$

which provides an output in the range $0 < f(x) < 1$. In most routines, the threshold function usually takes the form of a single-valued, hard-delimiter. The sigmoidal threshold function is chosen for mathematical convenience because it resembles a hard-limiting step-function for extremely large positive and negative values of the incoming signal and also gives useful information about the response of the processing unit to inputs that are close to the threshold value. Furthermore, the sigmoid function has a very simple derivative that makes the subsequent implementation of the learning algorithm much easier.

The output from the processing unit is then:

$$O_j = \frac{1}{1 + e^{-\sum x_i w_i}} \tag{2}$$

This output signal is subsequently carried along the weighted connections to the following layer of nodes and the process is repeated until the signal reaches the output layer. The one or more layers of processing units located between the input and output layers have no direct connection to the outside world and are referred to as *hidden layers*. The output signal can then be interpreted as the response of the ANN to the given input stimuli.

The ANN can be *trained* (i.e. calibrated) to produce known or desired output responses for given input stimuli. The ANN is first initialized by assigning random numbers to the interconnection weights. An input signal is then introduced to the input layer and the resulting output signal is compared to the desired output signal. The interconnection weights are then adjusted to minimize the error between the ANN output and the desired output. This process is repeated many times with many different input/output tuples until a sufficient accuracy for all data sets has been obtained. The adjustment of the interconnection weights during training employs a method known as *error back-propagation* in which the weight associated with each connection is adjusted by an amount proportional to the strength of the signal in the connection and the total measure of the error (see Rumelhart and McClelland, 1986). The total error at the output layer is then reduced by redistributing this error value backwards through the hidden layers until the input layer is reached. The next input/output tuple is then applied and the connection weights readjusted to minimize this new error. In this way, the back-propagation algorithm can be seen to be a form of gradient descent for finding the minimum value of the multidimensional error function. This procedure is repeated until all training data sets have been applied. The whole process is then repeated starting from the first data set once more and continued until the total error for all data sets is sufficiently small and subsequent adjustments to the weights are inconsequential. In many situations, it is recommended to utilize a *cross-validation* data set in addition to the training data set. The error between the network output and the cross-validation data is continuously monitored during the training process. Although the error on the training data may continue to decrease, the error on the cross-validation data may begin to increase. By stopping the training procedure at this time, the problem of *overfitting* can be avoided (*see* **Chapter 19, Data-driven Modeling and Computational Intelligence Methods in Hydrology, Volume 1**).

The ANN is now said to have *learned* a relationship between the input and output training data sets. The exact form of this relationship cannot be extracted from the ANN but, rather, is encapsulated in the stored series of weights and connections between nodes. The absolute values of the individual weights cannot usually be interpreted to have any deeper physical meaning (Minns, 1995), although some success has recently been claimed in studying the pattern of weights (Dibike *et al.*, 1999a; Minns, 2000; Wilby *et al.*, 2003).

Although the error back-propagation method does not guarantee convergence to an optimal solution since local minima may exist, it appears in practice that the back-propagation method leads to solutions in almost every case (Rumelhart *et al.*, 1994). In fact, Hornik *et al.* (1989) concluded that standard multilayer, feed-forward networks are capable of approximating any measurable function to any desired degree of accuracy. They further state that errors in representation appear to arise only from having insufficient hidden units or the relationships themselves being insufficiently deterministic.

For details of other ANN architectures, which include recurrent neural networks (RNN), self-organizing feature maps (SOFM), Hopfield networks, radial basis function

(RBF) networks, support vector machines (SVM), and so on, the reader is referred to Hertz *et al.* (1991), Haykin (1999), and Kecman (2001). Several commercially available software packages provide a wide variety of network architectures and learning algorithms. For Windows-based PCs, the NeuroSolutions package is probably the most advanced and flexible package available. **http://www.neurosolutions.com/products/ns/index.html**

For users familiar with the Matlab working environment, the Matlab Neural Network Toolbox provides an excellent alternative. **http://www.mathworks.com/products/neuralnet/index.html**

The Stuttgart Neural Network Simulator SNNS may be downloaded free-of-charge, but this package is only available for Unix/Linux workstations. **http://www-ra.informatik.uni-tuebingen.de/SNNS/**

RAINFALL-RUNOFF RELATIONSHIPS

The majority of hydrological textbooks (e.g. Bras, 1990; Hornberger *et al.*, 1998) provide succinct descriptions of the physics of hydrograph generation. The forcing function to the catchment system is obviously precipitation in general, and the variations of rainfall intensity over time in particular. However, the relationship between the rainfall intensity and the response of the catchment in terms of changes in discharge at the outlet is primarily dependent on the action of the intervening processes within the hydrological cycle. Overland flow supply and subsurface flow are essentially functions of the soils and vegetative cover, and are, therefore, dependent on the state of wetness of the catchment prior to the rainfall. The contribution of groundwater is a function of geology and the height of the phreatic surface in relation to the channel system (*see* **Chapter 145, Groundwater as an Element in the Hydrological Cycle, Volume 4**). The slope, roughness, and geometry of the latter then shape the formation of the outlet hydrograph.

Such influences are well appreciated in a qualitative sense, and models of individual processes, such as interception on a vegetal canopy or soil moisture depletion, are readily available. Their integration into spatially distributed, physically based models of the land phase of the hydrological cycle has been pursued vigorously for almost two decades (*see* **Chapter 127, Rainfall-runoff Modeling: Distributed Models, Volume 3**). Perhaps the most widely known of the modern generation of physically based, distributed catchment modeling systems is the Système Hydrologique Européen (SHE), the original structure of which was described by Abbott *et al.* (1986). The structure of a typical SHE model may be visualized as a three-dimensional grid, with the vertical layers running from the deep groundwater through the surface layers and the vegetal cover to the overlying atmospheric boundary layer. As a general guideline, the pixels forming the horizontal grid should be about one per cent of the total catchment area (see Bathurst, 1986). However, in their account of an application of SHE to a river basin of some 4955 square km in India, Refsgaard *et al.* (1992) have acknowledged that their use of 2 km by 2 km grid squares still did not provide a fully physically based and fully distributed description of the basin, even though it was entirely sufficient for the practical application in question. There remained a certain degree of empiricism in the representation of particular hydrological processes, even in these systems, so that process identification and the associated determination of parameter values by direct measurement continues to necessitate the use of extensive calibration procedures.

These and similar reported experiences lead to the conclusion that, for many problems of rainfall-runoff modeling involving, for example, record extension or forecasting, without any significant changes in land use or other such factors and over a certain range and distribution of antecedent soil conditions, simpler models would in most situations be equally accurate and much cheaper to apply. However, in fairness to the distributed, physically based models, their use is primarily directed to the representation of processes other than simple rainfall-runoff. Indeed, from the point of view of practical applications, problems of waste disposal, erosion, changes in vegetation, and so on, have wider societal implications than rainfall-runoff alone.

In contrast, hydrology in general and rainfall-runoff modeling in particular, provides ample opportunities to take advantage of data-driven techniques, such as artificial neural networks. The principal advantage of ANNs is that, even if the precise relationship between input and output data streams is unknown but is acknowledged to exist, the network can be trained to learn that relationship. The use of the data as recorded, that is, the total rainfall volumes instead of the rainfall excess volumes and the recorded discharges instead of the direct runoff rates, is an added incentive to avoid unnecessary empiricism. However, the user must be assured at the outset that the relevant input and output data sets have been selected in the first place.

To date, ANNs have been applied to model the rainfall-runoff relationships of anything from laboratory catchments (Hall and Minns, 1993; Carriere *et al.*, 1996) to drainage areas in excess of 19 000 square km (Zealand *et al.*, 1999) – see Table 1. For the larger sizes of catchment, the use of stage or flow records for sites upstream of the outlet may be possible, so that the ANN is implicitly routing hydrographs as part of the learning process (e.g. See and Openshaw, 1998). Indeed, ANNs have been applied directly for the routing of flood and stage hydrographs by Zhu and Fujita (1994), Raman and Sunilkumar (1995), Thirumalaiah and Deo (1998), and Teegavarapu (1998). Minns (1998, 2000) showed that for these types of simple

advection and dispersion processes, an ANN is capable of encapsulating the same knowledge that is contained in the governing partial differential equations. In fact, the governing continuum equations could actually be restored for the particular choice of ANN configuration by analyzing the weights of the ANNs that had been trained with measured data.

The following discussion, however, is more specifically concerned with the art of rainfall-runoff modeling, which, despite being a fertile area for exploration, offers several less-than-obvious traps for the unwary. The first choice to be made by the ANN modeler is the mode of presentation of the data to the network, that is, how are the input and output patterns to be defined? One possibility is to take the n successive ordinates of the rainfall hyetograph and feed these into the n input nodes of a network whose m output nodes carry the m successive ordinates of the flow hydrograph. This was the approach followed by both Smith and Eli (1995) and Lange (1998), but in the former case, the outputs were the coefficients from a truncated harmonic series representation of the hydrograph, which had the added advantage of already being standardized within the interval ± 1.

An alternative method of defining patterns is the so-called dynamic approach in which the input is a set of concurrent ordinates of (say) the rainfall totals from p rain gauges within the catchment and the output is the concurrent rate of outflow. In this mode, each time step defines a pattern, and, therefore, a single storm event provides as many exemplars as there are runoff ordinates, rather than only a single input-output pairing. This is the approach that has been adopted by the majority of writers on rainfall-runoff modeling using ANNs, but requires a much higher level of hydrological insight into the working of the catchment system.

Within the dynamic approach, Minns and Hall (2004) identified three types of model:

- naïve dynamic model

$$Q(t) = f(r(t), r(t-1), \ldots) \tag{3}$$

- rainfall-runoff simulation model

$$Q(t) = f(r(t), r(t-1), \ldots, Q(t-1), Q(t-2), \ldots) \tag{4}$$

- "auto-regressive" model

$$Q(t) = f(Q(t-1), Q(t-2), \ldots) \tag{5}$$

where $Q(t)$ is the outflow at time level t and $r(t)$ is the rainfall ordinate at time level t.

The simplest, naïve dynamic rainfall-runoff model (equation 3) would consist of an ANN with inputs from one or more rain gauges at time t, and an output of concurrent flow. A simple scatter plot of input(s) against output is sufficient in this case to indicate that the description of the input pattern is inadequate. Some improvement is obtainable by allowing for the time lag between the occurrence of the flow and the incidence of the causative rainfall. Since the flow at any instant is effectively composed of contributions from different subareas whose time of travel to the outlet covers a range of values, both the concurrent and antecedent rainfalls can be considered to be contributing to the outflow. Use of a moving window of rainfall at time t and the k previous intervals provides some improvement (e.g. Hall and Minns, 1993; Karunanithi *et al.*, 1994).

The choice of length for the moving window of rainfall can significantly affect the accuracy of the resulting ANN model. If the window is too short, the input data does not contain enough information about the entire rain event that is contributing to the concurrent outflow. Output hydrographs tend to represent only the shape of the rainfall bursts, and there is a very poor representation of the rising limbs and the recession limbs. Conversely, if the window is too long, the input contains too much information, which may even include historical rainfall events whose effects have long since passed out of the catchment, and so are no longer contributing to the concurrent flow. In this case, an ANN can no longer generalize the relationship between rainfall and runoff. There is simply too much data being presented at the input layer and – to maintain the biological analogy – the ANN becomes "confused". Hall and Minns (1993) showed that the most accurate results are obtained using a moving window length that broadly encompasses the range of centroid-to-centroid lag times of the training data.

A further problem with the naïve model is that the simplistic input patterns may easily result in ambiguous results. More specifically, intervals with zero rainfall inputs are encountered in two contrasting situations: immediately prior to the beginning of the storm at the start of the rising limb; and some time after the end of the storm event when flows are moderately high and in recession. The ANN has no information to discriminate between these two "no-rainfall" conditions and once more becomes "confused". These conditions have to be differentiated by the addition of another input if the ANN is to achieve the correct mapping. The most obvious candidate is a flow ordinate, which is most easily provided by the output at time t to become an input at time $t+1$ (Hall and Minns, 1993; Minns and Hall, 1996; and similar use of stage outputs by Campolo *et al.*, 1999). This approach is described above as model (equation 4). In effect, the flow (or stage) ordinate is employed as a crude measure of catchment wetness.

Model (equation 5) is then the logical extension of models (equation 3) and (equation 4) into purely "auto-regressive" time series prediction. This model does not make use of any rainfall data at all but uses only antecedent

outflow values as input to the ANN to predict the concurrent outflow. Minns (1998) demonstrated that model (equation 5) suffers from a persistent phase error. In this case, the ANN has no information available that tells it at which level the rising limb should stop until the actual measurements indicate that this is so. That is, at the top of the rising limb, the output from the ANN wishes to continue rising in magnitude based only upon the pattern of the preceding flows. It is not until several time steps have passed for which the measured values are all constant that the ANN "recognizes" that the equilibrium level has been reached. Similarly, the phase error that occurs at the beginning of the recession limb is caused by the ANN having no knowledge about the cessation of the rainfall until one or two time steps after the actual measured values have started to decrease.

In general, the plethora of literature involving the application of ANNs to rainfall-runoff modeling confirms the exceptional accuracy of ANN models for short forecasting intervals. Longer forecasting intervals may be obtained by utilizing $Q(t+1), Q(t+2), \ldots$ and so on, as outputs during the training of the ANN. Unfortunately, the performance of the ANN decreases quite rapidly with an increasing prediction time horizon (Campolo *et al.*, 1999; Zealand *et al.*, 1999). Another approach is to use a trained ANN with a "feedback" loop in which the predicted output is used directly as input data for the subsequent time step. Unfortunately, the error accumulation associated with this approach also means that the performance of the ANN deteriorates quite rapidly after only one or two iterations (van den Boogaard *et al.*, 1998). Although Abrahart (1998) describes a method to deal with the accumulated error, the most promising approach would appear to involve the use of (partial) recurrent neural networks, which contain feedback loops in both the training and recall modes of the network. Hertz *et al.* (1991) describe the architecture of these so-called Jordan/Elman Recurrent Networks. Proaño *et al.* (1998), van den Boogaard *et al.* (1998), and Chiang *et al.* (2004) show significant improvements in long-term predictions using recurrent neural networks. In addition, Varoonchotikul *et al.* (2002b) and Varoonchotikul (2003) have demonstrated that a Jordan Recurrent Network can be trained more quickly and can provide an improvement in performance over a standard MLP-type ANN. van den Boogaard (2004) describes the theoretical background of partial recurrent neural networks and provides two applications that demonstrate the practical relevance of these tools for modeling dynamic hydrological systems.

In terms of the number of patterns that can be extracted from a given data set, the above-mentioned dynamic models are superior to those based simply on the use of the whole hyetograph as the input and the complete hydrograph as the output. However, the problem then arises as to the set of time points for which those patterns are extracted. Here, a clear perspective is required as to the purpose of the modeling, since with any series of discharges, the (positive) skewness of its marginal distribution tends to increase as the time interval at which the data are recorded reduces. This effect is manifested in the appearance of sustained recessions to the hydrographs as the time interval becomes shorter, such that with (say) daily data, they become the dominant features of the time series. In these circumstances, the rising limbs and peaks of the storm hydrographs form only a small portion of the total number of patterns in the time series, and the mapping of inputs to outputs is biased in favor of the recession behavior. If, therefore, the purpose of the modeling is to capture the essence of the flood regime of the catchment, then the inputs should be restricted to the major storm events. For convenience, these inputs and outputs may be arranged in the form of an artificial time series in which the flow transitions between successive events are smoothed to provide continuity. In the absence of seasonal influences, this approach has been found to work satisfactorily (Hall and Minns, 1993; Minns and Hall, 1996, 1997; Minns, 1996; Campolo *et al.*, 1999). If the full range of flow behavior is of interest, then an alternative approach might be to carry out *a priori* classification of event types or hydrograph features – perhaps employing a Kohonen network – and to develop a separate ANN rainfall-runoff model for each class (e.g. See and Openshaw, 1998). Hsu *et al.* (2002) have also proposed a novel structure of ANN incorporating an SOFM to classify the input vectors.

Dawson and Wilby (1998) concluded that ANNs for long flow series at short time intervals should ideally be calibrated and validated on data for a common period of the year. Seasonal influences can, of course, be incorporated by extending the list of input variables. For example, Abrahart and Kneale (1997) and Abrahart (1998) employed an annual hour count converted into its sine and cosine equivalents to denote "time of year". Alternatively, Zealand *et al.* (1999) added a "period of the year" (in effect, a week number) and cumulative precipitation since the previous 1st November to the current time period, up to 1st April, to their inputs, the latter being intended as a measure of winter snowpack accumulation. Yet another approach to incorporating a seasonal variable is to use temperature data as an additional input (Lorrai and Sechi, 1995; Poff *et al.*, 1996; Zealand *et al.*, 1999).

Despite the potential significance of seasonal influences, the majority of ANN rainfall-runoff models have tended to rely on combinations of current and antecedent rainfall totals and antecedent flow (or stage) ordinates as inputs (see, e.g. Hsu *et al.*, 1995; Minns and Hall, 1996, 1997; Jayawardena and Fernando, 1998; Fernando and Jayawardena, 1998; Campolo *et al.*, 1999). Gautam *et al.* (2000) included soil moisture data as inputs and Bin Zhang and Govindaraju (2003) incorporated knowledge of catchment geomorphology in the construction of their ANNs. More

elaborate inputs derived from the basic records have been introduced in some studies, such as the derivative of the rainfall intensity and the integral of the rainfall intensity over the previous five time steps employed by Mason *et al.* (1996). Shamseldin (1997) defined a series of rainfall indices consisting of weighted sums of previous rainfall ordinates, the weights being derived from the ordinates of a gamma distribution. Burian and Durrans (2002) have also applied ANNs to disaggregate hourly rainfall records into subhourly increments in order to improve runoff hydrograph predictions.

The predominant objective of the rainfall-runoff models that have been developed using some form of ANN has been that of forecasting future flows given the knowledge of past flows, rainfalls, and other relevant variables. Interest in this topic has continued unabated (e.g. Hu *et al.*, 2001; CiGizoGlu, 2003; Chibanga *et al.*, 2003; Campolo *et al.*, 2003; Rajurkar *et al.*, 2002, 2004; Lin and Chen, 2004b). Comparisons between ANNs and other approaches are not always completely favorable to the former (e.g. Sivakumar *et al.*, 2002; Xiong and O'Connor, 2002; Laio *et al.*, 2003) largely because the basic MLP-type of ANN is not ideally suited to this application. The sigmoidal activation function adopted by many authors imposes a scaling on the network output such that the network is incapable of predicting a flow larger in magnitude than the one contained within the training data set. This effect is amply demonstrated by Minns and Hall (1996) based upon trials with synthetic data. Consequently, if an ANN were to be applied to a real catchment, even if the training data included all the available measurements, there remains always a small but nonnegligible probability that an extreme event beyond the range of recorded experience might occur in future.

An alternative approach suggested by Minns (1996) and Minns and Hall (1997) is to use the *change* in flow as the output rather than the absolute magnitude of the discharge. This variable was used independently by Zhu and Fujita (1994) for forecasting purposes, but without explanation. Change in stage was adopted as the forecast variable by See and Openshaw (1998), presumably because of the scaling problem outlined above. However, Karunanithi *et al.* (1994) claim that a (clipped) linear activation function allows extrapolation. This property arises due to the unbounded nature of the linear activation output. However, if this type of ANN is applied with little or no hydrological insight, this apparent luxury of "unlimited" extrapolation may lead to quite unacceptable linear extrapolations of some very nonlinear hydrological processes. The results may then be not only meaningless, but also quite dangerous to apply.

A further alternative suggested by Varoonchotikul *et al.* (2002a) and Varoonchotikul (2003) involves a careful selection of the standardization range of the activation function based upon the maximum and minimum contained in the raw data set. In order to provide "room" for extrapolation, an arbitrary factor is applied to the maximum. A value of two was found to provide a reasonably satisfactory compromise, allowing extrapolation up to peak discharges with return periods of between 33 and 100 years, depending upon the rapidity of catchment response. In contrast, Imrie *et al.* (2000) proposed the addition of a *guidance system* to the output layer of the cascade correlation architecture of ANN to overcome the extrapolation problem. Unfortunately, this approach depends upon the use of information from the testing data set, thereby disrupting the training and verification cycle.

Another possibility, proposed by Hettiarachchi *et al.* (2005), is the incorporation of independent domain knowledge into the modeling process. Such knowledge can be developed from the standardized procedures for estimating design flood hydrographs that are available in many countries. Since such procedures are invariably based on regionalization exercises on data from many catchment areas, they incorporate information beyond that of a single river basin. Such procedures can be employed to develop (say) the 100-year design flood hydrograph and its associated rainfall hyetograph, the ordinates of which can then be added to the training data set. Hettiarachchi *et al.* (2005) demonstrate that an Estimated Maximum Flood, which provides an approximation to the physical upper limit of runoff of which the catchment is capable, can be included in training without affecting the ability of the network to generalize. The authors also paid attention to the method of standardization of the input and output data, including the use of logarithmic transformations. Bowden *et al.* (2003) have also examined the use of different standardization procedures for the input and output data, but found little improvement on the standard linear transformation approach.

CONCLUDING REMARKS

The results of all of the numerical experiments reported to date indicate that suitably configured ANNs are capable of identifying usable relationships between runoff discharges and antecedent rainfall depths to an exceptional degree of accuracy. The relationships are obtained using only the raw, measured data and do not require the use of any derived or artificial calibration parameters. In particular, the ANN model provides these exceptional results unhindered by constraints of volume continuity in the input and output data and, in fact, the units of the data are chosen simply for convenience of measurement and representation (e.g. rainfall depths in mm, discharges in m^3/s). Furthermore, simple, nonhydrological parameters such as the percentage of impervious area may be easily incorporated into the model at the discretion of the modeler. These types of parameters may be derived from simple measurements or may even be highly intuitive, and are likewise unrestricted in

terms of conditions of dimension or hydrological-physical consistency. Clearly, the understanding of the underlying physical processes is enhanced if dimensionally consistent parameters are used (*see* **Chapter 21, Rainfall-runoff Modeling Based on Genetic Programming, Volume 1**). In general, applications of evolutionary computing in hydrological sciences benefit greatly if available knowledge and understanding of the underlying physical processes is incorporated before introducing *artificial* intelligence methods (*see* **Chapter 22, Evolutionary Computing in Hydrological Sciences, Volume 1**).

Despite the expanding literature on neural network modeling, certain errors of procedure remain all too common. Once a suitable combination of input and output parameters has been chosen – in itself not necessarily a simple task, since this already requires some insight into the mutual interactions of not yet fully understood processes – attention needs to be turned to the choice of the network architecture. Assuming that an MLP-type of ANN is being applied, the key features are the number of hidden layers and the number of processing elements in each. Previous experience has indicated that little advantage accrues from having more than one hidden layer in hydrological applications (e.g. Minns and Hall, 1996). The number of nodes in the hidden layer may then be determined by trial and error, but care is necessary to ensure that the number of training exemplars is well in excess of the number of processing elements, perhaps by a factor of 4 or 5 (see, e.g. Walczak and Cerpa, 1999). With large numbers of processing elements, the danger exists of each becoming associated with a subset of input tuples. In these circumstances, the ability of the trained ANN to generalize is compromised, and its performance on an independent verification data set falls well below that of the training data set.

A similar problem can arise if the training is continued for too long. The network then "learns" both signal and noise, and the generalization properties of the network are again impaired. However, this effect may be controlled by choosing a third set of data for *cross-validation*. Training is stopped at arbitrary intervals, and the fitting error of the cross-validation set is examined. If the error in both the training and the cross-validation data sets decreases, then the training is continued. However, once the error in the cross-validation data set increases, training is stopped. Coulibaly *et al.* (2000) provides a detailed description of this problem and Smith (1993) suggests procedures for overcoming it (*see* **Chapter 19, Data-driven Modeling and Computational Intelligence Methods in Hydrology, Volume 1**). The optimal division of the available records into the three data subsets has been investigated by Bowden *et al.* (2002) using both SOFMs and Genetic Algorithms. An alternative approach involving bootstrapping of the data was proposed by Abrahart (2003).

The discussion above has demonstrated that, although an ANN may be regarded as some form of "black-box" model (Minns and Hall, 1996), the potential user is not absolved from devoting some thought to the mode of presentation of data to the network. The principal question to be posed is: what exactly constitutes the pattern of inputs that produces the pattern of outputs? Moreover, do the selected input and output patterns contain additional information that is not strictly relevant to the purpose of the exercise? These questions are inevitably problem-dependent, but in all cases, the selection of inputs, whether data as recorded or variables derived from operations on recorded data, requires the application of hydrological insight as much as any conventional physical/conceptual rainfall-runoff model. Provided that such insight is applied, the performance of ANN models on independent testing data sets can be undoubtedly superior to conventional hydrological models in situations that do not require more detailed knowledge of the hydrological system.

21: Rainfall-runoff Modeling Based on Genetic Programming

VLADAN BABOVIC AND MAARTEN KEIJZER

DHI Water & Environment, Agern Alle, Hørsholm, Denmark

The runoff formation process is believed to be highly nonlinear, time varying, spatially distributed, and not easily described by simple models. Considerable time and effort has been directed to model this process, and many hydrologic models have been built specifically for this purpose. All of them, however, require significant amounts of data for their respective calibration and validation. Using physical models raises issues of collecting the appropriate data with sufficient accuracy. In most cases, it is difficult to collect all the data necessary for such a model.

By using data-driven models such as genetic programming (GP), one can attempt to model runoff on the basis of available hydrometeorological data. This work addresses the use of GP for creating rainfall-runoff (R-R) models both on the basis of data alone, as well as in combination with conceptual models (i.e taking advantage of knowledge about the problem domain).

INTRODUCTION

The runoff formation process is believed to be highly nonlinear, time varying, spatially distributed, and not easily described by simple models. Considerable time and effort has been devoted to model these processes, and many hydrologic models have been built specifically for this purpose. These models are generally referred to as rainfall-runoff (R-R) models. The R-R model is a hydrologic model, which basically determines the runoff signal that leaves the watershed basin from the rainfall signal received by this basin. According to the traditional hydrologic classifications R-R models are grouped into three categories, namely: empirical black-box models, lumped conceptual models, and distributed physically based modeling systems. The great majority of the R-R modeling systems used in practice are from the first two categories.

Empirical black-box models are entirely lacking in an explicitly well-defined representation of the physical processes involved in the transformation of rainfall into runoff. A large number of black-box models have their origin in the unit hydrograph theory of (Sherman, 1932) and are considered to be at the lower end of the scale in terms of inclusion of physical laws into the model structure. These models depend on rainfall and discharge observations for the estimation of their parameters and for further refinement of their structure. It is believed that the black-box models do not work very well outside the conditions used for their development and calibration. However, experience over decades has shown that these models are useful operational tools, and indeed, they are the only option in cases where there are no other meteorological data available except rainfall, or these data are of poor quality.

Conceptual R-R models are designed to approximate (in some physically realistic manner) the general internal subprocesses and physical mechanisms that govern the hydrologic cycle. Conceptual models are usually based on simplified forms of the physical laws and are generally nonlinear, time-invariant, and deterministic with parameters that are representative of the watershed characteristics. Such models ignore the spatially distributed, time-varying, and stochastic nature of the rainfall-runoff process and attempt to incorporate realistic representations of the major nonlinearities inherent in the R-R relationships. Again, despite their simplicity, many such models have proven quite successful in representing an already measured hydrograph. However, the implementation and calibration of such a model typically presents various difficulties, requiring sophisticated

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

mathematical tools, significant amounts of calibration data, and some degree of expertise and experience with the model.

While there are a large number of existing black-box and conceptual models, there are only a few distributed physically based hydrologic modeling systems suitable for research purposes and for real world projects. Deterministic models are explicitly based on our current understanding of the physics of the constituent hydrological processes. Perhaps the most widely known such system is the Systeme Hydrologique Europeen (SHE) (Abbott *et al.*, 1987) created jointly by the Institute of Hydrology, the Danish Hydraulic Institute, and SOGREAH. SHE is a general, physically based, distributed modeling system for constructing and running models of all or any part of the land phase of the hydrological cycle for any geographical area. These types of modeling systems have extensive data demands. They utilize quite a large number of parameters in their operation, which have a direct relation to physical catchment characteristics (topography, soil, vegetation, and geology) and operate within a distributed framework to account for the spatial variability of both physical characteristics and meteorological conditions. Even so, deterministic models also need calibration mainly because the parameters they require could not or are not directly measured everywhere in the modeled basin. The physically based distributed models do not have the applicability shortcomings of the models from the first two groups. In general, they are not directed only towards studying the R-R processes but also some other processes like erosion, conjunctive use of ground water and surface water, and environmental impacts of land use changes related to the agricultural and forestry practices, which are much more important than R-R alone. To model the runoff of a certain river basin using physical models raises issues of collecting the appropriate data with sufficient accuracy. In most cases, it is difficult to collect all the data necessary for such a model. Furthermore, this kind of model requires significant amounts of data for their calibration and validation.

An alternative to the outlined approaches may be to use new data-driven black- or grey-box type techniques that can model the process using only basic hydrometeorological data. Artificial neural networks (ANNs) have already gained much popularity in hydrologic circles (Minns and Hall, 1996). Another such technique is genetic programming (GP) (Koza, 1992). GP is a relatively new domain-independent method for evolving computer programs for solving or approximately solving problems. GP's learning algorithm is inspired by the theory of natural evolution and by our current understanding of biology and natural evolution.

The road map for the rest of the paper is as follows. First, evolutionary algorithms (EAs) as a method for constructing equations on the basis of data are described. Then, a case study, Orgeval catchment, is described in greater detail, and finally the rainfall-runoff process in the catchment is modeled using GP. Several approaches are presented and discussed in the concluding sections.

EQUATION BUILDING

When refining a model of a physical process, a scientist focuses on the agreement of theoretically predicted and experimentally observed behaviour. If these agree in some accepted sense, then the model is "correct" within that context. Here, we consider the problem inverse to verification of theoretical models: how can we obtain the governing equations directly from measurements? To do this, we will extend the notion of qualitative information contained in a sequence of observations to consider directly the underlying dynamics. We will show that, using this information, one can deduce the effective governing equations. The latter summarize up to an *a priori* specified level of correctness or accuracy, the deterministic portion of the observed behaviour. The observed behaviour on short timescales unaccounted for by the reconstructed equations will be considered as extrinsic noise.

Evolutionary Computation

According to the Darwinian theory of evolution, all animals and plants inhabiting our planet are actually descendants of a few primitive progenitors. Darwin, in the illustrious work *The Origin of Species by Means of Natural Selection* (Darwin, 1859), claims that all complex and intricate life forms that surround us are actually direct offsprings of these original prototypes. However, the offsprings differ from the original ancestors. They are not exact copies of their ancestors, but rather variations that possibly provide competitive advantages over other, similar, specimens in the same environment. And so, claims Darwin, through the process of copying (reproduction) with variations (mutation) and competition for resources, the organisms that evolve possess capabilities that are best adapted to the environment they are situated in. Survival of the fittest thus results in a situation in which a given environment is populated with the best adapted (most fit) organisms.

Evolutionary algorithms (EAs) are processes that are closely inspired by the Darwinian theory of evolution and have one principal objective: to evolve solutions to the problems, rather than to solve problems directly. The fundamental idea is no more original than plagiarism of natural processes, which corresponds to providing "algorithmic organisms" with hereditary capabilities, allowing them to reproduce and let them, through competition for resources, evolve those traits that maximize their benefits in a given environment. The environment to which entities adapt in the EA context is actually formed by a problem

domain for which solutions are being evolved. Thus, EAs attempt to mirror evolutionary processes from nature that allow for adaptation of evolving entities to the problem domain, which in turn emerges as a solution to a problem in question.

Here, we first outline properties of natural evolution, and then attempt to mirror those in an artificial media, as exemplified through EAs.

Properties of Natural Evolution

Natural evolution has been extremely successful in creating many "useful" things. Technology can be nothing but jealous about the successes of natural evolution. The success of adaptation achieved by living organisms to their environment can hardly be matched by human creations. For example, the rate of energy consumption for a given speed of any modern submarine, let alone surface vessel, exceeds that of a fish swimming in the water by several orders of magnitude. What are the processes that enabled natural evolution to construct such effective creations? According to the prevalent views, there are three main criteria for an evolutionary process to occur (Maynard-Smith, 1975):

Criterion of heredity	Offsprings are similar to their parents: the genotype copying process maintains a high fidelity;
Criterion of variability	Offsprings are not exactly the same as their parents: the genotype copying process is not perfect;
Criterion of fecundity	Variants leave a different number of offspring; specific variations have an effect on behavior and behavior has an effect on reproductive success.

The three requirements above are the necessary and sufficient conditions for an evolutionary process to occur. The criterion of heredity assures that offspring inherits information from parents, assuring their similarity. Variability is ensured through mutations, whereas the criterion of fecundity provides, on an average, more fit individuals with possibilities to reproduce more often, thus generating more and better-surviving offspring.

Evolutionary Algorithms

EAs are engines simulating grossly simplified processes occurring in nature and implemented in artificial media – such as a computer. The family of EAs today is divided into four main streams: evolution strategies (Schwefel, 1981), evolutionary programming (Fogel *et al.*, 1966), genetic algorithms (GAs) (Holland, 1975), and genetic programming (Koza, 1992). Although different and intended for different purposes, all EAs share a common conceptual base (schematized in Figure 1). In principle, an initial population of individuals is created in a computer and allowed to evolve using the principles of inheritance (so that offspring resemble parents), variability (the process of offspring creation is not perfect – some mutations occur), and selection (more fit individuals are allowed to reproduce more often whereas less fit, less often so that their "genealogical" trees disappear in time). One of the main advantages of EAs is their domain independence. EAs can evolve almost anything, given an appropriate representation of evolving structures. Similarly, in processes observed in nature, one should distinguish between an evolving entity's genotype and its phenotype. The genotype is basically a code to be executed (such as a code in a DNA strand), whereas the phenotype represents a result of the execution of this code (such as any living being). Although the information exchange between evolving entities (parents) occurs at the level of genotypes, it is the phenotypes in which one is really interested.

The phenotype is actually an interpretation of a genotype in a problem domain. This interpretation can take the form of any feasible mapping. For example, for optimization and constraint satisfaction purposes, genotypes are typically interpreted as independent variables of a function to be optimized. Along these lines, one can employ

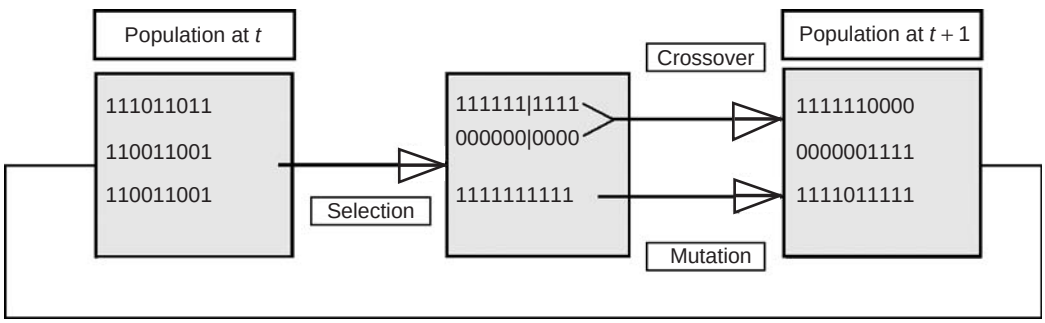

Figure 1 Schematic illustration of an evolutionary algorithm

mappings in which genotypes are interpreted as roughness coefficients in a free surface pipe flow model with the GAs directed toward the minimization of the discrepancies between model output and measured water level and discharge values. The resulting GA represents an automatic calibration model of hydrodynamic systems (Babovic *et al.*, 1994) (Madsen, 2000). Several other applications of GAs, which make use of various kinds of genotype-phenotype mappings and with a specific emphasis on water resources, are described, for example, in (Babovic, 1996).

Genetic Programming

Genetic Programming is one instance of the EA family. In GP, the evolutionary force is directed towards the creation of models that take a symbolic form. In this evolutionary paradigm, evolving entities are presented with a collection of data and the evolutionary process is directed towards the creation of a closed-form symbolic expression describing the data. In its primitive form, GP lends itself quite naturally to the process of induction of mathematical models based on observations: GP is an efficient search algorithm that need not assume the functional form of the underlying relationship. Given an appropriate set of basic functions, GP discovers a (sometimes very surprising) mathematical model that approximates the data well.

Individual solutions in GP are computer programs represented as parse trees (Figure 2). The population of the very first generation is usually generated through a random process. However, subsequent generations are evolved through genetic operators of selection, reproduction, crossover, and mutation. GP thus iteratively applies variation and selection on a population of evolving parse trees representing symbolic expressions. Standard variation operators in GP are subtree mutation (replace a randomly chosen subtree with a randomly generated subtree) and subtree crossover (replaces a randomly chosen subtree from a formula with a randomly chosen subtree from another formula – Figure 3). For a detailed description, see, for example, (Babovic and Keijzer, 2000).

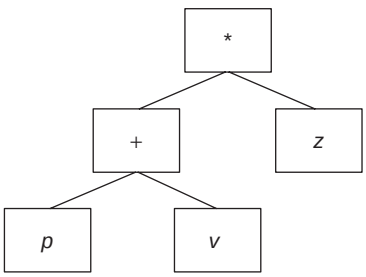

Figure 2 An equation $(p + v) \cdot z$ represented as a parse tree

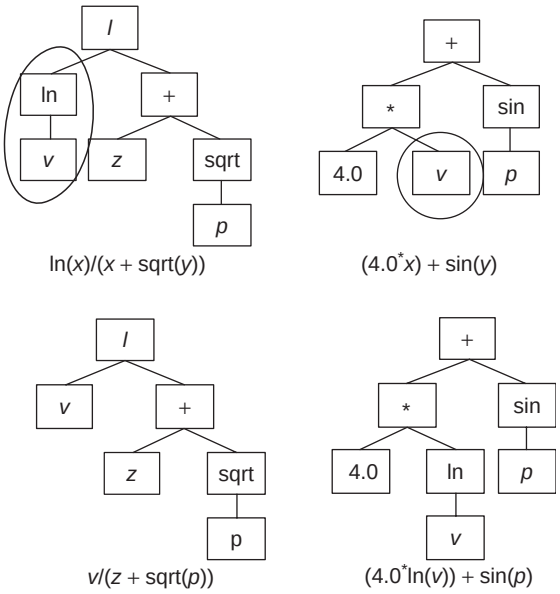

Figure 3 The action of the crossover operator: subtrees of selected parents (above) are swapped in crossover to generate the offspring (below)

The types of functions used in this tree structure are user-defined. This means that they can be algebraic operators, such as sin, log, +, −, and so on, but they can also take the form of if-then-else rules, making use of logical operators such as OR, AND, and so on.

The search process in GP is guided by fitness (i.e., a measure of accuracy). Determination of the fitness function to be adopted is an important aspect in GP since its performance largely depends upon how well this fitness function represents the objective or goal of the problem at hand. In the present work, we adopt a multiobjective approach in which both root mean squared error (RMS) and Coefficient of Determination (CoD) are used as fitness functions. The evolutionary process is then guided towards simultaneously minimizing RMS and maximizing CoD towards the value of unity. It has been shown empirically (Babovic and Keijzer, 2000) that this combination of objective functions implicitly promotes parsimony and results in simpler expressions.

A number of applications of GP has been reported, such as studies in which salt intrusion data were analyzed (Babovic and Minns, 1994), experimental data for bed concentration of suspended sediment (Babovic and Keijzer, 1999), analysis of roughness forces induced by vegetation (Babovic and Keijzer, 2000), as well as rainfall-runoff modeling (Babovic and Abbott, 1997a) (Khu *et al.*, 2001). In all of the above-mentioned studies, GP-induced relationships provided more accurate descriptions of data than those obtained using more conventional methodologies. An extensive survey of the applications of GP in water

resources is provided in (Babovic and Abbott, 1997b) and (Babovic, 1996).

Symbolic Regression

Regression – linear or nonlinear – plays a central role in the process of finding empirical equations. In its most general form, regression techniques proceed by selecting a particular model structure and then estimating the accompanying coefficients based on the available data. The model structure can be linear, polynomial, hyperbolic, logarithmic and so on. The only requirement in such an approach is that the coefficients in the model can be estimated using an optimization technique. In generalized linear regression for instance, the only requirement is that the model is linear in the coefficients. The model itself can consist of any functional form. Another technique may be a nonlinear regression where the only requirement is that the model is differentiable both in the inputs and in the coefficients. Supervised ANNs belong to this class of regression techniques.

Genetic programming can also be understood as a regression technique, a so-called *symbolic regression*. The specific model structure is not chosen in advance, but is part of the search process. In this algorithm, both model structure and coefficients are searched for simultaneously. The user has to define some basic building blocks (function and variables to be used); the algorithm tries to build a model using only those specified blocks. As a space of model structures is, in general, not smooth, not differentiable, nor linear in any useful sense (it is in fact highly discontinuous), standard optimization techniques fail when trying to find both the model structure and the coefficients.

CASE STUDY

The catchment under consideration is the Orgeval catchment, in France (Figure 4), which has been studied extensively in the World Meteorological Organization's intercomparison project (WMO, 1992). The catchment is located about 80 km east of Paris and the main river that drains the catchment runoff is the Orgeval. The catchment has an area of about 104 km^2. The catchment comprises mainly rural area, with only 1% of the total being urban areas or roads, and 18% of the total being covered by forest.

In this study, a total of 10 storm events – from 1972 to 1974 – hourly flow record are selected for training the GP while a total of six storm events (denoted as Storms 1–6) between 1979–1980 are selected and used for the verification of the updating procedure.

Forecast based on Conceptual Model – NAM

In order to establish grounds for intercomparison, the widely used R-R simulation model NAM (Nielsen and Hansen, 1973) is used to simulate the runoff for the entire period of interest. Since the main interest is the investigation of the skill related to the modeling of runoff processes (i.e. runoff as a response to forcing by rain), in all cases a so-called *ideal rainfall forecast* (measured rainfall was used in place of forecasted values) is assumed.

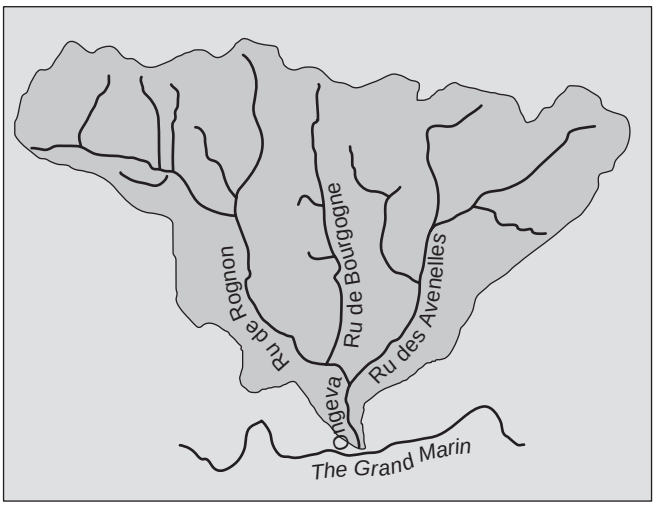

Figure 4 The Orgeval catchment

NAM represents a model of an R-R process. Given the ideal rainfall forecast, the quality of runoff forecast will not deteriorate the forecast horizon. For the present case, the forecast skill is summarized in Table 1.

Naïve Forecast

Another, almost trivial, possibility is to use a so-called *naïve forecast*: one simply assumes a forecast value which is exactly the same as the presently observed discharge. Owing to the strong autocorrelation, the forecast skill is expected to be good for very short lead times, but also to quickly deteriorate with forecast horizons. The results for the naive forecast are summarized in Table 1.

Forecast Based on Genetic Programming

A forecasting system is based on information of the past and current states of hydrometeorological and catchment conditions as inputs, as well as forecasted values of forcing term (rainfall R in this case) in order to forecast the catchment's response (runoff $\widehat{Q}$) in the future. Mathematically, this relationship can be expressed as:

$$\widehat{Q}(t+1) = F(Q_{\text{obs}}(t), Q_{\text{obs}}(t-1), \ldots, Q_{\text{obs}}(t-5), R(t+1), R(t), \ldots, R(t-5)) \quad (1)$$

In the present case, the choice of orders for $Q_{\text{obs}}(t)$ and $R(t)$ of the immediate past 5 time-steps were based on

Table 1 Statistical measures of accuracy (mean absolute error – *MAE*, Correlation coefficient – r, and Pearson's R^2) for the GP forecast as well as for the naïve forecast 1–12 hours

Forecast Horizon	GP Forecast			Naïve forecast		
	MAE	r	R^2	*MAE*	r	R^2
1 h	0.0161	0.9995	0.9991	0.0483	0.9973	0.9946
2 h	0.0245	0.9990	0.9980	0.0954	0.9899	0.9798
3 h	0.0322	0.9984	0.9969	0.1412	0.9787	0.9578
4 h	0.0390	0.9979	0.9957	0.1857	0.9646	0.9305
5 h	0.0445	0.9973	0.9947	0.2285	0.9484	0.8995
6 h	0.0495	0.9969	0.9938	0.2698	0.9307	0.8662
7 h	0.0537	0.9966	0.9932	0.3099	0.9118	0.8315
8 h	0.0571	0.9964	0.9927	0.3482	0.8921	0.7958
9 h	0.0597	0.9962	0.9924	0.3851	0.8715	0.7594
10 h	0.0623	0.9960	0.9920	0.4202	0.8500	0.7224
11 h	0.0647	0.9958	0.9916	0.4533	0.8276	0.6850
12 h	0.0682	0.9955	0.9911	0.4846	0.8044	0.6471

the catchment's concentration time, which varies up to a maximum of 5 h, that is, 5 time-steps (WMO, 1992).

For forecasts that extend longer into the future (α time-steps into the future), a slightly different, so-called *iterative approach* was utilized:

$$\widehat{Q}(t+\alpha) = F(\widehat{Q}(t+\alpha-1), \widehat{Q}(t+\alpha-2), \ldots, \widehat{Q}(t+\alpha-5), R(t+\alpha+1), R(t+\alpha), \ldots, R(t+\alpha-5)) \quad (2)$$

To be precise, in the present case, GP was utilized to forecast the temporal difference between the current and the future discharge $dQ(t+1)$, rather than the absolute value of the discharge $Q(t+1)$. There are two strong reasons for adopting such a setup. Firstly, due to a very strong autocorrelation of the discharges, there is a pronounced local optimum for forecasting discharges of the form $Q(t+1) = \beta Q(t)$, β being a constant, typically smaller than one. Such a local optimum may be statistically very accurate, but the associated phase error discredits its use as a forecasting tool. Once the temporal differences are introduced, the strong autocorrelation is removed, and the GP is forced to approximate change in response $dQ(t+1)$ as a function of forcing terms (rainfall R) and past discharges $Q(t)$. Secondly, temporal differencing of time series of discharges $Q(t)$ removes any of the possible trends that may exist in raw data and, consequently, yields a less biased forecast.

$$dQ(t+1) = (Q(t) - Q(t-1)) * \sqrt{\frac{R(t) + \sqrt{Q(t-1) + Q(t-2)^2}}{\frac{Q(t)}{Q(t)+Q(t-1)+Q(t)}}} + Q(t) \quad (3)$$

Equation (3) fundamentally models $dQ(t+1)$ by multiplying $dQ(t) = Q(t) - Q(t-1)$ with a nonlinear, time-varying correction factor. The correction factor is based on past discharges $Q(t)$, $Q(t-1)$ and $Q(t-2)$ as well as forecast rainfall intensity $R(t)$, and this explains the absence of phase error (see Figure 5). For longer lead times, the quality of iterative forecast deteriorates only due to errors introduced through calculated discharge. The ultimate result is that an approach based on GP outperforms NAM even for lead times of 12 h (see Figure 6).

Updating

The previous two sections demonstrated that forecast based on data deteriorates as a function of forecast lead time. At the same time, the forecast based on NAM was not as accurate; however, the quality of the forecast did not deteriorate with the forecasting horizon. A logical idea is to combine the two and provide a hybrid in which the best of the two approaches is combined, yielding a highly accurate forecast that does not deteriorate with forecasting lead times. This corresponds to a form of data assimilation, namely, the one of error-correction (for more details see (Refsgaard, 1997)).

This method is particularly interesting in real-time forecasting, where the originally forecasted values may be updated or modified as measured data become available and, thus, prediction errors can be determined and used to improve forecast skill. In real-time runoff forecasting with rainfall-runoff simulation models, rainfall time series up to the desired runoff forecast horizon must be available. A similar idea has been utilized before for hydrological problems (see e.g. Khu *et al.*, 2001; Madsen *et al.*, 2000) as well as in marine problems, albeit using neural networks, and for the forecast of current speed in Danish coastal waters (Øresund) (Babovic *et al.*, 2001).

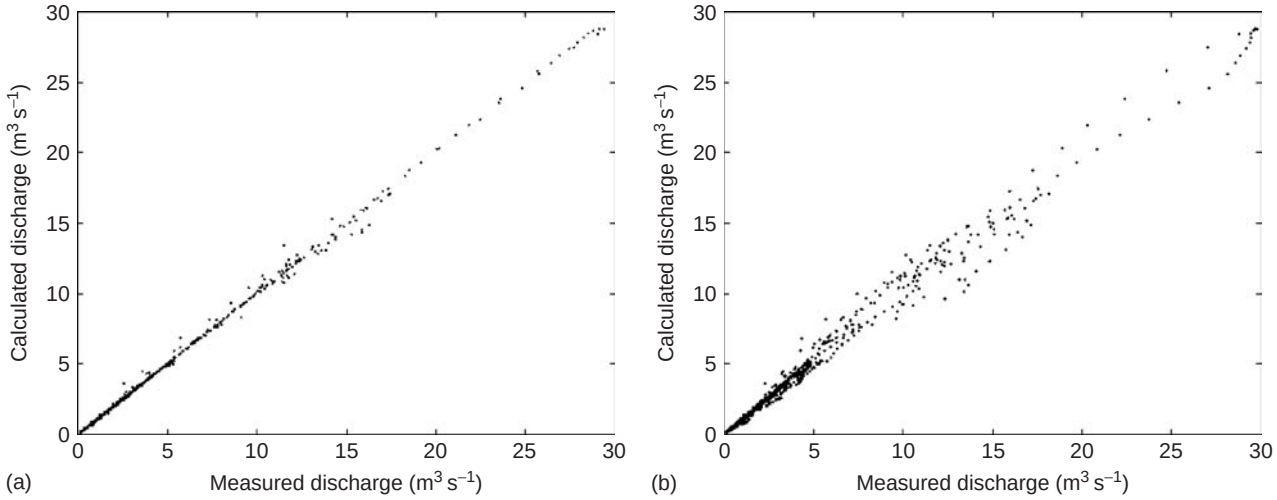

Figure 5 Scatter plots for GP based forecast utilizing equation (3) for lead time of (a) 1 h and (b) 12 h

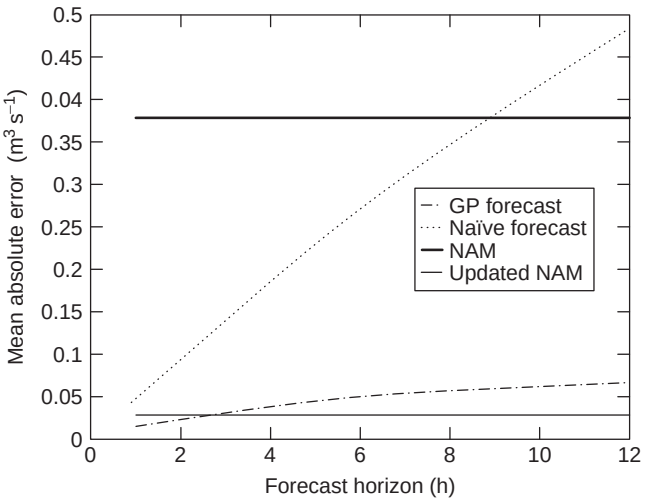

Figure 6 Evolution of mean absolute error as a function of forecasting lead time. The performances is calculated for 6 verification storm events. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Here, NAM is first used to simulate the discharge, Q_{sim}, for the entire period of interest based on the rainfall data R. Then the prediction error ϵ obtained by comparing the simulated discharge Q_{sim} with the observed discharge, Q_{obs} is computed. The improved discharge $\widehat{Q}$ is computed by adjusting Q_{sim} for each forecast lead time within forecast horizon. Mathematically, the measured discharge $Q_{\text{sim}}(t)$ can be expressed as

$$Q_{\text{obs}}(t) = Q_{\text{sim}}(t) + \epsilon(t) \tag{4}$$

Obviously,

$$\epsilon(t) = Q_{\text{obs}}(t) - Q_{\text{sim}}(t) \tag{5}$$

Genetic programing can then be used to approximate the functional relationship between the prediction error and the simulated discharges, the past simulation errors up to the current time as well as rainfall intensity up to forecast horizon. For lead time of 1 h, the functional relationship for the prediction error $\widehat{\epsilon}$ may be expressed as follows:

$$\begin{aligned}\widehat{\epsilon}(t+1) = F(&Q_{\text{sim}}(t+1), Q_{\text{sim}}(t), \ldots, Q_{\text{sim}}(t-5),\\ &\epsilon(t), \epsilon(t-1), \ldots, \epsilon(t-5),\\ &R(t+1), R(t), \ldots, R(t-5))\end{aligned} \tag{6}$$

while the forecast for improved discharge $\widehat{Q}(t+1)$ can be calculated as:

$$\widehat{Q}(t+1) = Q_{\text{sim}}(t+1) + \widehat{\epsilon}(t+1) \tag{7}$$

For longer lead times of $2, 3, \ldots, \alpha$ hours, the recursive form of equation (7) can be written as

$$\begin{aligned}&\widehat{\epsilon}(t+\alpha)\\ &= F(Q_{\text{sim}}(t+\alpha), Q_{\text{sim}}(t+\alpha-1), \ldots, Q_{\text{sim}}(t+\alpha-5),\\ &\widehat{\epsilon}(t+\alpha-1), \widehat{\epsilon}(t+\alpha-2), \ldots, \widehat{\epsilon}(t+\alpha-5),\\ &R(t+\alpha), R(t+\alpha-1), \ldots, R(t+\alpha-5))\end{aligned} \tag{8}$$

Note the use of error estimates $\widehat{\epsilon}$ instead of true error ϵ. The forecast for improved discharge $\widehat{Q}(t+\alpha)$ can now be calculated as

$$\widehat{Q}(t+\alpha) = Q_{\text{sim}}(t+\alpha) + \widehat{\epsilon}(t+\alpha) \tag{9}$$

The real-time flood forecast updating procedure for 1-h lead time could be summarized as follows:

Table 2 Statistical measures of accuracy (Mean absolute error – *MAE*, Correlation coefficient – *r*, and Pearson's R^2) for 'raw' NAM values as well as for updated model. Lead time 1 h

Statistic	NAM	NAM after update
MAE	0.3784	0.0279
r	0.9028	0.9612
R^2	0.8150	0.9240

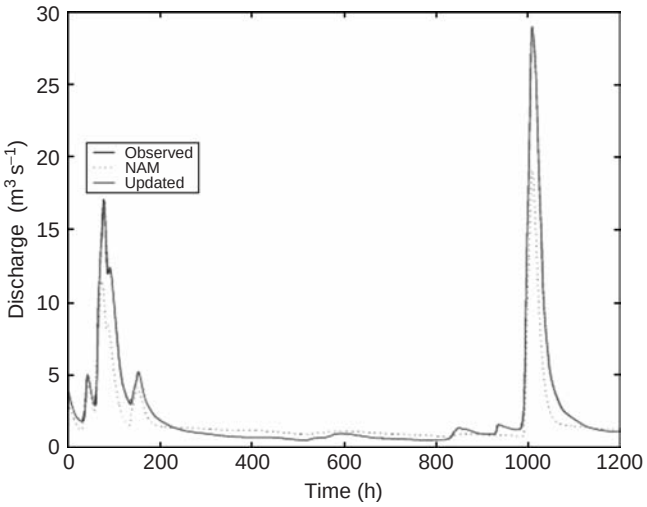

Figure 7 Time series of observed discharge, the one calculated using NAM and the one obtained through updating for two validation events. Lead time is 1 h and the difference between observed and the updated cases is so small that it cannot be optically distinguished

1. Surface runoff has been simulated with parameter values of the NAM model calibrated on 1972–1974 period for the validation period of 1979–1980.
2. The prediction errors, ϵ between the NAM simulated and observed runoff for each time interval are computed.
3. GP is then used to derive the functional relationship between the present prediction error $\widehat{\epsilon}$, the NAM simulated discharge Q_{sim}, the past prediction errors $\widehat{\epsilon}$, and rainfall intensities $R(t)$ as given in equation (6).
4. The improved simulated discharge, $\widehat{Q}$, is finally calculated, using equation (7).
5. For $t > 1$, the above procedure is repeated following equations (8) and (9).

As before and for the same reasons, GP was actually used to approximate a temporal difference in error evolution $\mathrm{d}E(t+1)$ rather than $E(t+1)$.

$$\begin{aligned}&\mathrm{d}\epsilon(t+1)\\&= \epsilon(t) - \epsilon(t-1) + ((\epsilon(t-3) - \epsilon(t-1))\\&\times (0.054 - \epsilon(t-1)) - 0.054(0.064(\epsilon(t) - 6.536)\\&+ ((2\epsilon(t) - 0.0644)R(t-3)Q_{\text{sim}}(t-3))) \qquad (10)\end{aligned}$$

The first two terms in equation (10) are the error at the t^{th} time-step $\epsilon(t) - \epsilon(t-1)$. This error is then corrected by introducing a high-order correction term which utilizes past rainfall $R(t-3)$ as well as output of conceptual model $Q_{\text{sim}}(t-3)$. Once this equation is used to calculate the error, and this error is in turn appended to NAM output Q_{sim}, the updated results provide a manyfold improvement over raw model outputs (see Table 2 and Figure 7).

CONCLUSIONS AND DISCUSSION

Several issues have emerged in the preceding sections.

1. Forecasting on the basis of data is possible, and in some cases can do considerably better in short term than forecasting and modeling on the basis of (conceptual) models.
2. The quality of forecasts created on the basis of data alone deteriorates with forecast horizon. This is perfectly reasonable since the initial conditions (in this case, observed discharges) are "washed out" and replaced by calculated discharges. Through the iterative process, inaccuracies are introduced, which amplify with the forecast horizon.
3. Modeling on the basis of our (albeit, conceptualized) insights about the physical processes cannot match short-term forecast skills created on the basis of data alone. However, the quality of such forecasts does not deteriorate with time.
4. It appears that the best approach is to combine the best of the two worlds: Use the data to improve the short-term forecast and use knowledge (in the form of a conceptual model) to help in extending the forecasting horizon without deterioration of the forecast skill. It is rather interesting to observe that the updated model is more accurate than the NAM model alone for lead times well beyond the catchment's concentration time (in this case, around five hours). This is due to the fact that GP forecasts errors created by NAM, and in principle "explains" phenomena not resolved by a conceptual model.
5. Genetic programming proves to be a powerful tool in the context of the rainfall forecast. The convenience of a single and simple equation, yet of extreme accuracy defends its use as an approach to short-term forecast.
6. Finally, it is very important to emphasize that it is the updating approach that provides the most accurate results. This clearly demonstrates that an amalgamation of knowledge (in the form of a conceptual R-R model) with a data-driven approach (in the present case, in

the form of GP) provides the best forecast skill. The authors strongly believe that it is a combination of the two approaches that will enable us to gain new insights, which may ultimately lead to better and more accurate rainfall-runoff models.

22: Evolutionary Computing in Hydrological Sciences

DRAGAN SAVIC AND SOON-THIAM KHU

Centre for Water Systems, School of Engineering, Computer Science and Mathematics, University of Exeter, Exeter, UK

With the advent of data acquisition techniques and data processing capabilities (computers + algorithms), evolutionary computing (EC) has found its way into a wide range of applications in hydrological science as demonstrated in this article. These applications range from the use of EC to assist in the understanding of hydrological processes, to improve the performance of simulation models for almost all aspects of hydrologic applications, and most recently, to quantify risk and uncertainty with the aim of providing decision support.

In this article, an attempt is made to provide a detailed review of the applications of EC in different hydrological science topics. References are divided into six main categories: hydrologic processes research, rainfall-runoff modeling, reservoir operations and control, groundwater systems, urban water systems, and water quality studies. These are broad categorizations, and many applications of EC span across multiple groupings.

Evolutionary Computing is a continuously and rapidly growing area of academic research for computer science, mathematics, economics and management, engineering, physical science, and many others. As such, it is futile to try to provide a comprehensive overview of the currently available EC tools and techniques and therefore, no such attempt is made in this article.

INTRODUCTION

With the advent of data acquisition techniques and data processing capabilities (computers + algorithms), evolutionary computing (EC) has found its way into a wide range of applications in hydrological science and indeed, forms one of the main thrust of a new water discipline known as *Hydroinformatics*.

EC refers to a broad range of computing techniques that uses a common algorithmic framework consisting of the following salient features:

- utilizing a set of solutions instead of a single solution;
- generating new solutions from previous solutions through heuristics; and
- modifying previous solutions through a combination of subtle and sudden changes;

In the process of generating new solutions and modifying old ones, EC imitates the mechanisms of heredity, variation, and selection at an abstract level. As such, EC has the ability to tolerate deteriorations of the quality of previous solutions during the search process and overcome local suboptima in order to find global or near global solutions.

Very generally, EC mimics the processes of biological evolution with its ideas of natural selection and survival of the fittest to provide effective solutions for optimization problems. EC uses algorithms based on natural evolution to solve a wide range of problems, which may not be solvable by standard and/or conventional optimization techniques. Examples of EC are genetic algorithms (Holland, 1975; Goldberg, 1989), genetic programming (Koza, 1992), evolutionary strategies (Schwefel, 1981), evolutionary programming (Fogel *et al.*, 1966), shuffled complex evolution (Duan *et al.*, 1992), and many other hybrid methods. Readers are encouraged to refer to the Handbook of Evolutionary Computation (Baeck *et al.*, 1997) for a general understanding of EC.

The applications of EC in hydrological science range from the use of EC to assist in the understanding of hydrological processes, to improve the performance of simulation

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

models for almost all aspects of hydrologic applications, and most recently, to quantify risk and uncertainty with the aim of providing decision support. For the purpose of clarity, the research in hydrological sciences may be grouped in the following sections:

- hydrological processes including evaporation, transpiration, rainfall, fundamental understanding of hydraulics and fluid flows, sediment transport, and so on.
- rainfall-runoff simulation and modeling including catchment model calibration, hybrid modeling with artificial neural network (ANN) and data-driven methods, process modeling, and so on;
- reservoir control and operations including reservoir planning and operations, irrigation, flood and drought control, and so on;
- groundwater (hydrogeological) system including groundwater remediation, monitoring and sampling network design, inverse problems or parameter identification/estimation, and so on;
- urban water systems including water distribution systems, urban drainage systems, and wastewater systems; and
- water quality issues including water pollution control, waste load allocation, health risks, and so on.

The above grouping is purely for the convenience of the discussion of application of evolutionary computation in hydrological science and is not an attempt to draw clear distinction between different branches of HS. The reader should understand that there are considerable overlaps between different groupings, or research may span across multiple groupings.

EVOLUTIONARY COMPUTING IN HYDROLOGICAL PROCESSES RESEARCH

One of the most widely researched topics in hydrological process is infiltration and indeed, the application of EC also found its way to optimize, calibrate, and model infiltration. Zeigler *et al.* (1996) proposed a fuzzy system designed by a genetic algorithm (GA) to solve the Green–Ampt equation without using the iteration method. They found that the GA fuzzy system was very efficient compared to traditional methods such as the Newton–Raphson iterative search. Vrugt *et al.* (2001) used a hybrid GA to calibrate the root water uptake model, HYDRUS, for 1D, 2D, and 3D cases. A simple GA was used to estimate the approximate global model parameter and fine-tuned using a simplex algorithm. In Ines and Droogers (2002), GA was used to estimate the parameters for Richards' equation to model soil water transport in the saturated zone where most plant activities are concentrated. A modified μGA (Krishnakumar, 1989) was developed incorporating creep mutation.

Other applications of EC in hydrological processes research include the use of GP to induce simulation models for flow through idealized vegetation (Harris *et al.*, 2003). Formulae or expressions were derived automatically on the basis of laboratory data collected in a flume with steady flow over a deep channel with relatively shallow vegetated floodplains. The resultant expression indicated that parameters describing the shading due to vegetation dominated the hydrodynamic behavior of the compound channel. This was in close agreement with other studies and support the belief that GP is a feasible tool for knowledge induction;

Nicklow *et al.* (2003) used the modified GA coupled with HEC-6 sediment transport simulation model to minimize sediment degradation and deposition in order to control the change in river channel bed morphology. The modification to GA was in the form of a blending crossover operator (Haupt and Haupt, 1998). Kisi (2004) used a differential evolution (Storn and Price, 1997) coupled with fuzzy logic to model suspended sediment transport behavior.

In the area of rainfall modeling, Yoo *et al.* (2003) used a simple GA to estimate six (out of nine) parameter values of the Waymire-Gupta-Rodriguez-Iturbe (WGR) multidimensional rainfall model. The results were compared with those using other rainfall models as well as the WGR model parameters estimated using the Davidson–Fletcher–Powell algorithm. The proposed method was applied to characterize the monthly and regional variation of rainfall fields of the Han River basin in Korea. They found that the parameter values estimated by GA were more consistent and better.

Evolutionary Computing in Rainfall-runoff Simulation and Modeling

There have been a large number of research works applying EC to calibrate runoff models, and one of the earliest applications of EC in hydrological science is the seminal work by Wang (1991) who calibrated the Xinanjiang conceptual rainfall-runoff (CRR) model (essentially a soil moisture accounting model) using a simple binary GA. In Wang (1991), GA was used to estimate the values of seven parameters (five water balance parameters and two linear transformation parameters) when the Xinanjiang model was applied to the Bird Creek catchment in the United States. The objective function used was a modified residual variance formulation taking the initial variance into account. The results obtained from GA were further tuned using the sequential simplex method. Wang (1991) had indicated that the simple binary GA had performed adequately in terms of locating good solutions and fine-tuning of GA may be useful if the GA is trapped in some local optima. He also concluded that GA could also be used to calibrate other hydrological models.

Many studies involving simple GA and runoff simulation have been performed and some of the works published in peer-reviewed journals are summarized here.

Liong *et al.* (1995) used a single-objective GA to calibrate the SWMM urban runoff model and applied it to a small urbanized catchment in Singapore. The GA used was the simple binary GA, known as *GENESIS*. Sixteen storm events of durations ranging from 5 h to 30 h were used for calibration and validation. They found that good results could be obtained for both calibration and validation storm events. Balascio *et al.* (1998) calibrated the SWMM model using a GA with manual fine-tuning option. They found that better results were obtained using manual fine-tuning after a limited number of GA searches. Cluckie *et al.* (1999) and Yuan *et al.* (1999) used a mutation-lead GA to calibrate the RHINO urban drainage model and applied to the Bolton Town Centre in the northwest of England. The mutation operator in their GA is directed (biparous) consisting of "positive" (forward) and "negative" (backward) steps, taken with reference to a random single gene position at any population. This scheme is similar to EC in some way. However, the results from their studies were not discussed and therefore difficult to assess the performance of their calibration algorithm.

Franchini (1996) also suggested a two-step procedure, GA–SQP (a simple GA and Powell's sequential quadratic programming local search) in which the GA was used to locate globally good solutions and the local search was used for fine-tuning the GA search result. They calibrated the 11-parameter CRR model, known as *A Distributed Model* (ADM), which was analyzed for two cases: error free data and actual data. It was shown that GA–SQP was able to achieve 100% success rate on the error free data and only slightly poorer on the actual data. Further research was performed to compare 11 GA schemes with various selection, reproduction, and mutation operators in order to analyze the effect of different GA structure on its capacity to find regions of optimum solutions. They found that GA seemed to be robust where the results obtained from different schemes did not differ from each other significantly. However, the authors also noted, "every objective function has its own intrinsic characteristics and therefore, the most appropriate optimisation algorithm may vary from case to case". With that, a further study was carried out to compare GA with two commonly used calibration techniques: pattern search with sequential quadratic programming (PS-SQP) (Henrickson *et al.*, 1988) and shuffled complex evolution (SCE-UA) (Duan *et al.*, 1992). They found that SCE-UA was able to provide slightly more consistent estimates of parameter values even though none of the algorithms were able to locate the optimal solution for a complex catchment with known parameter values.

Kuzcera (1997) compared different probabilistic optimization algorithms including GA and found that SCE-UA to be superior to the GA. However, since the simple GA was used, Kuzcera (1997) pointed out that "improved genetic algorithm performance is therefore possible" without indicating the method of improving GA.

Mohan (1997) used a simple binary GA to estimate the parameter values of the three-parameter nonlinear Muskingum equation and compared the results with those of traditional gradient-based optimization techniques. They found that GA was able to estimate the model parameters with reasonable accuracy.

Wang (1997) investigated the usefulness and robustness of GA when used to calibrate the expanded nine-parameter Xinanjiang model. The technique was applied to three medium-sized catchments: Bird Creek (United States); Wollombi Brook (Australia); Kizu (Japan); and a small catchment: Halton (Australia). In order to evaluate the robustness of GA, the runoffs were synthetically generated using known parameter values. The models were then calibrated using GA, assuming that the parameter values were unknown, in order to determine whether GA was able to locate the exact parameter values. The results showed that GA was, in general, capable of locating the regions where the exact parameter values lay. However, the author highlighted that, at times, GA was trapped in local optima closed to the known global optima. This is perhaps an indication that either the Xinanjiang model is over-parameterized (resulting in numerous parameter values with similar objective function values), or the objective function used in the study was not able to constrain the search (hence requiring more objective functions).

Cooper *et al.* (1997) calibrated the TANK CRR model using three algorithms: GA, SCE-UA, and simulated annealing (SA). They were concerned with the efficiency of the algorithms, as measured by the number of model simulations required, and accuracy of the parameter values. Four objective functions were considered as performance measures and they were: Nash coefficient, root-mean-square-error of the peak discharges, root-mean-square-error of the average flow, and ordinary least squares. It was found that SCE-UA performed better than GA, which in turn is better than SA. However, for the FLW criteria, the performance of GA was less variable compared to SCE-UA. This study showed that the choice of performance criteria would affect the calibration outcome.

Ndiritu and Daniell (1999) used a hybrid elitist GA to calibrate the 10-parameter MODHYDROLOG CRR model and applied it to a south Australian catchment. The hybrid GA consisted of a combination of fine-tuning (reducing and refocusing of search space), periodic hill-climbing, and subpopulation searches with shuffling. The strategy of forming subpopulation and shuffling was similar to that used in SCE-UA (Duan *et al.*, 1992). Ten separate

simulation runs were performed and the results indicated that the hybrid GA was able to locate the "optimum" parameter values that were very similar to each other for each run. The same algorithm was later applied to calibrate the SIXPAR CRR model with artificially generated runoff time series (Ndiritu and Daniell, 2001). Results showed that the hybrid GA was effective in locating the optimum parameter value, but was less efficient compared to SCE-UA.

Senbeta *et al.* (1999) also endorsed the need for local search to be coupled with GA. The simple binary GA was used, followed by the Rosenbrook method (Rosenbrock, 1960) and the Simplex method (Nelder and Mead, 1965). This sequential search technique was used to calibrate the probability-distributed interacting storage capacity (PDISC) model and applied to six catchments with daily data including three large catchments in Nepal and China and three midsize catchments in Bangladesh, Nepal, and Australia. The PDISC model consists of two submodules: a six-parameter water balance module and a three-parameter routing module. They found that the sequential calibration technique was able to provide satisfactory parameter estimates.

In most recent years, how to improve the efficiency and effectiveness of GA as a calibration technique has been the main focus of the following research.

Seibert (2000) used GA for multicriteria calibration of the HBV model. The method was applied to a synthetic runoff series generated by the HBV model and later to two catchments with different geological characteristics. Seibert (2000) took advantage of the population-based characteristics of GA and formed three subpopulations of parameter sets. Each of the subpopulation was used to optimize a different objective function. After a certain number of iterations, part of each subpopulation was exchanged between the subpopulations. In this way, characteristics of good parameter sets were transferred, and information regarding different objective functions was passed to different subpopulation. Furthermore, the performance criteria (one for runoff and the other for groundwater level) were fuzzified and combined into a single measure taken as the geometric mean of the two fuzzy measures. Seibert (2000) found that the use of multicriteria and additional data helped to constrain the ranges of the parameter values and provided a more realistic representation of the actual process. The same GA was also applied to calibrate three catchments of different sizes, each nested in the other (Seibert *et al.*, 2000). The purpose of this study was to investigate the issues of scale dependency of the similar catchments and simultaneous calibration of runoff series from different sub-catchments. They found that all three sets of optimal parameter were similar in values, indicating that these parameters accounted for the similarity in catchment characteristics but not size/scale. Variations existed in two parameters but they were found to be insensitive within the optimal range. One of the parameters also differs for all three catchments and it could be accounted for by the difference in the slope of the three catchments. It was found that the multicriteria approach had provided good estimates for the catchment parameter values.

Liong *et al.* (2001) proposed a hybrid multicriteria method to calibrate HydroWorks, a urban runoff/drainage model. A modified GA (known as *ACGA*) was used to generate the Pareto front (or trade-off surface), and an artificial neural network was used to provide an inverse mapping of the front. The purpose of the hybrid approach was to generate additional points on the Pareto front for the purpose of decision making. The approach was applied to calibrate the eight-parameter HydroWorks for the Upper Bukit Timah catchment in Singapore. Comparisons were made with a number of multiobjective genetic algorithms, and ACGA was found to be more efficient in their study.

Cheng *et al.* (2002) used a simple GA with fuzzy objectives to calibrate the 17-parameter Xinanjiang model applied to Shuangpai catchment in south China. Thirty four flood events were used for calibration and 11 flood events for validation. Three objectives were considered: peak discharge, time to peak, and total runoff volume. All these objectives are fuzzified and grouped into a matrix and a value of membership degree was assigned. Selection and reproduction were based on a weighted distance that took into account the membership degree matrix. The authors reported that fuzzification of the objectives had assisted the GA to evaluate and simplify the otherwise difficult multiobjective calibration problem.

EC has also been applied in the area of modeling rainfall-runoff process. Babovic and Abbott (1997) used GP to simulate the rainfall-runoff transformation generated from RORB CRR model. They compared GP with ANN and found that both techniques gave equally good coefficient of determinations. However, GP was preferred because more physical insight may be obtained compared with ANN. Savic *et al.* (1999) applied GP to a real case study in the United Kingdom, and compared their results with those obtained from a nine-parameter HYRROM CRR model, a 35-parameter land-use model, and ANN. Again, GP was preferred because of its ability to provide more insight into the form of the rainfall-runoff relationship. Whigham and Crapper (2001) applied GP on two catchments with very different runoff characteristics: (i) Glan Teifi catchment in Wales, a catchment with quick response, but also with large subsurface contribution (ii) Namoi river catchment in Australia, where the runoff ratio was less than 10% and was highly variable depending on seasons. GP results were compared with the IHACRES model results and it was found that GP was able to simulate runoff satisfactorily for both catchments, but IHACRES had problem simulating low flows in the Namoi river catchment. Liong *et al.* (2002)

and Davidson *et al.* (2003) modified standard GP in order to simulate the rainfall-runoff process better. Dorado *et al.* (2003) proposed a coupled ANN–GP approach to simulate rainfall-runoff in an urban catchment.

The use of ANN as a rainfall-runoff simulator is gaining popularity, but researchers often faced the problem of deciding the ANN network architecture to use. Abrahart *et al.* (1999) addressed this problem by using GA to optimize the network configuration. They compared GA with a network pruning technique and found that GA offered distinct advantage in terms of flexibility in network design. See and Abrahart (2001) used GA to optimize a hybrid fuzzy neural network for the purpose of continuous river level forecasting using both rainfall and upstream river level as inputs. Khu *et al.* (2001) used GP as a real-time forecasting technique to update the discharge obtained from MIKE11/NAM model. The technique was applied to a small catchment in France and it was found that GP outperformed all standard updating techniques including ARMA and Kalman filter. Good results were obtained for real-time forecasting horizon of up to 6 h. The use of ANN in hydrology is discussed in **Chapter 20, Artificial Neural Network Concepts in Hydrology, Volume 1**.

Evolutionary Computing In Reservoir Control and Operation

In the area of water supply management, most applications of EC are for reservoir operations and control with a small number of applications in irrigation management. One of the earliest applications of EC in reservoir control was by Esat and Hall (1994). They applied a GA to a four-reservoir problem in order to maximize the benefits from power generation and irrigation water supply subjected to constraints on reservoir storages and releases. Esat and Hall (1994) demonstrated advantages of using GA over standard dynamic programming techniques in terms of computational requirements. Subsequently, there were a number of works in or related to this area.

Oliveira and Loucks (1997) developed a GA-based approach to search for effective operating policies for dynamic models of multipurpose multireservoir systems. They found that their approach provided decision makers with significant flexibility and benefits in defining operating rules and policies.

Wardlaw and Sharif (1999) extended the work of Esat and Hall (1994) by examining different GA schemes to solve the four-reservoir problem. The different GA schemes considered different arrangements in terms of representation, selection, reproduction and mutation methods, and the use of elitism. They found that a real-value representation incorporating tournament selection, elitism, uniform crossover, and modified uniform mutation produced the best results. They also applied this GA scheme to a 10-reservoir problem. Sharif and Wardlaw (2000) applied GA to optimize a real multireservoir problem – Brantas Basin in Indonesia. Four case studies were considered: (i) maximizing hydropower returns; (ii) maximizing hydropower and irrigation returns; (iii) same as (ii) but including a future water resources development scenario; and (iv) same as (iii) but including more reservoirs in the system.

Cai *et al.* (2001) used GA combined with LP (linear programming) to improve the efficiency and effectiveness of solving highly nonlinear systems. They applied the GA and LP approach to: (i) a five-reservoir operation problem for hydropower generation, water supply, flood control, and flow augmentation; and (ii) a long-term dynamic, multi-period river basin planning model for irrigation planning and water allocation. The authors found that the multi-period planning problem was too complex even for GA and LP to solve with limited resources and time and the solutions obtained from GA and LP can be improved using gradient-based nonlinear programming.

Merabtene *et al.* (2002) used GA to derive reservoir operation rules (release) for drought management. The approach was applied to the Fukuoka city water supply system, where drought is a major concern due to water sharing conflicts among users – pumping, streamflow depletion for irrigation, water quality deterioration, and slow recovery rate. A decision–support system was developed and GA was used to generate risk-based scenarios. It was found that the optimal solution was biased towards certain scenarios and weight allocations. The authors proposed that future work should include the possibility of fuzzy inferencing to take into account the experience of engineers.

There are a number of research applications on using fuzzy logic to form operation rules and then optimized using GA. Chang and Chen (1998) used a real-code GA to locate good fuzzy control rules for operation of a simplified flood control reservoir. Chang and Chang (2001) used GA to locate the optimal reservoir operating rules based on a given inflow series, which was then used to train the adaptive network-based fuzzy inference system for water release operations. In Miles *et al.* (2002), GA was used to locate the optimal rule set for training a classifier system that was used for deriving control strategies of reservoirs. In Ponnambalam *et al.* (2002, 2003), GA was used to optimize the parameters in the neural fuzzy inference system for a single reservoir operation under stochastic inflow condition.

Chaves *et al.* (2003) proposed a GA coupled with DP approach to optimize reservoir storage taking water quantity and quality into account. Firstly, the reservoir water quality model, PAMOLORE, was calibrated using GA. Stochastic dynamic programming and fuzzy inference system was used to optimize the water quantity model. Then the water quality and quantity models were linked and optimized using deterministic DP and GA.

Chang *et al.* (2003) applied a simple GA to optimize and determine the rules used for flushing a reservoir to avoid excessive sedimentation. A flush model was developed and linked to a reservoir operations model. An optimal level of flushing was desired in order to flush out the sediments, but a high concentration of sediments may create a large impact on the ecological system and water uptake downstream.

Cui and Kuczera (2003) compared the use of GA and SCE (Duan *et al.*, 1992) to optimize the management of a urban water supply headworks system. The headworks system consisted of one reservoir and had three decision variables to be optimized. They found that SCE was more efficient compared to GA, but because of its implicit parallelism, GA was preferred.

In summary, the benefits of using GA for reservoir control and operations can be stated (Sharif and Wardlaw, 2000)as follows:

- Discretization of state and decision space is not required;
- Initial trial state trajectories are not required;
- Complex reservoir systems need not be decomposed as in successive approximation-based approaches;
- It has the ability to work with highly complex, even discontinuous objective functions;
- Noninvertible systems can be easily handled without introducing dummy state variables as in DP-based approaches.

In the area of irrigation management, Chen (1997) applied a simple GA to maximize the economic benefit that could be gained by distributing water resources to each district. In Kuo *et al.* (2000), GA was used to optimize the on-farm irrigation demand on the basis of a climate-soil-plant model. The approach was applied to an actual irrigation scheduling project in Delta, Utah, United States, by optimizing the crop area water allocation thereby maximizing crop production benefits. In a similar application, Nixon *et al.* (2001) applied a GA for optimizing off-farm irrigation scheduling in order to find the optimum delivery schedules. In Montesinos *et al.* (2001), GA was used to locate the optimal schedule for furrow irrigation in a maize field located in Cordoba, Spain. Since the problem was heavily constrained, the authors found that the level of penalty imposed was crucial to the success of GA. Nevertheless, GA was able to find good solutions compared to standard scheduling (heuristic approach).

Recently, Vink and Schot (2002) presented a case study looking at generating drinking water production strategies that allows minimization of production cost and environmental impact. The case study was performed on a catchment scale taking into account variable cost such as drawdown options, damage to wetland vegetations, impact on agriculture sector, reduction of river baseflow, soil subsidence, and so on. A multiobjective GA was used to optimize the model and applied to the water supply system in south of the Netherlands.

EVOLUTIONARY COMPUTING IN GROUNDWATER SYSTEMS

Applications of Evolutionary Computing in groundwater and hydrogeological systems have seen a steady growth since the early 1990s and the hydrogeological community has introduced various new developments in EC such as new fine-tuning techniques and the use of heuristics and multiobjective optimization to the hydrological science community. Three subgroupings are considered hereafter.

Evolutionary Computing in Groundwater Remediation

It is extremely costly to implement a groundwater remediation scheme and thus, every effort is made to identify the most cost-effective way of implementation (Cunha, 2002). In this aspect, EC is ideally placed to offer an effective means to optimize the cost of groundwater remediation. This is certainly true judging from the large number of research publications in this area. Leitao (1998) offers a detailed discussion on the various measures currently available for groundwater remediation.

McKinney and Lin (1994) and Ritzel and Eheart (1994) are generally regarded as pioneers in applying GA to groundwater remediation problems. In McKinney and Lin (1994), GA was used to solve three problems: maximize the pumping rate from an aquifer; minimize the water supply development cost; and minimize the total aquifer remediation cost. In the aquifer remediation problem, the objective was to obtain a steady-state policy/schedule for a pump-and-treat design problem, taking capital and operating cost of treatment, extraction, and injection systems into account. They found that GA was able to locate a better solution than the nonlinear programming approach.

In Ritzel and Eheart (1994), the concept of multiobjective optimization using GA was introduced to solve the groundwater pollution containment problem (using the pump-and-treat method). The authors compared several GA and multiobjective GA schemes (including vector-evaluated GA (VEGA) and a Pareto rank-based GA) with those from mixed-integer chance constrained programming (MICCP). Even though the performance of MOGA(multiple objective genetic algorithm) closely matched that from MICCP, the MOGA formulation had the advantage of easily incorporating different fixed costs that maybe associated with the pump-and-treat system.

There are a considerable number of applications of EC to groundwater remediation (mainly pump-and-treat system) and only some of them are summarized here.

El Harrouni *et al.* (1996) used a binary GA to optimize the pumping rates in a homogeneous aquifer simulated using a dual reciprocity boundary element method. The results were compared with an analytical and a FEM(finite element model) (optimized by LP) solution, and were found to be very close to the analytical solution and indeed better than the FEM/LP solution.

Huang and Mayer (1997) and Wang and Zheng (1997, 1998) used simple GA to determine optimal dynamic policies in which the policies change with each management period. Their objectives were to minimize the remediation cost of contaminated plumes with specific well configurations while minimizing cross contamination. Hsiao and Chang (2002) used a simple GA coupled with constrained differential dynamic programming (Murray and Yakowitz, 1979) to optimize the pumping wells setup, while considering both fixed well-installation costs and operating cost of time-varying pumping simultaneously.

In Aly and Peralta (1999a, b), GA was used to solve a nonlinear mixed-integer problem aimed at minimizing the capital and operating cost of pump-and-treat system. Single and multiple planning periods were considered as different scenarios for optimization. They compared GA with a formal mixed-integer nonlinear programming approach and found that GA was clearly better. Gumrah *et al.* (2000) solved a similar problem, but using a groundwater transport simulator based on Method of Characteristics.

Yoon and Shoemaker (1999) dealt with optimizing *in situ* groundwater bioremediation instead of the pump-and-treat method. They compared a number of EA schemes such as real-code or binary GA, and de-randomized evolutionary strategy (DES), and also direct search methods. They found that DES performed well both in terms of speed and accuracy, but more importantly, no one algorithm was consistently accurate for all three test problems. In a later study (Yoon and Shoemaker, 2001), they found that with suitable modification (such as directed reproduction and screened replacement), the real-code GA performed significantly better than binary GA.

Recognizing the drawback of simple GA in optimizing pump-and-treat system, a number of improvements were made to GA, mainly to increase the computational efficiency of GA. Guan and Aral (1999a, 1999b) coupled their GA with a groundwater simulator (known as *progressive GA*), and this coupled model was then used to optimize the full numerical model. The progressive GA seemed to work well and was able to reduce the computation time significantly. Chan Hilton and Culver (2000, 2001) developed new constraint handling techniques and coupled them with the simple GA. They found that the multiplicative penalty method of constraint handling worked well for both cases of pump-and-treat problem. Morshed and Kaluarachchi (2000) coupled a simple GA with three different types of enhancements on the basis of heuristics developed from better understanding of the performance of simple GA on groundwater problems. The results showed that all three enhancements were able to improve the performance of the simple GA considerably.

In Smalley *et al.* (2000), a noisy GA was used to determine cost-effective options for reducing risk to acceptable levels in an uncertainty context. The risk-based corrective action approach was optimized, and they found that noisy GA was capable of identifying highly reliable designs from only a small number of samples, providing a significant advantage for computationally intensive groundwater management models.

Maskey *et al.* (2002) presented the use of GA to determine the optimal combination of pumping rates and well locations for the removal of a contaminant plume using particle tracking. They used MODFLOW and MODPATH for groundwater flow simulation and particle tracking. They compared GA with (i) controlled random search, (ii) multistart algorithm, and (iii) adaptive cluster covering techniques and found that GA seemed to be the most accurate technique despite requiring more computational effort than other techniques.

Erickson *et al.* (2002) used a multiobjective GA (known as *niched Pareto GA* (NPGA)) to the pump-and-treat groundwater remediation problem. NPGA was applied to simultaneously minimize two objectives: (i) remedial design cost and (ii) contaminant mass remaining at the end of the remediation horizon.

In order to reduce the simulation time required to solve the groundwater remediation problem, ANN was used as a fast surrogate model. Several researchers have used GA coupled with the ANN to find optimal remediation strategies (Rogers and Dowla, 1994; Rogers *et al.*, 1995; Fedra and Jamieson, 1996; Morshed and Kaluarachchi, 1998a, b). Rogers and Dowla (1994) and Rogers *et al.* (1995) used a GA to select pumping wells by maximizing the fitness defined by the combination of regulatory constraints on water quality, amount of extracted pollutant, and normalized cost. They used a trained artificial neural network instead of the direct use of simulation model to reduce the computational burden.

Evolutionary Computing in Groundwater Sampling Design and Monitoring

The applications in this section includes design and planning of groundwater recharge systems, design of monitoring points for contaminated land, and so on. In Cieniawski *et al.* (1995), MOGA was used to determine the optimal locations of monitoring wells by simultaneously minimizing the contaminated area and maximizing reliability. Four different MOGA formulation were tested and they were: (i) weighted aggregate objective function; (ii) vector-evaluated GA; (iii) Pareto rank-based MOGA; and (iv) a combination of VEGA and rank-based formulation. The GA approach

was also compared with the simulated annealing method. The authors found that the combined formulation (iv) outperformed the other formulations in terms of the ability to generate the entire Pareto front. In addition, the parameters of the combined formulations allowed decision makers to focus on the particular portion of the trade-off curve they are most interested in.

Wagner (1995) investigated the groundwater monitoring problem subjected to uncertainty. They minimized the uncertainties of model prediction with a constraint of fixed budget for design in order to identify the optimal sampling locations in a groundwater aquifer, which improves the reliability of groundwater and the contaminant transport model. The GA method was compared to the branch-and-bound algorithm. GA was also used by Katsifarakis *et al.* (1999) to minimize the pumping cost for any number of wells under various constraints. Reed *et al.* (2000, 2001) studied the long-term groundwater monitoring problem as a multiobjective problem. The goal of their application was to minimize long-term monitoring costs while still providing accurate information on the mass of contaminants present. They used the nondominated sorted GA-II (NSGA-II) (Deb, 2001) for the optimization and found that this algorithm was much more efficient than the previously known MOGA (Reed *et al.*, 2003).

Tang and Mays (1998) used a simple GA to optimize the operations of the soil aquifer treatment system, which is a commonly used method for combined groundwater recharge and municipal wastewater removal. They found that the advantage of GA for such a problem was that the upper bound cycle time for the reactor (a constraint) does not need to be prespecified, thereby providing flexibility in the solutions. With this in mind, the authors felt that even though the runtime for GA was more compared to traditional successive linear quadratic algorithm, possible enhancements to GA (such as progressive optimal algorithm (Howson and Sancho, 1975)) may warrant further research.

Evolutionary Computing in Inverse Modeling/Parameter Estimation

Inverse modeling is a commonly adopted technique for the determination of aquifer(s) parameters in order to characterize the aquifer(s) for modeling groundwater flow and contaminant/solute transport and for groundwater/water resource management. Despite issues such as range of applicability, transferability and nonuniqueness of parameter values, reliability and robustness of results, and so on, which cast doubts about the methodology of inverse modeling, it is still a technology that is widely acknowledged as practical and useful, especially when parameters are not directly measurable.

Simple, single-objective GA has been applied to estimate parameter values for a wide range of groundwater models, such as, single aquifer parameters (Lingireddy, 1998), transmissivities in zoned aquifers (Katsifarakis *et al.*, 1999; Prasad and Rastogi, 2001), groundwater model calibration (Solomatine *et al.*, 1999), determination of locations of accretion (Gentry *et al.*, 2001), velocity and dispersivity parameters (Giacobbo *et al.*, 2002), transmissivity, storativity, conductivity, and aquifer thickness (Lee *et al.*, 2002), and locations of small-scale aquitard leakage, (Gentry *et al.*, 2003) amongst others.

In Heidari and Ranjithan (1998), GA was combined with the truncated-Newton search technique to estimate groundwater parameters for a confined steady-state groundwater model. Although the combined technique was successful in estimating the parameter values, it was found that the use of prior information about the parameters was important in obtaining the global optimum. Acknowledging the complex nature of the objective function in groundwater parameter estimation, Karpouzos *et al.* (2001) proposed a multi-population-based GA approach to estimate the transmissivity values. The authors highlighted that for multi-population-based approach, an important parameter for GA is the emigration rate. If the emigration rate is too high, the diversity in different subpopulations could not be maintained; if the migration rate is too low, the convergence rate of GA will decrease and the solutions may be far from optimal.

In Aral *et al.* (2001), the progressive GA (Guan and Aral, 1999b) was used to solve the contaminant source identification problem by minimizing the difference between the observed and simulated contaminant concentration at different locations. The source location coordinates and the source release histories were regarded as unknowns and had to be determined through the optimization process. The authors found that progressive GA was a robust approach that could handle errors in the observations, and errors obtained from the calibrated model stayed within the known bounds of the measurement errors. Tsai *et al.* (2003) used a hybrid GA to determine and locate the number and locations as well as the values of the basis points associated with the Voronoi tessellation. The hybrid GA consisted of a simple GA fine-tuned by grid search and quasi-Newton's algorithm.

In the area of model induction, Hong and Rosen (2002) applied GP to model the dynamic behavior of groundwater fluctuation in a fracture rock aquifer. The results showed that the GP-induced model was capable of predicting groundwater fluctuation due to storm water infiltration and at the same time, provided insight into the dynamic behavior of the modeled system. Because the resultant model was highly efficient in terms of computational runtime, numerous simulations can be made to allow hydrogeologists to extract information for the studied area.

EVOLUTIONARY COMPUTING IN URBAN WATER SYSTEMS

Water Supply/Distribution Systems

There has been a long tradition of applying GA to optimize, calibrate, design, and improve the performance of water distribution network or system. One of the first civil engineering applications of GA is the optimization of a pipeline (Goldberg and Kuo, 1987). However, the first widely referred work in the area of water distribution network (WDN) is that by Simpson *et al.* (1994). Since then, there have been considerable efforts in applying EC to WDN, examples ranging from new applications and case studies, to improvement to GA and development of new algorithms. We will attempt to review works in refereed journal publications according to the different purpose of the applications.

In the area of using GA to design new WDN, Savic and Walters (1997) applied a simple GA to optimize the cost of designing the two-loop network and the Hanoi network. The two-loop network consists of six nodes and eight pipes and full enumeration of all possible designs requires 1.48×10^9 evaluations. Better solutions were found using only 0.017% of the full enumeration. The Hanoi network consists of 32 nodes and 34 pipes organized in three loops. A full enumeration requires 2.87×10^{26} model evaluations, which is not possible even with the present-day computing power. A better solution was found using a maximum of 1×10^6 model evaluations. Gupta *et al.* (1999) also worked on the two-looped network and used a modified heuristic-based GA instead. The heuristics used are: (i) division of WDN into diameter zones according to the judgment of the designer, (ii) equivalent pipe diameters, and (iii) local adjustment to pipe diameters based on head-loss per unit length and pipe flow velocity. They also applied the modified GA to a 23-nodes and 38-pipes WDN.

A number of researchers recognized that the optimal design of WDN is often a complex multiple-objective process involving trade-offs between the total cost and its reliability, functionality, water quality, level of service and other factors (Rowell and Barnes, 1982; Goulter and Bouchart, 1990; Gupta and Bhave, 1994; Todini, 2000). Savic (2002) showed some shortcomings of the use of single-objective optimization for water distribution system design and introduced a GA multiobjective model that promised to ease the difficulties in applying optimization and providing decision support for that important problem. The optimization model used simple and intuitive objectives and constraints that were not difficult to formulate in mathematical terms, for example, cost, number of nodes with pressure deficit, and the extent of pressure deficit. These objectives allow a decision-maker to visualize the trade-offs between different benefits and costs, and more importantly to consider uncertainty in future demands and performance levels. This type of optimization could also take into account the fact that the system needs to be implemented in stages.

In the area of network rehabilitation, Simpson *et al.* (1994) used a simple GA to optimize the rehabilitation cost of a two-supply-source gravity fed network (Gessler, 1985) and found that GA was able to provide near-optimal solutions at a fraction of the full enumeration cost.

Dandy *et al.* (1996) applied an improved GA for the New York City tunnels (NYCT) network. Variable power scaling of the fitness function, Gray coding, and creep mutation operators were used to improve the GA. Results indicated that the improved GA was significantly better than simple GA. Lippai *et al.* (1999) noted that most research work in optimization of WDN used in-house software and proposed a method to link EPANET with several commercial solvers. Their applications included the NYCT and a 15-loop Almos network. A number of researchers also applied different GAs to the NYCT network:

- Montesinos *et al.* (1999) proposed an index-based deterministic selection operator;
- Vairavamoorthy and Ali (2000) proposed to use real-coded GA with a variable penalty for constraint violation. They also applied their method to the Hanoi network;
- Wu and Simpson (2002) proposed using flexible penalty factor for constrained optimization and developed heuristic rules for adjusting the lower and upper bounds of the penalty factor. This method, known as *self-adaptive penalty factor*, was coupled with the fast messy GA;
- Eusuff and Lansey (2003) proposed a hybrid EC, known as *Shuffled Frog Leap Algorithm* (SFLA), which is a cooperative search method inspired by natural memetics. The SFLA draws ideas from different meta-heuristic methods such as, parallel searching – from GA; multiple population – from island model; information exchange – from Shuffled Complex Evolution (SCE) (Duan *et al.*, 1992) and local search – from particle swarm optimization (Eberhart and Kennedy, 1995). They also applied SFLA to the Hanoi network.

Simple GAs usually represent solutions as fixed length strings. Goldberg *et al.* (1989) proposed a variable length representation for GA, known as *messy GA*, which allows the string length to vary within population. Goldberg *et al.* (1989) demonstrated that the messy GA was able to identify good clusters of string patterns leading to good solutions. Halhal *et al.* (1997) applied the structured messy GA (SMGA) to the rehabilitation of a hypothetical network and Moroccan network, a real-world large WDN. This was a restricted form of messy GA in that the string lengths across populations were allowed to change but not within population. The SMGA starts with a complete

enumeration of all single elements to form the initial population. The best elements were retained to form the essential building block for subsequent populations with longer strings. The SMGA was able to take advantage of the problem structure and reduce the search space significantly. Moreover, they had included Pareto ranking as the basis of formulating objective functions, therefore, SMGA can be considered as a multiobjective GA. Walters *et al.* (1999) later applied SMGA to the hypothetical "Anytown" network with good results. The "Anytown" network is one of the more challenging networks, which simulates a full WDN expansion programme with duplications of pipes, addition of new pipes, addition and/or extension of pumping stations, and provision of new reservoir storage at any location. Wu and Simpson (2001) applied a fast messy GA to three case studies: the Gessler network, the NYCT network, and the Moroccan network, and found that messy GA gave consistent results in all the networks.

To make the implementation of GA more accessible and closer to engineering practice, Morley *et al.* (2001) demonstrated the integrated usage of GA optimization, GIS, and a hydraulic network solver, StruMap, on a real-world, large network-expansion and rehabilitation. Despite the complexity of the problem, the proposed method was able to find solutions that provided up to 35% cost savings.

Noting the inherent parallelism of GA and the advancement in network technology, Balla and Lingireddy (2000) implemented an optimization model based on distributed GA on a peer-to-peer network of PCs linked using Ethernet cards running on MS Windows 95/NT operating system. The network was tested to calibrate three WDN (system A, B, and C) with different complexity, that is, 52 pipes, 435 pipes, and 850 pipes respectively. They found that the computational advantage of the PC network roughly corresponded to the number of PCs within the network.

Water distribution systems, like other infrastructures, will age and are subject to deterioration over time, and hence require a long-term perspective in terms of design, maintenance, and rehabilitation scheduling. Dandy and Engelhart (2001) demonstrated the use of GA to find a near-optimal schedule for the replacement of pipes in order to minimize the present value of capital, repair, and damage cost. They applied their method to a case study in Adelaide, Australia.

In the area of network layout design, Walters and Lohbeck (1993) used a GA to evolve tree-like structures to identify good designs for a directed WDN. Smith and Walters (2000) extended the algorithm to undirected networks. Davidson (1999) applied a modified GA to optimize the layout of networks constrained to a fully looped geometry. Fully looped geometry is one in which node isolation of basic vertices will not occur when any single link in the network fails. The modified GA had customized crossover and mutation operators to ensure that newly generated solutions are contiguous and feasible.

The implications of uncertainty in input data and model parameters are not always understood or considered when designing water distribution systems. Therefore, there is a need to develop design methods that can model such uncertainties and produce "robust" designs. Here, robustness of a system is defined as its ability to provide adequate service to customers despite fluctuations in some or all of the design parameters. Kapelan *et al.* (2003a) and Babayan *et al.* (2003) formulated and solved the problem of stochastic (i.e. robust) water distribution system design under condition of uncertainty. The two methods differ in how the uncertainty is quantified within the EC algorithm; the former used reduced Monte Carlo sampling, while the latter used a numerical integration scheme to convert the stochastic problem into its deterministic equivalent. The objective in both cases was to minimize total design costs subject to a target level of system robustness. System robustness is defined as the probability of simultaneously satisfying minimum pressure head constraints at all nodes in the network. The source of uncertainty analyzed in their work is future water consumption. Later on, the same authors formulated and solved the optimal design problem by using a multiobjective GA with the second objective being the level of robustness achieved (Babayan *et al.*, 2004; Kapelan *et al.*, 2004).

In the area of network sampling design, Meier and Barkdoll (2000) addressed the optimal sampling locations for locating flow monitors within the WDN. A simple GA was applied to a network model for a small town I Ohio, US, to optimize the sampling design. de Schaetzen *et al.* (2000) proposed the use of GA with Shannon entropy function as a measure of optimality for the selection of pressure monitoring point locations in WDN. They compared their methods with the shortest path algorithm and expert design and found that there were potential cost savings based on more efficient equipment deployment as suggested by GA. Kapelan *et al.* (2003b) formulated the sampling design problem as a multiobjective optimization problem with relevant constraints. Two sampling design models were developed to solve this problem. They both used GA as a search engine. The first model is based on the single-objective approach in which two objectives (cost and calibration model accuracy) are combined into a single one using appropriate weights. The second model uses the multiobjective GA approach and is based on Pareto ranking. Both the sampling design models were applied to two case studies (literature and real-life problem). Results from the case studies showed the advantages of the multiobjective GA sampling design model when compared with the single-objective and several previously published sampling design approaches.

Water quality monitoring and control in urban water supply systems can also be formulated as an optimization problem, where the aim is to estimate the source dosages, locations of disinfectant boosters, and/or scheduling of boosters. Munavalli and Mohan Kumar (2003) presented a thorough study on the use of GA to estimate the optimal dosage for multiple locations in three actual WDNs. Different chlorine dosage model were studied and the three problems varied in network complexity. GA was found to be well suited for optimal scheduling of multiple chlorine sources.

Leakage detection and calibration of hydraulic models are important issues for the management of water and other distribution networks. Savic and Walters (1997) introduced GAs in the area of water distribution network calibration. The inverse transient problem (i.e. calibration of transient WDS models) was first solved with the use of GAs by Vitkovsky and Simpson (1997). They solved the inverse transient problem by linking GAs to a forward transient solver. Kapelan *et al.* (2003c) developed an inverse transient model based on a hybrid search technique. The inverse transient procedure is formulated as a constrained optimization problem of the weighted least-squares type. Initially, two optimization techniques were tested: the GA and the Levenberg–Marquardt method. After examining their performance, a new hybrid genetic algorithm (HGA) was implemented to exploit the advantages of combining the two methods. The resulting HGA-based inverse transient model is compared with the GA and Levenberg-Marquardt-based inverse transient models using two case studies. The HGA-based inverse transient model proved to be more stable than the Levenberg–Marquardt-based model and more accurate and much faster than the GA-based inverse transient model.

Evolutionary Computing in Urban Drainage/Wastewater Systems

Urban flood control often involves the design of channels, detention, and storage facilities and so on, for the purpose of peak flow attenuation. Flood detention facilities are the most common engineering approach to control the impact of storm water runoff (both quantity and quality), and the design concepts for a single storage component have been well established. However, any single method of flood control is often insufficient, and local approaches may aggravate responses in other parts of the drainage system. Hence, an integrated approach with multiple structures is often required. As a result, the problem of urban flood control becomes highly complex where full enumeration for optimal solutions may not be feasible, and multiple objectives must be considered.

Many urban flood control problems can be formulated as nonlinear mixed-integer problems and hence can be readily tackled through the use of EC. Rauch and Harremoes (1999a) discussed the potential of genetic algorithms in urban drainage modeling and highlighted model calibration and model predictive control as the main applications. Two simple examples, one of each case, were provided. They suggested that the application of GA in multicriteria decision analysis is a potential area in urban drainage modeling, which had been overlooked, and provided hypothetical benchmark examples to illustrate their point.

Yeh and Labadie (1997) applied multiobjective genetic algorithm to generate nondominated solutions for system cost and detention effect for the Pazam catchment in Taiwan. Three multiobjective formulations were considered: VEGA, Pareto ranked GA (Goldberg, 1989), and MOGA (Fonseca and Fleming, 1993). The results were compared with those of a heuristic-based dynamic programming approach known as *successive reaching dynamic programming* (SRDP). They found that although SRDP was computationally more efficient, multiobjective GA had the ability of accommodating more than two objectives easily and hence was preferable.

On the other hand, the use of single-objective GA in urban drainage and wastewater system design is more common. Diogo *et al.* (2000) applied GA to optimize the design of a 3D urban drainage. Crossover and mutation operators were modified to produce dendritic or tree-like network layout. In Harrell and Ranjithan (2003), a simple GA was used for the design and siting of detention ponds for a water supply catchment in North Carolina, US. Since the problem was subjected to pollution loading constraints, the multiplicative penalty function was implemented in the GA.

In the area of wastewater system, Rauch and Harremoes (1999b) used a simple GA to optimize and control the performance of an urban wastewater system in order to minimize pollution. The authors were able to achieve good results with hypothetical problem sets and indicated that GA showed great potential in nonlinear model predictive controls for wastewater systems. Tait *et al.* (2003) discussed the presence of high level of suspended solids in sewer especially during alternating wet and dry flow period for a combined sewer system. They proposed a new process model for in-sewer deposit erosion in order to predict sewer flow quality and used a simple GA to calibrate the proposed model. A commercial software "Evolver" was chosen for the optimization, but a large number of evaluations were required in order to achieve good calibration results.

In a separate predictive modeling application, GP was used to model the dynamic performance of a wastewater treatment plant (Hong and Bhamidimarri, 2003). The predictive accuracy of GP was compared with ANN and a well-known IAWQ ASM2 model. The authors highlighted that the strength of the GP approach are: (i) the induced model structure is interpretable and (ii) the transparency of

the models allow further development/modification of the models for scenario generation and strategy development.

In order to reduce the computational cost of running the simulator for optimization, ANN is commonly used (as can be seen in previous sections). In the area of urban water systems, Sanchez *et al.* (1998) used an ANN as a surrogate model for the nonfulfillment time (exceedance time of fecal coliforms concentration limits) in a sewer system. The ANN was applied to emulate the sewer system for the metropolitan area of Gijon in Spain. The singular value decomposition method was used to optimize the ANN weights, and a simple GA was used to optimize the ANN structure/architecture.

EVOLUTIONARY COMPUTING IN WATER QUALITY RESEARCH

In the area of water quality research, GAs have been applied to optimize waste load allocation and ANN surrogate models, calibrate quality models, generate quality models, and model induction.

Waste load allocation refers to the process of determining the required pollutant removal levels at a number of either point or nonpoint sources to attain a satisfactory water quality response in a receiving water body. Burn and Yulianti (2001) applied a Pareto rank-based multiobjective GA to a waste load allocation problem in order to evaluate the trade-off between total treatment cost and to maintain various steady-state water quality conditions. Vasques *et al.* (2000) noted that Burn and Yulianti (2001) did not account for natural variability and parameter uncertainty and proposed to evaluate the model reliability instead. They used the first-order reliability method (FORM) to estimate the model reliability and a GA to generate the trade-off between cost and reliability estimate. Both studies were applied to a case study for the Willamette River basin in Oregon, US.

In the area of water quality model calibration, uncertainty of estimates was also taken into account in some research works. Chen and Chang (1998) used a simple GA coupled with a fuzzy objective function to calibrate a water quality model taking uncertainty into account. Their approach was applied to a case study of water quality management and control problem for the Tseng–Wen catchment in Taiwan. In Mulligan and Brown (1998), the potential use of GA for calibrating the steady-state Streeter–Phelps dissolved oxygen model for predicting DO concentration in streams was investigated. Synthetic data with and without error were used, and GA's performance was verified with a case study using the QUAL2E model applied to a river stretch in New England, US. The use of multiresponse as objective functions was also investigated and found to be superior to single response data. More recently, Ng and Perera (2003) used a simple GA to calibrate both QUAL2E model and the Australian Yarra River Water Quality model. They investigated the effect of different GA operator settings for calibration as well as for sensitivity analysis of the model parameters.

There are a number of applications of GA to optimize ANN surrogate water quality models. Neelakantan *et al.* (2002) employed ANN to predict the risk of protozoa (Cryptosporidium and Giardia) by relating risk to other biological, chemical, and physical parameters in surface waters. Different ANN training algorithms such as steepest descent, conjugate gradient, quadratic programming, and GA were compared. GA was found to be the more robust compared with the other training algorithms. In Wang and Jamieson (2002), ANN was employed to replicate a process-based water quality simulation model, TOMCAT (Bowden and Brown, 1983) and trained using a GA. Recently, Bowden *et al.* (2002) proposed a systematic approach for the optimal division of data for ANN models. They compared three different approaches of data division: arbitrary division, using GA, and using self-organizing feature maps (SOFM) and found that SOFMs were significantly better when these three methods were applied to an ANN which was used to forecast salinity in the River Murray, South Australia.

Bobbin and Recknagel (2001) used evolutionary strategy (ES) combined with rule-set generator to predict algal blooms in a Japanese lake. ES was used to optimize the parameters in the rule-set generator and to construct the rule-based model. The application of process-based model improvement and model induction was examined in Whigham and Rechnagel (2001). A GA was firstly used to calibrate the difference equation within the lake ecosystem model, SALMO, which predicts algal growth. GP was then applied to the model to evolve new expression for the different terms (such as photosynthesis, respiration, or grazing) in the difference equation. Initial findings were very encouraging and the authors were going to extend their work to process understanding of the evolved terms.

23: Flood Early Warning Systems for Hydrological (sub) Catchments

MICHA GUIDO FRANCISCUS WERNER, JAAP SCHELLEKENS AND JACOB CORNELIS JAN KWADIJK

WL Delft Hydraulics, Delft, The Netherlands

Provision of early warning is an effective strategy in reducing flood damage and loss of life due to flooding. Flood forecasting and warning systems are important instruments in supporting relevant authorities issuing appropriate warnings. With the advent of computer-based simulation techniques, computer-based data processing capabilities, and computer-based communication facilities, the impact of hydroinformatics on flood forecasting in support of flood warning is manifest. In this article, an overview is given of flood forecasting systems for providing warnings in hydrological catchments. This overview is given from the perspective of the position of flood forecasting within the process of detection, forecasting, warning, and response. A categorization of flood forecasting systems is introduced, and the elements of a flood forecasting system are discussed.

INTRODUCTION

Floods pose a major natural hazard, and extensive losses from major and minor flood events are unfortunately commonplace. Recent flood events such as in the Rhine basin in 1995, the Mississippi in 1993, the Elbe basin in 2002, and the Yangtze in 1998 have firmly established the realization that natural hazards such as those posed by flooding cannot be brought under control simply through engineering measures. While the hazard cannot be avoided, mitigation of the consequences can help significantly reduce the risk posed. A thorough understanding of how flood events develop is fundamental to help mitigate these, and the development of this understanding is an important topic of much hydrological research. In the operational context, however, effective mitigation of the consequences of flooding can be provided through the provision of effective flood warning (Krzysztofowicz *et al.*, 1992; Parker and Fordham, 1996; Haggett, 1998; Penning-Rowsell *et al.*, 2000; De Roo *et al.* 2003).

The basic objective of the development of operational flood warning systems is to provide timely warning such that loss of property and life can be reduced, if not avoided completely, through implementation of simple, yet effective measures such as evacuation, temporary relocation, or implementation of a flood control strategy (Carpenter *et al.*, 1999). An operational flood warning system combined with these simple measures provide a much more cost-effective way of reducing flood risk and may help avoid large investments in traditional engineering flood control measures such as the raising of dykes or the building of flood control dams (Krzysztofowicz *et al.*, 1992). To be effective, the ability to provide timely warning must be complemented by awareness and preparedness by those at risk. A good example of how losses can be reduced was shown in the Meuse basin. Financial losses due to flooding in the Netherlands during the event of December 1993 greatly exceeded those of the event of January 1995, despite the two events being very comparable in magnitude. The reduction was partly attributed to the provision of early warning and the subsequent response (Wind *et al.*, 1999).

Operational flood warning systems have been developed or are under development in several river basins both in Europe (e.g. Parker and Fordham, 1996; Sprokkereef, 2001; Bürgi, 2002) and overseas (e.g. Grijsen *et al.*, 1992; Burnash, 1995; Jørgensen and Høst-Madsen, 1997; Du Plessis, 2002). All of these rely on the detection of floods through hydrometeorological observation networks, and the use of observation data is a primary element of a flood warning system. To increase the potential utility of the flood

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

warning service through extension of the lead time with which a flood event can be predicted, the state-of-the-art systems also incorporate some form of (model based) flood forecasting (Parker and Fordham, 1996). A wide range of techniques may be employed to provide flood forecasting capabilities, ranging from data-driven modeling techniques (e.g. Zealand *et al.*, 1999; Laio *et al.*, 2003; Young, 2003), through conceptual modeling approaches (e.g. Bürgi, 2002), to more complex networks of conceptual and physical models (e.g. Moore and Jones, 1998; Grijsen *et al.*, 1992, Van Kalken *et al.*, 2004).

How appropriate different types of techniques are is very much determined by the given requirement of delivering a forecast for a forecasting point at a minimum lead time. Lead time in the context used here defines how much warning can reliably be given of imminent flooding. The lead time at which effective warning can be delivered is clearly dependent on the lag times between precipitation falling and the flood peak reaching the point of interest. Warning lead times, therefore, vary greatly even in a single basin; for example, in the Rhine catchment warning lead times in the upper basin may only be in the order of 24 h (Bürgi, 2002), while in the lower basin, forecast lead times of up to four days can be provided using only hydrometeorological observations and a rainfall-runoff and routing model (Sprokkereef, 2001). The requirement to provide effective warning, together with the objective of increasing lead time and accuracy, poses new challenges in the implementation of flood warning systems.

This article explores flood forecasting systems from the perspective of its position within the flood warning process. A method for classifying the different approaches taken in flood forecasting is introduced before the elements of a present-day flood forecasting system are discussed in detail. Finally, the state of the art in developing flood forecasting systems is addressed including how to deal with specific challenges posed.

FLOOD FORECASTING AS A PART OF THE FLOOD WARNING PROCESS

The diversity of flood forecasting systems in operation or proposed in the literature is great. Flood warning systems are typically tailor-made to suit the specific requirements for the location(s) for which the warnings are to be provided, ranging from fast-responding local warning systems in the headwaters of a river (e.g. Krzysztofowicz *et al.*, 1992) or urban areas (e.g. Koussis *et al.*, 2003), to flood warning systems for lower reaches of large river basins (e.g. Sprokkereef, 2001). Often, flood warning systems are developed to cover all rivers within an administrative boundary, depending on the responsibilities of the authorities whose obligation it is to deliver the forecast (e.g. Moore *et al.*, 1990). The structure of the system in adjacent regions or countries may be very different (compare for example Moore *et al.* (1990) to Dobson and Davies (1990), who describe forecasting systems used for two adjacent regions in the United Kingdom). In some cases, differences may even occur within the same river system, such as in the Rhine basin. No less than 25 flood forecasting and/or flood warning centers are involved from the source to mouth, each with a different approach to flood forecasting (Steinbach and Wilke, 2000).

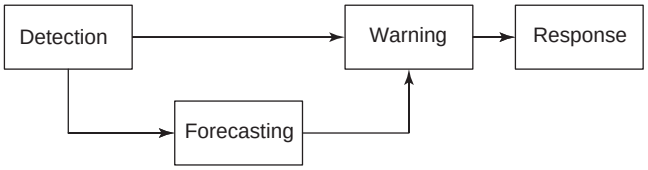

Figure 1 Stages in the delivery of effective flood warning

Despite the apparent variety in approaches, the elements on which the effective flood warning depends is an optimal combination of activities as depicted in Figure 1 (Parker and Fordham, 1996; Haggett, 1998);

1. *Detection*. In the detection stage, real-time data on processes that could generate a flood event are monitored. This includes primarily, monitoring of hydrological and meteorological conditions in the catchment through online information gathered through telemetry systems, climate stations, weather radar, and so on. The detection stage may also include techniques such as storm tracking and nowcasting (e.g. weather radar propagation), though this could also be thought to be a part of the forecasting stage.
2. *Forecasting*. In the forecasting stage, predictions are made of levels and flows, as well as the time of occurrence of possible forthcoming flood events. Typically, this involves the use of hydrological models, driven by both the real-time data gathered in the detection phase and forecasts of meteorological conditions such as rainfall and temperature. These are often obtained through external meteorological forecasts.
3. *Warning and dissemination*. The warning stage is a key factor in the success of operational flood warning. Using information derived from the detection and forecasting stages, the decision to warn appropriate authorities and/or properties at risk must be taken. The warning must be such that it gives an unambiguous message on the imminent flood potential.
4. *Response*. Response to flood warnings issued is vital for achieving the aims of operational flood warning. If the objective is to reduce damage through flood preparedness, an appropriate response by relevant authorities and affected persons must be taken following a warning, if it is to be realized.

Although the flood forecasting stage is an important part of the flood warning process, the most basic warning

systems do not include an explicit forecasting step and issue flood warnings on the basis of observations such as gauged rainfall and flows, combined with the judgment and experience of the forecasters (Cluckie, 2000). The detection step, together with the warning and response steps are the most important for a flood warning system to attain its objectives. This is reflected in the criteria used by Parker and Fordham (1996) in assessing and comparing the maturity of various operational flood warning systems in operation across Europe. Most of these criteria address the dissemination of the flood warning and the organizational embedding of the system. Indeed criteria were introduced to compare the importance of the flood warning element to the flood forecasting element. Systems where flood forecasting dominated and less importance was given to flood warning were deemed to be in an early stage of development. Failure of flood warnings to reach the public (Penning-Rowsell and Tunstall, 1999), or a large number of warnings issued to the public that prove to be false due to low accuracy of forecasts (Krzysztofowicz *et al.*, 1992), will lead to performance deterioration of the flood warning service as a whole.

Despite the need to view flood forecasting from within the perspective of the flood warning system as a whole, the flood forecasting step is one where hydroinformatics and an understanding of the hydrological processes involved can contribute to the improvement of a flood warning system. This is particularly relevant in view of the requirement to deliver a warning with a given lead time, with the required lead time achieved using forecasting techniques that may range from expert (hydrological) interpretation of the monitored data to more formal hydrological modeling setups. In view of this requirement, a categorization of flood forecasting methods can be developed on the basis of the hydrological and meteorological processes involved, which must be explicitly considered in the forecasting step to achieve the desired lead time.

Classification of Flood Forecasting Systems

A simple classification of flood forecasting systems can be found through comparing the desired lead time T_d to the hydrological response time T_p at the location for which the forecast is to be provided. The desired lead time is the time that is needed to effectively undertake the two final steps of *warning* and *response*. From the point of view of different lead times for forecasts with different objectives, we separate between nowcasting (a few hours), short-range forecasting (hours to two days), medium-range forecasting (2–10 days), and long-range and seasonal forecasting (between 10 days and a year). The hydrological response time T_p is similar to the more general hydrological concept of the *"time to peak"*. In the context of initiating a flood warning, it is more appropriate to consider the time between the rainfall event occurring and the crossing of a flood warning threshold. On crossing of such a threshold, a warning may need to be issued and appropriate response initiated. The hydrological response time can be further subdivided into the time that water needs to flow through the river channel (T_c) and the time the water needs to flow from the land phase into the river (T_s). The division between the land phase and the river channel is perhaps somewhat arbitrary, but generally, the river channel is considered to be the main river (system), while the response of the land phase is the response of (sub)catchments before the water flows into the main river system (see Figure 2).

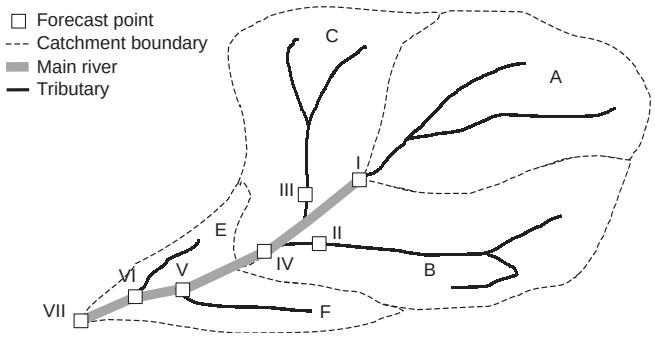

Figure 2 Schematic layout of a catchment, including the main river, tributaries, and catchments

On the basis of these characteristic times, four situations can be recognized (adapted from Lettenmaier and Wood, 1993);

1. $T_d < T_c$ or $T_s << T_c$. The desired lead time is such that the warning will be issued on the basis of water that is already in the main river channel; or, the time the water needs to flow from the land phase into the river is insignificant compared to the time the water needs to flow through the main river. This may be the case for forecast point VII in Figure 2, assuming that catchments E and F have only a minor contribution in flood genesis.
2. $T_d < T_p$ and $T_c \cong T_s$. The desired lead time is such that the warning will be issued on the basis of water that is still on the land phase, and the response time is determined both by the time this water needs to flow from the land phase into the river channel and by the time the water will need to flow through the main river. This may be the case for forecast point IV in Figure 2.
3. $T_d < T_p$ and $T_s >> T_c$. The desired lead time is such that the warning will be issued on the basis of water that is still on the land phase and the response time is mainly determined by the time this water needs to flow from the land phase into the river channel. This may be the case for forecast point I in Figure 2.
4. $T_d > T_p$. The desired lead time is such that warning may be issued on the basis of water that has not yet

fallen as rain. In this case also, the weather forecast is needed for a timely forecast.

Cases 1–3 are typically applied for short-range forecasting in medium and larger basins. Case 4 is typically applied in either medium to long-range forecasting in larger river basins or for forecasting in small (flashy) river basins.

Elements of a Flood Forecasting System

The choice of an appropriate forecasting method incorporated in the flood forecasting system used in the forecast stage will depend very much on how the desired lead time and the hydrological response time compare for the location at which a flood warning service is to be provided. Typically, the forecasting system will employ one or more models to simulate discharges and stages in the river system. These are simulated as a function of observed meteorological conditions and possibly short- or medium-term forecasts of these, depending on how the desired lead time compares with the characteristic hydrological response times. The models are obviously employed in a real-time environment, and this will pose specific requirements on the model in terms of robustness and efficiency. More important though is that the model is seen as a part of the flood forecasting system. Madsen *et al.* (2000) list key elements of a forecasting system operating in a real-time environment:

1. Real-time data acquisition for observed meteorological and hydrological conditions. This element is provided through the detection stage, and it is clear that the data must be made available. For use within the forecasting system, however, the data must be subjected to stringent data validation procedures to ensure integrity of the data used in model simulations on which warnings may be issued.
2. Hydrologic and hydraulic models for simulation. A wide range of modeling approaches may be applied where models take information on the current and past states of the system, and forecasts are made for the desired lead time as a function of boundary inputs on the system.
3. Forecast of meteorological conditions. Where necessary, forecasts of meteorological conditions are required to allow issue of warnings at sufficient lead time. Generally, these forecasts are sourced from meteorological services, and must be integrated within the flood forecasting system.
4. Updating and data assimilation. Through the process of data assimilation and updating, simulated data are combined with real-time data to provide a more accurate forecast. The use of an updating or data assimilation technique is an important aspect of applying models in real time.

REAL-TIME DATA ACQUISITION

Figure 1 shows the important position of real-time data acquisition within the flood warning process. Monitoring of hydrometeorological conditions in the catchment is paramount in the running of an operational flood warning and forecasting system. The availability of real-time observed data is also important to the flood forecasting stage, as these provide the boundary conditions to the models used. The observed data is used not only to bring the models up-to-date, but also for keeping the models in track with reality through data assimilation. Particularly, for forecasting systems of the first and second category described above, where lag times are such that desired lead times can be achieved through calculating runoff and routing of observed rainfall and flow, the availability of real-time data is essential.

Most monitoring data is typically provided from telemetry sites, including river gauges and rain gauges. These sites are typically used for a more general purpose than flood warning alone, providing data also to navigation authorities, water resources planners, irrigation agencies, and others. For flood warning, the timely availability of the data is obviously an important factor in determining the utility of the data, and also reliability of data transfer is an important aspect. Communication may simply be through telephone (e.g. Dobson and Davies, 1990), or where reliability of telephone networks is insufficient, through dedicated VHS or UHF radio links (e.g. Grijsen *et al.*, 1992). The advances in communication technology have in recent years significantly increased the reliability of data transfer, with off-the-shelf technology such as GSM networks and Internet providing reliable transfer mechanisms.

Although the problems of data transmission are being resolved through advances in communication technology, the reliability of the data itself is an issue that warrants close attention. Validation and checking of all real-time data prior to their use in a forecasting model is important to avoid warnings being issued on the basis of doubtful data. The data used is mainly that of rainfall accumulations from rain gauges and levels from river gauging stations. For upstream boundaries, water levels are typically transformed into discharge through stage-discharge relationships. Particularly in severe floods, these stage-discharge relationships may contain a significant degree of error, and the reliability of these relationships at high flows should be carefully assessed. For catchment rainfall estimates derived from rain gauges, the problem of scale arises, as the point measurements must be up-scaled to catchment rainfall estimates. Various interpolation techniques are available, but errors are introduced because of the correlation structure of rainfall and the low density of real-time rain gauges. Rain-gauge locations may also dominate in, for example, valleys in mountainous regions rather than in more inhospitable high

mountain areas (Bürgi, 2002), while the higher mountain regions will generally receive most rainfall.

The use of weather radar partially solves the problem of spatial coverage of rainfall estimates, and has been growing in popularity in recent decades (Todini, 2001). Weather radar provides a spatial estimate of precipitation as inferred through the radar reflectivity of the rainfall, and a reliable relationship between reflectivity and rainfall rate must be applied. Unfortunately, no unique relationship is available (Sharif *et al.*, 2002). In addition, there are a number of physical factors influencing uncertainties in radar derived rainfall estimates. These are not only due to atmospheric distortions such as the melting layer (Sharif *et al.*, 2002), but also due to, for example, radar beam shielding in mountainous areas (Borga *et al.*, 2000). An overview of potential sources of error can be found in Smith and Krajewski, (1991). In practice, integration of rain-gauge data and radar rainfall estimates can be combined through, for example, block Kriging to provide more reliable estimates of distribution and volume of observed rainfall (Todini, 2001).

An alternative method for estimating rainfall quantities is based on the analysis of clouds and cold-cloud duration, as shown by images from a geostationary satellite. This may provide some estimate of rainfall in areas otherwise inaccessible, as demonstrated successfully in the upper Nile basin by Grijsen *et al.*, (1992). However, this technique has not yet proved sufficiently reliable for application in small- or medium-sized catchments outside of tropical areas (Todini, 2001).

HYDROLOGIC AND HYDRAULIC MODELS FOR SIMULATION

Of the large number of hydrologic and hydraulic models that exist, a significant number is used in forecasting systems. However, the requirements are such that for a certain class of forecasting systems the choice of model concepts is usually limited. For an in-depth discussion on the different kinds of (hydrological) models that may be used, the reader is referred to **Chapter 122, Rainfall-runoff Modeling: Introduction, Volume 3**. The following model types used in forecasting can be distinguished:

- Correlation-based models use a linear or nonlinear relation between two or more locations to get to a forecast level or discharge. Water levels or discharge for one location (the forecasting site) can be derived from the level or discharge at one or more support sites (see example in Figure 3). A support site can be an upstream gauge, a gauge in a neighboring catchment, or a combination thereof. For peak flow forecasting, these systems are usually based on a database of events for which the peak flow and date-time information are stored in a database. When new events are recorded, they can be added to the database to improve the results. Depending on the river characteristics and the amount of historical events that are available, a correlation system can provide accurate forecasts. However, the lead time is limited to the travel time between the forecast location and the support location. Within the classification given above, the correlation model is therefore suitable only in the first class of forecasting systems, where the desired lead time for the downstream site is such that the event has been recorded at the upstream site.
- Transfer function models have been used widely in flood forecasting system. There are many different types of transfer functions, the most commonly used types being the Multiple Input Single Output (MISO), dynamic autoregressive exogenous (DARX) models (Lees, 2000a). Typically, transfer functions will be established to define a relationship between rainfall and runoff, or between flow at a downstream site and one or more upstream sites (comparable to the correlation models described earlier). The main attraction of transfer functions is that the model structure is identified using available data only, thus leading to efficiently parameterized model structures (Young, 2003). Transfer function models are also relatively simple to implement and computationally very efficient. To solve some of the difficulties found in representing the nonlinear rainfall-runoff response using linear transfer functions, a nonlinear rainfall loss term can be introduced prior to the linear transfer function to represent antecedent catchment conditions (Lees, 2000a). Young (2003) describes the Data-Based Mechanistic model, which extends the transfer function concept but allows the input parameters to be adaptive as a function of changes in flow, with flow effectively acting as a surrogate measure for catchment storage (see Young, 2003; Young and Tomlin, 2000). Transfer functions have been applied in several operational flood forecasting systems (e.g. Cluckie, 2000). Their reliance on availability of observed data does, however, mean that the effective lead times that can be achieved using transfer function is in the order of the response time of the catchment.
- Nonlinear forecasting methods such as nonlinear prediction (e.g. Laio *et al.*, 2003), Artificial Neural Networks (Laio *et al.*, 2003), and Genetic Programming (Babovic, 1997) extend the principles of transfer function modeling in identifying model structure and parameters through mining the available data. Despite good performance demonstrated in academic research, they are yet to be applied in true operational systems. More details can be found in **Chapter 21, Rainfall-runoff Modeling Based on Genetic Programming, Volume 1** and **Chapter 20, Artificial Neural Network Concepts in Hydrology, Volume 1**.

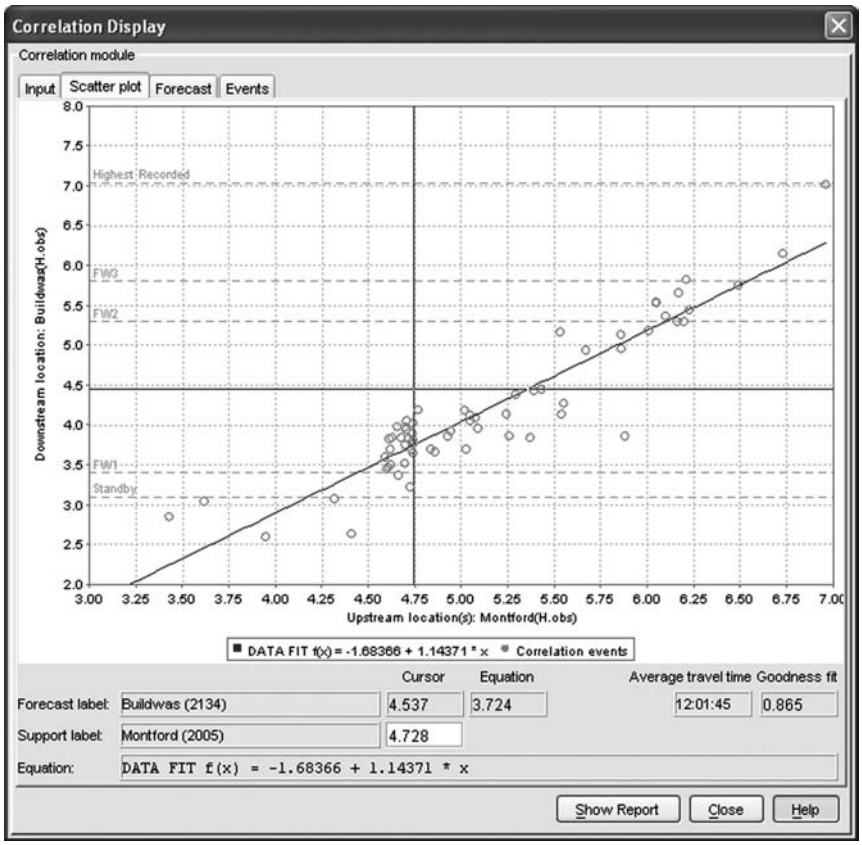

Figure 3 An example of a correlation established between an upstream and a downstream site. The recorded level at the upstream site can be used to derive a forecast for the downstream site through the relationship established. This example is taken from the UK Environment Agency Midlands Emergency Level Forecasting System, where it is used both as a backup and as a sanity check to the suite of hydrologic runoff and routing models normally used. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

- Conceptual hydrological models have also found wide application within flood forecasting systems. These models simplify the hydrological system in a number of concepts, each of which represents a specific part of the hydrological system. In many cases, the different types of dynamic response of the catchment are represented as linear stores. There are a great number of conceptual models in use in flood forecasting systems, including models such as NAM (Van Kalken *et al.*, 2004), Sacramento (Grijsen *et al.*, 1992), HBV (Bürgi, 2002), and PDM (Moore and Jones, 1998). An example of a conceptual model is the HBV model (Bergström, 1995), the structure of which is shown in Figure 4. These models can be applied from small to very large catchments, with larger catchments often being subdivided into several small catchments such that each has different model parameters. In this case, the models may be linked by an external routing model or include a simple hydrological routing procedure in the model itself. Recently, physically based hydrological models have also found application in flood forecasting systems, for example, the LISFLOOD model applied as a distributed model for a pan-European flood forecasting system (De Roo *et al.*, 2003). A comprehensive discussion on conceptual and physically based hydrological models is given in **Chapter 122, Rainfall-runoff Modeling: Introduction, Volume 3**. As both conceptual and physically based models claim to model the behavior of the catchment in response to rainfall (and snowmelt), these models can be applied both in forecasting systems with short desired lead times and those with long lead times, where the response of the catchment to medium to long-range precipitation forecasts is required.
- Once the flow has left the land phase and entered the river (as arbitrary as such a crisp division may be), flow routing is applied to propagate the flood wave from the catchment outlet to the forecasting location, for which a flood warning is to be established. A comprehensive overview of flood routing methods is given in Chow *et al.*, (1988), broadly dividing concepts into lumped routing concepts and distributed routing concepts. The lumped concepts include methods such

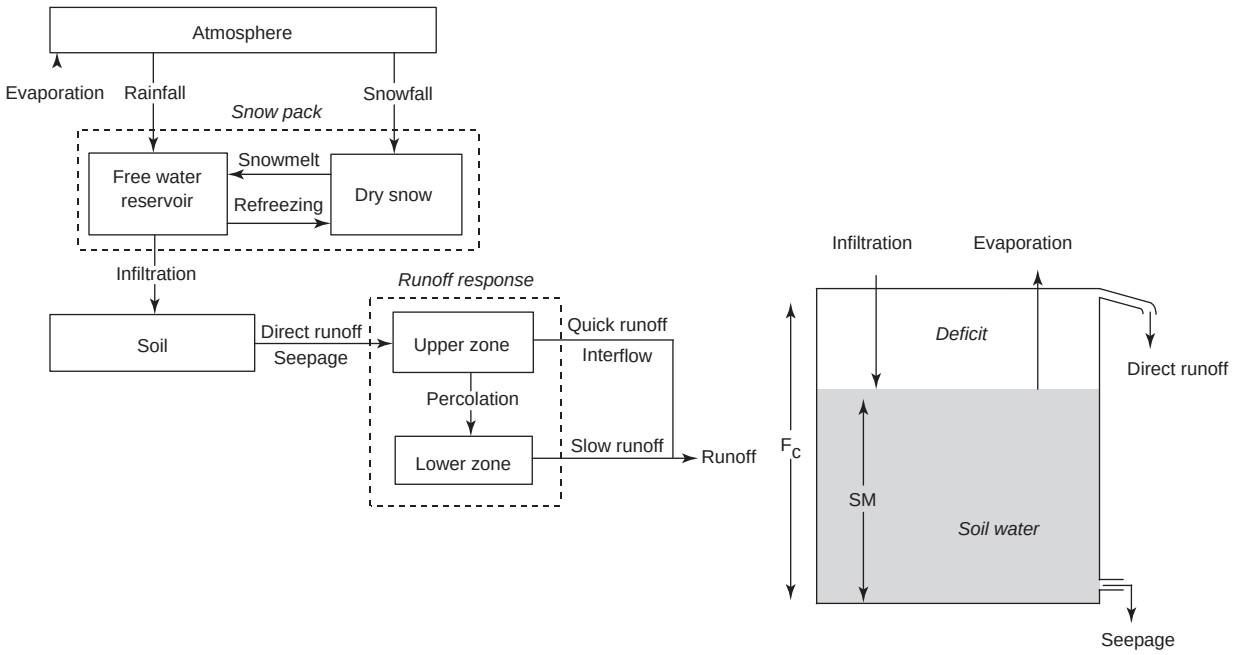

Figure 4 Schematic representation of the main components of the HBV model

as Muskingum routing, while distributed routing models include kinematic wave routing, diffusion wave routing, and full hydrodynamic routing (see **Chapter 16, Numerical Flood Simulation, Volume 1** for further details). The suitability of each of these concepts is very much dependant on the hydraulic conditions of the reach to be modeled. For steeper reaches, the simpler kinematic wave or Muskingum routing methods provide sufficient accuracy, and owing to their simplicity and computational efficiency, they have clear advantages over more complex full hydrodynamic modeling. These have been successfully applied in operational flood forecasting systems (e.g. Dobson and Davies, 1990; Moore *et al.*, 1990). For flatter reaches where backwater effects due to structures, confluences, or tidal influences affect the propagation of the flood wave, full hydrodynamic modeling is more appropriate. With the advance of computer processing power, these models can also be easily incorporated into flood forecasting systems, and have been employed in several operational system (e.g. Grijsen *et al.*, 1992; Jørgensen and Høst-Madsen, 1997). The use of routing models is important in forecasting systems of all lead times, where flood wave propagation through the river system is observed. The relative importance of these models in determining the overall accuracy of the forecasting will, however, decrease as the desired lead times increases beyond the response time of the catchment.

- Floodplain inundation models, with the potential of providing a real-time prediction of spatial flood extent have, with the increase of computing power, also been considered for application in operational flood forecasting systems. Jones and Fulford (2002) describe the use of a hydrodynamic code running in "near-real-time", where inundation maps are created as a parallel process to the operational forecasting system, delivering results a few hours later. De Roo *et al.* (2003) and Beven *et al.* (2000) demonstrate a simple inundation model for use in flood forecasting. The latter explicitly include model uncertainties in the predicted flood extent. This is an important aspect of issuing warnings on the basis of modeled flood extent, as although technically feasible, the use of inundation maps in operational warning must be considered carefully. The potential for misinterpretation of the visually powerful information in a flood map is not to be underestimated (Clark, 1998).

FORECAST OF METEOROLOGICAL CONDITIONS

As the desired lead times for flood warning increase (see the classification of flood forecasting systems in previous articles), the requirement to use quantitative precipitation forecasts (QPF) to provide boundary conditions to the hydrological runoff models increases. Obtaining a QPF at appropriate spatial and temporal scales is not an easy task as rainfall is one of the most difficult elements of the hydrological cycle to forecast (French *et al.*, 1992; Collier and Krzysztofowicz, 2000). For short lead

times, observation-intensive approaches such as nowcasting through, for example, propagation of observed radar rainfall (Golding, 2000) can be applied. Time series analysis techniques using stochastic models or artificial neural networks (Toth *et al.*, 2000; French *et al.*, 1992) can also provide short-term predictions.

For longer lead times, improvements of skill levels in numerical weather prediction models (NWP) have led to these being integrated with flood forecasting systems. Numerical weather prediction models are available either as global models or for a particular section of the atmosphere. The latter are typically local area models with a higher resolution and are nested in the global models. Examples of global models are the European Centre for Medium-Range Weather Forecasting (ECMWF) deterministic and ensemble prediction systems (Buizza *et al.*, 1999) and the German Weather Service global model (Majewski *et al.*, 2002). Many national meteorological agencies operate local area models, for example, the ARPS University of Oklahoma, (Xue *et al.*, 2000), DWD-LM (German Weather Service, Damrath *et al.*, 2000), and HIRLAM (Danish Meteorological Institute, amongst others, Sass *et al.*, 2000). Golding (2000) describes a range of products operated by the UK Met. Office, spanning short, medium, and long-range NWP. NWP products are easily linked to hydrological models, as demonstrated for several of these by De Roo *et al.*, (2003). Although useful in flood forecasting, systematic errors in NWP models, including underestimation, overestimation, and location and scale errors, will have significant impact on the accuracy of derived flood forecasts (Ebert and McBride, 2000).

Longer term flow predictions have also been attempted, though these predictions are primarily concerned with water management issues rather than flood forecasting. These predictions are often based on statistical time series analysis and may use indices such as El Niño/Southern Oscillation(ENSO) as indicators for predicted rainfall (Sharma, 2000; Anderson *et al.*, 2001; Chiew *et al.*, 2003)

UPDATING AND DATA ASSIMILATION

It is important to realize that a fixed model, calibrated to historical rainfall and flow data, cannot be expected to perform equally well when set in a real-time forecasting environment (Young, 2003). Both the model and the available real-time data must be seen as sources of information on the behavior of the catchment, and both will contain some degree of uncertainty, resulting in differences between the observed data and the simulated data. In short-term forecasting, these differences must be taken explicitly into account through some sort of feedback mechanism (Refsgaard, 1997), with the objective of reducing uncertainty in the forecast. Commonly referred to as *data assimilation or updating*, this feedback mechanism combines model results and observations and is a fundamental element of a forecasting system (Grijsen *et al.*, 1992; Kachroo, 1992; Madsen *et al.*, 2000). Four main approaches to data assimilation can be identified (WMO, 1992; Refsgaard, 1997). Figure 5 shows where these different approaches interact with the model. In all cases, the updating procedure is applied as a consequence of the comparison of model outputs and observed values. Model outputs are a function of the input variables, the model states, and the model parameters.

1. Updating of input variables (approach A in Figure 5). Particularly for hydrological rainfall-runoff models used in flood forecasting, the input variables are seen as the dominant source of error. These input variables, such as precipitation and temperature, or inflow discharge, are adjusted to minimize the differences between model output and observed variables. An advantage of input updating is that through adjustment of the input variables the model states are also updated. The two main drawbacks of the methods are that the model itself is in the optimization loop, and that the number of degrees of freedom in adjusting the input parameters results in a badly posed optimization problem. As model inputs are adjusted to minimize errors in model output, the model is considered as perfect. This is generally not the case, but the model should represent catchment behavior relatively accurately to avoid corrections to inputs to be unrealistic. The method of input updating is most applicable to the first three categories of forecasting system. Despite this, there are few practical examples of input updating applied in operational forecasting systems.
2. Updating of state variables (approach B in Figure 5). On the basis of the observed residuals, the state variables of the model are adjusted. These could be for example, soil moisture deficit (SMD) values in a hydrological model, or water levels and discharges at the computational nodes of a hydrodynamic model. A number of approaches can be followed, ranging from simple to complex statistical filters. The simplest method is direct insertion, where a state variable is substituted by an observed variable. This is, however, not always conceptually correct because of the differences in interpretation of what state variables and observed values represent, as well as issues of scale. More advanced methods include Kalman filtering approaches where state variables are adjusted in a physically consistent way using statistical assumptions of the spatial and temporal correlation of model errors (Brummelhuis, 1996). State updating has been applied widely in (operational) flood forecasting systems, varying from simple methods (Moore *et al.*, 1990; Van Kalken *et al.*, 2004) to more advanced Kalman filter approaches in precipitation estimation (Todini, 2001), hydrological models (Georgakakos, *et al.*, 1988; Grijsen *et al.*, 1992), and

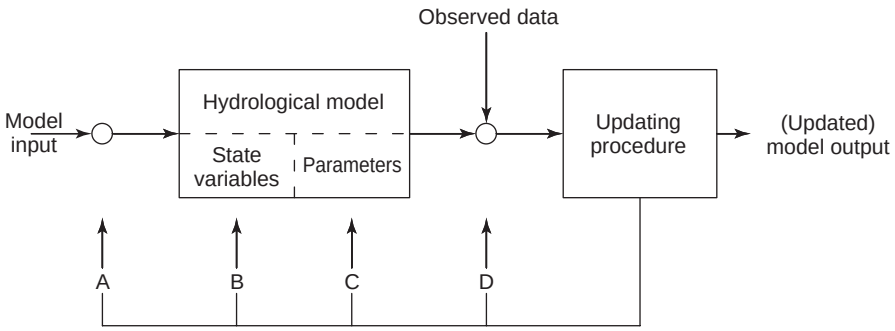

Figure 5 Schematic representation of four approaches in data assimilation (after Refsgaard, 1997)

hydraulic models (Grijsen *et al.*, 1992; Van Kalken *et al.*, 2004; El-Serafy and Mynett, 2004).

3. Updating of model parameters (approach C in Figure 5). Model error is minimized through adjusting model parameters as a function of the errors found in model outputs. The model is thus allowed to adjust to changes in response to small changes in catchment behavior not accurately identified when the model was initially set up (Young, 2003). This approach is particularly applicable to data-driven modeling concepts, and has been applied to transfer functions and data-based Mechanistic Modeling (Young, 2003). Application to more physically based models is less apparent. Here model parameters such as roughness coefficients and runoff coefficients can be considered for adjustment. The procedure could be seen as constant recalibration of the model. If, however, some physical meaning is to be attributed to these parameters, it is unlikely that these will vary with the same dynamics as model errors. Kachroo (1992) notes "it is intrinsically difficult to accept the operation of any hydrological system can change significantly over such a short interval as the observation time".
4. Updating of output variables or error prediction (approach D in Figure 5). Rather than correct the model or its inputs, in this approach, the statistical structure of the model error is considered, and based on the structure found a forecast of the model error is made. The forecast variable obtained from the model is then adjusted with the forecast of the error to obtain an updated forecast (see Figure 6). Commonly, statistical models such as an auto-regressive moving average (ARMA) model is used. The method is conceptually simple, and has the advantage that it is computationally efficient as no additional model evaluations are required. For models used in continuous forecasting, care must be taken that the model gives a reasonable representation of catchment behavior. Contrary to the previous methods, the model state is not updated, and if the model behaves poorly, simulated and updated results will diverge. Although the forecast may be reasonable, this will then rely primarily on the statistical updating method. Error correction is particularly applicable in a chain of models such as in the second and third categories of flood forecasting system. As the statistical correlation of model errors is often not very persistent, the method is less applicable where the desired lead time is relatively long as in the fourth category of forecasting system. Examples of application can be found in Moore *et al.*, 1990, Dobson and Davies, 1990, Refsgaard, 1997, and Madsen *et al.*, 2000.

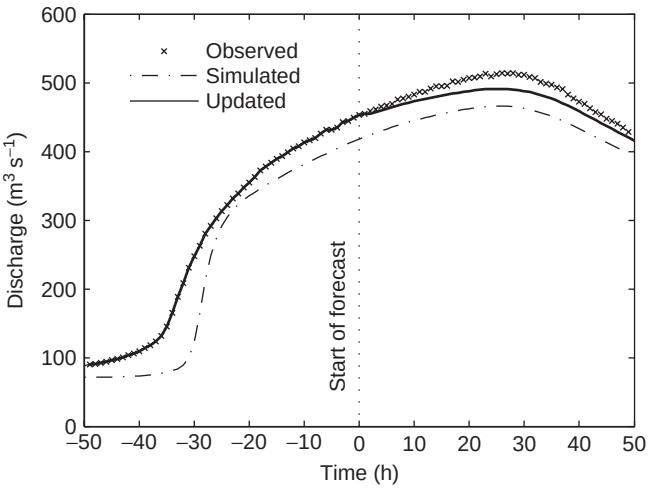

Figure 6 Example of updating simulated flows using error correction. Observed values up to the start of forecast (time zero) were used in identifying the error forecast model. This was then applied in updating the simulated model outputs after the start of forecast

EVALUATING FORECAST PERFORMANCE AND DEALING WITH UNCERTAINTIES

The level of confidence that can be placed in a model-derived forecast is an important factor, if a rational decision is to be made by the flood forecaster on whether or not

to issue a warning on the basis of that forecast. The uncertainty in the forecast may arise as a result of data errors, model structure, uncertainty in model parameters, and most importantly, uncertainties in the forecast model boundary conditions (Lees, 2000a; Beven *et al.*, 2000). Where meteorological forecasts are used to extend forecast lead time, particularly in the last category of desired lead time described in previous sections, the uncertainty of forecast precipitation will dominate resulting uncertainties.

To help make uncertainties explicit, numerous techniques have been applied, although most of these have yet to prove their value in operational flood forecasting, and remain largely academic exercises. A simple method to deal with uncertainties in input data used operationally has been the definition of so-called what-if scenarios. In these, the confidence level given by the meteorological forecaster to the precipitation forecast is implicitly translated into running a number of flow forecast scenarios with amended forecast precipitation (e.g. 10% additional or 10% less precipitation). Uncertainty in the observed precipitation, depending on the balance of desired lead time against hydrological run time, will also influence uncertainties in the forecast, and can be treated in the same fashion. Krzysztofowicz and Herr (2001) introduce a more formal way of translating a probabilistic precipitation forecast into a probabilistic river stage forecast. They use a Bayesian formulation to quantify hydrological uncertainty given a perfect precipitation forecast. This is then combined with the probability of precipitation to derive the probabilistic river stage forecast.

Integration of flood forecasting systems with weather radar nowcasting and numerical weather prediction models has led to the use of uncertainty of inputs in precipitation and temperature being derived from the use of

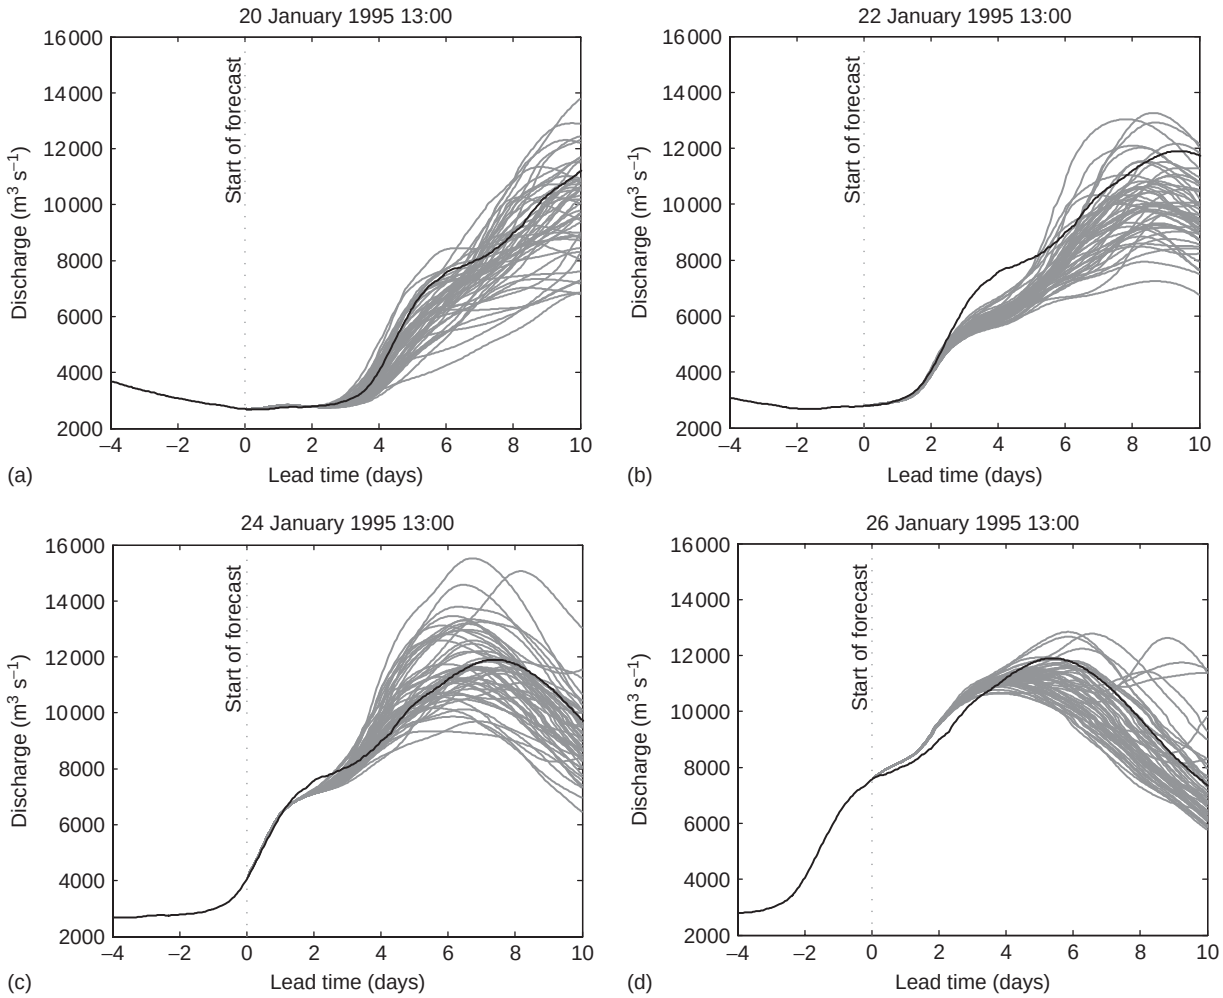

Figure 7 Ensemble forecasts for the January 1995 event on the River Rhine at Lobith. Forecasts shown are issued at two day intervals starting 20 January 1995 at 13:00. Grey lines show the results of ensemble runs, showing updated (simulated) discharge before the start of forecast and ensemble forecast results after the start of forecast. The black line is the observed discharge (after Werner *et al.*, 2004b)

different local or global weather models (De Roo *et al.*, 2003). Ensemble predictions such as those provided by the (ECMWF) Ensemble Prediction System (Buizza *et al.*, 1999), or the American National Weather Service (NWS) Ensemble Streamflow Prediction system (Mullusky *et al.*, 2003) have made the uncertainty in precipitation forecasting even more explicit. The EPS creates 50 ensemble members for a 10-day lead time weather forecast through perturbation of the initial conditions for each (see De Roo *et al.*, 2003 for details). Each ensemble member can then be used to derive precipitation and temperature boundary conditions for hydrological models of a catchment, as demonstrated for the Meuse catchment in De Roo *et al.*, (2003). Figure 7 shows the results of a series of ensemble forecasts for the forecasting location at Lobith on the River Rhine leading up to the January 1995 event. This location is at the lower end of the Rhine basin on the Dutch/German border. This explains why the ensemble weather prediction has almost no influence on the first two days of the forecast, as at these short lead times flows at Lobith are dominated by water already in the main river. At increased lead time, the influence of the ensemble spread starts to dominate the discharge prediction.

The influence of model uncertainties on the total uncertainty in the forecast may also be significant. As in the use of multiple meteorological models, multiple hydrological models may be applied, with each model giving different forecasts. More importantly, the effect of uncertainty in model parameters will influence model-derived predictions. A number of techniques are available for estimating this uncertainty. Lees (2000b) uses a Kalman Filter approach to produce confidence intervals for models derived using the data-based mechanistic approach. More common are Bayesian techniques for estimating posterior parameter distributions from parameter prior distributions, as conditioned on the available calibration data. Examples are the generalized likelihood uncertainty estimation (GLUE) algorithm described by Beven and Binley, (1992) and the shuffled complex evolution Metropolis (SCEM-UA) algorithm described by Vrugt *et al.*, (2003). The posterior distributions established in calibration can then be applied in the forecasting phase, thus creating an ensemble of model runs, with each run using a different parameter set sampled from the posterior parameter distributions.

Irrespective of the method used to quantify uncertainty, the confidence in the forecast must be made explicit by applying a suitable performance measure. Most of the performance measures, or objective functions, used in calibrating hydrological models such as described by Green and Stephenson (1986) may be less suitable for evaluating the performance of model-based forecasts. Although these can be used to give a general indication of model performance, statistics such as skill scores, correctly/incorrectly predicting thresholds, and the timings of threshold crossings may be more relevant in evaluating the performance of the forecasting system (see e.g. of performance measures (Moore *et al.*, 1990) and Krzysztofowicz *et al.*, 1992).

ADVANCES IN FLOOD FORECASTING SYSTEM DEVELOPMENT

The foundations of a scientific approach to flood warning systems had been laid down by numerous researchers during the 1970s and early 1980s (Krzysztofowicz, 1995). During those years, hydrological and hydraulic modeling made some impressive steps forward, partly driven by the rapid increase in computing power as a result of the developments in microchip technology. These models form the basis of many forecasting systems.

As a result, many forecasting systems have evolved around a specific (set of) models. For performance reasons, this made good sense; the forecasting systems is a calibrated model enhanced with the minimum requirements to transform it into an operational forecasting system. However, these systems are not very flexible. Adding new locations may be possible relatively easily, but adding new types of on-line data (that may increase the forecasting performance) is usually very difficult. Most important, however, is that new models cannot be included as the model itself lies in the heart of the system. This is not only an issue when new, potentially better models are considered, but also in the many cases where agencies strive to harmonize forecasting systems across different regions.

Besides these developments in modeling, the availability of data for use in flood forecasting systems has increased dramatically in recent decades. Particularly, the increasing operational availability of local and medium-range meteorological forecasting (De Roo *et al.*, 2003), with the potential of increasing flood forecast lead time, has shifted the challenge in developing flood forecasting systems not only run to the hydrological and hydraulic models as required, but to the handling, quality checking, and processing of large data sets, and finally integrating these with the models. To meet these challenges, the focus in developing flood forecasting systems is moving away from the tailor-made model-centered approach to the generic open-systems approach. These open systems must allow open integration of modeling techniques. More important is that these systems cater for the specific needs of handling data within the context of flood forecasting, including a broad range of data handling techniques such as validation, interpolation (spatial and gap filling), transformation, and algorithms to allow integration of models and data across spatial and temporal scales. Once established, different types of modeling approach can be easily integrated in the flood forecasting process. The choice of the most appropriate modeling strategy can then be established on the basis of the efficiency with which the

forecasting requirement in terms of lead time and accuracy is met, rather than through the simple argument that the flood forecasting system can run with only one particular model. While there are some early example of flood forecasting systems following this "open" approach (e.g. Moore *et al.*, 1990), these are still very much proprietary software packages. Advances in standard mechanisms for data exchange and communication such as the eXtended Markup Language (XML), and Internet communication protocols have more recently helped these systems to comply with international standards in systems development.

A relatively new system that sets the use of hydrometric, meteorological, and forecast data central, while providing both generic data handling utilities and an open interface to models, is DELFT-FEWS as described by Werner *et al.* (2004a). This system is applied in several operational flood forecasting schemes (e.g. Bürgi, 2002; Sprokkereef, 2001), and forms the basis of the National Flood Forecasting System (NFFS) under development for the UK Environment Agency. To illustrate some of the issues addressed through migrating from a model-centered approach to the data-centered approach, the remainder of this section describes the differences between the new "open" NFFS system (using DELFT-FEWS) for the UK Midlands regions and the existing FFS2 system currently in use for that region.

The FFS2 system, a first version of which is described in detail in Dobson and Davies (1990), was regarded as highly advanced at the time it was installed. It is constructed with a hydrological runoff and a flow routing model at the heart of the system. The hydrological (MCRM) model is a bespoke conceptual rainfall-runoff model that includes interception, evapotranspiration, a snow pack routine, and simple flow routing, as well as the ability to consider reservoirs in catchments. The flow routing model (DODO) is a two-layer Muskingum model. Both the hydrological and the routing models are equipped with an error model that updates the simulated discharge using observed discharge at each river gauging station, and the updated trace is subsequently routed into the downstream section. The models have been extensively calibrated over the years and perform well in most cases. The system also polls the telemetry system directly before each forecast, so that the most up-to-date data is available prior to running a forecast. The system holds 147 hydrological gauges, 124 meteorological gauges, and 272 forecasting points that may or may not coincide with a gauge location. Forecasts are made every 12 h but more frequently if alarm conditions occur. Forecasts (up to 50 h lead time) are made on the basis of a 6-h lead time precipitation forecast derived from radar image propagation (NIMROD, see Golding, 2000), extrapolated temperature, and a standard profile for evapotranspiration. SMD values in the hydrological models are updated manually (through direct insertion) using weekly SMD values provided by the UK Met. Office. The entire system currently runs on a DEC-VAX and was written in VAX-FORTRAN.

Given the fact that the current system generally works satisfactorily, would there be any reason to migrate to a new system apart from the fact that the number of people with VAX knowledge is declining rapidly? If migrating to a new system would mean replacing the current models by new ones for the entire region, (111 catchments models and 95 reach model) an enormous effort would be required, without necessarily improving the quality of forecasts. Moreover, the step of going to a new system *and* new models may prevent operational forecasters doing their work properly for a significant length of time. Therefore, a new system should be able to use the current models. In addition, most desires for improvements to the systems are related to newly available data and the desire to include hydrodynamic modeling in the tidal reaches where the flow routing procedure is not suitable. For example, the current numerical weather predictions made by the UK Met Office can provide improved lead times (e.g. 36 h) compared to the radar forecasts and also provide forecasts of temperature and evapotranspiration. This alone can improve the forecasts for longer lead times significantly.

Within the new system, all the functionality of the current system has been replicated, and the original model (MCRM and DODO) are now integrated through an XML interface under control of the DELFT-FEWS system. This XML interface is identical to all models, meaning that where a hydrodynamic model proves more reliable, the flow routing model can simply be replaced for that reach by a hydrodynamic module, without implicating the structure of the forecasting systems, nor the skills or procedures required in operational use. The relative ease with which this is accomplished has already been demonstrated with the limited effort required to include a hydrodynamic ISIS model for the tidal reaches of the Severn River. The system allows also for the hydrodynamic module to run alongside the current flow routing predictions so that the relative improvements by including the new model can be explicitly evaluated. The next steps in gradually improving the system while guaranteeing operational continuity include integration of more hydrodynamic model stretches and the use of NWP forecasts.

CONCLUDING REMARKS

This article focused on a comprehensive overview of flood forecasting systems from the perspective of these systems as a part of the flood warning process. It is clear from the large number of techniques given as examples that there exists a great variation in such systems, often tailor-made to cater for a specific forecasting requirement. Although a wide range of techniques is presently available, and much research has been directed at advancing flood forecasting

techniques, most operational flood forecasting schemes used today are rudimentary.

An important reason for this is that in contrast with the development of models used in design work, making flood forecasting systems operational is a much more complex task. Because of its position as an integrated step in the flood warning process, the difficulty in developing flood forecasting capabilities are more often institutional than technical. The flood forecasting system used by a forecasting authority will have profound influence on the operational procedures employed by that authority in delivering the forecasting and warning requirement. As a consequence, institutional development is as an important aspect to consider when a flood forecasting system is established as a step in the flood warning process. For an operational organization, the impact of a change in the models used in flood forecasting will be much less than the impact of adapting to changes in procedures following the introduction of a new or alternative flood forecasting and warning system. The challenge to hydroinformatics is therefore not only to make the latest techniques in, for example, quantitative precipitation forecasting and hydrologic or hydraulic modeling available for use in operational flood forecasting, but also to do so in such a way that fits into the whole process of flood warning. Where flood warning is already pursued operationally, the continuity of the operational warning is of great importance when introducing advances. Developing open systems that allow advances in sciences to be introduced smoothly into operational procedures is a first step in the right direction, and also closes many of the gaps between academic research on flood forecasting and warning and the procedures actually used operationally.

Acknowledgment

Erik Sprokkereef of the Institute of Inland Water Management, the Netherlands, is thanked for providing the data on which the ensemble forecasts in Figure 7 are based. Tim Harrison of the UK Environment Agency, Midlands Region, is thanked for his comments on the discussion of the migration of the Midland Region flood forecasting system.

24: Network Distributed Decision Support Systems and the Role of Hydrological Knowledge

ANDREJA JONOSKI

Department of Hydroinformatics and Knowledge Management, UNESCO-IHE Institute for Water Education, Delft, The Netherlands

This article introduces the hydroinformatics concept of new kinds of environments for supporting decision-making processes in the fields of water and the environment, under the name of Network Distributed Decision Support Systems (NDDSSs). These environments are designed to enable active participation of large numbers of interested stakeholders including the general public. The platforms for their development and deployment are the electronic networks such as the Internet and the wireless mobile telephony networks. Core components of such systems are instantiated hydrological models, acting as main fact providers for the participants' judgments and evaluations of the proposed courses of actions. For achieving the required performance within NDDSSs, these models need to be distributed (viz. capable of representing spatial variability as encountered in real situations) and capable of simulating integrated physical processes in the hydrological system, and open for wider integration with other kinds of models such as ecological or socioeconomic models. A brief overview of the software agent technology is presented, with its potential for the design and development of these new decision support environments. The manners in which full-fledged NDDSSs can be implemented into our present societies are also presented.

INTRODUCTION: THE NEW CONTEXTS FOR HYDROLOGY

During the last couple of decades, the developments in hydroinformatics have revolutionized the ways in which we deal with our contemporary water- and environment-related problems. This has been achieved by exploiting the explosive advances in the Information and Communication Technologies (ICTs) for maximizing the benefits of generation, communication, and application of water-related knowledge. The fundamental process through which hydroinformatics has been utilizing the advances in ICT is the process of knowledge *encapsulation*. Primary examples of knowledge encapsulators are the hydroinformatics modeling systems which encapsulate *generic* knowledge in a given discipline or integrated set of disciplines (e.g. hydrology, hydraulics, water quality, and so on; *see also* **Chapter 16, Numerical Flood Simulation, Volume 1**; **Chapter 17, Hydrological and Environmental Modeling of Transport Processes in Rivers and Estuaries, Volume 1**; **Chapter 18, Shallow Water Models with Porosity for Urban Flood Modeling, Volume 1**; *and also* **Chapter 23, Flood Early Warning Systems for Hydrological (sub) Catchments, Volume 1**). Through implementation of advanced user interfaces and a variety of data integration components, the application of these modeling systems for specific cases (building instantiated models) has been made both efficient and widely available. Nowadays, full hydroinformatics systems integrate observation and data gathering components, data storage facilities, integrated modeling systems, and their embedding into wider decision support tools and environments.

If we make an attempt to generalize the kind of transformation that these developments have brought about to the water-related knowledge, we can notice that what hydroinformatics did in this area is actually a part of a much wider

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

transformation of knowledge that we are witnessing in our contemporary societies. As the ICT developments enabled the processes of knowledge encapsulation, transmission, and application generally, the very nature of knowledge has been transformed. The term knowledge *production,* which is in frequent use at our present times, already suggests the kind of transformation that we are dealing with. Following Lyotard (1979, 1984), we will introduce the term "*knowledge commodification*" for describing this process. This term suggests that in our postmodern societies, knowledge is increasingly considered a commodity, and the direct intention of knowledge *trading* is becoming dominant legitimation for the knowledge "production" processes. The very notion of "knowledge products" and the possibility for their buying and selling is inextricable from the ICTs. The pervasion of these technologies to an extent that they would transform our traditional and established understanding of knowledge was clearly foreseen by Lyotard (1979, 1984) almost three decades ago:

> "The nature of knowledge cannot survive unchanged within this context of general transformation. It can fit into the new channels, and become operational, only if learning is translated into quantities of "information." We can predict that anything in the constituted body of knowledge that is not translatable in this way will be abandoned and that the direction of new research will be dictated by the possibility of its eventual results being translatable into computer language. The "producers" and users of knowledge must now, and will have to, possess the means of translating into these languages whatever they want to invent or learn. . . Along with the hegemony of computers comes a certain logic, and therefore a certain set of prescriptions determining which statements are accepted as "knowledge" statements".

Hydrological knowledge is certainly not excluded from these fundamental transformations, and is in fact, quite central in the above-described hydroinformatics developments. The processes of externalization and the consequent transmission and application of hydrological knowledge, which used to be limited to texts, images, and mathematical descriptions, are increasingly carried out by means of hydrological models and modeling systems. Much of the present research in hydrology (as many articles in this encyclopedia exemplify), and quite a lot more in hydroinformatics (as demonstrated in this article) is oriented towards further sophistication of these modeling systems in terms of their capabilities for encapsulating the hydrological processes in question, but also towards diversification of the modes of their application and making them easily accessible through improved user interfaces and data integration. The potential of the new communication media for these purposes, such as the Internet and the mobile telephony, is just beginning to be exploited. With the underlying intention of continuously increasing the number of users and broadening the user bases for these modeling systems, all such developments form a clear picture of hydrological knowledge commodification.

Analyzing only the side of knowledge production, however, will give an incomplete picture of the transformations within which knowledge commodification emerges. In fact, it is only made possible if corresponding transformations also appear on the side of knowledge application, or more broadly, the knowledge *demand*. If we again start with hydrological knowledge, which is our immediate concern here, we notice that recent decades have brought exponential growth in the number of problems where hydrological knowledge became indispensable. There is a reasserted relevance of hydrology for understanding global climatic or environmental phenomena and the effects of human interventions in the natural system. Even more significantly, there is now a clear awareness that any human intervention at regional and local level into the water-based natural "economy" has far-reaching consequences in many different, and rather diverse sectors of our societies. Consequently, increased numbers of social groups, institutions, as well as individuals or groups of individuals show direct interest in water and increasingly claim a stake in water-related affairs. This situation necessitates provision of efficient access to hydrological knowledge and capabilities for its application in very diverse application contexts.

At the same time, this rediscovered nature of our contemporary water-related problems puts new demands for combining and integrating hydrological knowledge with all kinds of other types of knowledge, such as, ecological, economic, social, political, and legal. Very often the framework of integration needs to include a kind of social knowledge that is variously described as "traditional", "custom", or "narrative", but has in fact, a unifying characteristic of not being fully susceptible to rational analysis in a modern scientific sense. These new requirements for integrating hydrological knowledge with such diverse types of knowledges (Used deliberately in plural following many writers on issues related to postmodern epistemology; see, e.g. Gergen and Thatchenkery (1997), and also in more familiar context, Abbott *et al.* in **Chapter 14, Hydroinformatics and its Contributions to Hydrology: From Computation to Communication, Volume 1**) bring formidable difficulties regarding the design of conceptual integrating frameworks or the development of environments, where the required knowledge exchange and integration might be enabled.

This relatively new situation on the application side inevitably changes and determines the nature of hydrological knowledge. Since the integrated approach described here is conceivable only by employing the power of enabling ICTs, the questions such as hydrological knowledge encapsulation, interfacing with other knowledges, and communication to a variety of users through appropriate translation are increasingly penetrating the hydrological agenda. In addition to the advances on the scientific fronts of hydrology (including those dealing with monitoring and observation of hydrological systems), which are also

critically dependent on ICTs, the above mentioned questions are becoming very important for the role and social relevance of hydrological knowledge.

Recognition of the *diversity of knowledge and knowledge needs*, together with the realization of the necessary mobilization of different knowledges when dealing with our contemporary problems is a second general characteristic of the postmodern knowledge transformation, in addition to the knowledge commodification. Again, quite independently from developments in hydrology and hydroinformatics, these transformations were steered by a mixture of social, technical, and historical developments during the last century. The catastrophes of the two world wars, the subsequent cold war, and the powerful awareness of the scales of environmental destruction brought about by modern development had strong influence on shaping this transformation. Explosive development of the mass media contributed to the widespread awareness of our existence in a "global village," which is at the same time sustained by cultural and social diversity, in a manner that is not so different from the sustaining role of biodiversity for natural ecosystems. *Diversity* has entered the scene in virtually all domains of human thought and action, and knowledge diversity appears as an inevitable consequence.

Recognizing that there are diverse knowledges as well as diverse interests and stakes in water affairs may have been the easier task, when compared to the need for integration of this diversity for purposes of improved decision making. As mentioned earlier, in the fields of water and the environment we are faced with immense integration-related difficulties at both conceptual and at implementation level. One attempt to capture and deal with the complexity of these integration problems has been through the introduction of the paradigms of Integrated Water Resources Management (IWRM) and Integrated River Basin Management (IRBM). These paradigms have been quite successful in providing the basic descriptive framework for analyses of water-related problems and as fundaments for shaping national, regional, and international policies on water to an extent that in some cases they are incorporated in legislation (e.g. the European Water Framework Directive, of the European Union). These frameworks have also been quite beneficial for understanding the new contexts in which hydrological knowledge has to be generated and applied (Environmental Impact Assessment – EIA and Social Impact Assessment – SIA frameworks, when dealing with water-related projects, bring similar broadening of the contexts for hydrological knowledge).

When it comes to implementation actions, however, these frameworks are simply not enough for achieving the desired results. Firstly, a lot of concepts are simply not possible to be properly framed in such paradigms. One good example is the proper institutional arrangement, which remains an outstanding problem even in most developed societies and countries (see Loucks, 2003). Secondly, some of the concepts in these paradigms are contradictory among themselves (integration/optimization, which presupposes cooperation and valuation consensus, versus stakeholder, and public participation, which inevitably brings value disagreements and even conflicts which require negotiations). Or, some concepts are rather detached from actual realities with no directions as to how they can be realized in practice. A clear example from IRBM is the frequently forgotten fact that the very concept of a river basin as a unit of analysis is still alien to many communities and, consequently, to many already established institutions. Rivers were (and still are), more often than not, natural boundaries and borders between different communities, regions, and countries, rather than geographical features of integration. River basins are rarely intimated to individuals and communities as something toward which they develop sense of belonging, and in view of their other social allegiances they may very often turn out to be less important, if not irrelevant.

In view of this situation, rather than imposing theoretical frameworks, the approach advocated by hydroinformatics is to proceed with the implementation of the required integrative approaches through design, development, and deployment of new kinds of ICT-based systems and environments. These systems would be specifically intended to enable direct participation of all stakeholders (including the "general public", which consists of a large number of *individuals*) in the decision-making and assessment processes. The envisaged deployment of these systems or environments is, in concrete projects, for enabling the participants to analyze the consequences of the proposed courses of action regarding issues of their *immediate* concern. These products must go beyond the mere exhortations concerning the need for environmental preservation, sustainable development, or proper integrated management of their resources. As Woods (1993) explained this within the context of his analysis of ICT contribution to development:

> Educating people *about* natural preservation is not enough. The education and training to achieve that preservation is needed. Interactive technology has immense potential as a tool for assisting communities to enter their own data on their own resources and to process it and weigh up alternative solutions. It carries the learning process into practical application in specific situations and can then provide technical instructional materials to suit the conditions of these situations. This capacity to help individuals, groups and communities to manage their own resource is being shown to have a remarkable 'mobilizing' effect.

At present, the obvious platforms for development and deployment of such tools are the electronic and wireless networks, such as the Internet and mobile telephony. The working title that has been given to such systems is Network Distributed Decision Support Systems (NDDSSs). Although the word "network" refers here primarily to the

fact that these systems will use the electronic and wireless network as their platforms, recent hydroinformatics studies emphasized the fact that the design and development of such systems cannot be considered as a purely technical task. Thus, the electronic networks are only technologies that enable the realization of these essentially sociotechnical systems. The systems themselves enable the creation of networks of people and institutions engaged in the processes of knowledge exchange for the purposes of improved assessment and decision making.

In what follows in this article we will try to present the basic concepts of NDDSSs, the role of hydrological knowledge, particularly the role of hydrological models within these systems, and the potential of a specific software design and development technology, known as *software agent technology*, for the realization of these systems. At the end we will identify the potential, social support for their future development. The theoretical basis, and the detailed description of NDDSSs have been introduced in Jonoski (2002).

The studies on NDDSSs are not yet in a mature stage of development, lacking full-fledged practical implementations. At this juncture, we need to stress the relevance of these studies in redefining hydroinformatics as a sociotechnical discipline and in highlighting the developments in hydrology from such sociotechnical perspective. As shown in most recent writings about future hydroinformatics directions, such analyses and redefinition are centered on the questions of knowledge, knowledge encapsulation and communication, and knowledge legitimation in general (*see* **Chapter 14, Hydroinformatics and its Contributions to Hydrology: From Computation to Communication, Volume 1**). By taking this meta-perspective on the fields of hydroinformatics and hydrology, NDDSSs studies can be considered as postmodern, theorizing attempts to "tell it as it might become" rather then "telling it like it is".

NETWORK DISTRIBUTED DECISION SUPPORT SYSTEMS (NDDSSs)

The basic idea of NDDSSs is to develop Internet-based environments as virtual platforms that will enable transmission of knowledge for three distinct purposes(Strictly speaking, "environment" is a more appropriate word for describing NDDSSs compared to the word "system", since there is no clear delineation of what constitutes the "system" in this case, or what its inputs and outputs are. These two words will be used interchangeably here, depending on the intended meaning in the local context). Firstly, they should enable all interested parties in the decision-making process to gather relevant knowledge and data about a given water-related system and particularly about consequences of any proposed, or projected interventions in the same system. Secondly, by combining this factual knowledge with their own beliefs, attitudes, and interests, these participants should be able to formulate judgments about the proposed interventions and even suggest new courses of action. Thirdly, after aggregating the judgments and positions of all interested parties, the system needs to act as a platform for negotiation and collaboration activities among all participating parties through which the decision-making process would move towards commonly complying actions. Although this is a rather general description, it connects the requirements of NDDSSs to fields such as environmental impact assessment and social impact assessment, risk assessment, and participatory policy analysis. The design of these systems will therefore need to rely on many concepts already developed in these diverse fields. It should also become clear that these systems have much more to offer in the areas of planning, design, and strategic development, while being less relevant when it comes to operational management of water-based systems.

Since we are concerned here with water-related problems, an NDDSS is best conceived as dealing with decision problems related to a particular spatially bounded object such as a river basin, a coastal region, or a groundwater system of aquifers, or even some or all of such features combined. At the simplest and most general level, an NDDSS can be seen as consisting of a "knowledge center", and a large number of user nodes distributed along a "user periphery" (Figure 1).

The knowledge center is the primary repository of all what we consider as scientific, or, more broadly, factual knowledge. This is primarily, electronically encapsulated knowledge, and first and foremost this means various models (hydraulic, hydrological, ecological etc.). The

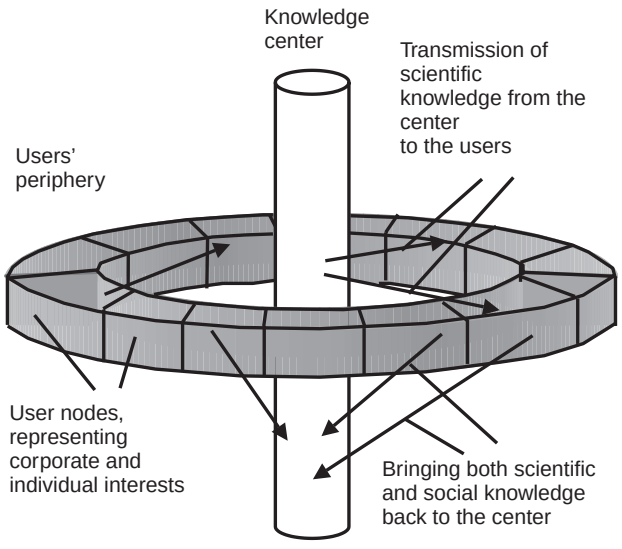

Figure 1 The general concept of NDDSS (adapted from Jonoski and Abbott, 1998)

knowledge center is also the repository of all relevant data that are needed for generating or supporting these models. In many cases, we may conceive that the knowledge center will have to maintain continuous links with all kinds of measurement facilities (both from data gathering equipment on the ground and from remote sensing data such as satellite imagery, radar data for rainfall prediction etc.). Although the gathering and distribution of this kind of knowledge is the primary role of the knowledge center, other kinds of knowledge that are not directly related to water sciences should also be located here. For example, any complete center will eventually have to encapsulate legal knowledge bearing upon the problems in question.

The users of the system may now be visualized as being distributed over the user nodes and connected to the knowledge center. These users are both corporate bodies with their own perceived interests, as well as individuals or groups of individuals grouped around some common concern.

It is very important to stress that the knowledge center should not be seen as a physical center of the system, or, even worse, to assume that this is a center only in technical terms and that it can be reduced to one, or even several server computers. The word "center" is used here only conceptually, and the models and data provided by this center might well reside at different physical locations, and, quite commonly, in different organizations.

Within this basic concept of the NDDSS environment, we can introduce its three functional components that will enable the three principal processes of knowledge transmission from the beginning of this section. These three functional components are correspondingly: *the fact engine, the judgment engine*, and a *collaboration and negotiation platform*. The principal processes of knowledge transmission in turn determine the main characteristics and tasks for these three functional components. Later in this section, we will introduce these features, together with some suggestions as to how these three components can be realized. In the following section we will focus mainly on the fact engine component and the important role of model-encapsulated hydrological knowledge.

Fact Engines

The fact engine component of the NDDSS is located in the knowledge center and is responsible for the production of the (scientific) facts, primarily by providing storage and access to a collection of models and databases related to various aspects of the physical system in question. Most of these models will initially be traditional numerical models, such as various hydraulic, hydrological, ecological, or water quality models. Since the main role of these models is to provide the facts about the physical system in question, we classify them under the category of fact engines. The access to these models is now necessarily going to be through the Internet, or some similar kind of electronic, or wireless network. Therefore the traditional user interfaces designed for using models as stand-alone applications will have to be decoupled from their computational engines and embedded in other media, such as, for example, a Web-browser.

However, the envisaged broad user base of NDDSSs indicates that these models may need to be stripped from their traditional user interfaces and replaced by new ones, which will be more adaptable to the diversity of the users. In fact, alternative kinds of user interfaces that will be able to represent the same facts in different forms must be provided. Because this aspect is actually closely related to the judgment-forming process that occurs at the user nodes and is to be handled by the judgment engines, the user interfaces within an NDDSS are not primary considerations in the design of the fact engine component. The existing user interfaces will certainly be indispensable for setting up or "instantiating" the models as fact engines – a task to be carried out by the modelers who are working at the knowledge center. However, the interfaces to these instantiated models that will be available at the user nodes will need to be reconstructed in such a way that their primary goal is to enable the judgment-forming process, and not the modeling process *per se*. This implies the representation of the modeling results in different forms that will support the diverse backgrounds and knowledge of the users. It also places limitations on the number of model inputs (or parameters) that can be manipulated. In fact, these manipulations must be limited to those inputs that are of direct concern for the actual user/participant in the process.

The processes of fact generation are still rather diverse, and apart from running models and preparing appropriate material for transmission, they will involve tasks such as interrogating measurement stations, requiring and interpreting satellite images, or querying databases and knowledge bases for other non "water-related" facts. It is clear that by far the greater part of the scientific and other factual material is available and can be supplied by existing organizations which will become in their turn "knowledge providers" to the center. Efficient interoperation of such diverse fact engines, located at different knowledge providers will necessarily require new kinds of institutional arrangements.

Judgment Engines

The judgment engine component will usually and primarily be distributed over the users' periphery, where we may envisage that all the users who will participate in the impact assessment process and the decision-making process will be situated. The judgment engines have the task of assisting the users in making their own judgments about a particular intervention in the system on the basis of the interaction

between their beliefs, intentions, and interests, and the received facts from the knowledge center.

Because of the diversity of the users/participants involved in the process, the first prerequisites in the formation of judgments are related to the ways in which the facts coming from the knowledge center are delivered. As we have already mentioned, the user interfaces of the fact engines may have to be significantly adapted for this purpose. The main orientation in the new design must be towards *customization* and *personalization* of the content delivered from the fact engines. Various techniques for provision of customized content, albeit in different areas and for different purposes, are already used on the World Wide Web by many content providers. In this case, the customization is related both to the *kind* of facts that are relevant to a particular user for making his or her judgment and to the *form* of delivery of these facts. The design of these interfaces should especially be oriented towards assisting users that are not directly familiar with the water- and environment-related scientific knowledge in their judgment-forming process.

The delivery of the relevant facts is, however, only one step in the judgment-forming process. The main role of the judgment engines is in enabling the *combination* of the facts with the users' beliefs and interests for forming judgments. It should be realized that the judgment engines of an NDDSS are envisaged as primarily supporting and facilitating the formation of judgments of *value*. The diversity in values and in value gradients of the users/participants requires that the judgment-forming process becomes understood within a framework where this diversity is respected, and the tendencies towards restriction of certain values, or towards reduction of all values to one (usually monetary) value, are discouraged.

In any NDDSS, there will be issues for which the valuation is relatively straightforward, and even uniform, across all the participants in the process. This is especially the case for those issues that are easily represented in the form of quantitative information. However, the problems arise when there are large number of issues involved, and especially when many of them cannot be represented as quantitative information. If we look at the approach taken in various environmental impact assessment procedures and tools, the value judgments for such issues are usually encapsulated in the so-called "*value-functions*", which are relationships between certain facts and user-perceived "environmental qualities" or "values". Each "environmental quality" or "value" is usually expressed on a scale between 0 (very bad) and 1 (very good). These relationships are usually preprepared by experts and the user only implements them in the assessment procedure.

This kind of expert knowledge should be provided in the judgment engine components of NDDSSs as well, but in a more appropriate form and mainly as information needed to support the judgment-forming process. The temptation to "lock" the judgments in the value-functions should however be avoided. Many participants will have specific knowledge about their local conditions, or have a different reasoning altogether as compared to the one underlying this expert advice, and this may lead to different patterns of valuation. In fact, the judgment engines of NDDSSs will have to allow for judgments which are in a sense "looser" as compared with the structured ones provided by traditional tools and systems for impact assessment, which are based on formalized procedures. Frequently, the only meaningful judgment provided by a given user about a certain state of affairs may be in simple linguistic terms, such as "good" or "bad". This indicates the potential for employing fuzzy sets for conversion of such linguistic terms into fuzzy numbers that can be used for further processing of the provided judgments. Some background on using fuzzy concepts in modelling are provided by Solomatine in **Chapter 19, Data-driven Modeling and Computational Intelligence Methods in Hydrology, Volume 1**.

When it comes to the fundamental theories in support of the actual design of the judgment engine, the basic and starting consideration is that the judgment-forming process is equally dependent on the judged objects and the mental model of the judging agent. It is a view that is sometimes named *interactionist* (see Klinkenberg, 1996, p. 100), and may be contrasted with the traditional dichotomy of the subjective/objective view. The answer to the questions of *how* this interaction actually occurs must be sought in the study of processes of *signification and communication*, as the embodiments and transmissions of all experience. General semiotics is the field that studies these processes at a level that can provide many guidelines for the design of judgment engines. The appropriate use of *signs and sign vehicles* will become a central question for good design of judgment engines, which enables the participants to make *autonomous* judgments.

This field is relatively new to hydroinformatics, and has not been studied sufficiently. In the design of modeling systems orientated predominantly towards specialists in water and environment, the need for a systematic study of the design of user interfaces has not presented such a crucial requirement. The discourse of this user base has been relatively limited and there have not been serious misunderstandings in this process (although we are capable of still distinguishing "good" from "bad" user interfaces). The broad discourse of an NDDSS requires a much more systematic approach to the designing of judgment engines, particularly when the provided "content" needs to be customized and personalized for different users.

A reminder that we are dealing for the most part with judgments of value may highlight how sensitive the proper choice of semiotic devices is. While the designers of the system will inevitably present a structure of meanings to

all users by virtue of the chosen sign vehicles, certain signification structure may steer the valuation process in some predetermined direction (the one of the most powerful interest involved in the process, or the one with the strongest valuation consensus). This situation may act as sophisticated obstruction to autonomous judgment forming, and discredit the whole concept of NDDSS. The study of such employment of "technologies of persuasion" by contemporary media, and particularly by the advertising industry, may be indispensable for the proper design of judgment engines in order to prevent such kinds of NDDSS abuse.

An integral part of the judgment engine is the further processing of judgments after their formation by the users/participants. Two main tasks require such further processing: Firstly, it may be expected that an individual user/participant of the system will provide judgments about several issues of his or her concern. This means that these judgments will have to be aggregated in such a way that an overall position of that user towards the proposed courses of action will be presented both to that user and to all other interested users. Secondly, in order to facilitate the processes of negotiation and collaboration that should follow the judgment-forming processes, the judgments and evaluations of all users need to be aggregated. This aggregation should somehow provide the overall response of the whole community involved in the decision-making process (the so-called *social landscape*). In this way, any individual participant will be able to analyze his or her position against the "background" of all the others participating in the process. These tasks can be supported by the well-developed methods of multicriteria analysis, with the important difference in employment of their results as starting points for negotiation and collaboration, instead of "ultimate solutions".

Collaboration and Negotiation Platforms

The collaboration and negotiation platform is required to support human interaction. The NDDSS concept supports an interactive, emergent approach to decision making, where interactions between participants may lead to options – and therefore decisions – which could not have been foreseen. The collaboration and negotiation platform must be designed in such a way that it will support open and transparent approaches to negotiation and limit as much as possible the opportunities for abusing the process.

As individual participants make judgments on possible courses of action and with the judgment engine assisting by aggregating those judgments into a social landscape, alliances may form on the basis of shared interests and values. This process can be facilitated by providing measures of various kinds of *closeness* between a given participant and other groups or individual participants within the social landscape of judgments made by all participants mentioned earlier. For this purpose, various techniques may be used from the field of data-driven approaches for knowledge discovery, and then particularly those dealing with classification problems (*see e.g.* **Chapter 21, Rainfall-runoff Modeling Based on Genetic Programming, Volume 1** and **Chapter 22, Evolutionary Computing in Hydrological Sciences, Volume 1**). Many recent hydroinformatics studies have explored such techniques for more standard problems of modeling various hydraulic, hydrological, and ecological systems. This valuable experience can be used in the future for designing important support components of the negotiation and collaboration platform.

Still, these processes of collaboration, cooperation, and negotiation take the form of a highly nonlinear discourse and are not at all amenable to formalization. This component of an NDDSS cannot be designed as an encapsulation of a given set of procedures to be followed. Individual-to-individual communication will entail some synthesis of email, instant messaging, web logs, and web fora, enriched with support for the management of content, including scenarios, tools for visualizing positions in a social landscape, and other similar devices.

HYDROLOGICAL MODELS AS FACT ENGINES

When dealing with NDDSSs specifically designed for water- and environment-related problems, hydrological knowledge becomes crucial for providing facts about the physical systems in question. Quite obviously, the main encapsulators of hydrological knowledge that will be incorporated into NDDSSs will be the hydrological computer models. It is not straightforward, however, to identify any particular model or even class of models that will immediately satisfy any decision-making context for which a given NDDSS is developed. There are, on the other hand, several key properties that hydrological models need to possess in order to be treated as candidates for becoming fact engines within any NDDSS.

The first required property is that these models need to be *distributed*. It seems rather obvious that this property is essential for the given purpose. All hydrological processes are spatially distributed and the requirement for distributed modeling is considered necessary solely for more accurate process representation and better prediction of hydrological responses. However, there is an additional reason that requires distributed models within the context of NDDSSs. It is the spatial distribution of the users of the system with their spatially distributed, and very often quite localized, interests. This is an essential characteristic of NDDSSs, which practically excludes all nondistributed hydrological models as candidates for becoming core fact engine components. Nondistributed hydrological modeling components

may find their role only in some cases, for minor, supporting tasks to the main distributed hydrological models.

Dealing with distributed hydrological modeling is nowadays almost exclusively done with the support of Geographical Information Systems (GIS). Some hydrological modeling tasks can even be carried out with a sophisticated GIS system alone (*see* **Chapter 15, Digital Elevation Model Analysis and Geographic Information Systems, Volume 1**), without employing separate hydrological models. Other hydrological models depend on interfacing with GIS data for their construction and execution like in flood modeling (*see* **Chapter 16, Numerical Flood Simulation, Volume 1**). Within the NDDSSs, the power of GIS will also need to be harnessed for designing the judgment engine and the platform for negotiation and collaboration. The term "social landscape" introduced in the previous section already suggests that the presentation and analysis of the user's own judgments and positions versus those aggregated for the whole community can be best achieved through GIS-based dynamic maps (For developments in this direction, see Jankowski, 2000).

In relation to the distributed property of the employed hydrological models and the GIS support, it is important to stress that within an NDDSS the knowledge about the effects of proposed courses of action needs to be provided at a suitable, sufficiently high resolution. It can be expected that the real value of any given NDDSS to an individual user/participant will depend upon the possibility thereby provided to follow effects on certain features that correspond to his or her individual interests, such as the flooding of an individual house or street, or the lowering of the groundwater table at an individual field. While for many other corporate participants this level of resolution may not be that relevant, bringing NDDSS to the level of individual participants will be critically dependent on it (For an example related to flooding problems, see Martin and O'Kane, 2000).

The second property of hydrological models, which is essential for fact generation within an NDDSS, is that they are *physically based.* Although different terms have sometimes been used in literature, such as process-based, or theory-based models, the term chosen here, suits best for describing the needed property. Physically based hydrological models are based on mathematical representations of physical processes that occur in the hydrological system. Sometimes, the argument is put forward that most hydrological models have this property, because they are all based on satisfying at least *some* physical laws. It should become obvious that when the term physically based is used in the context of NDDSSs, we are considering models that include *as many relevant physical processes as possible*, and that they include them in an integrated manner. At present, the most advanced physically based models in this sense are those based on the concept of SHE (Systéme Hydrologique Européen), (Abbott *et al.*, 1986a,b), which allows for simulation of the whole land phase of the hydrological cycle. Examples of modeling systems of this kind are the MIKE SHE commercial package of the Danish Hydraulic Institute (`http://www.dhisoftware.com/mikeshe/`) and SHETRAN, a modeling package developed by the Water Resources Systems Research Laboratory, at the University of Newcastle, UK (`http://www.ncl.ac.uk/wrgi/wrsrl/models.html`).

If we question the reason why this property is so critical for a hydrological model to be a fact engine in an NDDSS, the answer is quite straightforward. Considering that NDDSSs are primarily going to be developed for decision-making contexts that involve planning and design, it is essential that the employed models are capable of simulating *changes* in the physical system in question. Only distributed, physically based models allow such simulations. If the processes are represented as components in an integrated manner, changes in one process component (for example, the groundwater system) which cause effects in other processes (such as the surface water component or the unsaturated zone) can be simulated and analyzed. Larger number of included processes bring more possibilities for simulating *diverse changes* in the hydrological system. The obvious importance of this property for the purposes of NDDSSs is related to the possibility of meeting diverse knowledge needs of the potential users of the system. While for many traditional hydrological problems there are situations in which a number of different models can be applicable, the new context of NDDSSs requires use of specific, distributed, and physically based modeling systems.

At the same time, however, these types of models are most difficult to be built, and most complex to understand. They are still associated with a number of problems (overparameterization being clearly one of these problems), and they need to be continuously developed. Particularly, in future they need to take the best advantage from the possibilities offered by new technologies for data collection (remote sensing, both satellite and airborne, but also the various experiences accumulated in fields such as oil exploration and meteorology). For the purposes of NDDSSs, these developments are necessary because there are no other hydrological modeling alternatives that can deliver the required performance.

This leads us to the third key property of hydrological models as fact engines, which is *integrated modeling*. Traditionally, and in full accordance with the established modern scientific approach, separate models have been developed for separate kinds of water-related problems. Hydraulic, hydrologic, water distribution, groundwater, or water quality models – all deal with separate kinds of problems. Within each class of these models there are numerous variations in terms of spatial and temporal

scales, as well as underlying assumptions, and indeed there are classes of models that are particularly suitable for particular classes of problems. Only more recently has much effort been put into providing integrated modeling systems that try to combine as many models as possible into one conceptual and computational framework. Beyond this again, seamless interfaces between modeling systems and GISs have already been extensively developed as means of integrating water-related results to corresponding geographical circumstances.

Within the framework of an NDDSS, integrated modeling gains an importance that proceeds beyond the need for providing more relevant, reliable, and accurate results. It also goes beyond the integration of hydrological processes only. The large number – and the diversity – of the needs of the users of the system imply integration of different domains as well, such as those of hydrology, ecology, economics, and even models of social behavior. An intervention in one part of the physical system in question can have such far-reaching consequences to other parts, and many modelers are already aware of this aspect. But with NDDSSs a need arises to simulate how such consequences spread across different domains.

There are many developments towards integrated modeling, and some existing modeling systems are already employing quite integrative approaches, but the above mentioned requirements will require a level of integration that is on a completely different level again. Water movement in all different phases of the hydrological cycle will increasingly have to be combined with water quality models, models of urban networks for drinking and wastewater, and models of water and wastewater treatment processes. All these water-related models will then have to be combined with ecological or other socioeconomic models. Even if a general framework of this integration is inconceivable outside of a given decision-making context, the development of the fact engine components of NDDSSs will be greatly facilitated if such integrated modeling is achieved.

The realization that hydrological models, and even more generally water- and environment-related models, will not be the only fact engines in the fact engine component, and yet they will have to be somehow integrated with other kinds of fact engines, leads us to the key problem of the fact engine design: achieving *software interoperability*, which will be sufficiently general for a given decision-making context. This problem already arises at the level of integrated modeling, of course, but in the light of the existence of other fact-providing software the extent of this problem becomes even clearer. A fact engine component of a particular system may contain dozens or even hundreds of different individual fact engines that would have to work with large dependencies on each other. Achieving their interoperability is then a formidably difficult task. General recipes for achieving software interoperability do not exist and various technologies may be employed for different tasks and domains. In the following section we will describe one recently proposed framework based on a so-called *agent orientation*. As we shall see, the framework is in fact much broader because, in addition to providing support for the key problem of the fact engine component, it can also support the design of the other two NDDSS components – the judgment engine and the platform for collaboration and negotiation.

SOFTWARE AGENTS FOR NDDSSs

Although the study of agents and agency has a long history, the emergence of agent orientation as a new conceptualization paradigm can be attributed to several recent and concurrent developments in different scientific and technological disciplines. Advances in such diverse fields as Distributed Artificial Intelligence (DAI), studies of complex adaptive systems with their applications in different areas such as biology, sociology, or economics, network distributed software development, and the explosive growth of the Internet, have all contributed to the development of this new paradigm. The notion of an agent and the understanding of the meaning, the rationale, and the justification for adopting the agent-oriented paradigm therefore vary very much, depending on the respective field of application. The common underlying ground for all these different disciplines and application fields is sought in the new kind of abstract conceptualization offered by the new paradigm of agent orientation.

As a first step, the new approach "expands" the traditional conceptualization of knowledge domains beyond their description solely in terms of different objects, with their properties and relations. In fact, it "replaces" the basic notion of "knowledge domain" with a much broader notion of an "environment", where the basic conceptualization units are not objects, but new kinds of entities called *agents*. The fundamental property of the agents is that they are embedded in their environment, and they are able to perceive and affect the environment. In addition to that, in their interaction with the environment they express goal-oriented behavior. This is in fact very close to a general definition of an agent provided by Russell and Norvig (1995, p. 31) who define an agent as any entity which operates in some environment (physical, virtual, cyberspace) and which possesses sensors to perceive this environment, effectors to act in this environment, and goals of its own which may or may not be explicitly represented in the agent itself.

One of the radical changes that this shift in the mode of conceptualization brings about is that it allows the agents to have their own representation of knowledge domains, which *may or may not be part of their own environment*. An agent's environment is therefore not to be confused with a knowledge domain. In some sense, the exclusive role of

the (human) observer in the traditional, purely rationalistic, approach of conceptualizing and representing domains in terms of objects has been now attributed to these new kinds of entities called agents. This is certainly one of the most fundamental changes brought about with the new approach, primarily because it allows for different perspectives (or points of view) between the human observer and the agent, and/or between the different agents themselves.

As we have mentioned, this same paradigm is being developed and applied within several very different disciplines. For example, the very broad area of computer-simulation-using agents has already been applied in many different fields, such as biology, ecology, sociology, economics, business or industrial process management, transport, and others. In all these fields, the agent-based simulation is used to observe some emergent phenomena which result from the individual actions of large number of individual agents. Of course, in different domain areas, the agents represent different entities (individual organisms in ecological simulations, human agents in social simulations, customers, and producers in economic simulations, etc.). For examples of agent-based simulations for water resources management combined with socioeconomic aspects, see for example, the European research project FIRMA (`http://firma.cfpm.org/`).

However, the advantages of agent orientation for the design and development of NDDSSs are in another wide area, namely, that of *software agents*. In the area of software engineering, the shift towards agent orientation means primarily the use of software agents as more useful, higher level mental abstractions, which can be beneficially used for software development. There are two general streams of software agent development. The first one is concerned with the most important characteristic of complex distributed software systems, which is the one of *interaction*. This stream deals with *collections* of agents, which are most commonly described as Multi Agent Systems (MASs). The second stream of software agent development is concerned with construction of individual agents, where the stress is much more on developing *intelligent* software component capable of learning and adaptation. A very important application area for these agents is the construction of intelligent user interfaces for human interactions with computer systems. Of course, both classes can benefit from each other's properties (MASs involving learning and adaptive agents, and individual agents using interaction with other agents for improved performance), and the developments frequently overlap.

Software agents are best defined as "computer systems *situated* in some *environment*, and capable of *autonomous* action in this environment in order to meet their design objectives" (Wooldridge and Jennings, 1995). The environments of software agents are determined by the nature and tasks in an actual application, while they are generally described with various properties and the degree to which these properties are satisfied (accessibility, determinism, static versus dynamic, discrete versus continuous, etc; Russell and Norvig, 1995, p. 46).

The important term in the above definition of a software agent is "autonomous action". This is one basic property of software agents that distinguishes them from the more familiar software *objects*. As summarized by Wooldridge (2002, p 21):

- Agents embody a stronger notion of autonomy than objects, and, in particular, they decide by themselves whether or not to perform an action on request from another agent;
- Agents are capable of flexible (reactive, pro-active, social) behaviour, and the standard object model has nothing to say about such behaviour
- A multiagent system is inherently multithreaded, in that each agent is assumed to have at least one thread of control

It should be noted that the autonomous action also covers the area of interagent communication, collaboration, competition, and other types of social behavior. Such behaviors in agent orientation are considered possible only via autonomous action of the involved agents. The overall objectives of the designers of the systems are achieved as emerging from interactions of the individual agents. For designing complex software systems, in which it is rather difficult to specify the operation of the system as a whole, the agent orientation approach is a viable alternative.

Without going into the details of the various agent architectures, we will now focus on the properties of MASs and of individual, and particularly *interface* agents, which are relevant for design and development of NDDSSs (For an overview of different agent architectures, and their different applications see Russell and Norvig (1995); Wooldridge and Jennings (1995); Nwana (1996); and Wooldridge (2002).)

The social ability of agents in MASs is dependent on the ability of the agents to communicate with each other. This is usually achieved by making use of specially designed, highly expressive Agent Communication Languages (ACLs). Agent communication is of such importance in MASs that some researchers propose that the ability to communicate through a high-level communication language is the first criterion for agenthood. The most widely used ACL is the so-called *KQML* (Knowledge Query and Manipulation Language), developed by Stanford University. It is based on speech act theory, where, like most of the approaches used in developing ACLs, the message exchanged between the agents is divided into two parts. The first part conveys the *intent* of the sender to the receiver (whether it is a request, question, response etc.) for which KQLM uses the so-called *reserved performatives*. They determine the kinds of interactions that are possible with a KQLM-speaking agent. The second part of the message is the message itself, usually called the *content* of the message

that is attached to a performative. Another similar ACL language is the so-called *FIPA-ACL*, developed by an Agents Standards body called the *Foundation for Intelligent Physical Agents* (FIPA).

Second key components for social interactions within MASs are the so-called *ontologies*. Ontologies are the formal specifications of conceptualization of any particular domain about which the agents communicate. They are the "vocabularies" that are used to build the content of the messages in a consistent way. They are in fact very important for interagent communication, regardless of the ACL in question, because they contain the descriptions of the domains about which the agents exchange messages. At the same time, however, the "ontology problem" is probably one of the most significant in the whole field of agent-oriented software engineering (see Nwana and Ndumu, 1999). It relates to the fact that the creation of an ontology for a given domain, which can then be used by various agents, still requires an *explicit definition of every concept that needs to be represented*. Moreover, same domains can have different ontological descriptions for different *tasks*. General-purpose ontologies are therefore still practically impossible, and this turns the developers towards building domain-specific ontologies.

We now turn to the primary problem of the fact engine component of a given NDDSS – the problem of software interoperability – and see how this can be approached from the MAS perspective. The heterogeneous software components introduced earlier, which constitute the fact engine component such as the various models, databases, documents, or expert systems, can become equipped with communication capabilities using ACL. Existing software applications may actually be converted into agents, by "wrapping" them with such a communication layer, while new applications can possibly be equipped with communication capabilities of this kind from the beginning.

Such a design approach would then mean that each agent from the agent component would basically become capable of two kinds of actions, which we can call *private* and *communicative*. The private actions are those related to the internal tasks for which a given software component is built (execution of a model run, extraction of a query result from a database or a knowledge base etc.). For its private actions each agent operates within its own, internal, and rather restricted domain, and the way in which such agents are implemented is independent of the processes in the agent communication layer.

In order to be able to exchange meaningful messages, the agents will need to use a common ontology (or several common ontologies). In a concrete decision-making context, the fact engine component will still operate in a relatively controlled and bounded environment, where both the domain and the tasks can be well defined, and the use of common ontologies will be feasible.

In analyzing the second class of individual agents, we will focus on the so-called *interface agents*. These are not predominantly developed for operation in a society with other agents but as assistants to human users when using a particular application. These agents change the way in which the creation of user interfaces for software applications is understood. Most existing user interfaces are built for tasks that involve closed, static, relatively small, and well-structured application domains. Furthermore, they rely completely on direct manipulation by their users. Interface agents (sometimes called user assistants, or personal assistants, or expert assistants) assume that the applications operate in an open, dynamic, and sometimes unstructured and unpredictable environment (e.g. the Internet). Interface agents are active without their users' direct manipulation and they try to match the user's interests, habits, and preferences with the changing conditions that they experience in their dynamic environment. Crucial properties of interface agents are their ability to learn from the actions of their human users and adapt to changes in the environment or to changes in user preferences or behavior.

These properties of interface agents are actually quite adequate for the requirements of the judgment engine component of an NDDSS. Firstly, in order to achieve its main function, the judgment engine component has to provide customized and even personalized interfaces for users who can have very diverse beliefs, intentions, and interests. At the same time, the whole "background" against which the users are forming their judgment is dynamic and may change over time (users with new kinds of interests join in, new facts are being provided, the social landscape changes as a result of negotiations, etc.). This means that these interface agents will have to deal both with the changing attitudes of their users and with such changing situations in this "background environment". These aspects make the judgment component of an NDDSS an "open" application domain, open also to its human agents.

The most recommendable approach would certainly be if these agents could be built with the abilities to learn and adapt to continuous changes in both the user attitudes and in the "background environment". The advantages from having learning and adaptive interface agents will be twofold. Firstly, such interface agents will be able to act as true "personal assistants", as they will be able to suggest beneficial actions to the user in a changing dynamic environment. Secondly, such agents would in principle be capable of "replacing" the human users and continuing to act autonomously on their behalf when they are absent. The achievement of this second advantage involves the difficult issue of trust that the human users can put on such autonomous applications.

It has to be realized, however, that building interface agents with such sophisticated learning and adaptation capabilities is extremely difficult. As Nwana and Ndumu (1999)

point out, the design of such agents has to meet the so-called *intelligent tutoring and mentoring problem*, for which the agent is required to have four key knowledge modules: domain knowledge on the application, a model of its user, strategies for assistance, and some sort of a catalogue of the typical problems (situations) that arise within the particular environment. These requirements suggest that such agents need necessarily to use deliberative architectures, with explicit representation of the required knowledge in these four modules. The alternative approach of Maes (1994) of using more reactive architectures built out of competing competence modules that produce emergent learning and adaptive behavior, has been successful in several applications, but in domains that are still rather simple. This area is still under active research, but it seems that some kind of hybrid architecture will be needed in order to meet the requirements of complex application domains like the judgment engine component of an NDDSS.

Because such applications are still an intention rather than a reality, the judgment engine interface agents can, as in many other cases besides, take a more simplified approach. Instead of continuously learning every "move" of its user, the agent can use the so-called *user profiles* created from the user input, and then try to "match" situations occurring in the "background environment" with such representations of the user. This approach is similar to applications for providing customized content, as exemplified by many existing Internet applications.

An agent-based NDDSS design will also need to address the problem of connecting the interface agents to the heterogeneous agents that constitute the fact engine component. With the envisaged large number of interface agents that will serve all the users/participants and the diversity of the facts that they will require for supporting the judgment-forming process, it may become very difficult to maintain direct connections between the interface agents and the fact engine agents. Such direct connections may be very expensive in terms of computational resources and prohibitively increase the complexity at the implementation level.

In order to overcome problems of this kind, one common solution is that of employing another kind of agents, the so-called *facilitators*. Instead of using direct communications, the interface agents communicate through these agents, which thus act as their intermediaries. The facilitators, envisaged to be located in the knowledge center, establish and maintain connections across all interface agents and ensure a coordinated exchange of messages between them and the heterogeneous agents acting as fact engines. In communicating with the fact engines, the facilitators then need to be capable of using the same ACL as all other heterogeneous agents. All the agents involved can then be organized in a so-called *federated system*, where the communication overhead is significantly reduced.

The combination of fact engines interoperating through an ACL, and interface agents communicating with them via facilitator agents, is, in fact, also suitable for the requirements of the platform for collaboration and negotiation. The collaboration and negotiation processes involving "many parties and many issues", are impossible to be automated and will essentially be carried out by the human participants. Nevertheless, the system still needs to provide support for these processes and then both at the users' nodes and in the knowledge center. At the "users" nodes, the interface agents can have their role extended so as to provide both the social landscape emerging from the interactions of all participants and the embedded position of that particular user in such a landscape. For this purpose, the interface agents need to act as a kind of "medium" through which the "moves" of all the participants are made transparent. This transparency should enable the users to discern the actions by which they can orientate their attitudes relative to one another, and therefore enhance the collaboration process. This implies that the interface that is actually presented to each user will depend on the actions of all the other users/participants, which means that the interface agents need to interact *among themselves.* With the large number of interface agents, the so-called *broadcast message-passing* approach seems again infeasible for this purpose, and the solution needs to be sought again in the federated system, making use of the facilitator agents that act as intermediaries between the interface agents.

Apart from this basic technical task of coordinating the communication exchange between the interface agents, the facilitator agents will need to encapsulate all the necessary knowledge for supporting the collaboration and negotiation processes. These agents therefore need to take upon themselves the necessary tasks of aggregation of the individual judgments and positions, as well as the creation and updating of the social landscape presented to the users through the interface agents. The support in terms of calculating similarities of users' positions that can be used for coalition and alliance building, or the determination of alternatives with mutual gains, are also tasks to be handled by the facilitator agents. The facilitator agents may integrate these additional tasks within their own agent architecture, or they can maintain separate connections with other "back-end" agents specially built for this purpose.

This general overview of the software agents' potential for designing NDDSSs does not touch any of the numerous difficult implementation issues. Any concrete NDDSS design and development problem will certainly open up many such implementation issues, and possibly even raise the question of whether the agent-oriented approach is suitable at all at the implementation level. Nevertheless, there seems to be a lot of value in adopting the agent-oriented approach at the conceptual level. The essential problem in

the design of NDDSSs is the integration of the three functional components into one design framework. The tasks that these three components need to perform are very different, and the use of more traditional design methodologies may lead to design specifications that are too complex. This in turn will make the implementation even more difficult. The adoption of an agent-based approach offers the possibility to provide an abstract, high-level conceptual design, which is comparatively less complex, and which emphasizes the key integration issues. Once the entire system is decomposed and specified in terms of agents, many implementation issues can be approached separately for each agent.

In conclusion, it is obvious that fully developed NDDSSs, as they are proposed here, are still some way removed in the future. Their design and development still requires a lot of research, testing, and prototyping with different agent architectures for different decision-making problems. It is entirely possible that in some cases the agent-oriented approach may not be required at all. As a general approach to NDDSSs design and development, however, the software agent technology clearly has a lot of potential, and its advances elsewhere need to be followed closely and constantly related to the present applications.

THE FUTURE FOR NDDSSs

While the concept of NDDSSs, including the technical possibilities for their development, is quite developed, the question of their introduction in practice still remains open. The need for systems like NDDSSs becomes more and more apparent as we are facing increased complexity in the water-related decision-making problems. On the other hand, there seems to be enough human and technical potential for developing full-fledged real-world NDDSS applications. As with any new development of this kind, the actual realization may critically depend on the existence of certain supportive social ethos. We can postulate that the locus of possible social support for such systems with sufficient inclination towards their real-world application may emerge in three different ways:

1. Introduction of Internet-distributed NDDSS-like systems in the form of multiplayer role-play games. This approach is also known as the *edutainment* (education + entertainment) approach. In order to be successful, this approach requires strategic alliance between the developers of more traditional hydroinformatics tools and systems and professional game developers. It is envisaged that both groups may benefit from such a development, even though difficulties may arise as to what the right balance between "real-world" and "entertainment" content is. If the balance is not appropriate, such games can teach unintended lessons, and those lessons may be counterproductive. On the other hand, successful developments of such scenarios would mean that through the penetration of such games into the culture of our societies, the realization of the potential benefits of the NDDSS approach might be significantly increased.
2. The second locus of support for development and introduction of such systems may come from governmental organizations and various Non-governmental Organizations (NGOs) involved in water- and environment-related issues. In most countries, water- and environment-related problems fall mainly under governmental jurisdiction, even if they involve many other, and different, interests. This makes the governmental organizations an obvious place from where such systems can be disseminated. Particular NGOs, on the other hand, may become natural supporters of such systems, since they promote most of the things for which these organizations stand for. One could even envisage partnership between governmental organizations and NGOs on development of such systems.
3. The third approach for developing of such systems may be directly through the market. This is a more likely scenario for developed countries and societies, where concerned citizens and institutions can afford to pay for services offering relevant water-related knowledge and information. It is an approach that looks directly at the opportunities offered by the processes of knowledge commodification. It is very often stressed how these processes are driven by technology, such as continuously improving Internet solutions, or the introduction of third-generation (3G) telephone networks. At the same time, this process of constant introduction of new, more efficient, technologies is countered by the lack of appropriate and useful "content" that is to be delivered through them. Water- and environment-related problems are certainly one area where fast and always-available personalized content delivery is needed. The initiatives for such businesses need to come again primarily from organizations involved in the development of hydroinformatics systems, but now the strategic alliances need to be sought with market-oriented companies that are promoting new technologies and are searching for appropriate and useful content. The involvement of government in water-related issues indicates that such attempts may need to be developed through strategic public-private partnerships.

The three proposed approaches only point towards the potential areas from where the introduction of NDDSSs into our societies may be taken up. Clearly, for different decision-making contexts, and especially for different societies and cultures, different approaches or combinations of approaches will be suitable.

As a general conclusion for future developments, it can be envisaged that forthcoming developments in the field of information and communication technologies (as understood in the term *informatics*) are likely to continue to change all fields of hydrological sciences – which in essence, is the contribution from the field of hydroinformatics.

PART 3

Meteorology and Climatology

25: Global Energy and Water Balances

ATSUMU OHMURA

Swiss Federal Institute of Technology (ETH), Zürich, Switzerland

The earth's energy and water balances are summarised with the most recent observational and computational results. A special reference is given to the earth's surface. After a brief discussion of the limits of the observational accuracy, the author explains the mean state of the energy balance starting with the sun, through the atmosphere and to the earth's surface. The main contents are the Total Solar Irradiance (earlier called solar constant) and its variability, the climatic effect of the earth's orbital change, extinction processes of solar radiation in the atmosphere, the distributions of solar radiation on the earth's surface, reflection and albedo, terrestrial radiation from the atmosphere and the earth's surface, net radiation, sensible and latent heat fluxes, subsurface heat flux, and latent heat of melt. The distributions of the individual components are presented in maps. The important points of geographical distributions and energy fluxes are explained in the text. The energy balance climatology in the present article differs from earlier works mainly on three topics: 1) larger atmospheric absorption of solar radiation; 2) smaller solar radiation on the earth's surface; and 3) larger terrestrial counter radiation. These new situations are the results of the recent advances in spectrometry, observational technology both on the earth's surface and in the space, and also in computational skill. Therefore, the historical development of the understanding of the earth's energy balance is added. The article ends with a brief description of the mean hydrological cycle, allowing unsteady conditions due to the melt of glaciers during the twentieth century.

INTRODUCTION

Solar radiation is practically the only energy source for the earth's climate system. The global climate is to a great extent determined by the equilibrium maintained between the solar radiation absorbed by the atmosphere and earth's surface system (planetary system) on one hand and the emission of terrestrial radiation to space on the other. A destabilization of the equilibrium leads to climate changes. The entire cycle of energy flow in the climate system begins with the absorption of solar radiation by the atmosphere and the earth's surface, whereby the latter plays a dominant role. The major transformation of the solar radiation into enthalpy and latent heat happens at the earth's surface. Of these two components, the latent heat of evaporation is by far more important. Further, the water vapor contributes upon condensation for heating the middle and upper troposphere. This is also the process through which the energy and hydrological balances are closely connected. Globally averaged, the earth's surface gains more energy than it loses as a result of radiation exchanges. In the meridional direction, the radiation balance of the planetary system creates a net energy gain in lower latitudes and a loss in higher latitudes. This is how the net flow of enthalpy and water vapor takes place from the earth's surface to the atmosphere and from the lower to higher latitudes. The major climatic and hydrological phenomena are closely associated with this equalizing process of uneven energy balance. These processes will be quantitatively presented. In considering energy fluxes, accuracy is of prime importance. The absolute limit in accuracy for radiation measurements is the accuracy limit of the World Radiometric Reference (WRR). The current limit in the WRR is estimated at $\pm 0.3‰$ or approximately $\pm 0.3\,\mathrm{W\,m^{-2}}$. The highest accuracy in the operational measurements of all energy fluxes is attributed to direct solar radiation. The smallest unsystematic error of direct solar radiation is about $1\,\mathrm{W\,m^{-2}}$. To achieve this accuracy, a pyrheliometer of the absolute cavity type must be used without a filter. If a commercially available pyrheliometer with a thermopile-type sensor and a quartz filter are used, errors larger than $\pm 2\,\mathrm{W\,m^{-2}}$ must be expected. Pyranometers for 2π-irradiance measurements

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

have an unsystematic error larger than ±2.5% or typically ±5 W m^{-2}. The same error for a pyrgeometer for longwave measurement is estimated at ±8 W m^{-2}. The heat flux of conduction into and out of the ground can be determined with a typical error of ±3 W m^{-2}, mainly because of the nature of the small absolute value of this flux. The errors of turbulent heat fluxes are usually much larger and more difficult to estimate than for the fluxes of radiation and conduction. It is not uncommon to experience differences of up to 30% between two instruments located side by side. These errors are estimated with the data obtained under favorable conditions. In reality, the influence of adverse weather conditions such as rain, snow, and frost on instruments reduces the above accuracy. The most important factor for the accuracy, however, is the experience, skill, and dedication of the observers. Energy fluxes are difficult to measure without personal interest and an alert mind. For a general discussion of the observational errors for irradiances, see Ohmura *et al.* (1998).

THE SUN

The intensity of the solar radiation received without atmosphere at the mean sun/earth distance is defined as solar constant. The recent direct observation of the solar constant from space provided evidence that the solar constant is in fact variable. As a result, we apply today to this concept a new term, Total Solar Irradiance (TSI). The TSI has been monitored from space since 1978 with a comparable accuracy and scale to the present level. Since then a quarter century has passed. The time series in Figure 1 which is due to Fröhlich (2004) and a recent supplement by C. Fröhlich (personal communication) shows four important facts: (i) TSI changes with 11 year sunspot cycle; (ii) the amplitude of the 11 year cycle is the order of 0.6 W m^{-2}; (iii) beyond the 11 year periodicity, there is no statistically significant trend; and (iv) its mean value is 1366.0 W m^{-2}.

There are some publications that indicate an increasing trend in TSI, offering an alternative explanation for the present warming (Willson, 1997). These works were subsequently found to have ignored certain key corrections of the instruments. This does not mean that TSI does not change over a longer period. It was simply not detected during the last 25 years of observation. There have been a number of attempts to relate the long-term variability of TSI to some observable phenomena such as sunspot number, length of the sunspot cycle, or ^{10}Be and ^{14}C concentrations in the atmosphere, but all these hypotheses are highly speculative. Because of the spherical shape of the earth, one-quarter of TSI, 324 W m^{-2} can be regarded as the mean solar irradiance at the top of the atmosphere (TOA), and hence the primary energy source for the climate system.

EARTH'S ORBITAL EFFECT

The solar irradiance at TOA is completely describable with three orbital parameters, eccentricity, longitude of perihelion (seasonal variation of the distance to the sun), and the tilt of ecliptic. The present eccentricity of the earth's orbit is 0.0167 (Berger, 1978), a rather small value within the

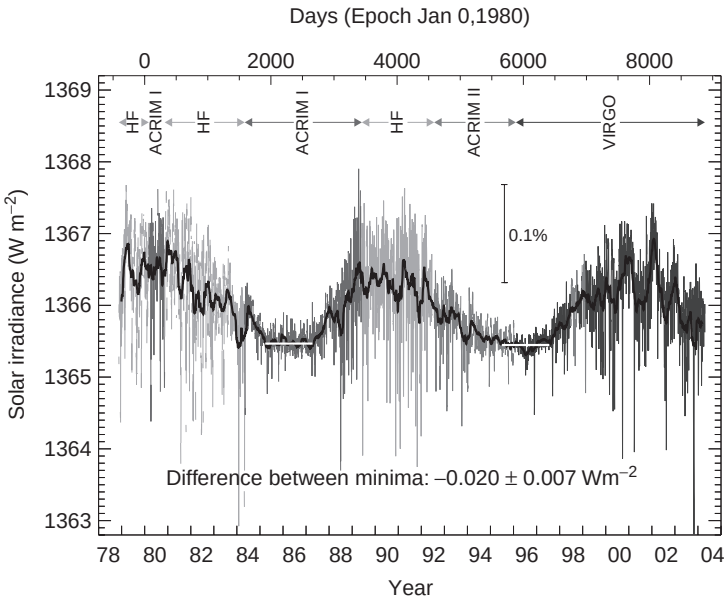

Figure 1 Observed total solar irradiance (solar constant) from space.Fröhlich (2004) supplemented by C. Fröhlich (personal communication). The long-term mean TSI is 1366 W m^{-2}. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

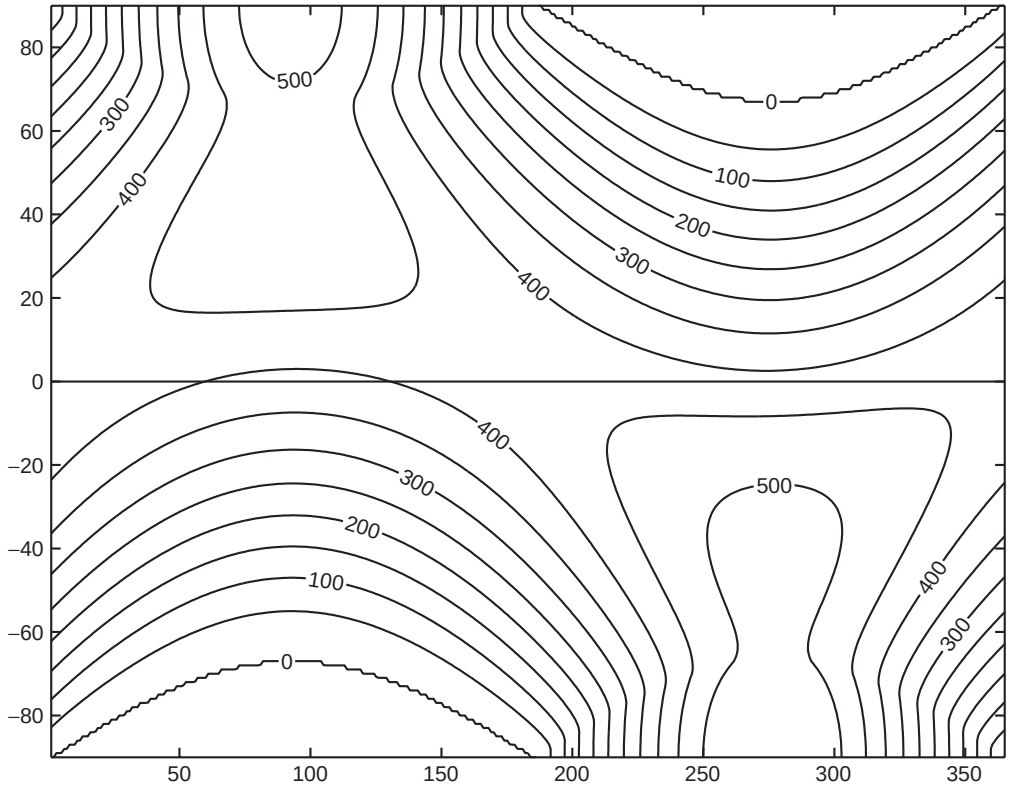

Figure 2 Irradiance at the top of the atmosphere under the present orbital parameters. The asymmetry between both hemispheres is due to the present eccentricity of 0.0167

entire Quaternary. This small eccentricity, however, yields a significant variation of the solar irradiance of ±3.5% between the perihelion and aphelion at TOA. The seasonal course of the TOA solar irradiance is presented in Figure 2. The earth is presently at the perihelion around January 4 and at the aphelion around July 4. Consequently, the Southern Hemisphere receives 7% more TOA solar radiation than the Northern Hemisphere, in their respective summers. Whetherald and Manabe (1975) show that 1% variation of the TOA solar irradiance causes approximately 1 K temperature change at the earth's surface or at the bottom of the atmosphere (BOA). The orbital effect produces a rather significant contrast in climate between both the Hemispheres. For example, the serious situation of the Ultraviolet radiation in summer in the Southern Hemisphere is caused mainly by this astronomical condition, rather than its proximity to the ozone hole over the Antarctic.

EFFECT OF THE ATMOSPHERE

Solar radiation undergoes a substantial transformation in the atmosphere before reaching the earth's surface. The important processes in the atmosphere are Rayleigh scattering due to molecules, Mie scattering by aerosol, reflection by clouds, and absorption by all these components. The climate system loses 30% (Barkstrom *et al.*, 1990) of the primary solar radiation back to space by reflection. The reflective loss is 3% due to Rayleigh scattering, 1% due to Mie scattering, and 22% due to reflection by clouds, the remaining 5% being the reflection from the earth's surface that will be discussed later in detail. This total reflectance of the earth is called a *planetary albedo*.

The atmospheric absorption of solar radiation is of medium strength. This is a process presently far better understood than it was 20 years ago. Earlier the earth's atmosphere was considered very transparent for solar radiation. An absorption rate of 17 to 20% of the primary solar radiation was most often suggested. Recent investigations based on field experiments and numerical computations indicate that the atmosphere absorbs more than 25% of the primary solar radiation (Budyko *et al.*, 1988; Ohmura and Gilgen, 1993). The most likely atmospheric absorption is $28 \pm 2\%$. The gross underestimation in the past is due to an improper treatment of the near-infrared (IR) absorption by water vapor and the neglect of a number of weak absorption bands in trace gases. Although they exert only weak absorptions individually, the effect of their sum can be significant. It has also become known recently that the effect of clouds on absorption of solar radiation was often overestimated in the past (Ohmura and Raschke, 2005). The strength of the

Table 1 Atmospheric absorption with MODTRAN

$[H_20]25$ mm we	70.1 W m^{-2}

Cloud (ISCCP)	2.8
Total absorption	96.0

Source: TOA solar irradiance (342 W m^{-2}).

absorption by individual components of the atmosphere is presented in Table 1. Of all these components, water vapor and clouds deserve further discussion. Water vapor, which occupies only 0.24% of the atmosphere, plays the most important role in the radiation budget of the atmosphere. It absorbs 70 W m^{-2} solar radiation. Previous underestimation of this effect was often due to a heavy reliance on Fowle's equation (Fowle, 1915). Many works also neglected the absorption in the wavelength range beyond 2.8 μm, where more than 30 W m^{-2} of TSI is contained and water vapor absorption is strong. The effect of clouds on atmospheric absorption is rather modest. Clouds have two counteracting effects. Firstly, they enhance the absorption of solar radiation through the elongated optical paths within the cloud layer as a result of the multiple scattering by cloud droplets. The increased optical paths make weak and intermediately strong absorptions, strong enough to be considered. A minor contribution is also made through the absorption by cloud droplets. Secondly, strong and diffuse reflection at the upper layer of the clouds promotes the absorption by the atmosphere above the cloud layer. Finally, the existence of the cloud layer deprives the atmosphere below of potential absorption because so much solar radiation is already lost before reaching this level. The recent database from the International Satellite Cloud Climatology Project (ISCCP), Level D2 (personal communication by W.C. Rossow) indicates that the global mean cloud effect on the solar radiation absorption in the atmosphere is 3 W m^{-2}, that is, just about 1% of the primary solar irradiance. The other substances, such as ozone, carbon dioxide, methane, and aerosol, absorb 23 W m^{-2}, making the total absorption of the solar irradiance 96 W m^{-2}, corresponding to 28% of the primary radiation from the sun.

SOLAR RADIATION AT THE EARTH'S SURFACE

Solar radiation at a point on the earth's surface is determined by TSI, the earth–sun distance, the solar zenith angle, and the extinction effect of the atmosphere. Solar radiation arrives at the earth's surface in two components, direct solar and diffuse sky radiation. The sum of the two is referred to as *shortwave incoming radiation* or, in brief, *global radiation*. On a cloudless day in a clear atmosphere, up to 90% of the global radiation is made of direct radiation, while on an overcast day 100% of the global radiation can be due to diffuse sky radiation. Globally averaged, direct and diffuse radiation divide global radiation at about 50 to 50%. Global radiation is presently the best-known component among all fluxes at the earth's surface. The wide range of the proposed values of global radiation in earlier literature can be narrowed down with presently available observational data of high quality. Satellite investigations have fixed the long-term mean value of the planetary albedo at 30%. The analysis based on Table 1 shows that the atmosphere absorbed as much as 28% of TOA solar irradiance. These values state that the absorption of global radiation by the earth's surface must be around 42% of the TSI, that is, between 142 and 147 W m^{-2}. This consideration eliminates all works other than Budyko (1963), Budyko *et al.* (1988), Ohmura and Gilgen (1993), Ohmura and Raschke (2004), and the numerical simulation by ECHAM4 (Wild *et al.*, 1998), and indicates that globally averaged shortwave incoming radiation at the surface must be in the range of 170 W m^{-2}, which is supported by the recent reevaluation of global radiation (Ohmura and Raschke, 2004). Further, global radiation has large spatial and seasonal variations. The following discussions on geographical distribution of the fluxes will be made on the basis of ECHAM4 simulations. This simulation is considered to represent most accurately the seasonal distribution of energy fluxes in the global scale.

ECHAM4 is a general circulation model (GCM) developed at the European Centre for Medium-range Weather Forecasts (ECMWF), adapted for climate simulations at the Max-Planck-Institute for Meteorology at Hamburg. This model is equipped with one of the most advanced radiation codes. The model was used to simulate the present climate in a high-resolution grid-equivalent of 120 km by using the climatological sea-surface temperature during the period 1979–1988. In many regards, the fluxes computed in these simulations can be considered to offer one of the most realistic distributions of surface fluxes.

The annual mean shortwave incoming radiation (global radiation) at the earth's surface in Figure 3 ranges from the smallest value of 70 W m^{-2} over the Barents Sea in the North Atlantic to the largest value of nearly 300 W m^{-2} in the subtropical East Pacific. Generally, the largest global radiation is not found under the equator, despite its largest TOA irradiance in the world, because of the cloud development associated with the Intertropical Convergence Zone (ITC). The largest global radiation appears in the subtropical horse latitudes where potential solar radiation at TOA is still large and the atmosphere is relatively dry and cloud-free. On land this is the major desert regions of the world, such as, the Sahara, Arabian, Kalahari, Australian, Mojave, and Atacama. In these regions, the annual global

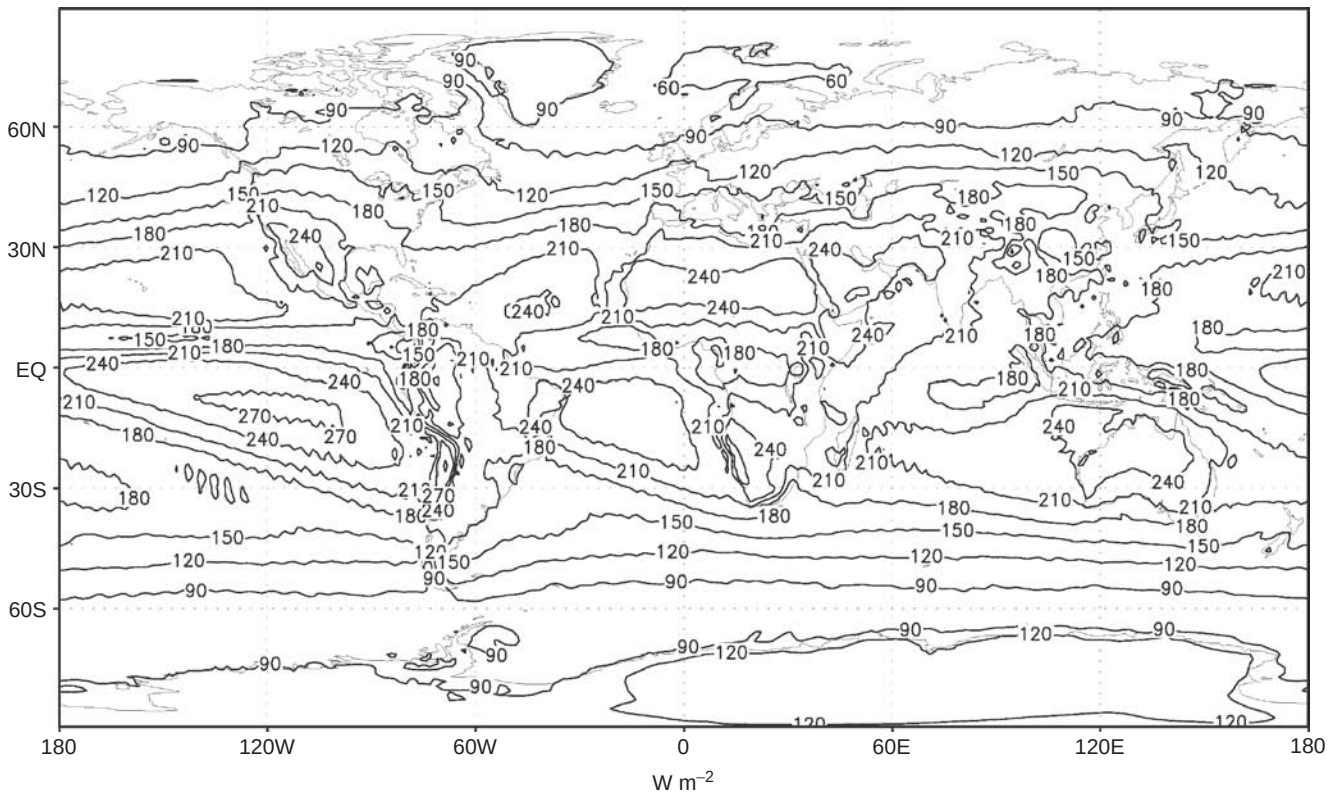

Figure 3 Annual global radiation computed by ECHAM4T106. Among all general circulation models (GCM), ECHAM4 developed at the European centre for medium-range weather forecasts (ECMWF), adapted for climate simulation at max-planck-institute (MPI) for meteorology, Hamburg most closely simulates the present distribution of shortwave incoming radiation (global radiation). The global annual mean on this figure is 170 W m^{-2}

radiation exceeds 250 W m^{-2}. The Gobi and Takla Makan are excluded from this category because of their locations at higher latitudes. The largest instrumentally measured global radiation on land was observed at Riyadh, on the Arabian Peninsula and at Tammanrasset in the Sahara, where global radiation reaches 260 W m^{-2}. Yet, the world largest global radiation is probably not found on land, but over an ocean. The area of the tropical East Pacific between the ITC and the Southern Pacific Convergence Zone (SPCZ) is considered to be the sunniest spot in the world. In this area, the annual global radiation exceeds 270 W m^{-2}. The largest annual global radiation of 298 W m^{-2} is reported at Canton, on Canton Island in Kiribati. This is basically a westward extension of the desert climate to the ocean, but the atmosphere contains much less aerosol in comparison with the sites in the continental desert. The middle latitudes are the regions of a large gradient of global radiation with a rate of -3 W m^{-2} per one degree of latitude. The smallest global radiation does not appear right at the pole but in subpolar regions from latitudes 60° to 70° in both Hemispheres. These are regions of larger cloud amount owing to the subpolar cyclones. From here toward the poles, global radiation increases. The higher surface albedo in the Arctic Ocean and the Antarctic continent also enhances global radiation through multiple reflection between the surface and the atmosphere. At the North Pole, annual global radiation is estimated at about 90 W m^{-2}, while at the South Pole the long-term mean of the observed annual global radiation is found to be 130 W m^{-2}. The difference in annual global radiation between North and South Poles is caused by the earth's orbital effect the difference in altitudes, cloud conditions, and the surface albedo.

Globally averaged, the earth's surface receives 7% more global radiation in January than in July because of the occurrence of the perihelion in January and the present eccentricity of the earth's orbit around the sun amounting to 0.0167.

The seasonal fluctuation of global radiation is very large except for the equatorial zone as is witnessed in the example of Singapore shown in Figure 4. In regions poleward of 10° N and S, the global radiation experiences considerably large seasonal fluctuations. The distribution of global radiation in winter is strongly affected by the solar elevation, hence latitudes, while in summer it is greatly influenced by the distribution of clouds. Thus, in

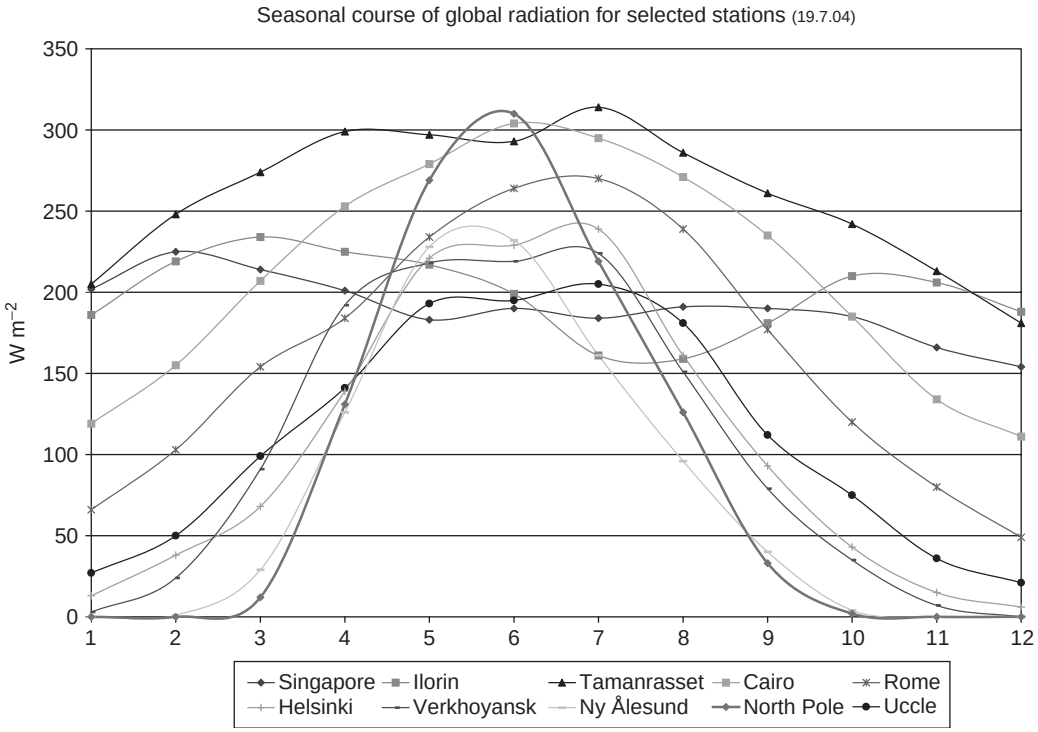

Figure 4 Monthly mean global radiation for selected stations. The figure represents the meridional variation of the seasonal global radiation based on the long-term measurements at 10 stations. These stations are spaced approximately by 10° in latitude, starting at the equator for Singapore and ending at north pole. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

the months of extreme solar declinations of June (Northern Hemisphere) and December (Southern Hemisphere) the latitudinal distribution of global radiation forms a maximum near the pole and a secondary maximum at around 30° of latitude in the summer hemisphere. During these months the summer hemisphere receives 70% of the total global solar radiation. In December, the world's largest monthly global radiation of $450\,W\,m^{-2}$ is observed on the plateau of East Antarctica and the lowest in the regions pole-ward of 70° N, where the monthly global radiation is zero due to the polar night. In June, the largest monthly global radiation is found in the central region of Greenland ($380\,W\,m^{-2}$), while in the region of the North Pole it remains smaller at around $300\,W\,m^{-2}$ because of larger optical air mass and cloud amount, and lower albedo of the melting sea ice. Across the equator in June, the global radiation declines into the Southern Hemisphere at a rate of $3\,W\,m^{-2}$/degree of latitude, reaching zero at 70° S, which closely touches the Antarctic coast of the Eastern Hemisphere.

REFLECTION OF SOLAR RADIATION AT THE EARTH'S SURFACE

Reflection is influenced to a great extent by albedo, a ratio of reflected to global radiation. The earth's surface albedo is of fundamental importance for energy balance, as this quantity greatly influences net radiation. The albedo values depend on the material of the surface and its condition on one hand, and on the incident direction and the spectral composition of the incoming radiation on the other. Under natural conditions, the albedo of the earth's surface is strongly influenced by vegetation, wetness, solar elevation, and the amount of clouds. Depending on the nature of the surface, the existence of the snow cover has a variable effect on the albedo. In Table 2, representative albedo values for the entire solar spectral range are presented for various surfaces.

The global distribution of albedo is strongly influenced by the location of continents and oceans. The lowest albedo is seen over water bodies such as oceans and lakes. The albedo of the ocean increases with solar zenith angle. While the minimum monthly albedo of 0.06 is expected over the ocean at the equator in months with equinoxes, the ocean albedo increases beyond 0.1 between 47° and 50° of latitude in the same months. The albedo of the water surface just off the sea–ice margin at the beginning of the melt season is also about 0.1. The monthly mean albedo of the ocean water surface is summarized in Table 3. The albedo in high latitudes is further enhanced by sea ice. The seasonal variation of the sea ice albedo is summarized in Figure 5. On

Table 2 Albedo for global radiation (total albedo) (monthly values, not instantaneous values; albedo-ranges given in brackets in the second lines are those with a snow cover)

Surfaces	Albedo values	
	Observed range	Most frequent value
Glacier, accumulation area	0.57–0.85	0.75
Glacier, equilibrium line area (during melt)	0.37–0.77	0.65
Glacier, ablation area (after snow melt)	0.11–0.70	0.35
Seasonal snow cover, clean (before melt)	0.65–0.85	0.7
Seasonal snow cover, clean (during melt)	0.3–0.6	0.4
Dirty snow cover	0.2–0.4	0.3
Tundra (in snow-free period)	0.07–0.22	0.15

Jaeger (personal communication), Kobayashi *et al.* (2001), Kondrat'ev (1973), Kondratyev (1969), Lee (1978), Liljequist (1956), Oguntoyinbo (1970), Ohmura (1982, 2001), Oke (1978), Payne (1972), Perovich *et al.* (2002), Pinker (1982), Ross *et al.* (1998), Roth (1985), Sellers (1965), Shuttleworth (1989), Shuttleworth *et al.* (1984), Sie (1994), Takeuchi (2002), Takeuchi *et al.* (2001), Tsay *et al.* (1998), Z'graggen (2001).

the continents, the albedo also increases toward the poles because of the snow cover and glaciers. The annual mean albedo of the earth's surface ranges from the lowest value of 0.065 at the equator over the ocean to the highest value of 0.82 to 0.84 in the central plateaus of Greenland and Antarctica. Consequently, the meridional distribution of the surface albedo increases very steeply in higher latitudes and forms an important basis for the formation of the present climate. The annual mean albedo for the global oceans including the sea ice is estimated at 0.082. The mean albedo of the land surfaces including seasonal snow covers is estimated at 0.31 and is considerably higher than that of the oceans. The global mean earth's surface albedo is most likely to be 0.15.

The distribution of the reflected solar radiation is the product of the global radiation and the albedo, which was already discussed in detail. In terms of annual means, the regions with more than $30\,W\,m^{-2}$ of reflected solar radiation are witnessed only in the polar and arid regions. In the former, the coverage by snow and ice and the lower solar elevation angle are responsible for larger reflected

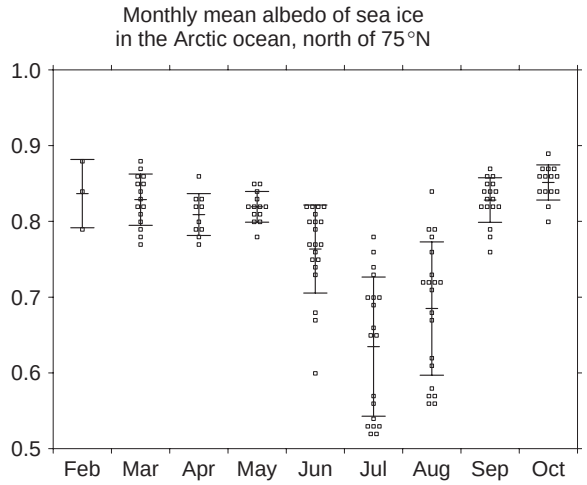

Figure 5 Monthly mean albedo of sea ice in the Arctic ocean, observed at north pole stations

radiation. In the arid regions that have a generally high albedo of the dry surfaces, the larger global radiation due to the lack of clouds and the location in lower latitudes are responsible for larger reflection. In this area, the greater portion of the reflected radiation is lost directly into space, causing the negative net radiation of the atmosphere/earth's surface in the lower latitudes. Globally averaged, the annual mean reflected radiation falls between 24 $W m^{-2}$ (ISCCP D2) and 30 $W m^{-2}$ (Kiehl and Trenberth, 1997). The most likely estimate is 25 $W m^{-2}$ (revision after Ohmura and Gilgen, 1993). The uncertainty is due to the different estimates of the albedo for water, which covers 67% of the earth's surface.

LONGWAVE ATMOSPHERIC RADIATION

Minor atmospheric components, such as water vapor, carbon dioxide, methane, dinitrogen oxide (nitrous oxide), ozone, and a number of chlorofluorocarbons and their substitutes have strong absorption bands in the wavelength range between 4 and 50 μm where terrestrial emission takes place. Because the Kirchhoff law applies to the troposphere and stratosphere, these molecules emit in the same wavelengths. Of these constituents, water vapor plays the most important role, followed by carbon dioxide. The total emission by these gases and clouds, which we call longwave incoming radiation, is as large as TOA solar radiation. The longwave incoming radiation is the source of the atmospheric greenhouse effect. The longwave radiation received at the earth's surface is the result of the emission and absorption by the entire atmosphere and clouds. Presently, there is a set of commercially produced pyrgeometers that can provide the accuracy of $\pm 3\,W m^{-2}$ (Philipona and Ohmura, 2001). The computation of the longwave incoming radiation involves essentially the numerical integration of the Schwarzschild equation and the atmospheric profile from the stratopause to the earth's surface. In practice, however, in the absence of clouds it is the bottom 1 km of the atmosphere that contributes more than 90% of the longwave incoming radiation at the surface.

The longwave incoming radiation is numerically the second largest component in the earth's surface energy balance, next to the longwave outgoing radiation. The absolute magnitude of this flux was until recently grossly underestimated. The underestimation was caused by an insufficient knowledge of the water vapor continuum in the computation. The underestimation was also induced by the convective heat loss in pyrradiometers that were often used before pyrgeometers were developed. The progress in infrared spectrometry, numerical computations, and the development of the instruments during the last 20 years contributed to achieve more realistic values. With an annual global mean of 345 $W m^{-2}$, it is considerably larger than the absorbed solar radiation of 144 $W m^{-2}$. The regional difference of this flux is also much larger than that of the global radiation as is presented in Figure 6. In the Northern Hemisphere at sea level, it ranges from 225 $W m^{-2}$ at the North Pole to 420 $W m^{-2}$ in cloudy regions under the equator. The Hemisphere's observed minimum is recorded in the central region of the Greenland ice sheet (Summit: 167 $W m^{-2}$). The distribution of the longwave incoming radiation is also strongly influenced by the distribution of the continents and oceans. While drier continents tend to shift isopleths southwards, relatively large fluxes are seen over the eastern halves of the oceans. In the Southern Hemisphere, the distribution is less affected by the distribution of continents and oceans. The isopleths run more or less parallel to latitudes. The longwave incoming radiation decreases from about 420 $W m^{-2}$ at 10 °S to 230 to 250 $W m^{-2}$ in the coastal region of Antarctica at a rate of 3 $W m^{-2}$/one degree in latitude. It decreases further in the interior of Antarctica. The central plateau region of Antarctica receives the smallest flux. At about 100 $W m^{-2}$, there is no other region on the earth where the longwave incoming radiation underscores this value.

The longwave incoming radiation decreases in general with altitude, as a result of the reduction of air temperature, water vapor, and other greenhouse gas concentrations. The vertical gradient for the midlatitude mountainous regions is $-3\,W m^{-2}$/100 m (Marty *et al.*, 2002).

In terms of monthly means, the maximum measured longwave incoming radiation is 420 $W m^{-2}$ over equatorial oceans. The minimums are located in the interiors of Greenland and Antarctica where they reach 130 $W m^{-2}$ and 75 $W m^{-2}$ respectively in midwinter (Kuhn *et al.*, 1977; T. Yamanouchi, personal communication). It is indeed in these high-latitude regions where a large annual amplitude of the longwave incoming radiation is also registered. The July

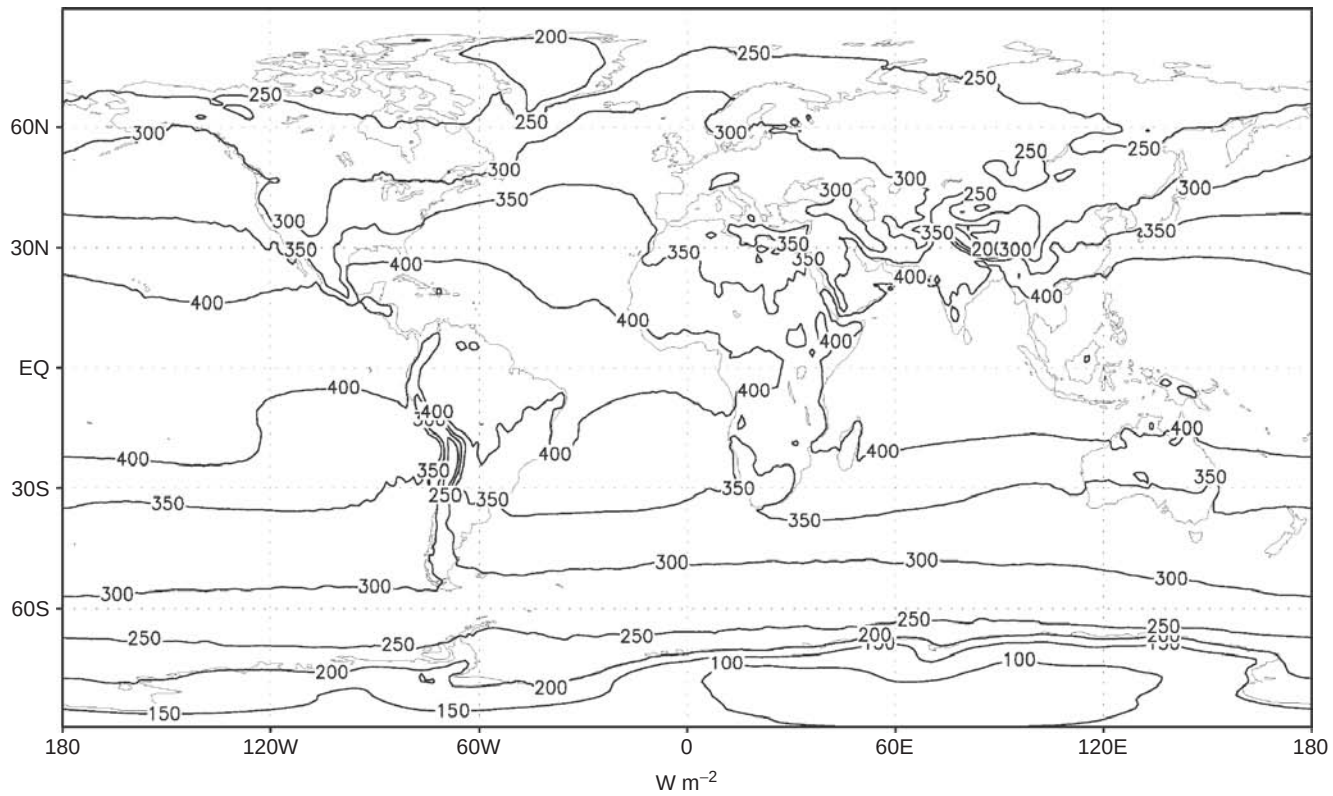

Figure 6 Annual longwave incoming radiation computed by ECHAM4T106

and January mean fluxes reach 220 W m^{-2} and 190 W m^{-2} respectively (Hoch *et al.*, 2004; Putnins, 1970; Rusin, 1964) in the interior of Greenland and on the Antarctic plateau in summer. Although located in higher latitudes than Greenland, the Arctic Ocean receives a considerably larger longwave flux owing to the higher air temperature and absolute humidity (145 W m^{-2} in January and 300 W m^{-2} in July). The unpublished data in the present section are from Global Energy Balance Archive (GEBA) and Baseline Surface Radiation Network (BSRN).

LONGWAVE OUTGOING RADIATION

The longwave outgoing radiation is the ultimate reaction of the earth's surface under a given energy balance condition. This term is passive and determined by all other fluxes. The best instrument to measure this component is longwave radiometers specified as pyrgeometers directed to the surface. The measurement of the brightness temperature by a radiation thermometer together with the Planck equation with the Kirchhoff law also gives a good estimate of the longwave outgoing radiation. The uncertainty of the emissivity does not play a significant role in this matter, as the longwave outgoing flux contains the reflection of the longwave incoming radiation with the reflectivity which is complementary to surface emissivity.

Since measurements of the surface temperature by radiation thermometers are not widely available, a possible use of a standard meteorological element, such as air temperature should be investigated. The effective temperature of the surface as mentioned above can differ a great deal from the standard meteorological air temperature observed at the standard screen-level. If short-term temperatures such as one minute means are compared, a discrepancy of up to 10 °C can occur for radiatively strongly cooled or heated dry surfaces. Differences of up to 15 °C are measured under strongly positive or negative net radiation and calm conditions. Theoretically, one can expect a difference up to 20 °C (Ohmura, 1981). If sufficiently long-term observations are compared, such as monthly means, the difference between the surface effective temperature and the standard meteorological air temperature decreases to within 1 °C (Z'graggen, 2001). This is a useful feature in calculating the longwave outgoing radiation for climatological purposes, as the surface effective temperature is usually not measured. This feature also helps analyze the geographical distribution of the longwave outgoing radiation in terms of climatological air temperature, which is widely available. The best estimate of the longwave outgoing radiation is 385 W m^{-2} which corresponds to a mean surface temperature of 14 °C (Jones *et al.*, 1999).

NET RADIATION

The global distribution of the annual mean net radiation is presented in Figure 7. Net radiation at the earth's surface is generally larger over the ocean due to the lower albedo. The maximum annual net radiation of 180 W m^{-2} is seen at the equator over the ocean. The annual net radiation on oceans is on an average 30 to 50 W m^{-2} larger than on the continents of the same latitude. The annual net radiation declines from the equator to the pole at an average rate of 2 W m^{-2}/degree in latitude, rarely falling into negative values on the earth's surface. The earth's surface is basically an energy source. There are three regions of limited surface areas where negative net radiation is observed on an annual basis. They are the central region of the Greenland ice sheet above 2500 m a.s.l., the relatively cloud-free regions of the Antarctic ice sheet, and the upper accumulation area of mountain glaciers.

Various independent sources indicate that the global mean annual net radiation at the earth's surface lies between 100 and 105 W m^{-2} (Budyko *et al.*, 1988; Ohmura and Gilgen, 1993; Kiehl and Trenberth, 1997).

Seasonal fluctuations in net radiation are large. The summer (JJA or DJF) hemisphere is characterized entirely by positive net radiation including the high-altitude zones of the major ice sheets and the accumulation areas of mountain glaciers. There is a weak equator-to-pole gradient of 1.5 W m^{-2}/degree in latitude. The largest net radiation is seen over the subtropical oceans. In this region, the mean net radiation during the three summer months reaches 220 W m^{-2}. The energy exchange with the atmosphere is, however, relatively inactive, as almost half of the net radiation is kept in the ocean for the release during winter, not only in the same area but also in the higher latitudes. During the winter (DJF or JJA), 25% of the hemispheric surface, mostly the regions pole-ward of 50° N, S lie under negative net radiation, with a mean equator to pole gradient of 4 W m^{-2}/ degree in latitude. In most regions of the negative net radiation, the magnitude remains rather small, except for the following regions. The ocean areas in high latitudes tend to be strongly negative (-30 W m^{-2} or less) owing to the heat release by the ocean. In some areas on the land, net radiation falls into the strongly negative range. They are the high-latitude/high-altitude regions with a small cloud amount, such as the Brooks Range in Alaska, the McKenzie Mountains, the northern Rocky Mountains and the parts of the Canadian Arctic Islands with less cloud amounts, Greenland, Scandinavia, and a part of East Antarctica. In the lower altitudes, the regions such as the basins of the Lena and Yenisey with relatively small cloud amounts in winter show strongly negative net radiation. In these areas,

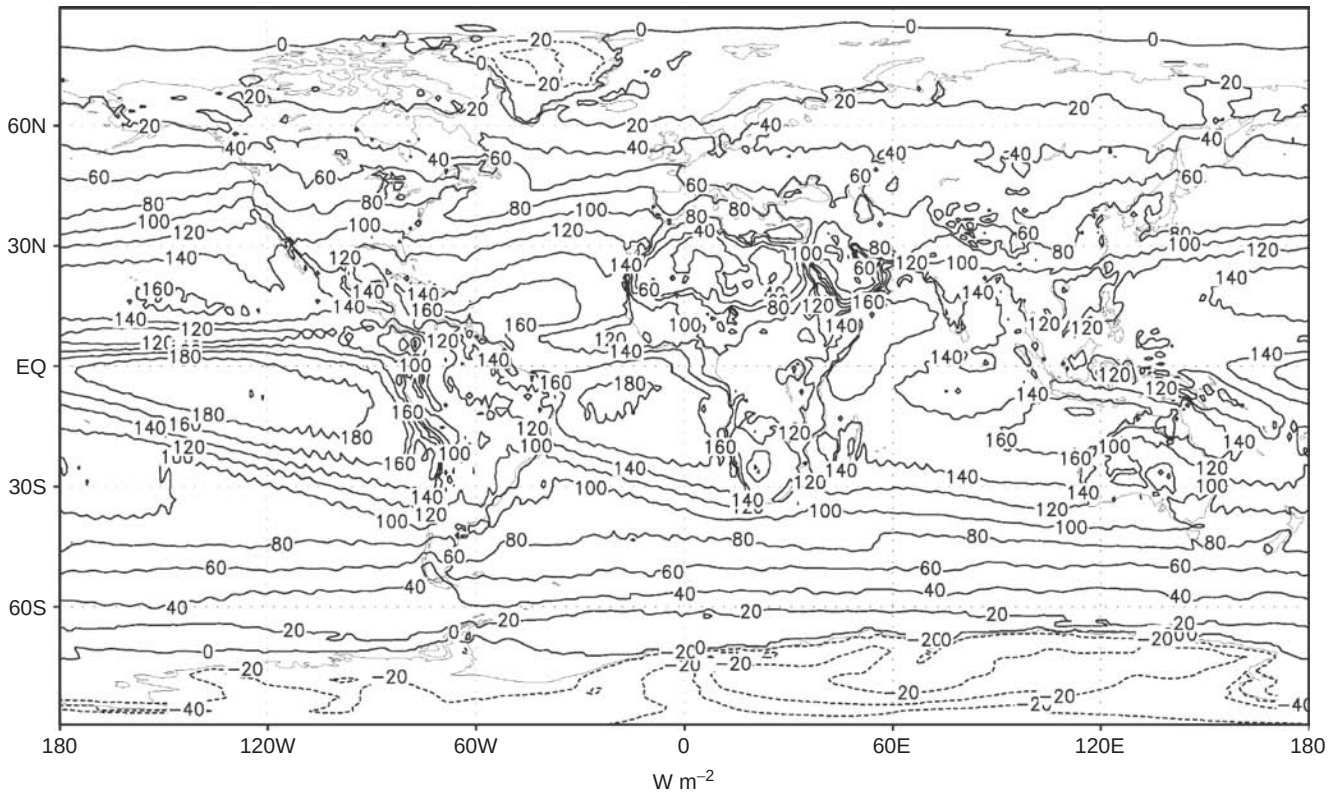

Figure 7 Annual net radiation computed by ECHAM4T106

sensible heat from the atmosphere is the main heat source during winter.

Net radiation strongly influences evapotranspiration. This feature is used to determine evapotranspiration with rather limited instrumentation. Well-known examples are the Bowen ratio/energy balance method (Bowen, 1926) and the Penman equation (Penman, 1948). Naturally, both methods are subsequently refined to improve the accuracy (Doorenbos and Pruitt, 1977; Ohmura, 1982). The strength of these methods is the fact that they do not rely heavily on aerodynamic methods, since the major error for turbulent heat fluxes is induced by wind measurements. The Bowen ratio/energy balance and the Penman methods rely on net radiation, which is accurately measurable with an inexpensive instrument such as a net radiometer. These methods are especially suited for long-term observations with minimum maintenance requirements. The nature of these fluxes will be detailed in the next section.

TURBULENT HEAT FLUXES

Figure 8 shows the annual mean sensible (a) and latent (b) heat fluxes. For the global mean, latent heat flux of vaporization with $85\,W\,m^{-2}$ accounts for majority of net radiation at the surface. Sensible heat flux accounts for ($19\,W\,m^{-2}$) only 18% of surface net radiation. These fluxes correspond to 25% and 6% of the primary solar radiation at the TOA, respectively. It is noteworthy that these two turbulent heat fluxes that are carried by similar eddies and propelled by the same energy source, namely the surface net radiation, differ by as much as factor 4. The main reason is found not on the surface but in the middle troposphere where water vapor condenses to form clouds, generating heat. This wet convection is responsible for creating two fundamentally different vertical gradients in the lower troposphere, the sharp decrease in water vapor concentration, and the increase in sensible heat with altitude. This situation results in different geographical distributions of latent and sensible heat fluxes. While latent heat flux is directed upward almost everywhere on the earth's surface, sensible heat flux is often directed downward. Henceforth, in a large area in high latitudes, pole-ward of 70° N and S sensible heat flux is directed to the surface. Sensible heat flux can easily flip downward even in an area with positive net radiation. In lower latitudes when an arid continent is located windward, sensible heat flux turns downward as is witnessed over the Arabian Sea. The lower SST on the equator suffices to reduce the magnitude of evaporation but causes in many regions a downward flow of sensible heat.

The ocean evaporates 88% of global atmospheric water. Further, the surface of the ocean within 25° N and S of the equator accounts for 50% of global evaporation. The land surface contributes only 12%. Per unit area the latent heat flux on the ocean ($110\,W\,m^{-2}$) is far larger than over the land ($36\,W\,m^{-2}$). This difference is due to the limit in surface water availability on the land. Hence the land surface generates sensible heat more easily than on the ocean: $26\,W\,m^{-2}$ on land versus $15\,W\,m^{-2}$ on ocean. Taking the respective surface areas into account, 40% of the global sensible heat is transferred into the atmosphere from the land, and the remaining 60% from the ocean.

Seasonally analyzed, however, the largest sensible heat flux is seen on the ocean in winter and on the desert in summer. In winter, in the monsoon regions where strong cold air flows from the continents on to the surface of the warm western boundary currents, some of the largest sensible heat fluxes can occur. In the regions off New England and Japan, sensible heat fluxes in January can reach more than $100\,W\,m^{-2}$. The outbursts of the winter monsoon are also dry and the same regions also see the largest latent heat flux of evaporation in the world ($250\,W\,m^{-2}$). Both these large fluxes are supported by a strong convection in the ocean mixing layer that delivers in places as much as $400\,W\,m^{-2}$-ocean surface heat flux. Oceans are in general very active evaporating regions in winter. Although often overlooked, both hemispheres evaporate substantially more during winter than in summer (Ohmura and Wild, 2002). This situation shows that temperature alone does not determine large-scale evaporation. The strength of the atmospheric circulation is equally influential in determining evaporation.

As winter is a season with active evaporation on oceans, summer is the season for actively generating sensible heat on land. The year's peak of sensible heat flux on land is usually observed in early summer (May and June in NH, October and November in SH). During these months, the sensible heat flux in arid regions of both hemispheres reaches 50 to $100\,W\,m^{-2}$, and becomes a heat sink that is similar but more powerful than longwave net radiation.

The computed turbulent fluxes are very difficult to validate with observations, as there are not many high-quality flux observations carried out long enough to be climatological data. It is possible, however, to check the quality of the global estimate of latent heat or evaporation. Various numerical experiments showed a close relationship between the annual global latent heat flux and the annual global net radiation as is presented in Figure 9. Since the surface net radiation is much more accurately known than the latent heat flux, the figure allows a first-hand estimation of the global mean latent heat flux. The latent heat flux corresponding to the most likely value of the surface net radiation (100 to $105\,W\,m^{-2}$) is $85\,W\,m^{-2}$. There is a second quality check. Since annual mean global evaporation must be very close to the annual mean global precipitation, these two components can be compared. The water equivalent of $85\,W\,m^{-2}$ is 1100 mm, which fits between the estimations of annual

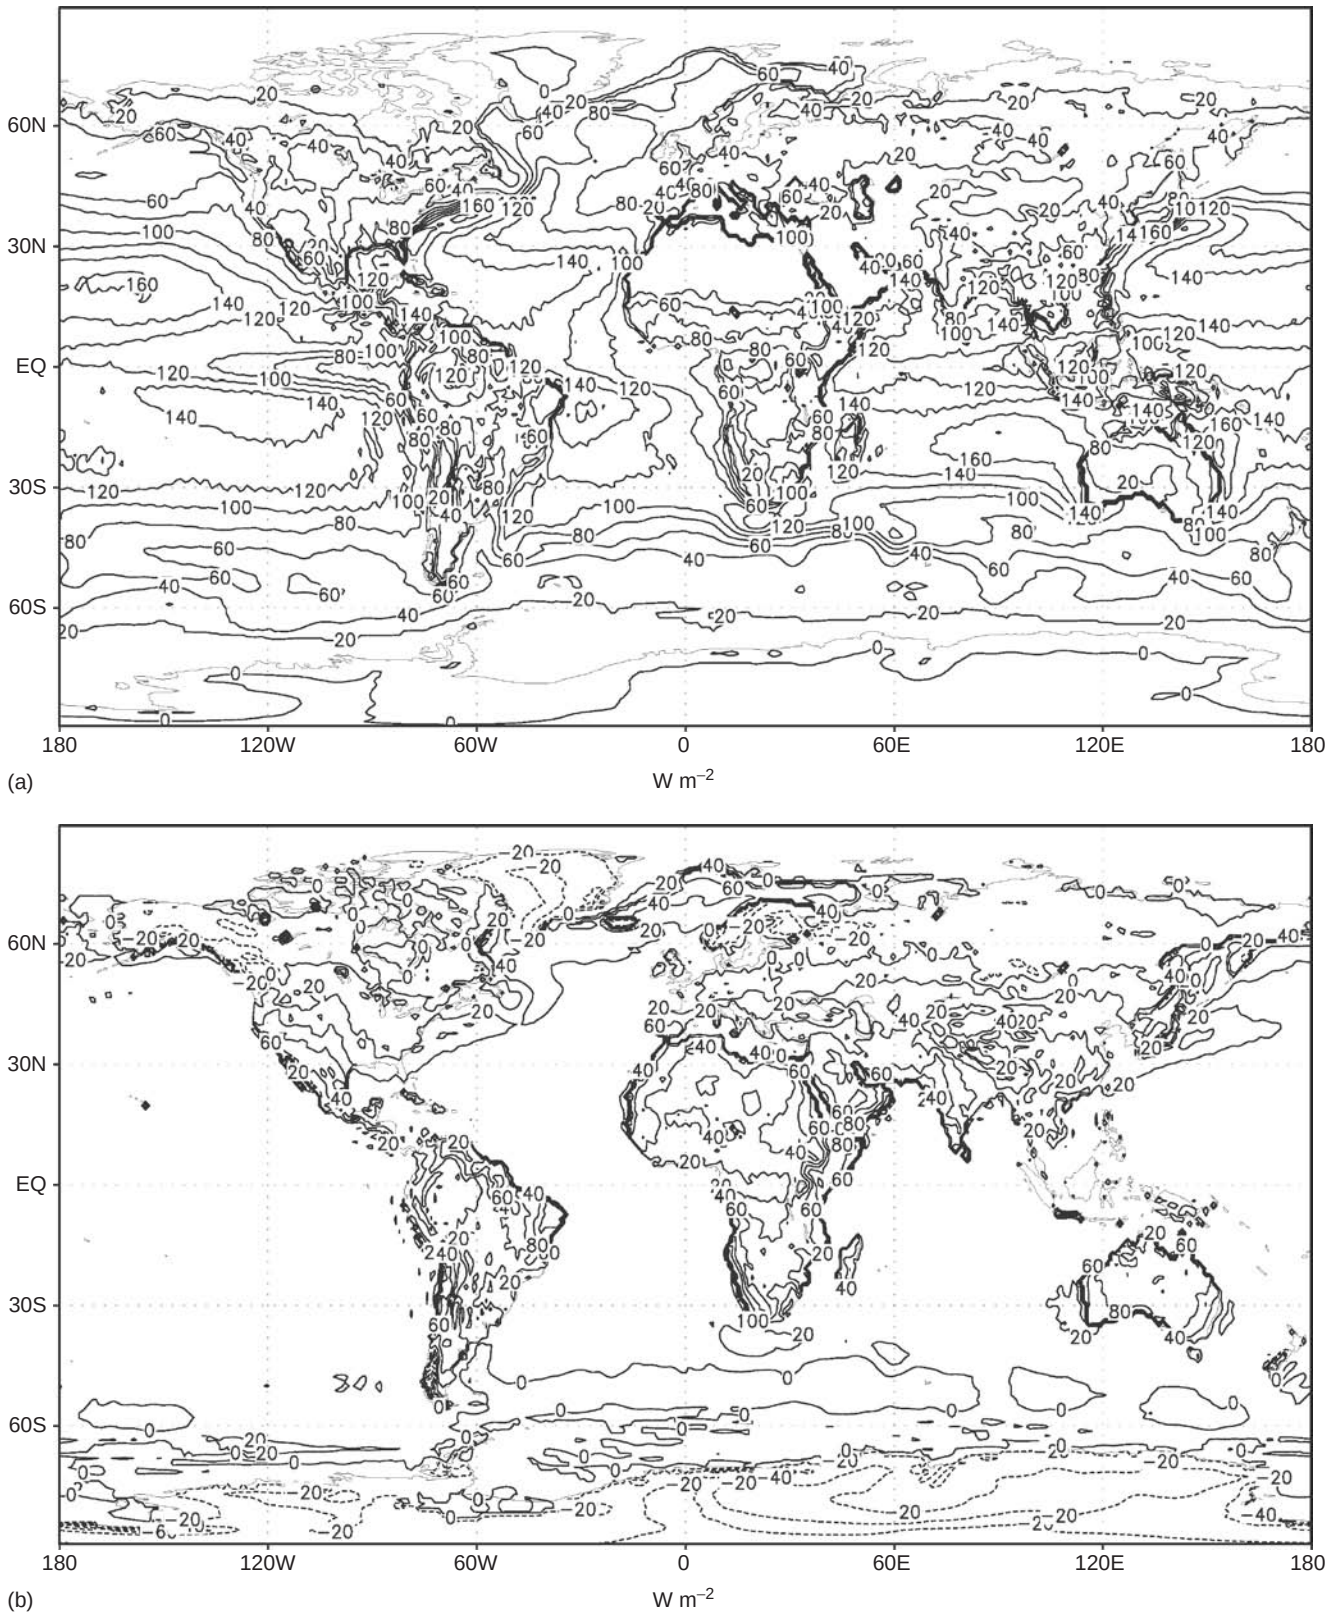

Figure 8 Annual latent heat flux (a) and sensible heat (enthalpy) flux (b)

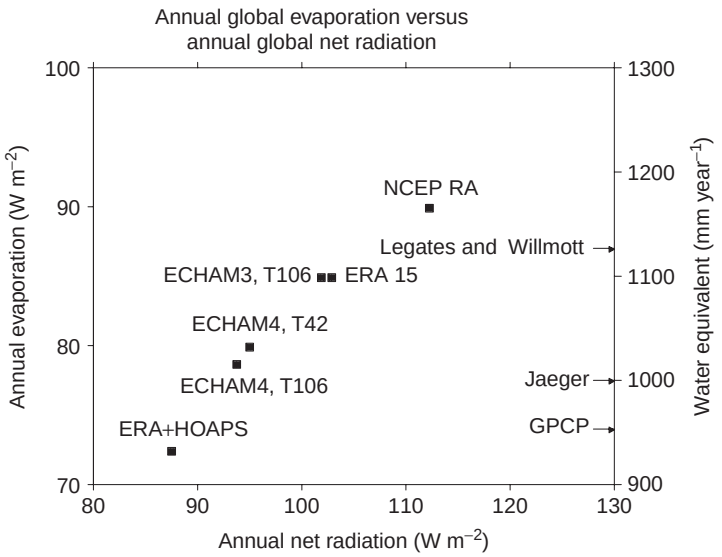

Figure 9 Relationship between the annual global mean latent heat flux and surface net radiation in various models

global precipitation by Jaeger (1976) and Legates and Wilmott (1990). This agreement indicates that the present estimation is realistic.

SUBSURFACE HEAT FLUX

Since the subsurface heat flux has fundamentally different mechanisms on land and on a water body, it will be discussed separately for these surfaces. Ground heat flux is normally one order of magnitude smaller than other fluxes and it plays a limited role in surface energy balance. The main reason for this is the relatively small thermal diffusivity of the material composing the ground in comparison with the eddy diffusivity of the near-surface atmosphere. The thermal diffusivity of common soils and rocks is 10^{-4} to 10^{-6}, when usually observed values for the eddy diffusivity in the first 10 m of the atmosphere are taken as unity. Nevertheless, this heat flux determines the thermal conditions of the near-surface layers of the pedo- and lithosphere. Ground heat flux turns downward in spring and reaches the year's maximum heat flow in early summer, usually one month ahead of the summer solstice. The flux declines throughout the summer and turns upward in autumn until the following spring. At the year's maximum, it attains about 10% of the net radiation. The phase and the magnitude of the ground heat flux can be seriously affected by the snow cover, the thickness, the timing of its onset, and the melt. The annual mean ground heat flux observed for more than several years is very close to zero or becomes the same as the geothermal heat flux.

The subsurface heat on the ocean surface is the ocean surface heat flux or net downward heat flux in oceanography (Figure 10). This component is substantial in diurnal and annual surface energy balance as well as in climate changes. The importance of the ocean in the climate system is due to its large heat storing function. This function is not only due to the large heat capacity of water, but to a great extent to the transparency of ocean water for solar radiation, and to the oceanic turbulence and convection which promote diffusion. The annual amplitude of the ocean surface heat flux reaches up to $200\,\mathrm{W\,m^{-2}}$ on the midlatitude ocean. In the course of a year, the ocean flips between a heat source and a sink on the hemispheric scale. Globally observed are three belts of heat sinks for the surface energy balance (sources for the ocean), one on the equator and the two others in the higher midlatitudes around 40° to 50° N and S where a substantial amount of heat flows downward. Of these three, the region under the equator is a permanent energy sink. In the equatorial ocean, large shortwave incoming radiation, supported by relatively weak longwave net radiation (due to cloud amount) and smaller turbulent heat losses (due to higher humidity and lower SST), form the basis of the permanent energy sink for the surface (source for the ocean). The other two belts in the higher midlatitudes are sinks on an annual basis, but are in a delicate balance between the sink in summer and the source in winter. Unlike ground heat flux, the annual mean ocean surface heat flux assumes large values. The eastern half of the higher midlatitude ocean surfaces where the temperature is lower is especially important as a sink region. Further in higher latitudes, in the Arctic Ocean (Central Polar Ocean including marginal oceans, such as Norwegian, Barents, Kara, Leptev, East Siberian, and Beaufort Sea) and the Antarctic Seas near the continent, ocean surface flux is an important heat source keeping the polar and subpolar regions relatively mild.

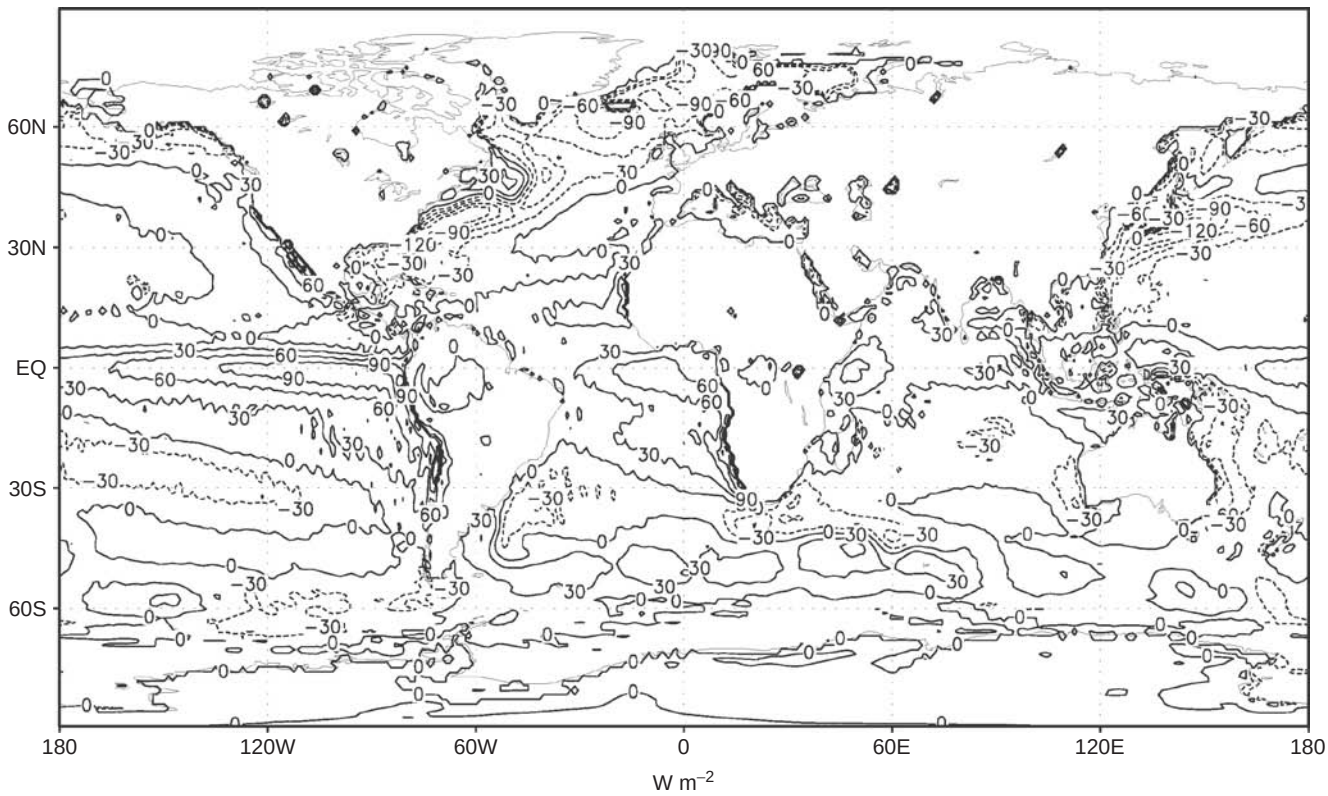

Figure 10 Annual subsurface heat flux computed by ECHAM4T106. Signs are taken positive when directed downward

LATENT HEAT OF MELT

Latent heat of melt (fusion) globally averaged is the order of 1% of the extraterrestrial solar radiation. Because this value gives an impression of numerical insignificance, the latent heat of fusion is often not considered in energy balance climatology (Budyko, 1956). Regionally viewed, however, the latent heat of melt plays an extremely important role. This component is the main heat sink and averages at around 100 W m^{-2} during the melt season on glaciers, sea ice, and snow cover. The reason for the low air temperature of the Arctic in summer, despite one of the largest global radiation of the hemisphere, is due not only to the high albedo but also due to the heat consumption by the latent heat of melt. Latent heat of melt is determined in the field either by measuring the lowering of the surface or the discharge of the melt water. In theory, one can explain the amount of the melt by evaluating all terms of the equation in the equation of energy balance. In practice, the melt is so closely related to the air temperature that the air temperature alone can become a powerful index for estimating the rate of the melt. The relative importance of the energy source terms for the melt varies considerably depending on the site characteristics, such as altitude, albedo, air temperature, and humidity. One common feature of all energy balance measurements made over the melting snow and ice is the fact that the longwave incoming radiation is by far the most important energy source for the melt. It was pointed out earlier that the majority of the longwave radiation originates from the atmospheric layers very close to the surface. This is the basic reason why air temperature alone is such a good indicator of the melt rate.

MEAN STATE OF THE GLOBAL ENERGY BALANCE

The above discussion is summarized in Figure 11 to represent the present mean state of the energy exchange in the climate system. The global radiation at the surface, 169 W m^{-2}, accounts for 49% of the primary energy source from the sun. This value is smaller than previously used, 186 W m^{-2} by Sellers (1965), 185 W m^{-2} by Salby (1996), and 198 W m^{-2} by Kiehl and Trenberth (1997). The discrepancy of 15 to 30 W m^{-2} for global radiation is one of the most important findings of recent years. The present value can be compared with 168 W m^{-2} proposed earlier by Budyko *et al.* (1988). The new value presented here is the result of the improved network of direct observations of global radiation at the earth's surface. The earth's surface albedo was also newly evaluated and found to converge at around 15%. This value is somewhat larger than 14% by Budyko (1956), 11% by Sellers (1965), and 9% by Salby

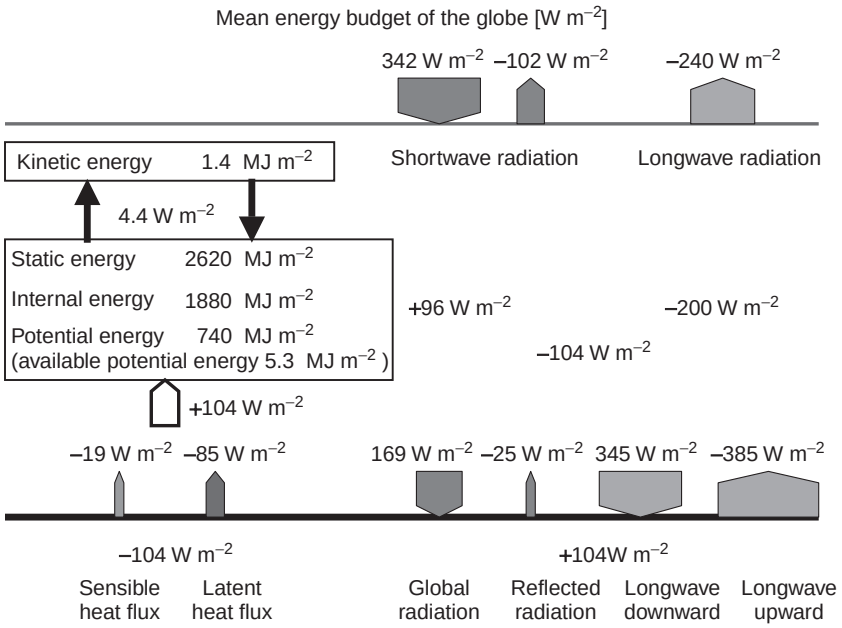

Figure 11 Mean state of the global energy balance. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

(1996). The present value of 15% coincides with those proposed by Budyko *et al.* (1988) and Kiehl and Trenberth (1997). The present value of the earth's surface albedo is mainly from the accumulated data on albedo measurements over a variety of surfaces by terrestrial and airborne instruments, the long-term mapping of the distributions of sea ice and snow cover obtained by satellites, and the detailed investigations of the albedo of water under variable solar elevation angle and cloud conditions. Keen readers probably have noticed that the terrestrial incoming radiation from the atmosphere in Figure 8 is considerably larger than in previously published sources. The recent advances in infrared radiometry have corrected previous underestimations. A proper treatment of the water vapor continuum and the effect of clouds are also responsible for the present improvement. The longwave outgoing radiation is calculated on the basis of the recently obtained earth's surface temperatures by Jones *et al.* (1999).

The difference in the net radiation at BOA and TOA is separately evaluated for solar and terrestrial radiation. The divergence of solar radiation is negative due to atmospheric absorption; it amounts to $-96\,\mathrm{W\,m^{-2}}$. This component was previously grossly underestimated. The most frequently quoted value for the atmospheric absorption of solar radiation is about $60\,\mathrm{W\,m^{-2}}$ (or 17% of the TOA solar irradiance) by Sellers (1965). The absorption due to water vapor beyond $2.8\,\mu\mathrm{m}$, the collective effect of a number of minor absorption bands, aerosol, and clouds supports the present result of larger absorption. The divergence of longwave radiation is positive and is equivalent to radiative cooling of $200\,\mathrm{W\,m^{-2}}$. The net divergence of atmospheric radiation is positive; it amounts to $104\,\mathrm{W\,m^{-2}}$. It is balanced by the convergence of vertical convective fluxes (sensible and latent).

The present state of the observation network does not allow the evaluation of the global mean turbulent heat fluxes based solely on observations. The evaluation of turbulent heat fluxes is a case for which model-based computations play an important role. The present evaluation is mainly based on the computations by ECHAM4 and ERA15. Latent heat flux is, however, better understood than the sensible heat flux, as the evaporation is measured at more sites than the sensible heat flux. The global mean evaporation can also be estimated from the global precipitation. Summing up the above discussions, the annual mean global latent heat of evaporation is very likely to be $85\,\mathrm{W\,m^{-2}}$. The sensible heat flux of $19\,\mathrm{W\,m^{-2}}$ is estimated as the difference between the net radiation and latent heat flux. The kinetic energy, and the conversion rate of the available potential energy to kinetic energy are due to Kung (1988).

The mean energy flow through the climate system can be interpreted in the following manner: The earth receives a quarter of TSI, $342\,\mathrm{W\,m^{-2}}$, of which $102\,\mathrm{W\,m^{-2}}$ leaves the planet by reflection. The remaining $240\,\mathrm{W\,m^{-2}}$ is absorbed by the atmosphere and the earth's surface. The atmosphere absorbs solar radiation of $96\,\mathrm{W\,m^{-2}}$, leaving the remaining $144\,\mathrm{W\,m^{-2}}$ to be absorbed by the surface. The terrestrial net radiation at the surface is $-40\,\mathrm{W\,m^{-2}}$. The net radiation at the earth's surface ($104\,\mathrm{W\,m^{-2}}$) is transferred to the atmosphere primarily as latent heat of vaporization ($85\,\mathrm{W\,m^{-2}}$)

and somewhat less as enthalpy flow (19 W m^{-2}). The sum of these two terms (104 W m^{-2}), augmented by the atmospheric absorption of solar radiation (96 W m^{-2}) and net longwave radiation from the surface (40 W m^{-2}), is emitted by the Earth into space at the rate of 240 W m^{-2}, exactly the same amount as solar radiation originally absorbed by the planetary system. The errors of the radiative fluxes of Figure 11 differ for the individual components. Ohmura and Raschke (2005) estimate $\pm 5-7$ W m^{-2} as error for the TOA net radiation.Ohmura *et al.* (1998) estimate the error at $\pm 5-10$ W m^{-2} for the BOA net radiation, and ± 12 W m^{-2} for the total atmospheric radiation flux divergence.

MEAN STATE OF THE GLOBAL HYDROLOGICAL CYCLE

The global mean hydrological cycle is summarized on the basis of the preceding and following discussions. The global annual precipitation is estimated at 1030 ± 90 mm year^{-1} by combining the estimations by Jaeger (1976), Legates and Wilmott (1990), Roads (2002), and model computations mentioned earlier. On an average, the precipitation over an ocean (1150 mm year^{-1}) is factor 1.5 larger than on continents (740 mm year^{-1}). Because 71% of the earth's surface is the ocean, the total precipitation on oceans and the continents are estimated at 415 and 110 km^3 year^{-1}, respectively. The average flux density of evaporation is almost exactly three times stronger over oceans (1285 mm year^{-1}) than continents (415 mm year^{-1}). Total evaporation over the ocean is estimated at 463 km^3 year^{-1}, while that from the land surface is 62 km^3 year^{-1}. This situation causes a large imbalance in the hydrological budget between the ocean surface and the land. The ocean surface generates an evaporation surplus of 48 km^3 year^{-1}, while on land surfaces there is exactly the same magnitude of the precipitation surplus that results in a discharge from the continents into oceans.

The hydrological balance of the globe is, however, presently not in equilibrium. One of the most important events in the recent hydrological cycle is the systematic loss of ice from glaciers. Presently, 15.9×10^6 km^2 or 11% of the land surface is covered by glaciers. The total mass of water held in glaciers is 30.1×10^6 km^3 water equivalent (w.e.) which corresponds to about 80% of the fresh water on the earth. With respect to ice mass, 92% is in the Antarctic, 8% in Greenland, and the remaining 0.15% is distributed among all mountain glaciers and small ice caps of the world. The geographic statistics are given in Table 4 (Ohmura, 2004). During the second half of the twentieth century, glacier mass balance was observed on more than 100 glaciers including short-term measurements. There are only about 40 glaciers with more than 30 years of mass balance observations. The fact that the mass budget of the Greenland is negative has just become known in recent years. The sign of the mass budget of the Antarctic has not yet been established. A crude estimation suggests a small negative budget, however. The estimations of mass balance for three categories of glaciers, Antarctic, Greenland, and mountain glaciers and small ice caps are presented in Table 4 for the second half of the twentieth century. According to this estimate, the glacier mass balance contributed to the sea-level rise at a rate of 0.7 mm year^{-1}. Among these three glacier types, the contribution by the mountain glaciers and small ice caps was the most important.

The global water balance discussed above is graphically summarized in Figure 12. The figure represents the hydrological balance of the second half of the twentieth century, as this is the only period with sufficient data to discuss this subject. About 10% of the ocean evaporation is contributed to the land area where there is a systematic imbalance. The hydrological imbalance on the land surface is caused by the consumption of the storage in glacier ice at a rate of 300×10^3 km^3 or 18 mm year^{-1} in favor of the sea-level rise at a rate of 0.7 mm year^{-1}. The negative mass balance on glaciers, however, was not constant. As the analyses of the seasonal mass balances on mountain glaciers and small ice caps indicate so far, the mass loss was accelerated at a rate of 12 mm year^{-2}, which was caused by

the acceleration of the melt at a rate of 13 mm year^{-2}. The change in the accumulation during the same period was statistically insignificant and the accumulation on the glacierized regions of the world can be considered as constant (Ohmura, 2004).

26: Weather Patterns and Weather Types

IAN G MCKENDRY

Department of Geography, The University of British Columbia, Vancouver, BC, Canada

In popular usage, the terms "weather pattern" and "weather type" are used variously and often imprecisely to describe states of the atmosphere. An understanding of weather processes and patterns has important applications in such diverse areas as air-quality management, hydrology, water management, human health, forestry, agriculture, energy demand, transportation safety, the insurance industry, economics, and tourism. These terms are formally defined and the various classification techniques that form the basis of synoptic climatology are described. In summarizing the various methods used to identify weather patterns and types, it is abundantly clear that underlying such approaches are significant assumptions about the state of the atmosphere together with varying degrees of subjectivity inherent in the techniques themselves. It is important that these constraints are adequately acknowledged in all applications of the techniques outlined. Finally, the impacts of computing advances, new techniques, and enhanced datasets on synoptic climatology are described.

INTRODUCTION

"Weather" is defined as the instantaneous state of the atmosphere at a particular location and is typically characterized by a range of meteorological variables (or weather elements) such as pressure, temperature, humidity, wind, cloudiness, and precipitation (Barry and Chorley, 1995). Weather at any particular location is a consequence of the movement and evolution of "weather systems". These may be considered to operate at several time and space scales, ranging from the microscale (e.g. small-scale eddies recognizable as gustiness in winds) to the mesoscale (e.g. sea breezes), through the synoptic scale (e.g. midlatitude cyclones and tropical storms), and finally to the planetary scale (e.g. jet streams and Rossby waves). Variations in weather occur fundamentally because the atmosphere is a highly dynamic fluid that moves both horizontally and vertically in response to the differential heating of the earth by solar radiation. Such variability has significant impacts on human activities. Consequently, an understanding of weather processes and patterns has important applications in such diverse areas as air-quality management, hydrology, water management, human health, forestry, agriculture, energy demand, transportation safety, the insurance industry, economics, and tourism. Given such important applications, it is not surprising that considerable scientific effort has been invested in identifying the linkages between particular states of the atmosphere (as manifested by weather patterns and types) and the environment. This field of investigation, characterized by a variety of classification techniques, forms a significant part of the subdiscipline of *synoptic climatology* (Yarnal, 1993) and will be the focus of this entry.

In popular usage, the terms "weather pattern" and "weather type" are used variously and often imprecisely to describe states of the atmosphere. For example, in the popular media a tornado might be described as an "unusual weather pattern" that is associated with a particular type of weather (severe). Alternatively, an El Nino event in the central Pacific may be referred to as part of a global "weather pattern" that results in particular weather "types" (e.g. wet winters in California or drought in Australia). Although such usage does implicitly recognize the inherent scales, regularity, and interconnectedness of weather processes and systems, use of these terms in the atmospheric and hydrological sciences tends to be somewhat more specific, most commonly referring to the association of a characteristic combination of weather elements (e.g. marked by specific states of the atmosphere with respect to temperature, pressure, cloudiness, wind, and temperature) with particular weather systems. Furthermore, "weather patterns" and "weather types" tend to be most commonly linked to the

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

synoptic scale of atmospheric phenomena. At this scale, the day-to-day movement and evolution of weather systems modulates and influences a wide range of human activities to a considerable degree. Implicit in both terms are notions of classification. In this context, the terms "pattern" and "type" are often used interchangeably and with sometimes subtle nuances in meaning. For example, "pattern" can be used in both its spatial and temporal senses. A repeatable sequence of weather may be regarded as a weather pattern, or more commonly, "pattern" refers to a particular arrangement of isobars on a weather map (sometimes referred to as a map pattern, synoptic type, or circulation type).

THE ORIGINS OF PATTERN

Throughout human history there has been recognition of pattern within atmospheric behavior. At the simplest level, this can be seen in the regularity of the seasons or in the association of particular wind directions with temperature (e.g. cool winds from the north in the Northern Hemisphere). At larger scales, sailors have noted and exploited the remarkable persistence of the easterly "trade" winds in the tropics, in marked contrast to the constant and somewhat chaotic succession of cyclonic systems forming and dissipating as they move eastward through the midlatitudes. In the twentieth century, development of a conceptual model of the midlatitude cyclone formalized patterns in weather elements associated with the passage of such low-pressure systems (or depressions). For example, passage of a cold front is typically associated with a particular sequence of cloud types, winds, pressure changes, precipitation, and temperature changes. Typically, in the midlatitudes, cold front passage is marked by the arrival from the west of a band of cloud (often convective in form) accompanied by rainfall and sharply decreasing temperatures, a change in wind direction (often from the south-west to the north-west in the Northern Hemisphere). Behind such a front there is often rapid clearing, rising pressures, and occasional showers. Although cold fronts exhibit considerable variability, the weather pattern described above is recognizable to most inhabitants of the midlatitudes whether in the Northern or Southern Hemispheres, and forms the basis of simple predictions that can be made on the basis of cloud and/or pressure observations.

Given the constancy of Earth's orbital characteristics, solar output, boundary conditions (earths distribution of land and water and atmospheric constituents), and axial tilt, and the universal application of forces governing atmospheric motion (i.e. linked to gradients in atmospheric pressure, friction, and the earth's rotation), it is not at all surprising that patterns in atmospheric behavior emerge across a wide spectrum of spatial and temporal scales. For example, toward the poles, the seasonal cycle increases in amplitude and significance because of the tilt of the earth on its axis. Furthermore, at the global scale, broad latitudinal bands can be identified in which particular types of weather predominate and which arise as a result of the differential heating of the planet and the application of the particular forces influencing atmospheric motion. This average condition is known as the *general circulation* of the atmosphere and in essence represents a "gigantic heat engine" (Barry and Chorley, 1995, P97). Although interrupted and modified by the global distribution of land and water, the dominant features are persistent winds from an easterly quarter in the tropics (the trade winds) and the broad zone of midlatitude westerly winds in which midlatitude depressions are constantly forming and dissipating. These features are represented for the idealized case of the Northern Hemisphere in Figure 1. Essentially the same patterns are evident in the Southern Hemisphere (i.e. south-easterly trade winds and midlatitude westerlies). However, significant differences between the two hemispheres with respect to the distribution of land (continents) and water results in significant differences in the nature and variability of the major circulation features. For example, the absence of significant landmasses in the Southern Hemisphere mid- and high latitudes, results in much stronger and persistent midlatitude westerlies than observed in the Northern Hemisphere (hence, the southern latitudes renown for their strong westerly winds: the "roaring forties", "furious fifties", and so on).

The particular scales of motion (both time and space) mean that the atmosphere assumes patterns that are geographically constrained and quasi-repetitive. Superimposed on these broad geographical patterns is variability in a range of scales. For example, west coast midlatitude continental locales (e.g. Washington State and British Columbia, southern Chile, The British Isles, and Norway) are exposed to a succession of eastward moving cyclonic systems during winter. Then, during summer, the subtropical high-pressure systems expand poleward providing some relief from the characteristic cool, moist, and highly variable weather patterns that tend to dominate in these regions due to their continental location and latitudinal position. In other areas (e.g. southeast Asia and Africa), monsoon patterns may dominate the annual weather cycle (such patterns are associated with a continental-scale seasonal wind reversal accompanied by distinct changes in precipitation). Furthermore, at large scales, natural modes of oscillation in the atmosphere/ocean circulation, as manifested in the El-Nino-Southern Oscillation (ENSO), the North Atlantic Oscillation (NAO), the Pacific Decadal Oscillation (PDO), the Arctic Oscillation (AO) and the Madden–Julian Oscillation, play an important role in modulating weather patterns at interannual and decadal timescales.

Perhaps the best known are the oscillatory patterns associated with ocean–atmosphere interactions in the Pacific

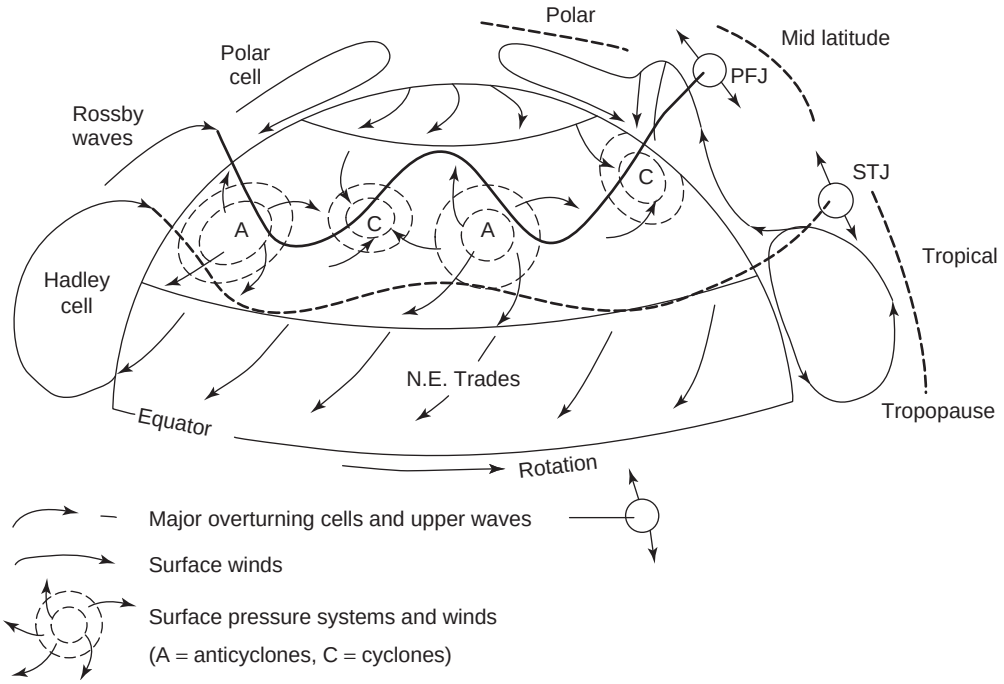

Figure 1 A model of the general circulation of the atmosphere for the northern hemisphere. Note that this is essentially a tropospheric view of the atmosphere with the vertical extent of the circulation constrained to the bottom ~20 km of the atmosphere. **STJ** and **PFJ** refer to the subtropical and polar front jets respectively (Reproduced from Oliver and Hildore, 2002, © Pearson Education)

Basin. Clear evidence exists that ocean–atmosphere interactions in the entire Pacific Basin induce significant climatic variability at a range of timescales with an influence that extends well beyond the Basin itself. Because of the sheer size of the Pacific Ocean, these interactions represent the clearest signal of such atmosphere–ocean interactions globally. These interactions are by nature cyclic and are manifested in changing spatial patterns of sea surface temperature (SST) that in turn drive changes in tropical convection and precipitation that ultimately influence the position and intensity of the jet stream in the midlatitudes (an example of a *teleconnection*). Consequently, midlatitude storm tracks, storm frequency, and intensity are affected (Cayan *et al.*, 1998, 1999). At timescales of years to decades, two principal modes of variability have been identified in the Pacific Basin:

El Niño-Southern Oscillation (ENSO): a well-known phenomenon characterized by an east–west "seesaw" pattern in tropical SSTs that operates on timescales of months to years (the last major El Niño events occurred in 1983, 1992–1993, and 1997–1998). The atmospheric mode of the phenomenon is known as the *Southern Oscillation*, the intensity and phase of which is measured by the southern oscillation index (SOI – the surface pressure difference across the tropical pacific) (between Tahiti and Darwin). During *El Niño* events (negative SOI), SSTs in the tropical eastern Pacific (off Peru) are higher than "normal" and produce excess convection and precipitation in that region. *La Nina* events (positive SOI) are characterized by unusually warm SSTs in the western Pacific and produce strong convection and precipitation over those regions.

Pacific Decadal Oscillation (PDO): a recent discovery, the PDO is manifested by El Niño–like changes (so-called *regime shifts*) in the SST distribution over the tropical and northern Pacific evident at decadal timescales (Mantua *et al.*, 1997). The warm (positive) phase of the PDO is characterized by below-normal SSTs in the central and western north Pacific and unusually warm SSTs along the west coast of North America. The cold phase (negative) produces the reverse distribution.

Individual phases of this oscillation typically last for 23–35 years resulting in a 50–75 year cycle (Minobe, 1997). This century, "cool" PDO regimes prevailed from 1890 to 1924 and again from 1947 to 1976, while "warm" PDO regimes dominated from 1925 to 1946 and from 1977 through (at least) the mid-1990s (Figure 2). Studies utilizing tree-ring analysis suggest that the PDO has played an important role in Pacific climate since at least the 1700s (D'Arrigo *et al.*, 2001; Biondi *et al.*, 2001).

This pattern is strongly linked to atmospheric circulation over North America and the North Pacific as commonly expressed by the Pacific North American (PNA) atmospheric pressure index (PNA). Low values of the PNA index are associated with a weak Aleutian low pressure,

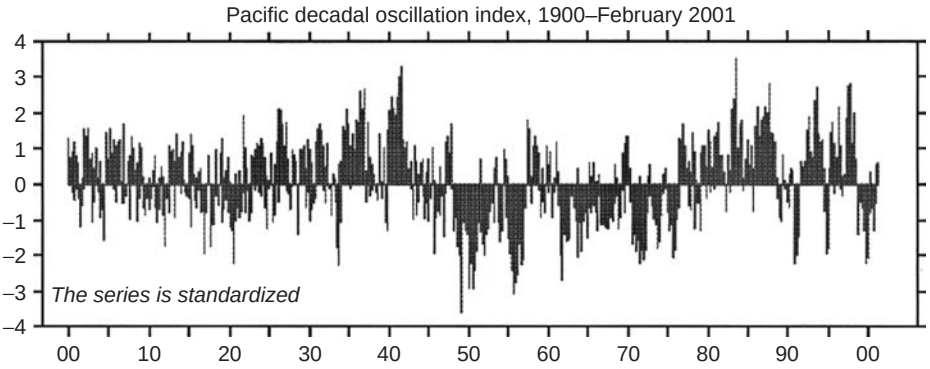

Figure 2 The Pacific Decadal Oscillation Index 1900–2001 (Reproduced from **http://www.jisao.washington.edu/data_sets/pdo/**)

while high values are associated with a strong Aleutian low. High values of the PNA tend to be associated with the warm phase of PDO (e.g. 1977 to about 1998) and El Nino events (Hsieh and Tang, 2001).

North Atlantic Oscillation (NAO)

Many of the elements of atmosphere–ocean variability found in the very large Pacific Basin are also evident in the Atlantic Ocean (Hurrell and van Loon, 1997). The NAO is the dominant mode of winter climate variability in the North Atlantic region encompassing central North America, Europe, and much of Northern Asia. It represents a large-scale seesaw in atmospheric mass (pressure) between the subtropical high and the polar low. The NAO index exhibits considerable year-to-year variability, but also shows a tendency to remain in one phase for several years. The positive NAO index phase has a stronger-than-usual subtropical high-pressure center and a deeper-than-normal Icelandic low. This leads to a higher frequency of, and more intense, winter storms crossing the Atlantic Ocean. As a consequence, winters in Europe tend to be warm and wet, while Canada and Greenland experience dry, cold conditions. In contrast, the negative NAO index phase is characterized by a weak subtropical high and a weak Icelandic low. This condition typically brings moist air into the Mediterranean, cold air to northern Europe, and a higher frequency of cold air outbreaks to the eastern United States of America.

TECHNIQUES TO IDENTIFY AND CLASSIFY WEATHER PATTERNS AND WEATHER TYPES

Given the obvious tendency of the atmosphere to exhibit patterned and repetitive (if not necessarily predictable) behavior at a range of spatial and temporal scales, it is hardly surprising that climatologists have attempted to identify and classify such pattern in order to provide a linkage between myriad human activities and/or the surface environment and atmospheric circulation. This has been an ongoing and developing research focus in the atmospheric and hydrological sciences over the twentieth century and provides the basis for the scientific meaning of the terms "weather pattern" and "weather type". Many techniques have been developed in order to identify and classify weather patterns and conditions. These are summarized in an excellent primer on the topic by Yarnal (1993) and updated in Yarnal *et al.* (2001). Yarnal's terminology and taxonomy of techniques is discussed in the following sections.

Manual Classification

In this approach, "weather patterns" and weather types" are established on the basis of a subjective classification of synoptic data (i.e. weather observations of various types or weather maps) by the researcher. Because of the current predominance of computer-assisted approaches, this technique has lost favor somewhat. However, subjective classification of weather/circulation patterns or types from visual analysis of synoptic weather maps remains the foundation of three well-known classification schemes that have demonstrated remarkable longevity: (i) the Muller classification of synoptic types over the United States (Muller, 1977) (ii) the Lamb Catalog for the British Isles (Lamb, 1972), and (iii) the Grosswetterlagen (Hess and Brezowsky, 1977) for central Europe.

The Lamb catalog neatly illustrates the manual approach. Using daily weather maps, Lamb (1972) recognized seven basic weather types based on the curvature and orientation of surface isobars:

A. Anticyclonic
C. Cyclonic
W. Westerly
NW. Northwesterly
N. Northerly

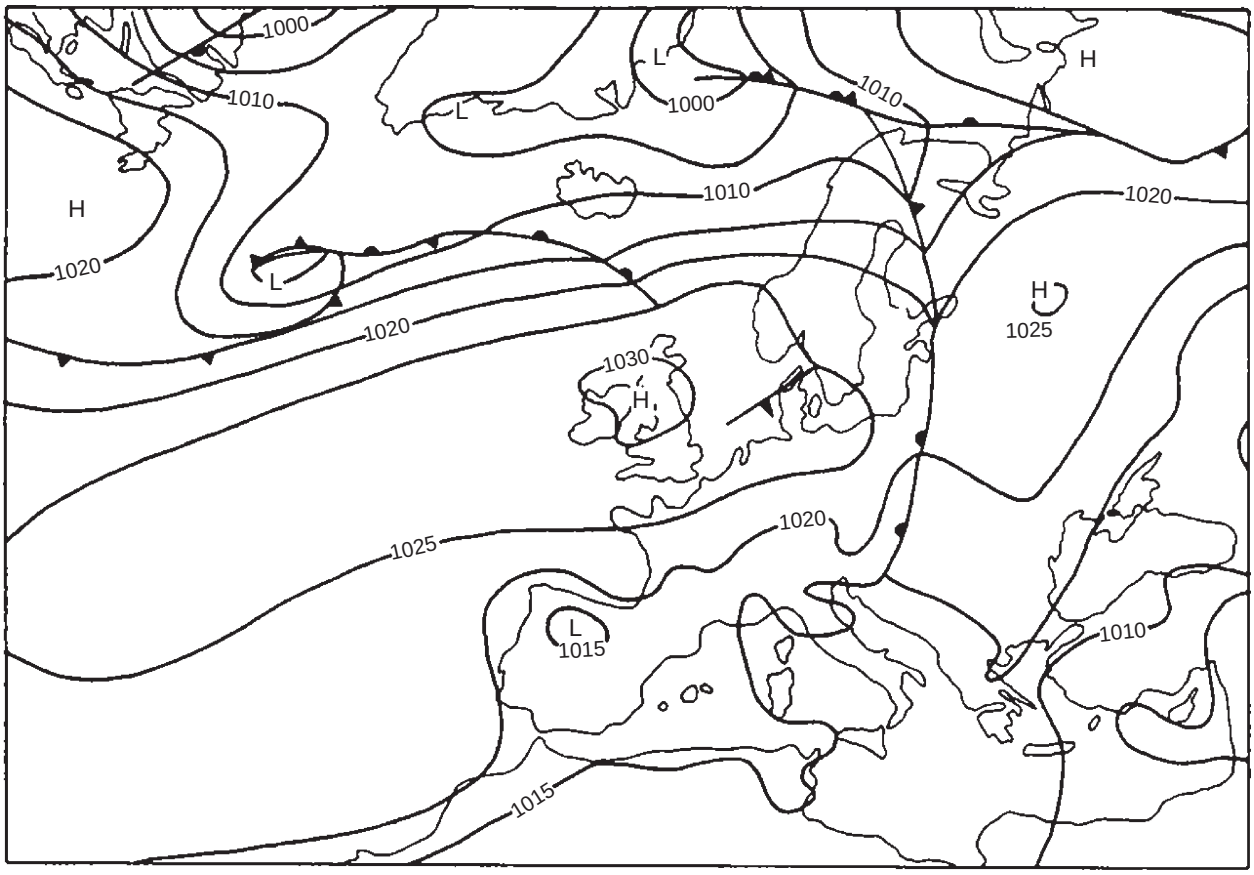

Figure 3 An example of Lamb's weather type A (Anticyclonic) (Reproduced from Henderson-Sellers and Robinson, 1986)

D. Easterly
S. Southerly

For example, Type A was associated with high-pressure areas dominating over the British Isles (Figure 3). Typical weather conditions include light winds, warm weather in summer, and cold conditions in winter. The catalog was further extended on the basis of unclassifiable and hybrid days. Consequently, anticyclonic northwesterly isobaric curvature over the region would give rise to ANW types and could be distinguished from CNW types. On this basis, a total of 27 types could be identified. Lamb subjectively classified each day's weather over the British Isles from 1861 to February 1997. All the years' data have been published, except for 1996–1997, in Lamb (1972) and Hulme and Barrow (1997). Since Lamb's death, an objective version of the scheme has been developed by Jenkinson and Collison (1977) and continues to be updated.

Although labor intensive, subjective, and not easily reproduced, manual approaches to identifying weather patterns and types are still utilized (see for example, Buishand and Brandsma, 1997), primarily as a result of the degree of control and specificity they offer the researcher.

Correlation-based Approaches

In many respects, correlation-based approaches simply represent an automated version of the manual approaches described above. In its simplest sense, the approach involves the correlation of synoptic weather maps (pressure fields) with one another in order to form weather types. Correlation threshold values are used to determine the membership of discrete types or categories. This approach was first introduced by Lund (1963) using Pearson product moment correlations and later by Kirchhofer (1973) using a sum-of-squares algorithm that has been shown to be essentially identical to Lund's technique.

In this procedure, each grid of pressure values (a weather map) is first normalized to remove the seasonal cycle:

$$Z_i = \frac{x_i - \overline{x_i}}{s} \tag{1}$$

Where Z_i is the normalized value of the grid point i, x the mean of the N-point grid, and s the standard deviation of the grid. Each normalized grid (map) is then compared

with all other grids by the sum-of-squares equation:

$$S = \sum_{i=1}^{N} (Z_{ai} - Z_{bi})^2 \qquad (2)$$

Where S is the Kirchhofer score, Z_{ai} the normalized grid value of point i on day a, Z_{bi} the grid value of point i on day b, and N the number of data points. Days a and b represent any pair of maps from which the Kirchhofer score S is calculated.

Subscore values for each row and column of the matrices are also calculated using equation (2) in order to ensure pattern similarities in all areas of the grid. Maps are considered to be similar, based on predetermined thresholds. Within the period of maps being considered (usually several years), the day that has most S values meeting the threshold criteria associated with it is designated *keyday1*. This key day is then removed from the analysis as are all days that met thresholds of correlation with that day, and all days associated with those days. This analysis is then repeated with all remaining days to find *keyday 2*, and so on, until all days are classified into m groups of five days or more. The remainder are deemed "unclassified".

Once the *keydays* are established, equation (2) is then used to compare each of the *keydays* with all other grids (maps). Each day is then assigned to the class associated with the *keyday* for which it produces the lowest S value. This represents the final step in establishing classes.

Although still involving subjective decisions, correlation-based approaches are intuitive, simple to implement and reproducible. Consequently, they have been used extensively in a wide range of applications. For example, McKendry (1994) uses a combination of correlation-based approaches and compositing (see the following text) to elucidate meteorological impacts on air quality in the Lower Fraser Valley (LFV) of British Columbia. Twelve of the 17 types identified for mean sea level maps by the Kirchhofer approach are shown in Figure 4. The relation between weather types and ozone concentrations is shown in Figure 5 and demonstrates the association of elevated concentrations of ozone with anticyclonic conditions and an appropriately positioned ridge of high-pressure at 500 hPa.

The critical importance of coupling between the surface and upper-level flow patterns to O_3 concentrations in the LFV (McKendry, 1994) suggest that traditional synoptic climatological approaches that emphasize classification of a single atmospheric level (usually the surface) within a static framework may have limited applications. This LFV ozone analysis highlights the extent to which particular surface circulation types may be associated with a range of 500 hPa types. Consequently, only by explicit consideration of the three-dimensional structure of the atmosphere can the meteorological controls on O_3 concentrations be satisfactorily explained. Furthermore, the LFV example confirms that meteorological controls on air quality can only be examined within a dynamic framework. Elevated O_3 concentrations appear to be strongly controlled by antecedent synoptic conditions and the degree of persistence in the evolving synoptic state. Within this context, the sequencing and compositing techniques developed by Comrie (1992) are particularly useful.

Eigenvector-based Approaches

With the growth and accessibility of computing power, more sophisticated, elegant, parsimonious, and statistically robust techniques have emerged for the classification of weather types and patterns. These approaches exploit a variety of eigenvector-based techniques that permit the isolation of clusters in large and diverse data sets and include principal components analysis (PCA), empirical orthogonal functions (EOF), discriminant analysis and cluster analysis. Application of such techniques requires a high degree of statistical competency, but provides significant reward with respect to statistical rigor and interpretation. Recent examples of the application of such multivariate techniques include Kidson's (2000) investigation of weather regimes affecting New Zealand and the study of Romero *et al.* (1999a, b) on precipitation patterns over the Spanish Mediterranean.

Eigenvector-based techniques have found greatest application in synoptic type classifications (where a range of weather variables such as temperature, cloud cover, wind speed, and direction are classified) rather than map-pattern classification. This may be attributed to the fact that maps of component loadings are less easily interpreted than the pressure fields that result from other classification techniques (Yarnal, 1993).

Kalkstein and Corrigan (1986) nicely illustrate the approach as developed primarily by Kalkstein and his collaborators at the University of Delaware. With a view to examining the meteorological controls on sulfur dioxide concentrations, they took seven weather variables (recorded 4 times per day) over five winters (451 days) to create a 28 by 451 P-mode data matrix. This was then converted to a correlation matrix and an unrotated PCA applied. Five principal components were retained (explaining 78% of the variance). A clustering technique was then used to reduce the component scores matrix to 10 synoptic types. Means of the weather variables were then calculated for each of the types. Representative weather maps were also examined for each type as an aid to understanding and interpretation.

Despite the complexity and rigor of the eigenvector-based approaches, the researcher exploiting this approach is faced with myriad decisions regarding mode of decomposition, types of rotation, and type of dispersion matrix. In essence, each application is, therefore, unique.

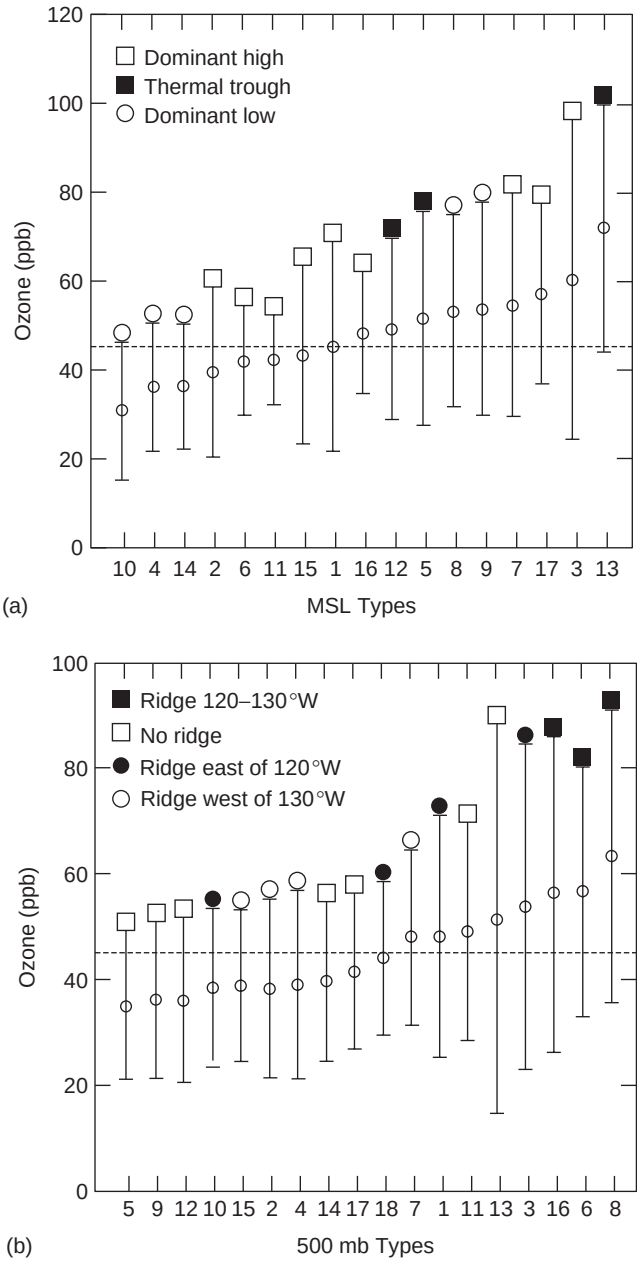

Figure 5 Mean (with standard deviation bars) daily maximum ozone concentrations for a Vancouver, B.C., station 1978–93 (May–September) by (a) MSL and (b) 500 hPa synoptic types (Reproduced from McKendry, 1994)

Compositing and Indexing

Composites represent "average" weather maps or weather patterns and are easily developed on the basis of a particular criterion. For example, gridded pressure fields (synoptic weather maps) for days on which ozone concentrations or precipitation totals reach a particular threshold over a region, may be averaged to produce a composite map. For example, McKendry (1994) produced composite map and weather condition sequences associated with exceedances of the 82 ppb Canadian ozone "objective". One such example is shown in Figure 6.

Indexing, on the other hand, involves the assignment of a single number or "index" to capture the essence of a particular weather pattern or type (Yarnal, 1993). Using this approach, one can develop a time-series that can be compared/correlated with other indexes such as those used with large-scale climatic fluctuations like ENSO, PDO, or AO. Recent examples of this approach include studies by Greene *et al.* (1999), who constructed a synoptic climatology of air pollution in the United States by using a synoptic index, and Speer and Leslie (1997), who matched frequencies of Australian ridging events with ENSO variations.

New Developments

To date, approaches to the specification of weather patterns and types have spanned a continuum, from simple manual classification techniques to highly sophisticated computer-assisted statistical approaches. Both extremes have their advantages. Recently, new approaches have been developed that exploit the simplicity of the manual approach while maintaining the rigor of the automated statistical methodologies. An example of such a hybrid scheme is the Spatial Synoptic Classification (SSC2) as described by Sheridan (2002) and produced for the coterminous USA. This approach exploits six subjectively defined weather types (similar to the air mass types defined by Bergeron (1930) as developed by Kalkstein *et al.* (1996). These are dry polar (DP), dry moderate (DM), dry tropical (DT), moist polar (MP), moist moderate (MM), and moist tropical (MT). Each weather type is defined for all locations across the continent using statistical analysis of meteorological data for each station (temperature, dew point wind, cloud cover, and sea level pressure). Output of year-round weather types for each day is achieved by an equally weighted-sum of squared z-scores and results in a daily calendar of weather types for each station. These can be found at `http://sheridan.geog.kent.edu/sscnow.html` for stations across Canada and the United States.

Modifications to the traditional classification approaches described above continue to be developed, but they are largely variations on a theme. Perhaps the most promising is the exploitation of Geographical Information Systems (GIS) and artificial intelligence approaches (e.g. artificial neural networks) in the identification of weather patterns and types. Yarnal *et al.* (2001) note, that as yet, GIS has made few implicit inroads into synoptic climatology. In the areas of data visualization and data management, GIS has contributed to the evolution of the discipline, but has made little progress analytically.

The free availability of large high quality data sets (such as the National Centers for Environmental Protection

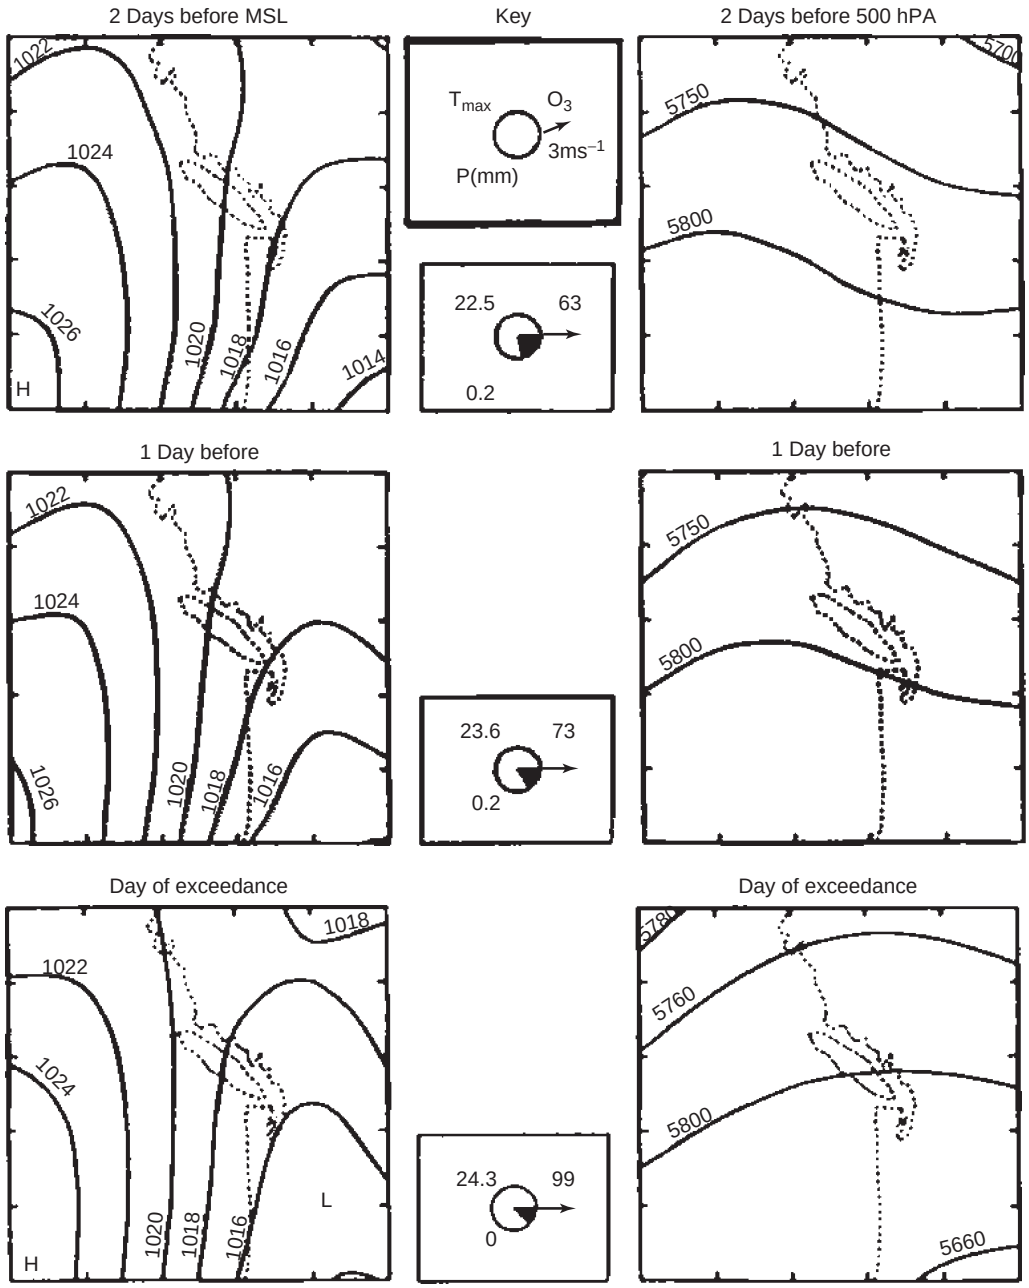

Figure 6 A three-day composite synoptic sequence showing MSL and 500 hPa maps associated with severe ozone episodes (''exceedances'') in south-western British Columbia. Also shown are station circles representing the average weather (cloud cover, wind, maximum temperature (°C), precipitation and ozone concentration (ppb)) associated with the composites (Reproduced from McKendry, 1994, © American Meteorological Society)

(NCEP) reanalysis) together with improved computational power and user-friendly computer interfaces has made synoptic typing a much more accessible activity. An excellent example is the "Synoptic Typer", an application designed in Australia to perform automated objective synoptic typing using a pattern recognition scheme. A history of grid point analyses is used to develop the synoptic types using both principal component and cluster analysis techniques. Real-time NWP model output is then classified to produce synoptic type forecast guidance (**`http://www.bom.gov.au/inside/cosb/mss/projects/synoptictyper/`**).

Assumptions and Limitations

In the field of synoptic climatology, considerable energy is being spent in the identification of weather types and

weather patterns. In doing so, much has been achieved with respect to improving understanding of the means by which weather modulates human activities, together with a broad range of environmental variables. Furthermore, this enterprise has provided a firm basis for prediction in such areas as air quality, water management, tourism, and transportation. However, Yarnal (1993) draws attention to important assumptions that should be borne in mind, when considering weather patterns and types as derived by the various techniques above. Generally, it is assumed that

1. *atmospheric circulation is a critical determinant of the surface environment* – this is clearly the case with respect to air quality, but may not be the case for some environmental processes (e.g. tectonic activity);
2. *current conceptual models of the midlatitude cyclone are correct* – there are still uncertainties with respect to the structure and behavior of midlatitude systems (e.g. the behavior and structure of rainbands and fronts);
3. *the atmosphere can be partitioned into discrete, nonoverlapping intervals (i.e. weather types)* – Yarnal (1993) suggests that the atmosphere is a multidimensional continuum and therefore, patterns and types really represent important clusters in multidimensional space;
4. *classification identifies all important map patterns or synoptic types* – establishment of weather patterns and types necessarily involves subjective decisions about the extent of within-class variability that is acceptable;
5. *classification techniques achieve what the investigator really expects* – classification with complex statistical packages often is akin to a "black-box" approach. The onus is on the climatologist to make informed decisions and interpretations;
6. *the temporal and spatial scales of observations and atmospheric circulation processes match* – for example, local air quality is strongly influenced by local winds such as sea breezes and slope winds. Such flows are not necessarily reflected in synoptic scale maps. Consequently, a perfect match between synoptic scale processes and pollutant concentrations should not be expected.
7. *variability within classes of weather patterns or types is not problematic* – in reality such variability is both problematic and inevitable.

For each assumption, Yarnal (1993) identifies significant concerns, and illustrates that in practical synoptic climatologies in which weather patterns and types are identified, each of these assumptions is violated to some degree. In essence, weather patterns and types can only be regarded as approximations, and they neglect the fact that the atmosphere really represents a continuum in which weather is infinitely varying.

CONCLUSIONS

Despite the marked variability and seemingly chaotic behavior of the atmosphere, it is, in fact, characterized by quite a remarkable order and regularity at a range of scales. This permits the identification of recognizable and repeatable weather patterns and types at particular localities. These form the basis of climate and are best expressed at the synoptic scale, the scale of weather variability seen over regions on timescales of hours to days. Such variability, expressed for example, in the passage of a midlatitude cyclone, a tropical cyclone, or the arrival of monsoon rains, has important implications for myriad human activities and environmental variables. Synoptic climatologists have adopted a variety of techniques of varying degrees of sophistication in order to identify and classify such synoptic weather patterns and types. These approaches range from the simple, subjective classification of weather maps into classes, to complex statistical analyses of multiple meteorological variables. Whatever the approach, important linkages between the atmospheric circulation and the environment have been identified. The range of applications is enormous. Such approaches have been successfully exploited to explore connections between weather patterns and human health, air pollution, precipitation, agricultural production, fluvial hydrology, severe weather events, to name just a few.

However, in summarizing the various methods used to identify weather patterns and types, it is abundantly clear that underlying such approaches are significant assumptions about the state of the atmosphere (Yarnal, 1993; Yarnal *et al.*, 2001) together with varying degrees of subjectivity inherent in the techniques themselves. It is important that these constraints are adequately acknowledged in all applications of the techniques outlined herein.

The science of identifying weather patterns and types is not static. The field continues to grow and change. Combinations of traditional techniques are being used to considerable advantage (e.g. hybrid classifications) while new approaches are emerging. As computing power continues to increase, together with application of new techniques and enhanced datasets, it is likely that synoptic climatology will grow in terms of its potential applications and sophistication. The possibility of classifying a fully three-dimensional atmosphere has become a realistic goal, and the availability of online synoptic climatologies and typing software holds the promise of much wider exploitation of the approach.

27: Storm Systems

CHARLES A DOSWELL III

University of Oklahoma, Norman, OK, US

The concept of a storm is defined as a weather disturbance that, in the context of hydrological science, produces precipitation or affects the formation and distribution of precipitation. Storm systems are reviewed in terms of their spatial and temporal scale, with the dominant storm system on large scales in midlatitudes being the so-called extratropical cyclones. Not only do such storms produce considerable weather in their own right, but they provide a setting in which the so-called mesoscale storm systems can develop. Mesoscale weather is not dominated by any particular form of disturbance, but can take many different forms. The intensity of the weather, including precipitation rates, in mesoscale systems can be much greater than in extratropical cyclones although the duration of such weather is typically less than in large-scale systems. Small-scale storms are dominated by convective storms, which can produce the most violent weather of all, including large hail, strong winds, tornadoes, and torrential rainfalls.

INTRODUCTION

The word "storm" is generally defined as a disturbance in the weather. In the context of hydrological science, the most obviously relevant type of weather disturbance is one that produces precipitation. The deposition of precipitation is the result of a number of processes, but the most basic requirement for precipitation is the ascent of air that contains water vapor. Ascending air cools by adiabatic expansion, and condensation begins when this cooling results in relative humidities at or near 100% (*see* **Chapter 28, Clouds and Precipitation, Volume 1**). This condensation produces clouds that can develop precipitation following continued ascent of the air (see Lamb (2001) for a more complete description of how precipitation is formed). Once it begins, the instantaneous rate of precipitation, R, is roughly proportional to the product Ewq, where E is the efficiency at which water vapor is converted to precipitation that reaches the surface, w is the ascent rate, and q is the water vapor mixing ratio (the mass of water vapor per unit mass of air) in the ascending air (Doswell *et al.*, 1996). When the average precipitation rate, $\overline{R}$, is multiplied by the duration of the precipitation, D, the result is the total accumulated precipitation during the storm. Typically, the efficiency of precipitation production by storms is not particularly high, perhaps being on the order of 50%, occasionally much more, and often much less, and can vary from one storm to the next, as well as during the life cycle of a single storm. Precipitation efficiency depends strongly on the environment in which a storm occurs – dry environments increase the likelihood that precipitation will evaporate before it reaches the surface. Strong variation of the horizontal wind with height, called *vertical wind shear*, is also thought to reduce precipitation efficiency.

The water vapor needed for precipitation is present in the air mostly as a result of the process of *evapotranspiration* – the combined effects of evaporation (*see* **Chapter 45, Actual Evaporation, Volume 1**) from open liquid water (frozen forms of water do not release much water vapor) and transpiration of water vapor by vegetation (*see* **Chapter 42, Transpiration, Volume 1**). However, precipitation does not always fall at or near the place where water vapor is first introduced into the air. Rather, the moving air, or *wind*, often transports that added water vapor away from its source before it ultimately falls out somewhere else as precipitation. Therefore, even nonprecipitating weather systems are hydrologically pertinent, because they are associated with the atmospheric water vapor *transport* component of the hydrologic cycle. As a result of this transport, precipitation can fall in geographic locations that have little or no local evapotranspiration (e.g. the polar regions, or deserts), for lack of vegetation and/or open

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

liquid water. The movement of air also alters the transpiration *rate*, so any discussion of hydrologically important storm systems must also consider those processes that control the wind.

Storm systems operate on a variety of spatial and temporal scales, and that is the basis for an orderly consideration of them herein. In order to understand storm systems, it is essential to know the basic physics that govern atmospheric motion. Air within the lower atmosphere is a mixture of many gases, but is mostly nitrogen (about 78%), oxygen (about 20%), argon (about 1%), carbon dioxide (less than 1%), and water vapor (variable, 1% or less). Of these gases, only the water vapor content varies much within the lower atmosphere. The fact that water vapor is a constituent gas that, unlike the others, can change phase to liquid or solid forms within the range of temperatures and pressures found within the atmosphere is a critical factor in the evolution of weather systems. The magnitude of this contribution to the total energy of storm systems by water substance is due to the relatively high *latent heat* of water. When condensation of water vapor occurs, latent heat is released, often enhancing the processes leading to upward air motions that initiated condensation in the first place. Storms systems on the Earth are stronger than they would be if the planet was dry and without significant latent heat release from condensation (like the atmosphere of Mars). Clouds produced by condensation also influence strongly the local radiation balance and so alter the spatial temperature distribution. Incoming solar radiation is the ultimate energy source for all weather, and clouds are important factors in the local energy budget.

Atmospheric processes are governed by a complex set of equations that are the mathematical expression of physical conservation laws: the conservation of momentum (Newton's laws of motion), the conservation of energy, and the conservation of mass, including the total mass of water in any form. Also included is a thermodynamic equation of state – for most practical purposes, the atmosphere is well-approximated as an ideal gas. The complete set of equations (see e.g. Holton, 1992) describing atmospheric motions can be simplified in different ways, depending on the temporal and spatial scale of atmospheric processes under consideration. By reducing the complexity of the governing equations, it is possible to gain a qualitative understanding of those storm systems associated with a particular scale of motion. Although the real atmosphere makes no such simplifications, the dominance of certain processes at specific scales is simply a result of the integrated dynamics. The fact that the dynamical system describing the atmospheric is substantially nonlinear means that a quantitative treatment of the atmosphere is only possible via computer simulations that are necessarily only approximations to the mathematical equations. These mathematical equations are, in turn, only approximations of the real atmosphere. Nonlinear dynamics is why weather forecasting is so widely recognized as challenging and subject to considerable uncertainty (Lorenz, 1993). Since our understanding of the atmosphere is incomplete and our measurement of atmospheric variables is neither perfectly accurate nor at infinite spatial and temporal resolution, forecasting storm systems is never going to be perfect. This uncertainty is tied to the nonlinearity of the dynamical system and so cannot be circumvented at any time in the foreseeable future.

The vertical structure of the atmosphere is broadly described in terms of layers. From the surface to a height of about 10 km, temperature decreases with height at a rate of roughly $6\,\mathrm{K\,km^{-1}}$. At a height of 10 km, the pressure has fallen to about 30% of the surface value. This layer from the surface to roughly 10 km is called the *troposphere*, the actual height of which varies, being generally lowest in the polar regions and deepest near the Equator. Above the troposphere is the *stratosphere*, within which the temperature generally increases with height up to around 40–50 km, where the pressure has fallen to less than one percent of the surface value. The boundary between the troposphere and the stratosphere is called the *tropopause*. Generally, most of what we call "weather" is confined within the troposphere and lower portions of the stratosphere. The depth of the troposphere compared to size of the Earth is comparable to the thickness of the skin on an apple. Thus, the complexities of storm systems are mostly confined to a very thin layer, and the fact that the atmosphere is so thin relative to the planetary scale is an important factor in the dynamics of large-scale storms.

LARGE-SCALE STORM SYSTEMS

Seen from space, the cloud patterns (Figure 1) show that cloudy regions in middle latitudes are broadly associated with relatively large disturbances that rotate cyclonically – that is, counterclockwise in the northern hemisphere and clockwise in the southern hemisphere. The main large-scale weather systems of middle latitudes are called *extratropical cyclones*, to distinguish them from tropical cyclones, which have very different dynamics. Outside of the tropics, the dominant contributions to the dynamics of the atmosphere are: gravity, planetary rotation (manifested by the so-called *Coriolis Force* that varies from a maximum at the poles to zero at the Equator), the sphericity of the Earth, the character of the topography (notably, the mountains and oceans), and the unequal distribution of temperature resulting from solar heating. Because storm systems of large scale within the troposphere are very flat, the airflow in such systems, therefore, is predominantly horizontal and the vertical motions are so weak (on the order of a few $\mathrm{cm\,s^{-1}}$) as to defy accurate routine measurement.

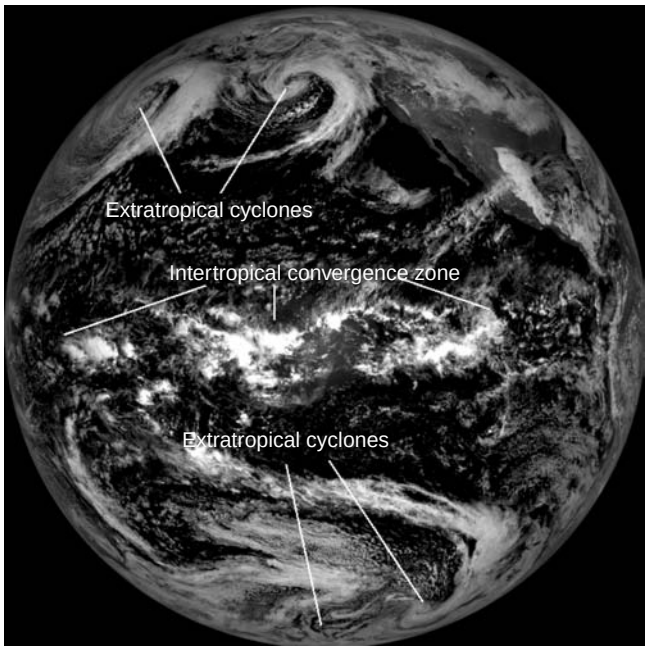

Figure 1 Full-disk image of the earth from the geostationary satellite GOES-12 on 11 March, 1997, showing two major extratropical cyclones in the northern hemisphere's Pacific Ocean: one approaching the west coast of North America, and another immediately behind it, in the central Pacific. Frontal cloud bands spiral inward toward their centers in a counterclockwise rotation. Others can also be seen rotating the opposite way in the southern hemisphere. A bright band of thunderstorm clusters marks the intertropical convergence zone between the northern and southern hemispheric circulations (NOAA image)

Broadly speaking, the fact that the Earth is a sphere means that incoming solar radiation per unit area is always largest in the tropics, decreasing as one moves poleward. This radiational imbalance is the key factor in large-scale weather of midlatitudes (*see* **Chapter 25, Global Energy and Water Balances, Volume 1**). The tilt of the Earth's axis, combined with the rotation around the Sun, produces the seasonal changes poleward from the tropics. Within the tropics, the effect of seasonality is much reduced compared to middle and polar latitudes. Hence, although the Earth is always warmer in the tropics than near the poles, the temperature difference between the poles and the tropics changes with the season, being at its maximum in late winter and its minimum in late summer. Cyclonic storms operate on the energy available as a result of the temperature contrast between the poles and the tropics. The extratropical cyclones are, therefore, most intense during the cool season and at their weakest in the summer. A cyclonic disturbance transports cold air from the polar regions toward the tropics, and warm air from the tropics toward the poles, thereby acting to reduce the horizontal temperature contrast.

Another important factor in the temperature distribution is the difference between oceans and land surfaces. Water has a much higher specific heat than that of land, so a given amount of incoming solar radiation changes the temperature of water much less than that of a comparable land surface. This damps the magnitude of the diurnal and seasonal temperature cycles over the oceans compared to that over land, and creates *land/sea breezes* on a daily timescale and *monsoons* on a seasonal timescale. Moreover, the ocean basins include large-scale currents (such as the Gulf Stream) of their own that modulate the structure of the overlying air and, in turn, are influenced by the airflow over the oceans. The oceans and the atmosphere together are a coupled dynamical system.

The existence of a north-south (or *meridional*) temperature gradient results in, among other things, a band of strong westerly winds at a height of about 10 km (near the tropopause) in midlatitudes called the *jet stream*. The meridional temperature contrast between the Equator and the poles is not evenly distributed but tends to be concentrated in a relatively narrow zone called the *Polar Front*. As a result of all the complicating factors already mentioned, the Polar Front itself varies in location and intensity from day to day and generally migrates poleward in summer and equatorward in winter. The overlying jet stream is in fact tied dynamically to the strength and location of the Polar Front.

On large scales, it turns out that extratropical cyclones are the size they are because disturbances of that size are most efficient at transporting heat from the equatorial regions poleward (and, equivalently, transporting cold air from the polar regions equatorward). The leading edges of cold air masses traveling equatorward are *cold fronts*, whereas the leading edges of warm air masses traveling poleward are *warm fronts*. Extratropical cyclones also provide some *vertical* transport of heat, as warm air involved in the storm typically ascends, whereas the cold air descends. The effect of the vertical heat transport is to carry the excess heat from solar radiation at the surface upward. The weak vertical motions on this scale are efficient at vertical heat transport only because of the large size of the air masses involved. On the average, it only takes about 3 to 6 extratropical cyclones per hemisphere to maintain the observed mean hemispheric thermal structure in the face of the continuing unequal solar heating (Palmén and Newton, 1969). Without extratropical cyclones, the tropics would become much warmer than they now are, while the polar regions would cool still more, perhaps to the point where the habitable portion of the Earth would be confined to a narrow strip in middle latitudes.

Generally speaking, extratropical cyclones have a life cycle (Figure 2) that includes a time of development, during which the increasing kinetic energy associated the winds of the storm is drawn from the potential energy available from

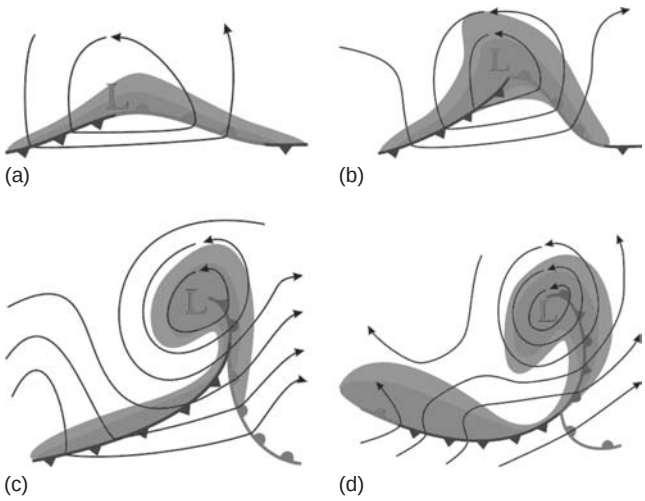

Figure 2 Schematic evolution of an extratropical cyclone (the center of low pressure is indicated by the letter ''L'') in the northern hemisphere, showing the development of a wave on the polar front (a), the amplification of that wave (b), the mature phase of the cyclone, which is beginning to ''occlude'' (c), and the beginning of the dissipation of the cyclone (d), as the occlusion process proceeds. Cold fronts are heavy lines with triangles, warm fronts are heavy lines with half circles, and occluded fronts are heavy lines with alternating triangles and half circles; darker shading indicates regions of precipitation and lighter shading indicates clouds; the black lines with arrows indicate the surface pressure with winds roughly parallel to the pressure contours (Schematic drawings provided courtesy of NOAA). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

the unequal distribution of temperature. The life cycle of an extratropical cyclone unfolds over several days. Given that these storms generally move from west to east in middle latitudes, owing to the generally westerly flow in which they are embedded, a new extratropical cyclone passes through a given region on the order of every few days. This results in a cycle whereby locations along the track of such storms experience warming as the extratropical cyclone approaches and cooling as the storm passes. The extratropical storm track is generally along the average location of the Polar Front, which can sometimes persist in the same area for many weeks, or it can shift as the overall airflow pattern changes.

When an extratropical cyclone develops, its horizontal and vertical wind speeds increase – the kinetic energy of the cyclone increases as it draws down the available potential energy. The airflow tends to organize itself in "conveyor belts" (see Browning, 1985) where the ascending currents become cloudy and the descending currents tend to be cloud-free, resulting in the characteristic cloud patterns associated with extratropical cyclones (Figure 1). The development of the storm also increases its overall rotation rate, drawing the clouds into spiral patterns.

Generally, the air to the east of an extratropical storm is rising, as well as moving poleward. If this poleward-moving warm air is also moist at low levels because at some point in the past it has passed over a moisture source (e.g. the warm waters of the Gulf of Mexico), then the likelihood of precipitation is relatively large. On the other hand, if the source of the warm air is from a dry region (like the Sahara Desert), then the likelihood of precipitation is relatively small. Conversely, the equatorward-moving cold air to the west of an extratropical cyclone is usually sinking, so the weather tends to be relatively fair. Depending on the local topography, various exceptions to these tendencies can be encountered.

It is noteworthy that the northern hemisphere has several large mountain ranges and other regions of relatively high terrain, and also has most of the land mass on the planet. On the other hand, the southern hemisphere has a much higher percentage of its area covered by oceans, with only one major mountain range, the Andes Mountains of South America. This asymmetry is also reflected in the complexity of the pattern of cyclones in their respective hemispheres: northern hemisphere weather patterns are far more complex, on average, than those in the southern hemisphere, where westerly flow (also called *zonal* flow) predominates in upper levels. The presence of complex topography also influences the distribution of weather within passing extratropical cyclones. Where airflows toward rising terrain, it is forced upward, which can cause precipitation if that ascending air is also moist (*see* **Chapter 30, Topographic Effects on Precipitation, Volume 1**). Thus, the western slopes of the Americas, with their coastal mountain ranges facing predominantly westerly winds from the Pacific Ocean, usually have abundant rainfall. When airflows downslope, it tends to dry out – deserts or semiarid regions are generally found to the east of the North American mountain ranges, for instance.

MESOSCALE STORM SYSTEMS

The distribution of precipitation within an extratropical cyclone (as illustrated schematically in Figure 2) can vary substantially from one situation to the next, depending on the availability of water vapor in the air currents, and from time to time within the life cycle of the storm system. Embedded within an extratropical cyclone are smaller storm systems that occur on an intermediate scale, often referred to as *mesoscale* storm systems. The horizontal scale of such storm systems ranges from about 100 km to about 1000 km and the timescale ranges from a few hours to a few days. The specific conditions that favor the development of mesoscale storms within an extratropical cyclone are modulated by the details of structure and evolution for that particular large-scale system. Whereas large-scale meteorology is dominated by extratropical cyclones, mesoscale storm

systems include a larger variety of processes than observed at large scales in midlatitudes. Hence, it is difficult to make broad generalizations about mesoscale storm systems. Although there are tendencies for certain weather patterns associated with extratropical cyclones (Figure 2), exceptions to those tendencies are common, because the distribution of weather within an extratropical cyclone depends on many factors (*see* **Chapter 26, Weather Patterns and Weather Types, Volume 1**). Extratropical cyclones are always present in midlatitudes, because there is always the temperature difference between the poles and the equator to drive them, but the smaller scale storm systems created within them are only present intermittently. Mesoscale storms themselves generally act to remove whatever large-scale conditions caused them in the first place. These mesoscale storm systems are complex in their variety, since on this scale, virtually no dynamical factor is always negligible. Mesoscale weather is therefore the most complicated and, therefore, the least understood – see Houze (1993) for a discussion of clouds and precipitation systems across a range of scales. Another factor complicating the understanding of mesoscale processes is the lack of quantitative observations of the needed resolution. Mesoscale storm systems can be broken down in two broad classes: (i) those tied to some topographic feature such as large lakes, coastal areas, orographic features, and so on and (ii) those resulting from inherently mesoscale internal atmospheric mechanisms (Emanuel, 1986).

1. *Topographically driven mesoscale storm systems*: Some examples of mesoscale storm systems associated with topography are lake-effect snowstorms, upslope precipitation, mountain precipitation systems, sea/land breeze systems, and so on. A critical issue in such storms is their intimate connection to processes on larger scales. For example, if we consider lake-effect snow storms (Figure 3), the occurrence and location of the snow depends very much on the wind direction of the large-scale flow relative to the lake in question. These mesoscale snow events arise as cold airflows across warm water, becoming moist and unstable at low levels as a result of sensible and latent heat flux from the water. As a large-scale system moves by, the direction of the prevailing low-level winds changes. Change that large-scale flow and the lake-effect snow will cease in one place but may commence in another. Hence, during the passage of an extratropical cyclone, the distribution of lake-effect precipitation will evolve and different areas could receive heavy snowfall on different days. Since each extratropical cyclone is different, the mesoscale details will vary, but large lakes are fixed topographical features, so there are *preferred* areas for lake-effect snow. Exactly which areas will be affected and at what time depends on the detailed structure of the particular extratropical cyclone.

Upslope rain events are another example of a topographically driven mesoscale storm. As moist air is forced upslope, it condenses and forms first clouds and then rain. As with lake-effect snows, the direction of the flow at large scales interacts with the topography to produce important weather. Upslope rain involves thunderstorms when the air flowing upslope is moist and unstable. Since the situations in which upslope thunderstorms form can persist for many hours, the result can be prodigious rainfall rates, up to $200\,\mathrm{mm\,h^{-1}}$, for extended periods

The fact that topographically driven mesoscale storm systems result from an interaction between topographic features and large-scale storms systems make them somewhat easier to predict. The greatest accuracy in weather forecasting is generally associated with the largest scale systems, so that when armed with a detailed knowledge of topography, it can be fairly straightforward to anticipate the general character of the topographically forced mesoscale features

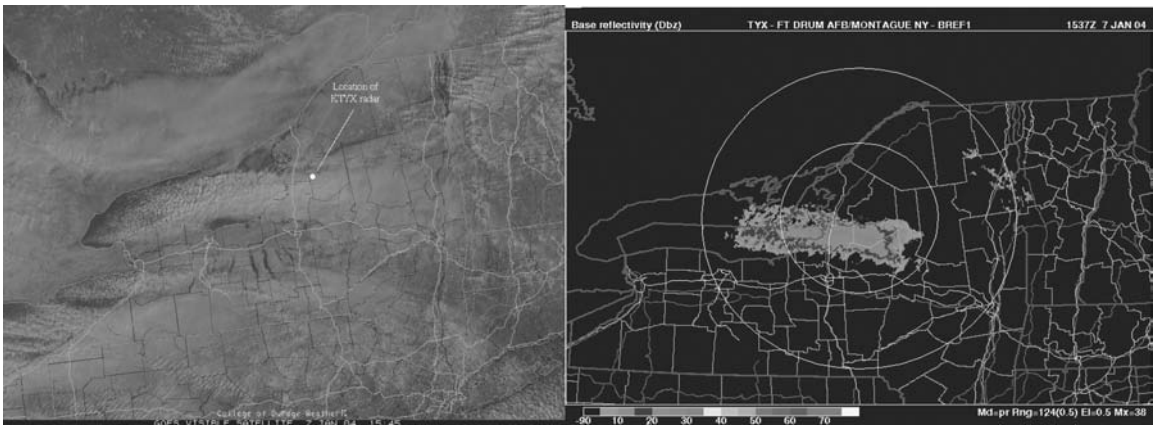

Figure 3 Visible satellite image (a) and radar-observed precipitation (b) associated with a lake-effect snow storm, showing flow from the west-northwest across lake Ontario, with multiple cloud bands producing snow over the eastern part of the lake and on into the state of New York (NOAA images provided by College of Dupage). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

that will occur during the passage of large-scale weather systems. Forecasting such systems is still neither easy nor perfectly accurate, because in forecasting, the small details are inevitably very important. The fact that topographic features are fixed or change only slowly means that the mesoscale storm systems tied to them can be somewhat more predictable than the other category of mesoscale storm systems – those that are driven by instabilities associated with internal atmospheric processes.

2. *Free mesoscale storm systems*: Although extratropical cyclones, the dominant large-scale storm systems, are the size they are as a result of a known scale selection mechanism that maximizes their efficiency at transporting heat meridionally, no such dominant scale selection dynamic process is known for mesoscale storm systems in general. Curiously, the so-called *fronts* that are characteristic of extratropical cyclones have a somewhat ambiguous scale: *along* such a front, they are clearly large-scale processes, extending for 1000 km or so, but perpendicular to a front, the front itself is mesoscale, with characteristic widths for the frontal zone being 10–100 km. The dynamics of fronts are reasonably well known, and frontal zones can include many complicated mesoscale structures that are important for modulating the weather but are only poorly understood. Fronts are an example of a mesoscale process driven by the dynamics of large-scale weather systems.

Mesoscale cyclonic storms called *frontal waves* are often found in association with fronts. These might at times represent the early stages of a developing extratropical cyclone or they might remain within the mesoscale size range, being relatively transient features that, nevertheless, can influence the weather during their mesoscale life cycle. Theory says that such mesoscale perturbations within an extratropical cyclone tend to be confined to near the surface, are shallow, and have shorter life cycles than the extratropical cyclones in which they occur (Gall, 1976). Note that fronts themselves can be important in development of mesoscale regions of ascending air, leading to precipitation. Mesoscale storm systems have vertical motions that can be 10–100 times as strong as those associated with extratropical cyclones – those vertical motions, therefore, are a few tens of cm s^{-1} to perhaps 1 m s^{-1}. Such relatively strong ascent is concentrated in mesoscale regions and contributes to much higher precipitation rates than would be found on the scale of the typical extratropical cyclone. In some regions, at certain times of the year, these mesoscale storm systems produce heavy rain and snow falls, such as within the East China Sea region in the wintertime, during the so-called *Baiu Front* season (Ninomiya *et al.*, 1988).

Although individual thunderstorms are small enough to be considered "small-scale" weather systems and, therefore, are considered in the next section, under certain circumstances (described in Maddox, 1983), many individual thunderstorms become organized into what are called *mesoscale convective systems* (MCSs) (see Fritsch and Forbes (2001) for more details). In many cases, the thunderstorms are linked together into lines of individual storms that interact strongly with each other to produce a mesoscale system, examples of which is shown in Figure 4. Such systems can persist for many hours, and sometimes even for days. They can be associated with very heavy precipitation as well as severe convective weather (discussed in the next section). MCSs arise in a variety of ways, but some of the largest and most persistent examples, given the special name of *mesoscale convective complex* (MCC), appear to have a

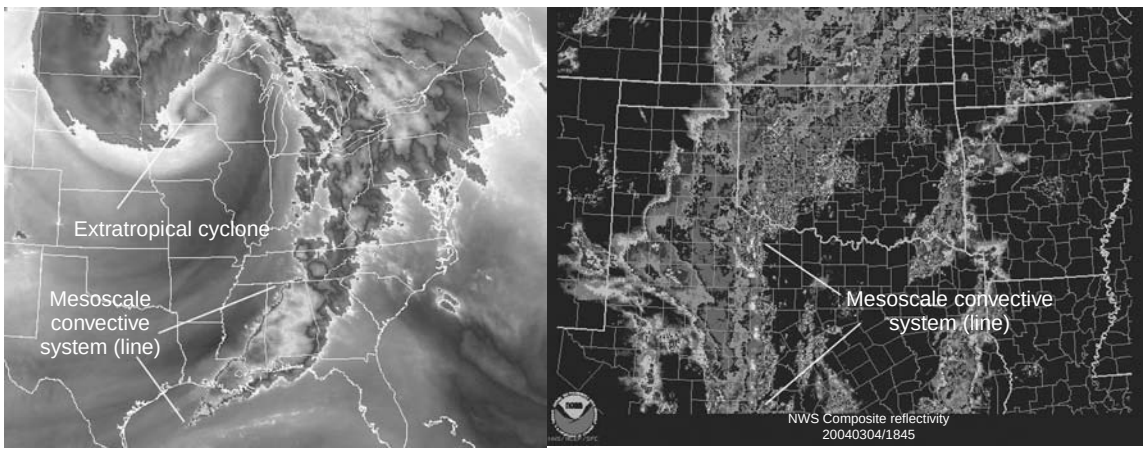

Figure 4 A mesoscale convective system (MCS) along the southern coast of the United States as seen in an enhanced image from a geostationary satellite (a – NCAR image, used by permission) and a radar image of a similar MCS-associated line of thunderstorms (b – NOAA image). Note the size of the MCS affecting the states along the southern coast, compared to the extratropical cyclone system that fills the image, centered west of the Great Lakes. Radar reveals the locations of the strong convective cells (in white) that are powering the MCS, whereas satellite images show the high, cold cloud tops near the tropopause that cover the whole convective system

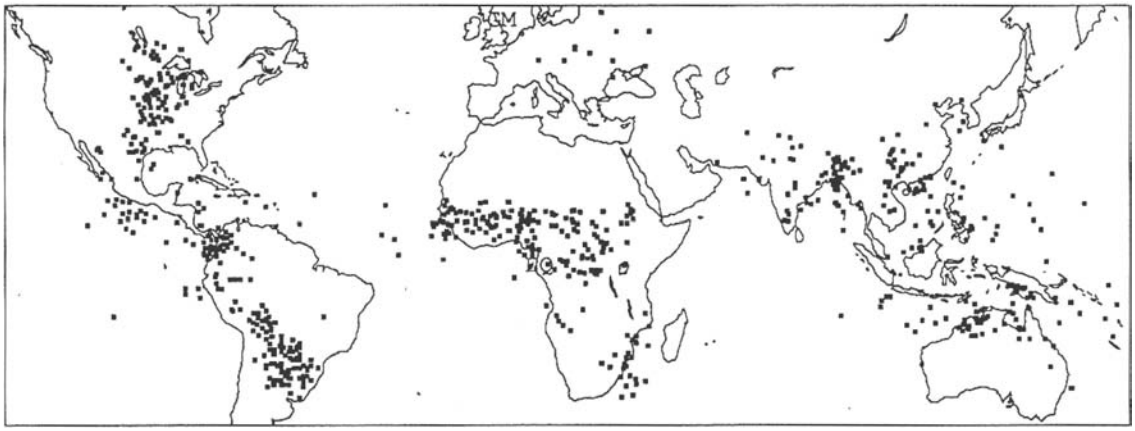

Figure 5 The global distribution of mesoscale convective complexes (MCCs), based on satellite imagery. Small squares indicate location of MCC at time of maximum extent; adapted from Laing and Fritsch (1997)

preference for certain regions of the world (Figure 5), which suggests that their occurrence might be linked to topographic effects. Note that many MCCs are observed in the tropics, as well as in middle latitudes.

Mesoscale features are often embedded within extratropical cyclones at any time of the year, including the winter. In addition to lake-effect snows, there can be mesoscale regions of intense snowfall that travel along with the extratropical cyclone, producing swaths of heavy snow (and/or freezing precipitation) along their tracks. Such bands of winter precipitation are typically on the order of a few hundred km in width (Figure 6), and so represent the track of traveling mesoscale winter precipitation maxima that are associated with processes within a much larger extratropical cyclone.

Within the wintertime polar airstreams often can be found the so-called *polar lows* (Rasmussen and Turner, 2003). These are mesoscale storm systems that take on two rather different forms: when occurring over the ice-free ocean waters, some have been found to have many characteristics in common with tropical cyclones, including relatively weak horizontal temperature contrasts, warm cores, and occasionally even cloud-free "eyes", despite their occurrence at high latitudes. Other types of polar lows are clearly small cousins to the extratropical cyclone, forming in association with strong horizontal temperature contrasts, sometimes associated with topographic features. Both can produce intense snowfalls in association with localized high winds.

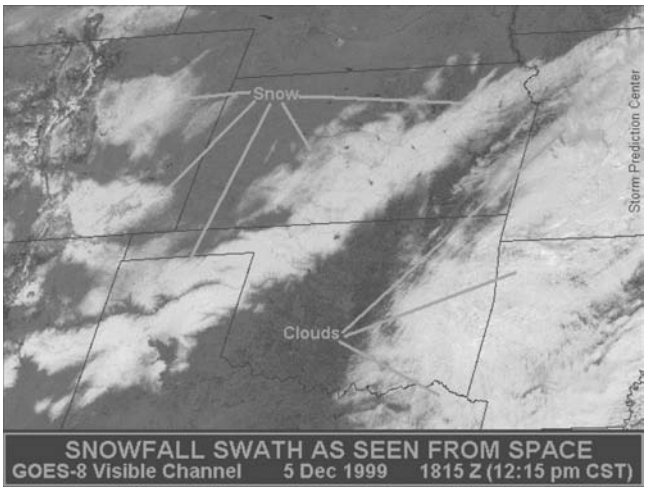

Figure 6 Satellite image from 05 December, 1999, 1815 UTC, showing a snow band of mesoscale width (roughly 100–150 km), from southeast New Mexico, across the Texas Panhandle, Oklahoma, and Kansas. The Canadian River valley can be seen as the dark line within the snow band in the Texas Panhandle, as can several large man-made lakes (the dark spots) within the snow band in Oklahoma and Kansas (NOAA Image provided by the Storm Prediction Center). SMALL-SCALE STORM SYSTEMS

As the scale of atmospheric phenomena decreases below that of the mesoscale, it again becomes possible to make simplifying approximations. For example, the curvature and rotation of the Earth can be neglected for many small-scale phenomena. Events that might plausibly be called storms on this scale are primarily *thunderstorms*. Thunderstorms arise when the input of latent and sensible heat at low levels cannot be moderated fast enough by processes on larger scales (Doswell, 2001). Thus, the occurrence of thunderstorms and the weather they produce (strong winds, hail, tornadoes, extreme rainfall rates, and lightning strikes) is associated mostly with land surfaces (Figure 7), as illustrated by the global distribution of lightning. Thunderstorms typically develop during the daytime within the warm season.

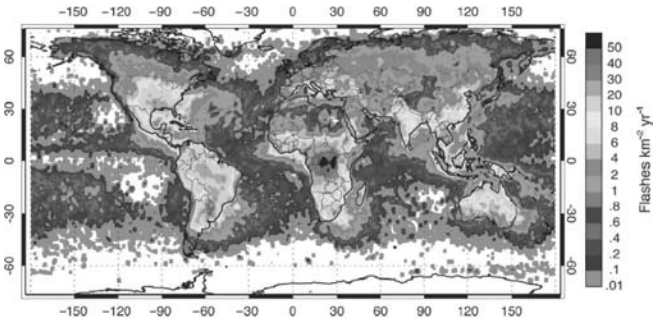

Figure 7 Global lightning flash distribution (from Christian, H.J., R.J. Blakeslee, D.J. Boccippio, W.L. Boeck, D.E. Buechler, K.T. Driscoll, S.J. Goodman, J.M. Hall, W.J. Koshak, D.M. Mach, and M. F. Stewart, 2003: Global frequency and distribution of lightning as observed from space by the Optical Transient Detector. *J. Geophys. Res.*, 108 (D1), 4005–4019. Reproduced by permission of American Geophysical Union). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Exceptions to this can be found, owing to topographic details, as in the relatively high thunderstorm frequencies over the warm waters of the Gulf Stream, east of the United States. When the low levels are warmed and the air contains sufficient moisture, the atmosphere is said to become gravitationally unstable – under such circumstances, plumes of heated air rising from near the surface reach condensation, becoming *towering cumulus* clouds (Figure 8a). These evolve rapidly into mature thunderstorm clouds, called *cumulonimbus* (Figure 8b). After maturity, ordinary thunderstorms dissipate (Figure 8c). The entire life cycle of such a prototypical *thunderstorm cell* is roughly 20–30 min (Byers and Braham, 1949), and most thunderstorms include a sequence of such clouds forming, moving through their life cycles, and dissipating. Thus, they are termed *multicell* thunderstorms and they can be rather ordinary, or they can become severe thunderstorms. The criteria for storms being called *severe* are generally arbitrary; in the United States, if a thunderstorm produces winds of 50 knots ($25\,m\,s^{-1}$) or stronger, hailstones of diameter 3/4 inch (2 cm) or larger, or a tornado, it is deemed a severe thunderstorm (Galway, 1989). Heavy rainfall is not considered officially severe in the United States.

The physical process driving thunderstorms is buoyancy and that buoyancy is strongly dependent on latent heat release. Thus, for thunderstorms to occur, the heat content at low levels must be high relative to that in middle and upper levels (instability), some process to cause air from low levels to rise to a height where it becomes buoyant is needed (lift), and there must be sufficient moisture in the ascending air to maintain the buoyancy. Without any one of these three ingredients (moisture, instability, and lift), thunderstorms cannot form. Thunderstorms act to reduce the instability by redistributing the heat (sensible and latent) from low

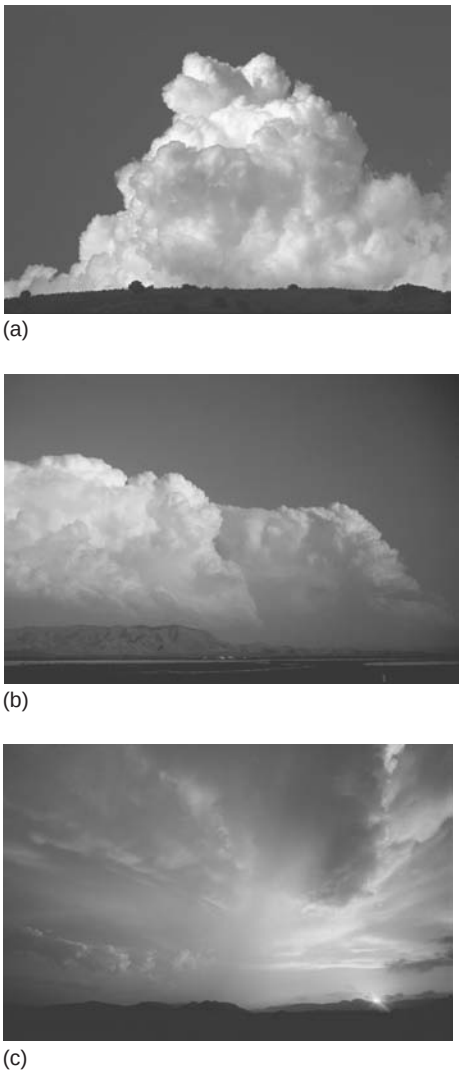

Figure 8 Life cycle stages of ordinary thunderstorms: (a) towering cumulus stage, (b) mature cumulonimbus stage, and (c) dissipating stage (Photographs © C. Doswell, used by permission). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

levels upward. Once they have accomplished the needed heat redistribution, then thunderstorm activity ceases.

Most thunderstorms are ordinary, in the sense that they do not produce phenomena that meet the criteria to be called *severe thunderstorms*. Perhaps a few percent of all thunderstorms become severe, with most of them only barely meeting the criteria. Out of all the severe thunderstorms, a small fraction (on the order of a few percent) of them are *supercell* thunderstorms. Almost all supercells (around 95%) produce one form or another of severe weather. A supercell develops under conditions that favor thunderstorms in the presence of strong vertical wind shear. Thunderstorms that develop in strong vertical wind shear transform that vertical wind shear into rotation about a vertical axis, at times visually evident

Figure 9 Tornadic supercell thunderstorm on 3 June, 1999, showing structures characteristic of a rotating storm, in which air in the storm is moving left to right in the foreground, into the photograph on the right-hand edge of the clouds, and right to left in the background, spiraling inward to the tornado, which is partially obscured by precipitation (Photograph © C. Doswell, used by permission). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

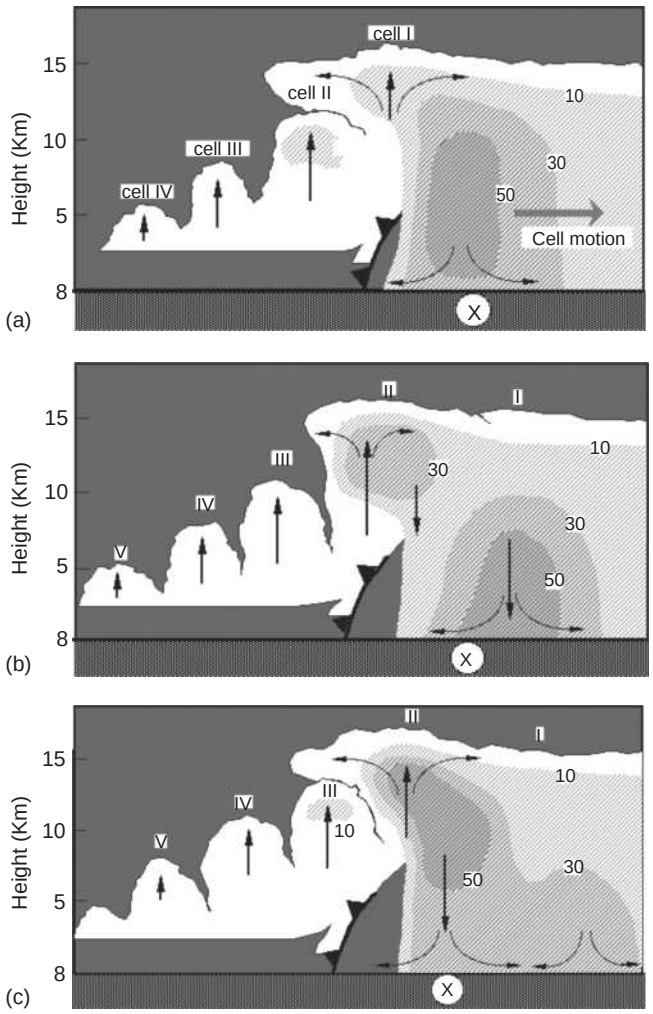

Figure 10 Schematic of the ''training'' effect. (a) At this time, there are four numbered thunderstorm cells in various stages of development. Cell I is mature, with both updrafts and downdrafts, and heavy rain is about to commence at point ''X''. Cells II, III, and IV are still developing, and have only updrafts. Cell II has precipitation forming aloft. The hatched contours are radar reflectivity, in units of dBz, which is related to the rainfall rate. (b) About 15 min later, Cell I's updraft is dissipated, and it is now dominated by downdraft. Heavy rain continues at ''X'' while Cell II is maturing and developing a downdraft. Cells III, IV, and now V are still immature. (c) About 15 more minutes have elapsed. Cell I's rainfall is continuing but it is now nearly dissipated, while Cell II is entering late maturity. It is still raining at ''X'' but now the rainfall is from Cell II, and heavy rain from Cell II is descending from aloft. Now Cell III is developing its first precipitation aloft. Cells IV and V are still immature (Doswell *et al.* (1996). © 1996 American Meteorological Society). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

in a spiral structure to the storm (Figure 9). In the northern hemisphere, this interaction results in counterclockwise rotation concentrated in the so-called *mesocyclone*. (Note that this term is something of a misnomer, since it seems to suggest a mesoscale process, but the horizontal scale of a mesocyclone is on the order of a few kilometers, too small to be properly considered mesoscale.) It is the presence of a deep, persistent mesocyclone that distinguishes supercells from ordinary thunderstorms. Owing to the organizing dynamics of mesocyclones, supercells can become quasi-steady and persist for several hours, much longer than the typical ordinary thunderstorm cell. They also can be responsible for the most violent severe thunderstorm phenomena: families of strong-to-violent tornadoes, hailstones with diameters exceeding 2 inches (5 cm), and wind gusts exceeding 65 knots ($32\,\mathrm{m\,s^{-1}}$). This is the result of dynamical processes that produce the supercell and enhance the vertical motions in such storms beyond that expected from buoyancy effects alone.

Thunderstorms also can become organized into lines of interacting thunderstorm cells, sometimes called *squall lines*. These often are large enough to be considered mesoscale in extent and so are properly termed *MCSs*. However, this tendency for linear organization of storms persists into scales arguably near or below any particular arbitrary threshold separating "mesoscale" from "small-scale". Any time that thunderstorms can become organized, the potential for severe weather increases. Although many heavy rain-producing thunderstorms are not severe by official criteria used in the United States (see above), they can be organized to produce dangerous flash floods under the right

hydrological circumstances. Generally, thunderstorms that produce heavy rainfall are associated with the repeated passage of mature thunderstorm cells over the same general region; this is the so-called *training effect*, illustrated schematically in Figure 10. Training of thunderstorm cells results in localized heavy rainfall amounts and is by far the most common evolution associated with flash-flood producing storms. Supercells often produce large instantaneous rainfall rates owing to their intense updrafts, but they typically do not remain in one place long enough to create high rainfall totals. Nevertheless, when the rainfall rate reaches $200\,\mathrm{mm\,h^{-1}}$, which some supercells have attained, they can produce dangerous urban flooding in as little as 15 min (Smith *et al.*, 2001).

Nearly stationary rainstorms can also develop when airflows upslope, as noted above. Sometimes, such rainstorms occur with little or no lightning, while at other times, upslope rainstorms are associated with considerable lightning and thunder. Whether they are thunderstorms or not, they can produce small-scale regions of very heavy rainfall when the upslope slow persists for many hours.

On rare occasions, some snowstorms are accompanied by lightning and thunder. In such events, the instantaneous snowfall rates can be quite high (instantaneous rates might be as high as $25\,\mathrm{cm\,h^{-1}}$, but such rates are not typically sustained for long). Although intense winter storms such as lake-effect snowstorms and upslope snowstorms are likely to be more properly considered mesoscale events, the peak values associated with such storms might be less than 100 km in spatial scale and so represent small-scale events embedded within a mesoscale storm system.

28: Clouds and Precipitation

GEORGE A ISAAC[1] AND JOHN HALLETT[2]

[1]Cloud Physics and Severe Weather Research Division, Meteorological Service of Canada, Toronto, ON, Canada
[2]Division of Atmospheric Sciences, Desert Research Institute, Reno, NV, US

Clouds and the precipitation that comes from them are important elements of the hydrological cycle. Clouds provide a blanket for our Earth, both shielding it from radiation from the Sun and trapping heat escaping from the surface. They also generate precipitation through the condensation-coalescence mechanism, which involves only liquid cloud drops, or through ice initiation leading to large ice particles and eventually snow or rain. Mean annual precipitation amounts reach a maximum near the equator, near 8 mm day^{-1}, and decrease poleward to about 1 mm day^{-1}. A good understanding of both cloud and precipitation processes is very important for climate and weather predictions. This paper outlines some of the most important processes and provides reference material where more detailed information can be obtained.

INTRODUCTION

Earth is covered with clouds as any satellite photo of our planet will show. Figure 1 shows a cloud climatology from the GEWEX Surface Radiation Budget data set (Whitlock *et al.*, 1995). Almost everywhere, the annual mean cloud cover is greater than 50% and in some large areas it is greater than 80%. These clouds literally provide a blanket for our Earth, both shielding it from radiation from the Sun and trapping heat escaping from the surface. Understanding clouds is extremely important for both climate and weather predictions because their presence or absence can strongly affect surface temperatures. Figure 2 shows that for a station in northern Canada, the presence of cloud in the wintertime makes the surface warmer, while it provides a cooling effect in the summertime.

Life cannot exist without water and in most cases we get our water from precipitation. Figure 3 shows the annual mean precipitation rate as compiled by Xie and Arkin (1996, 1997) using gauge observations, satellite estimates and numerical model outputs. Precipitation amounts reach a maximum near the equator, near 8 mm day^{-1}, and decrease poleward to about 1 mm day^{-1}. The higher temperatures in the tropical regions produce strong convection and more precipitation, with cloud base temperatures being greater than 20 °C. It should also be mentioned that the area of the earth in the tropical regions is much greater than that at the poles, which also accounts for a greater amount of precipitation in that region. At the poles, the temperatures are low and the stratiform clouds that exist barely produce precipitation, less than 1 mm per day.

There are many uncertainties in our knowledge about clouds and precipitation. However, much progress has been made and this article will briefly summarize our current knowledge, and point to more comprehensive articles where additional information can be found. Earlier textbooks on cloud physics which provide useful information include those written by Fletcher (1962) and Mason (1971). More recently, a general textbook on cloud physics has been written by Rogers and Yau (1989) and a more detailed book on the microphysics of clouds and precipitation was published by Pruppacher and Klett (1997).

CLOUD FORMATION AND TYPES

Clouds can exist in many forms in the atmosphere. See the World Meteorological Organization International Cloud Atlas (WMO, 1975, 1987), the AMS Glossary (Glickman, 2000) and Scorer (1972) for a full description of cloud types. Cirrus clouds form at temperatures below −40 °C, generally occur above 5 km, and they cover wide areas in a

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

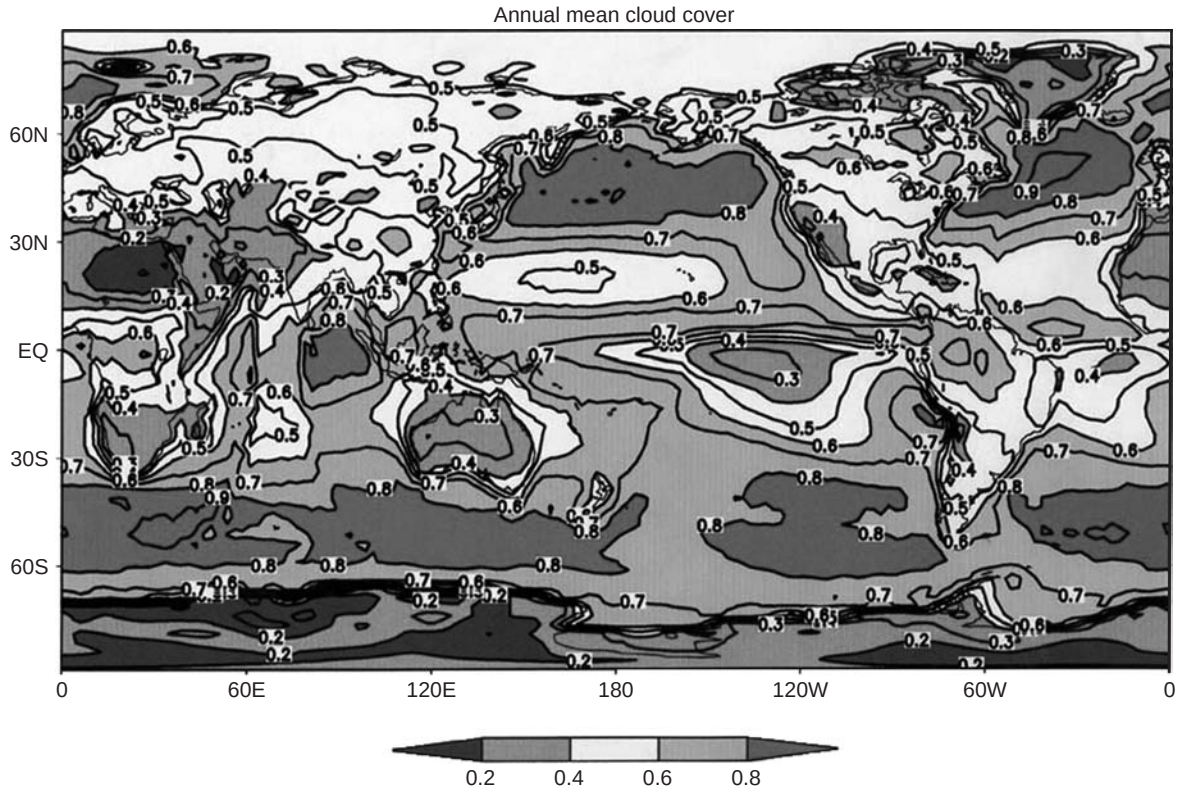

Figure 1 Mean annual cloud cover as seen from satellite as a function of latitude and longitude. From the GEWEX surface radiation budget data set (Whitlock *et al.*, 1995. © 1995 American Meteorological Society). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

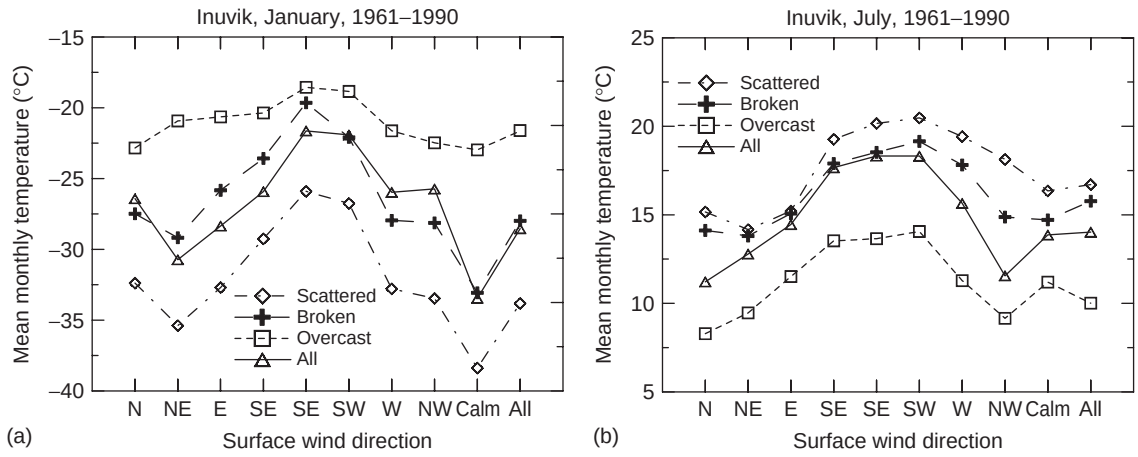

Figure 2 January and July mean monthly temperature at Inuvik, Northwest Territories, Canada, as a function of cloud cover and surface wind direction. ''Scattered'' indicates 0–1 tenth sky, ''broken'' 2–8 tenths, and ''overcast'' 9–10 tenths sky coverage (Isaac and Stuart, 1996. © 1996 American Meteorological Society)

sheet form, often with a fibrous aspect (Figure 4a). Below this temperature, ice crystals form even in the absence of insoluble nuclei in cloud drops and a few degrees lower in diluted haze droplets. Cirrus can form from broadscale uplift, in the outflow of thunderstorms, or even from the vapor trails caused by high-flying jet aircraft (Figure 4b). These clouds generally do not create precipitation that reaches the ground and they are primarily formed of ice crystals. However, they can start to precipitate (Figure 4c) and the falling ice crystals can "seed" lower layers of

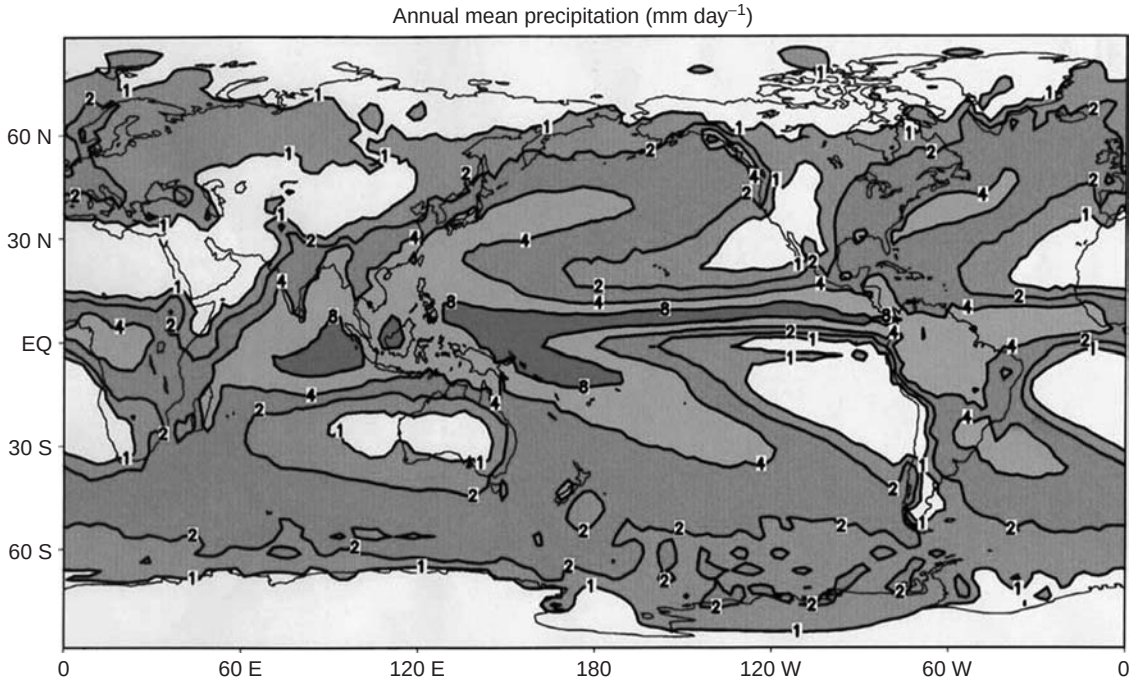

Figure 3 Annual mean precipitation (mm day^{-1}) as compiled by Xie and Arkin (1996, 1997) using gauge observations, satellite estimates and numerical model outputs (Xie and Arkin, 1996. © 1996 American Meteorological Society). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

cloud and initiate precipitation. Mid-level clouds such as altostratus or altocumulus are also formed by broadscale lifting, often produced by frontal systems. They can be composed of either ice crystals or liquid water, but they do not account for much of our precipitation. Lower-level cloud types such as stratus, and stratocumulus (Figure 4d, e) are associated with precipitation, either snow or rain. In midlatitudes, especially in winter, these cloud types account for most of our precipitation. Cumulus clouds (Figure 4f) and especially thunderstorms (Figure 4e) create most of our precipitation in the summer at mid- and lower-latitudes.

Clouds are generally formed in circulation around low pressure cyclonic storm systems, with precipitation taking place at fronts where higher temperature, moist air if lifted above cooler air. Mesoscale complexes and hurricanes form towards the tropics and easterly waves form convergence zones for precipitation in low-latitude tropical regions.

WATER PHASES, LATENT HEAT

Water in the atmosphere exists in three phases: vapor, solid, and liquid. Cloud and precipitation formation involve transforming vapor into the other two phases. A vapor to liquid phase change occurs through condensation and the reverse process involves evaporation. A vapor to solid phase change is called *deposition*, while the reverse is called *sublimation*. The liquid to solid phase change involves the freezing process, while melting occurs when solid water changes to liquid. Phase changes occur with the corresponding release or uptake of latent heat. For example, in order for water to change from the liquid to vapor state, latent heat is required to break the hydrogen bonds between water molecules in the liquid. This is called *the latent heat of vaporization*. Similarly, *the latent heat of fusion* is required to change from the solid to liquid state. The *latent heat of sublimation* is released when vapor changes directly into ice. Normally, phase changes from liquid or solid to vapor occur when the air is subsaturated with respect to liquid water or ice, and the reverse happens when the air is supersaturated.

The Clausius–Clapeyron equation, one of the most important in cloud physics, relates the saturation vapor pressure with respect to water (e_s) or ice (e_i) to the latent heat of either vaporization (L_v) and or sublimation (L_s) to temperature (T). For the saturation vapor pressure over water, the equation may be written:

$$\frac{de_s}{dT} = \frac{L_v e_s}{R_v T}$$

where R_v is the gas constant for water vapor (461.5 J kg^{-1} K^{-1}).

Table 1 shows the saturation vapor pressure over water and ice, and the latent heats of vaporization (condensation)

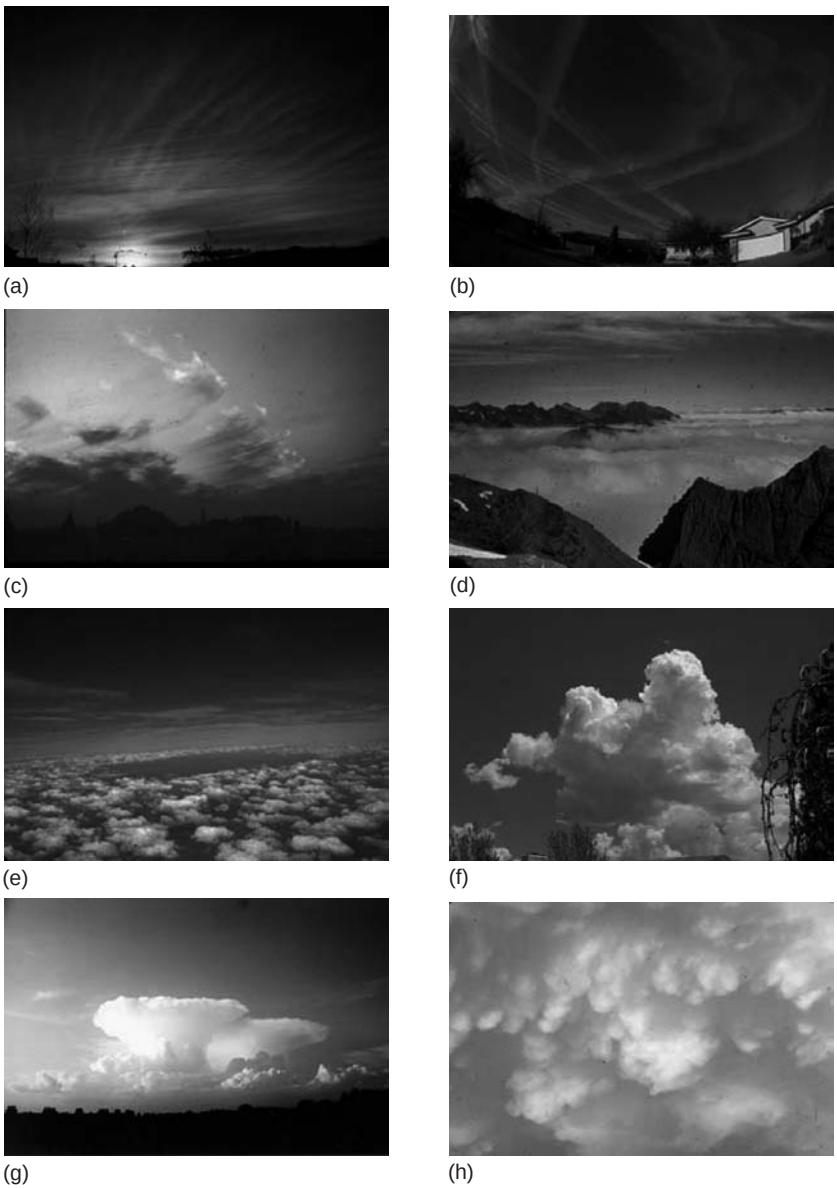

Figure 4 Some examples of cloud types such as: (a) cirrus cloud, (b) cirrus clouds produced by high-flying aircraft (contrails), (c) cirrus clouds with falling ice crystal streaks, (d) stratus clouds below an inversion, (e) stratocumulus deck, (f) cumulus cloud, (g) thunderstorm, and (h) mammatus. and sublimation as a function of temperature. The latent heat of fusion, which is released when ice changes to liquid, is the difference between L_v and L_s. The high values of the latent heat of vaporization of ice and water, compared with the latent heat of fusion (melting/freezing) show that water molecules are mostly bonded in both liquid and solid, and the bonding only changes by about 12% on melting. It is clear from Table 1 that warm air can hold much more water than cold air. For example, at $-10\,^{\circ}\mathrm{C}$, $0\,^{\circ}\mathrm{C}$, $+10\,^{\circ}\mathrm{C}$ and $+20\,^{\circ}\mathrm{C}$ and 1000 mb, the saturation mixing ratio over water is approximately 1.8, 3.8, 7.8 and 15.0 g of vapor per kg of air, respectively (List, 1968). This helps explain why there is more precipitation in the Tropics than in the Arctic.

ATMOSPHERIC STABILITY AND CLOUD FORMATION

In order to consider how clouds form in the atmosphere, it is necessary to understand atmospheric stability and the

Table 1 The saturation vapor pressure over water and ice, and the latent heats of vaporization (condensation) and sublimation as a function of temperature (from Rogers and Yau, 1989). Papers by Fukuta and Gramada (2003) and Marti and Mauersberger (1993) are examples of recent works that attempt to measure the saturation vapor pressure over water and ice more accurately

T (°C)	e_s (Pa)	e_i (Pa)	L_v (J g^{-1})	L_s (J g^{-1})

normal temperature profile of the atmosphere. Typically, as you go further up in height, the pressure falls and the temperature decreases. For a parcel moving upward, without condensation occurring, its temperature cools down following a dry adiabatic lapse rate of approximately 0.98 °C per 100 m. For a parcel where condensation has commenced, the release of latent heat slows the cooling of the parcel as it ascends and the parcel follows a wet adiabat (0.65 °C per 100 m at 0 °C and 1000 mb) approaching the dry adiabatic lapse rate at temperatures below −40 °C where the amount of vapor is minimal.

Figure 5 shows atmospheric soundings for two severe weather events. On 3 May 1999, intense tornadoes were generated by severe thunderstorms and killed 36 people near Norman Oklahoma (Thompson and Edwards, 2000; Brooks and Doswell, 2002). The sounding is unstable above about 1.5 km (a saturated parcel would keep rising through buoyancy), showing the potential for convection. The sounding on 9 January 1998 for Gray, Maine, was during an intense and very prolonged freezing rainstorm (DeGaetano, 2000). The atmosphere is stable in this sounding but shows a deep saturated layer with a warm section reaching about +12 °C near 1.5 km with a below freezing surface layer.

WARM RAIN PROCESS

Water generally condenses in the atmosphere around hygroscopic particles known as *cloud condensation nuclei* (CCN) Table 2 shows the relative sizes and fall velocity dependence on diameter of cloud nuclei (CN) which are only active at very high supersaturations, CCN around which most cloud droplets form, and Ultra Giant Nuclei, (UGN) which can form the nuclei of large cloud drops. Effective CCN are sodium chloride containing particles formed in sea spray or ammonium sulfate particles from anthropogenic sources, possibly also contaminated further by equally deliquescent organic materials. These CCN deliquesce at conditions less than about 80% relative humidity, or when the air is subsaturated with respect to water, resulting in haze. More typically in clouds, at supersaturations of less than 1%, small droplets are quickly formed around these CCN reaching sizes of 5 to 15 μm. The actual number activated depends on the chemical composition of the CCN particles. More efficient CCN, as are typically found in maritime environments, activate at lower supersaturations. Larger updrafts tend to create higher supersaturations, with more CCN activated, and thus higher droplet number concentrations. Typically, maritime clouds have lower droplet

Table 2 Function relationships for terminal velocity for different particle types. As a first approximation, spheres in the range from 1 to about 100 μm follow Stokes law, with velocity proportional to diameter squared. Smaller and large particles follow a linear relation; particles larger than 0.5 cm follow a square root relationship (assuming a constant drag coefficient) up to 10 cm hail. Snow flakes and larger ice crystals follow Stokes law below about 100 μm but have constant fall velocity with size beyond a few mm. Brownian motion gives an inverse relation for molecular cluster size pollution particles, and inverse square root relation for particles greater than 0.02 μm. The fall velocity and Brownian displacement random direction velocity are comparable for particles of diameter near a fraction of a micron, depending on particle density.

Diameter (d)		Terminal velocity or displacement dependence	Regime
cm	Rain, hail	$\sqrt{d}$	Constant drag coefficient
500 μm	Small rain, drizzle	d	
10 μm	Cloud droplets	d^2	Stokes
10 μm – 1 μm	UGN	d^2	Stokes–Cunningham
1 μm – 0.1 μm	CCN		
10^{-2} μm	CN	$\frac{1}{\sqrt{d}}$	Brownian motion
10^{-3} μm	Molecular cluster	$\frac{1}{d}$	Stokes/Cunningham/self diffusion

Note: CN – cloud nuclei, CCN – cloud condensation nuclei, UGN – Ultra Giant Nuclei

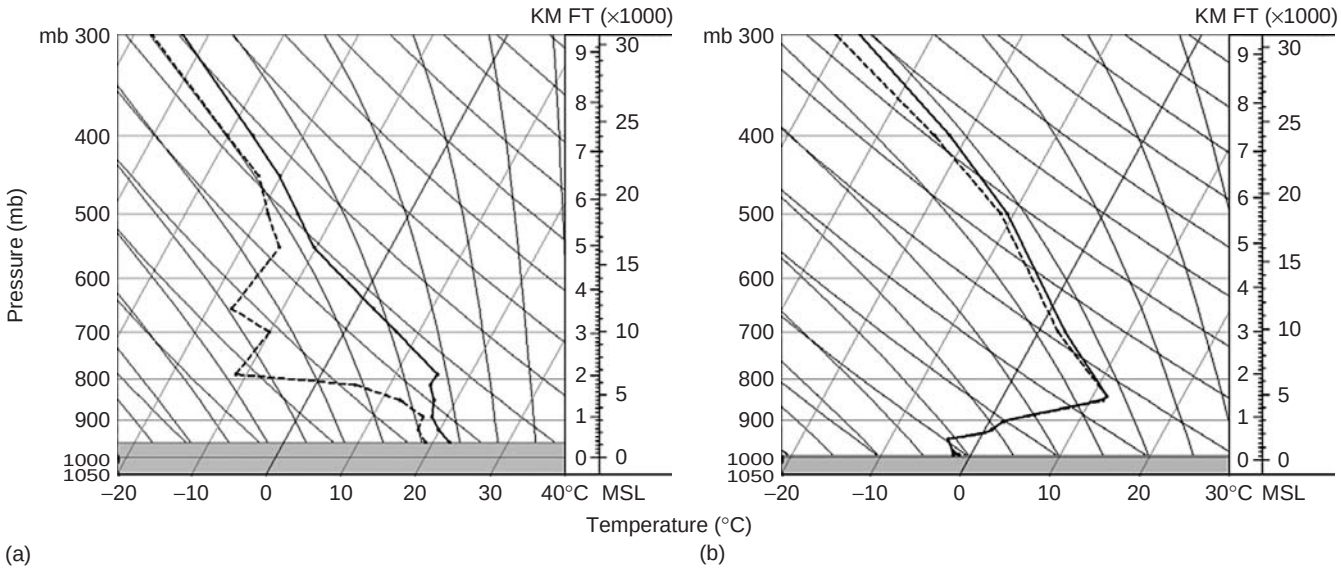

Figure 5 Pressure versus temperature atmospheric soundings for 4 May 1999 at 00 UTC for Norman, Oklahoma (a) and 9 January 1998 at 00 UTC for Gray, Maine (b). The horizontal lines represent pressure, the lines running from the bottom up to the right represent constant temperature, the curved lines running upwards towards the left represent wet adiabat lines, while the approximately straight lines running up and to the left represent dry adiabats. The dark line on the right represents the temperature profile in the atmosphere while the dashed line on the left represents the dewpoint. The altitudes below the station elevation are shaded. As an example, the 9 January sounding has a surface temperature near −2 °C, and it reaches a maximum temperature at +12 °C near 850 mb (1.5 km), and then gets colder than 0 °C at about 750 mb (3.5 km). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

number concentrations and larger droplet sizes than continental clouds (see Table 3).

The cloud droplets that form in a cloud grow by condensation in the presence of a persistent updraft that generates a small supersaturation. As they grow, the droplets also begin to collide with one another and grow by the collision-coalescence mechanism. This mechanism is most efficient when some of the droplets are larger than others (20 to 40 μm). It is more efficient in maritime clouds where for the same liquid-water content, because of the reduced droplet number concentration, the drops tend to be larger (see Table 3). As Rogers and Yau (1989) indicate "the central task of precipitation physics is to explain how raindrops can be created by condensation and coalescence in times as short as 20 min." Rain appears to form in such a time interval in nature. There are considerable uncertainties involved in this "warm rain" process but it is critical that the drop-size distribution widens, so that it permits the coalescence process to work effectively. It will take about 10^5 small cloud droplets to form a raindrop 1 mm in diameter. Drops have to be larger than 500 microns in order to be considered raindrops. Drops between 200 and 500 μm are considered as drizzle (AMS Glossary–Glickman, 2000). Figure 6 shows the relative sizes of cloud aerosols, cloud droplets and raindrops that are involved in the warm rain process.

Although the warm rain process is commonly used to describe the process of condensation followed by coalescence in clouds >0 °C, it also works in supercooled clouds down to at least −20 °C and probably below (e.g. Rasmussen *et al.*, 1995; Cober *et al.*, 1996; Kajikawa *et al.*, 2000; Lawson *et al.*, 2001). Such large supercooled drops forming at cold temperatures are important for aircraft icing processes and precipitation formation in tropical convection.

BERGERON–FINDEISEN OR ICE PRECIPITATION FORMATION PROCESS

Clouds exist in the atmosphere at temperatures colder than 0 °C. Many of these clouds contain liquid water in the supercooled state. When ice is also present, a precipitation formation process can commence whereby ice crystals grow by aggregation of ice particles or riming of cloud droplets. The resulting precipitation can fall to the ground as either snow or rain, depending upon the freezing level. Mixed-phase clouds which contain both liquid and ice occur quite frequently in the atmosphere, as the summary by Korolev *et al.* (2003) has shown. Liquid water typically will not freeze until about −40 °C unless it has some impurities in it known as *ice nuclei* (IN), such as clay mineral particles (Roberts and Hallett, 1968). Although ice melts at 0 °C, it does not form in the

Table 3 Cloud microphysical summaries, using 30 s or 3 km pathlength averages, for maritime and continental cases in terms of static temperature (Ta), droplet number concentration (Nd), total water content (TWC) and median volume diameter (MedVD). The ice crystal concentration is represented as I. As an example, 25% of the maritime droplet concentrations (Nd) were less than 16 cm^{-3}. These data were collected as part of the Canadian Freezing Drizzle Experiment (I and III) and the Alliance Icing Research Study I (from Isaac *et al.*, 2001) and they represent stratiform mid latitude winter clouds. Reproduced from Isaac *et al.*, 2001, © Canadian Aeronautics & Space Institute

[a]Liquid and mixed-phase, in-icing conditions.

atmosphere at any well-defined temperature. As described in cloud physics texts, generally insoluble IN can activate the process by allowing vapor to go directly into the ice phase (deposition nuclei), by condensation onto the IN followed by freezing (condensation freezing nuclei), by IN contact with a supercooled droplet (contact nuclei), or by IN immersion into a droplet followed by freezing (immersion nuclei). A typical concentration of IN might be 1 per liter near −20 °C, with a variability of X10 in concentration not being uncommon. Once ice is initiated, the concentration can increase via several ice multiplication mechanisms. For example, evaporation and melting of ice particles creates locally thinner regions leading to breakup, or during the riming process in the presence of graupel and large cloud drops, the freezing and shattering of favorably accreted drops can occur (Hallett and Mossop, 1974). Many have tried to show that ice nuclei concentrations are dependent on temperature (Fletcher, 1962), or both temperature and supersaturation (Meyers *et al.*, 1992). These relationships are often used in numerical models. However, observations often show (e.g. Gultepe *et al.*, 2001) that ice particle concentrations in the atmosphere do not depend on temperature, and appear to be the same in different geographic regions. Ice nuclei and ice particle concentrations found in clouds are not easily related to each other because of possible ice multiplication mechanisms and the redistribution of ice particles within clouds. The measurement uncertainties for both IN and small ice crystals are also substantial. Ice initiation in the atmosphere is a complicated process that is not well understood. It should be noted that the existence of any extensive region of supercooled drops depends on an absence of ice particles and nuclei, while the universal presence of ice suggests a remarkably efficient redistribution system, as in a mature hurricane or an extensive occluded cold, deep, midlatitude low pressure system.

Small ice crystals have many shapes generally based on hexagonal or sixfold symmetry. These can include columns, needles, plates, dendrites, and so on (Figure 6). Magono and Lee (1966) discuss ice particle shapes as a function of temperature (0 to −40 °C) and supersaturation. Bailey and Hallett (2004) have recently updated the work at temperatures colder than −20 °C and extended the temperature range to −70 °C. Much of this work on ice particle shape was done in the laboratory under controlled conditions. Measurements in natural clouds, especially lower-level layered cloud, show that ice particles tend to have quite irregular shapes, either consisting of faceted polycrystalline particles or sublimating (solid to vapor) ice particles with smooth curving sides and edges (Korolev *et al.*, 1999, 2000; Figure 7). More recent work on quantifying shapes has found that ice particles tend to be "rounder" when they are smaller, except for a small fraction which grow as pristine single crystals. As the remainder grow larger, having many crystal orientations, they tend to get more shaped (Korolev and Isaac, 2003).

The saturation vapor pressure over ice is less than the saturation vapor pressure over water for all temperatures (Table 1), resulting from the greater bonding of water molecules in the ice lattice as compared with supercooled liquid water. Consequently, in a supercooled cloud, once ice crystals begin to form, they grow rapidly by deposition while the surrounding droplets evaporate. If the cloud is not growing with a substantial updraft, the ice crystals will dominate and can quickly convert all the liquid to ice in a process called *glaciation*. Once the ice crystals reach a certain size they begin to fall and accrete water droplets through a process known as *riming*. They can

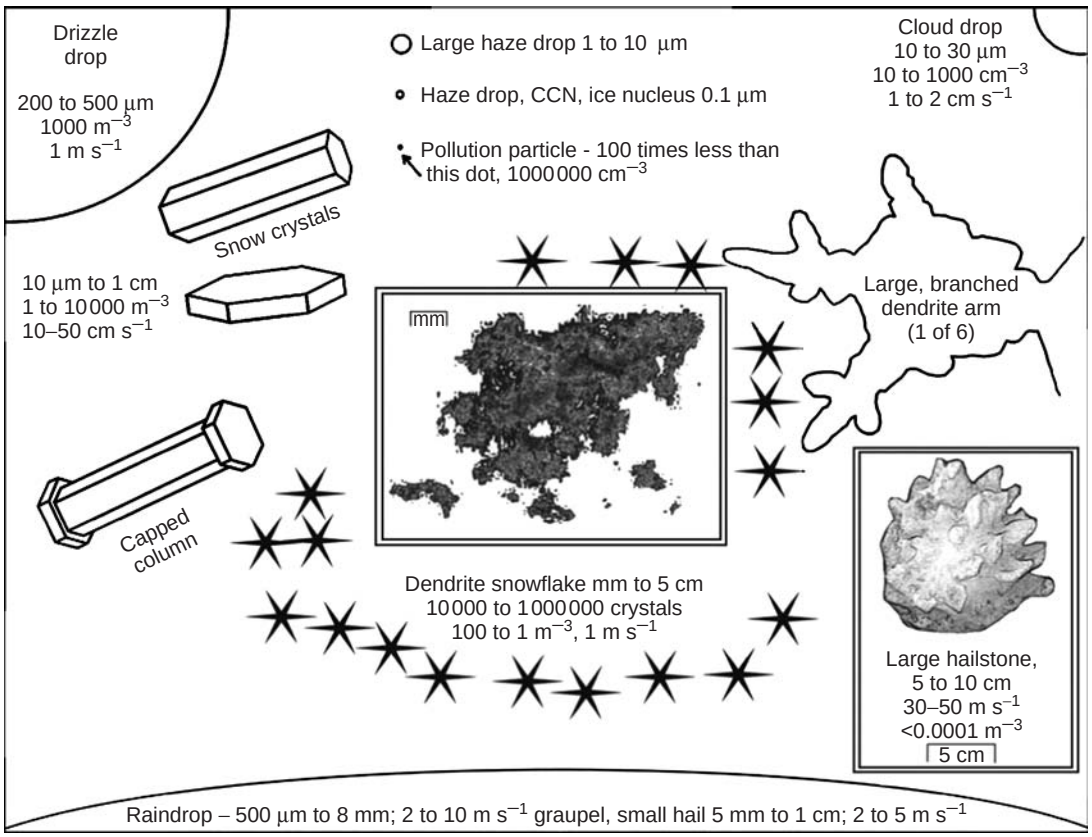

Figure 6 Relative sizes and shapes of cloud aerosols (haze particles, ice nuclei), cloud droplets, raindrops, ice crystals, snowflakes, graupel and hail (Adapted from Wallace and Hobbs, 1977; McDonald, 1958). Typical diameters, concentration, and fall velocities are given. For an additional sizing reference, a human hair is about 100 μm in diameter. The ice crystals shown are the classical hexagonal shapes, depending on the growth conditions. Columns form near −4 °C and plates at higher and lower temperatures, which sometimes lead to a capped column. Dendrite arm side branches may be symmetric or otherwise depending on the ambient turbulence (Hallett and Knight, 1994). Most ice particles have irregular shapes (e.g. Korolev *et al.*, 1999, 2000) resulting from different nucleation and changing growth conditions

also aggregate with other ice crystals to form snowflakes. Formation of precipitation via this mechanism accounts for most of the precipitation that forms in mid- and high latitudes. This theory was proposed by Bergeron (1935) and further refined by Findeisen (1938). Because it builds on the early work of Wegener (1911), it is referred to as the Bergeron–Findeisen–Wegener theory, or it is often shortened to the Bergeron–Findeisen process. As an illustration of this process, cirrus clouds often produce large ice crystals that begin to fall. If these ice crystals fall into lower-level supercooled liquid clouds, they can initiate precipitation. Much of the physical basis for cloud seeding or weather modification is to create the initial ice crystals by providing artificial ice nuclei, or through the use of a coolant such as evaporating dry ice which can produce temperatures well below −40 °C, near −80 °C.

This process produces rain because the resulting ice crystals typically melt when they fall into warmer air near the surface, with melting usually being complete for temperatures above +4 or +5 °C. However, most of our snow, when such a warm layer is not present, is also formed by the Bergeron–Findeisen process.

PRECIPITATION TYPES, DEW AND FROST

Precipitation as Rain

Precipitation may be defined as those particles falling from clouds in the atmosphere which reach the ground and remain for sufficient time to leave an observable residue of water. Table 2 shows how the fall velocities of different precipitation particles depend on their size. Precipitation it may be in the form of liquid-rain or drizzle as defined in Sections "Warm rain process" and "Bergeron–Findeisen or ice precipitation process" , either above 0 °C or supercooled below 0 °C. Drizzle and rain drops are spherical for sizes <0.8 mm. Larger raindrops deform during fall with the lower part flattening by the airflow (Figure 8). In contrast, cloud drops fall at a velocity of less than 100 cm s^{-1}

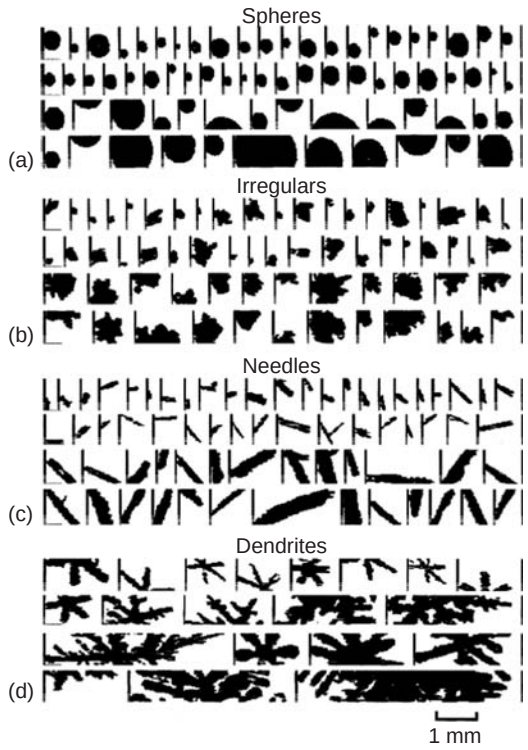

Figure 7 An example of different cloud particles as seen by a Particle Measuring System 2D imaging probe (Knollenberg, 1981) while flying through different clouds. (From Korolev *et al.*, 2000 by permission of The Royal Meteorological Society).

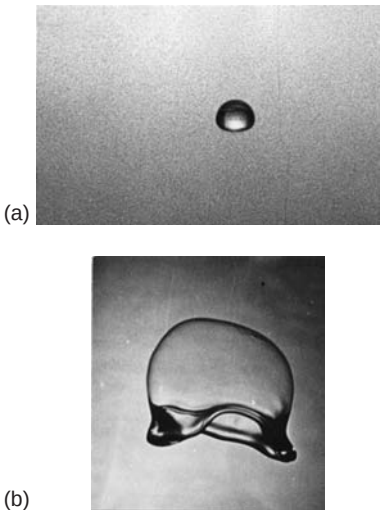

Figure 8 Shapes of drops. Drops in free fall in the atmosphere are in balance between their weight and drag forces resulting from both viscosity of the air and a hydrodynamic effect. With increasing size above about 20 μm, flow around the drop becomes increasingly asymmetrical, with a standing eddy wake and eventually shedding vortices, peaking by resonance with the drop surface tension for a size near 1 mm. Much below this size drops are spherical (Figure 9). Near this size resonance occurs and the drops move sideways during fall. At larger sizes the drop base becomes increasingly flatter (Figure 8a, 3 mm horizontal diameter), and eventually turn inside out and a large bubble forms, becoming greater than a centimeter in diameter (Figure 8b). As it blows up further, the film breaks and forms many small drops with intermediate size drops being formed from the lower ring remnant (© John Hallett)

dependent on the square of the size. Beyond about 6 mm, depending on ambient turbulence, the flat bottom may deform by the airflow, turning the drop inside out as a thin water film bag some 1–2 cm dimension with a ring at its base, which quickly breaks up into much smaller drops (Figure 8). This process limits raindrop size to 6 mm in more turbulent air, and up to >9 mm under quiescent conditions. The fall velocity of such particles increases to a maximum between 9 and 10 m s^{-1}. Figure 9 shows how the fall velocity of liquid particles increases from <1 cm s^{-1} for 10 μm diameter, approximately 100 cm s^{-1} for drizzle drops, >4 m s^{-1} for >1 mm raindrops. For a size a little less than 1 mm, the drop resonates with eddies shed from its rear and falls at angles as much as 40 degrees to the vertical. Larger and smaller drops fall straight down in quiescent air.

Drops splash and break on impact with the ground or vegetation, the splash depending on whether the ground is dry or wet and the depth of any liquid film. This spreads spores from fungi to considerable distances and aids their dispersal (Levin and Hobbs, 1971). Splash is different in fresh or ocean water and is highly complex (Hallett and Christensen, 1984). The drop impact yields first a crater, which subsequently retracts to an upward vertical jet which breaks. Small drops and drops from the breaking jet fall back into the water and penetrate to as much as 10 cm below the surface – but less in ocean water because freshwater has buoyancy (Figure 10).

Optical phenomena, such as rainbows, corona, and glory yield information on the nature of liquid cloud and precipitation particles from simple observation. Figure 11(a) shows the transition of snow scatter of white light to a well-defined rainbow as melting proceeds. The rainbow formed from large raindrops is a refraction process, but for smaller drops and cloud drops diffraction effects are increasingly important. Table 4 summarizes observations of common optical phenomena leading to inference of the form (drop size, crystal, shape, fall orientation) of the cloud or precipitation particles responsible. Distinction is made between phenomena viewed toward the sun, as ice halo and cloud corona and to phenomena opposite the sun as the rainbow or glory. Distinction is further made between phenomena having constant angular diameter as the primary and secondary rainbow (42, 50 degrees), rainbow and ice crystal halo (23 and 46 degrees) and variable diameter

Table 4 Inferences from common optical phenomena into the properties of atmospheric particulates. Distinction is made between phenomena viewed towards the sun direction (right column, ice halo, corona), opposite the sun direction (left column, rainbow, glory), and at 90 degrees, middle. Distinction is also made between phenomena depending on particle shape having near constant angle to the sun or antisun viewing direction (rainbow, halo) and phenomena having changing angles and colors depending on particle size (corona, glory). See Minnaert (1954), Greenler (1989), Tape (1994), Lynch and Livingston (2001)

Viewing direction		
Away from the sun direction (look at shadow of head)	At 90 degrees to sun direction	Toward sun direction
Primary rainbow: 42 degrees from sun; blue toward sun; red away from sun	Polarized light all directions; Haidinger's Brush Molecular scattering	22 degrees solar halo; red toward sun; blue away from sun
Two internal reflections inside near spherical raindrop $>100\,\mu$m diameter		Refraction by 120 degrees in hexagonal, ice crystals $>20\,\mu$m thick
Separation by Alexander's dark band		Dark outside of halo
Secondary rainbow 50 degrees away from antisun; inside red; outside blue		46 degrees halo; red toward sun; blue away from sun
Three internal reflections and refraction inside near spherical raindrop $>100\,\mu$m		Refraction by 90 degrees in hexagonal prisms $>20\,\mu$m in size
White rainbow; drop diameters 50–100 μm		Sun dog; enhanced colors at low angles in haloes
		Falling hexagonal crystals oriented horizontal by attached vortices
Diffraction effects and spread of drop-size wash out colors		
Supernumary rainbows, inside primary (brighter) and outside secondary bow, resulting from diffraction of different size drops leading to colors and different bow diameters. Intense with narrow drop-size spread >100um, < mm diameter		
Drops may oscillate with changing electric fields of a lightning discharge causing the rainbow to shake		
Away from sun/moon Glory (as around a shadow of head or aircraft)		Toward sun/moon Corona (as around sun or moon)
Colored rings around sun or moon resulting from diffraction effects from cloud droplets (occasionally ice spheres) A diffraction effect giving a wide range of ring diameters and colors		
Colors closer to primary colors (two adjacent primary colors missing)		Colors closer to complementary, white less primary interference color
Optical interference for $n\lambda/2 = d\sin\theta$ (λ = wavelength, d = droplet diameter, θ = half angle sun to ring, n = order of ring; sometimes $>n = 5$ visible). Smaller drops give larger diameter ring; sun angular diameter = 1/2 degree, rings visible to >10 degrees. Uniform droplet size gives intense colors, a spread gives washed out colors. Droplets size a few um to $>20\,\mu$m. Colors not uniquely related to drop size for values near few μm.		
For spatially uniform droplets, colors are in a well-defined ring. For clouds with drop size changing with viewing angle, as in clouds growing over a mountain, both corona and glory may change angle from place to place around the viewing direction. As a special case, for lenticular clouds up to >15 degrees from the sun, with limited dimension (5 degrees), the sun angle change is small compared with the drops in the cloud, which grow upstream and have a minimum size at the cloud leading and trailing edge and a maximum size in the middle. This leads to uniform colored regions tracing the cloud edge with constant d sin θ and changing orders of color. Turbulent cloud may also be colored (mother of pearl clouds) but with changing patchiness.		

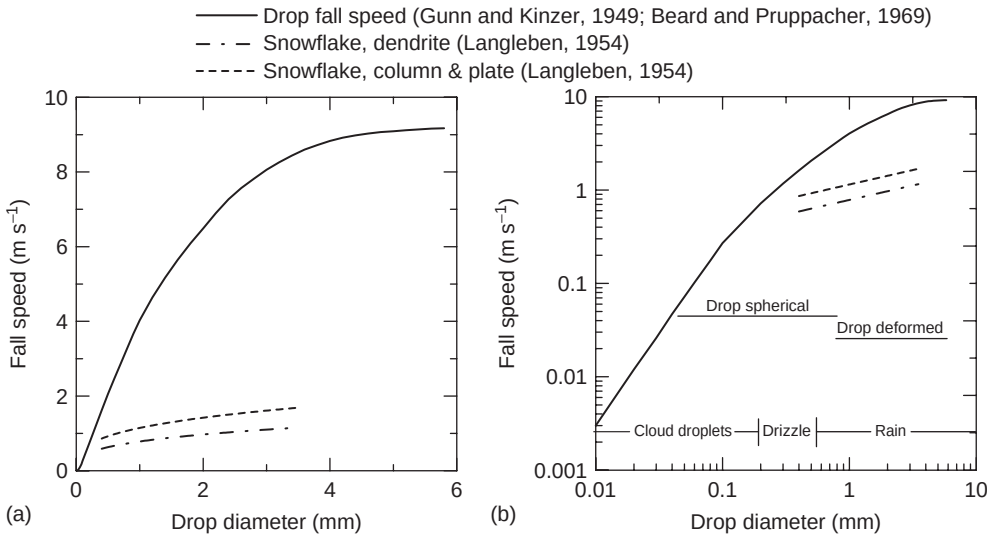

Figure 9 Fall velocity of drops, ice crystals and snow aggregates. Part (a) shows the fall velocity as a function of diameter on a linear scale, while part (b) shows it on a log scale in order to capture the full range of drops existing in the atmosphere. For the snowflakes, the melted equivalent diameter is used. Drops are spherical up to about 1 mm, increasingly deform by aerodynamic forces up to about 6–8 mm (depending on turbulence) and break up for larger size. Drops shed eddies and have a resonance with surface tension deformation with a resonance frequency of 320 hz for a diameter near 985 μm. They side slip during fall. Fall velocities decrease with deformation as compared with a frozen sphere

as the corona and glory. The former rely on the spherical shape of smaller raindrops and fixed angle of an hexagonal ice crystal, whereas the latter rely on different diameters of cloud drops in the viewing direction. A corona is observed looking toward the sun, and a glory is observed away from the sun with a distinction in the perceived color in the form of a ring for a uniform droplet size (Figure 11b and c). A smaller diameter implies larger cloud drops. Should cloud drop size be related to location (as in a lenticular wave cloud) well away from the sun, the contour of the cloud identifies the colors (Figure 11d and e).

Precipitation as Snow

Precipitation as ice occurs in many forms. Ice forms individual crystals as hexagonal columns or dendrites. These are ideal, pristine forms. It also occurs as rimed snow, graupel, or hail, as frozen drops, or as aggregates of other snow particles. Snow pellets and snow grains are variously defined (AMS Glossary – Glickman, 2000) and are more complex particles of ice precipitation often formed from multiple crystals grown from a frozen drop as an initial nucleus. The vapor growth habit of individual and also the component crystals of polycrystals (defined as the relative lengths of hexagonal direction compared with that at right angles) is related to growth temperature and growth supersaturation (relative humidity with respect to ice $>100\%$, up to about 140% for growth in cold supercooled clouds at temperatures approaching $-40\,^{\circ}$C). The local supersaturation also increases with fall velocity, which is dependent on the particle size and shape through the drag coefficient and the particle mass through its distribution of density. The density of snowflakes range from <0.1 to $0.4\,\mathrm{g\,ml^{-1}}$.

Figure 12(a–c) show individual crystals. Figure 12(d, e) show composite crystals resulting from growth under changing temperature. Snow flakes may be composed of pristine crystals or rimed crystals or mixtures of both. The presence of pristine crystals is readily inferred from observation by the presence of specific optical effects, Crystals in cirrus produce haloes of well-defined angles around sun or moon (Table 4, Figure 11f, g) and also sun dogs (parhelia) should the crystals become oriented during fall by attached wake eddies (Figure 11h). Thin section analysis in polarized light reveals a complex growth regime from the distribution of crystals and bubbles in small ice particles (Figure 12f, 12g). Fall velocities of ice particles are also shown in Figure 9. Ice particles and snowflakes fall much slower than liquid drops of the same size.

As snow falls to the surface, lower layers tend to compact because of the weight of the snow above. With temperature from some -15 to $-20\,^{\circ}$C and below, crystals retain their original habit for days or longer. Metamorphosis occurs by vapor evaporation from edges and redeposition at contact points. These processes eventually lead to bubbly ice, precursor to glacier ice and its ability to flow under the overlying stress. Bubbles shrink as the pressure increases and eventually disappear as the bubble air transforms to solid hydrate at hundreds of meters depth under pressures of many atmospheres. At higher temperatures, this change

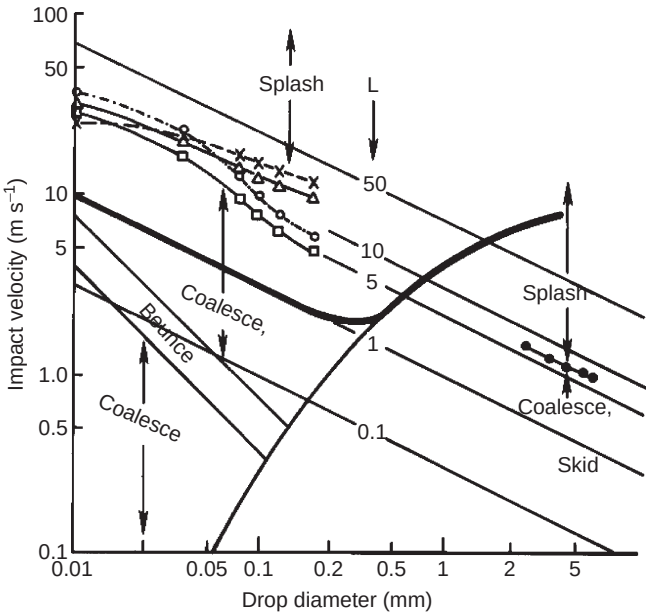

Figure 10 Drop Breakup and Splash Characteristics. Fog, drizzle or rain drops falling into a flat water surface, as a lake or ocean, behave in different ways depending on size and impact velocity. Assuming a terminal impact velocity (Figure 9), a drop, diameter <0.6 mm, forms a vortex ring which propagates into the liquid. The energy for propagation is the impact kinetic energy and the drop surface energy; the former dominates for large drops, the latter for small drops. L = ratio of kinetic to surface energy. Larger drops (diameter between 0.6 and 1.1 mm) leave a crater which collapses and projects a jet upwards which in turn breaks into smaller drops to fall back and reenter at a velocity well below terminal. Drops larger than 1.1 mm form a turbulent and wider jet which rises a shorter distance and also breaks before falling back. The jets are composed of liquid of the original drop and should sea water drops be lofted and evaporate under suitable wind conditions, provide large and ultragiant nuclei for cloud and drizzle drop formation. Drops diameter greater than 2 mm produce a rising thin film crown outward from their entry periphery, which may break up and produce a multitude of smaller drops, which provide smaller salt nuclei for smaller cloud drop formation. Some larger drops (>3 mm) entering the surface, without any local perturbation, produce a crown which closes at the top resulting in an air pressure reduction from the growth of the crater below and ultimately leave air bubbles, some 2 cm diameter with a flat base. These are readily seen in puddles and larger bodies of water under heavy rain conditions and persist a few seconds before draining and breaking. The splash is modified for a water layer of thickness comparable with the drop size (no crater or jet); freshwater entering sea water produces buoyant vortex rings which return toward the surface. Heavy rain on the ocean has a calming effect by providing a light water layer over a dense water layer and also transporting momentum from the top layer downwards. Local winds influence the splash pattern in even more complicated ways as does drop impact on wet sloping land, which influences the erosion of underlying soil

is much more rapid, leading to the granular (fraction of mm) nature of recently fallen snow near 0 °C. Vertical temperature gradients within the snow pack may lead to layers of vapor grown crystals close by layers of low-density snow, particularly near -4 and -15 °C. Such events are preludes to avalanches along these layers of weakness in mountainous terrain.

Dew and Frost Formation

Dew forms at the surface as drops up to 1–2 mm diameter, and may or may not wet the surface. They differ from guttation drops, typically formed on grass tips, formed by exuding water from the plant itself. In either case, a flux of vapor from moist air above or from damp soil vegetation below may be the source of dew or inhibit the evaporation of guttation drops. Dew formation follows radiative cooling of the surfaces when exposed to a clear sky or as moist air is advected over a cooled surface. With temperature below 0 °C, drops may supercool and nucleate over a temperature of several degrees below 0 °C. Most drops are frozen by -5 °C. With the initiation of ice, crystals grow from the vapor, in many ways having the same variability as snow crystals, although in the case of frost the ventilation varies from zero to ambient wind speed. Higher wind speed tends to mix out the cold surface layer producing the supersaturation. Most spectacular frost occurs with radiative surface cooling below 0 °C with moist air above, cooling and supersaturation spreading upward from the surface to give crystals at varying levels on surrounding vegetation (Figure 13a–c). Figure 13(d) shows ice boules that formed over a stream with the air temperature below 0 °C but the water temperature a few degrees above freezing.

Freezing Precipitation

Freezing drizzle and rain is a significant weather hazard involving rain falling into a layer colder than 0 °C at the surface, and then freezing upon contact. It can form either through the warm rain process, entirely at cold temperatures (Huffman and Norman, 1988), or by snow falling into a warm layer, melting, and then the rain supercooling in the cold boundary-layer air. Climatologies of freezing rain have been compiled for the US and Canada (Stuart and Isaac, 1999; Cortinas *et al.*, 2004). Stuart and Isaac (1999) showed a maximum in freezing precipitation occurrence at St. John's, Newfoundland, averaging about 150 h year^{-1}. The 5–9 January 1998 ice storm, which covered portions of northeastern US and southeastern Canada, yielding 90 mm of rain across a wide area, caused $4.4 billion in damages (see Gyakum and Roebber, 2001). An atmospheric profile during this storm is shown in Figure 5.

Graupel and Hail

Graupel and hail microphysical formation mechanisms have been summarized in Pruppacher and Klett (1997). Graupel

Figure 11 Optical phenomena that can yield information on particle type, size, shape and orientation (© John Hallett). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

is simply a heavily rimed snow particle that can either be lumpy or conical in shape, and is often considered as small hail. It can form in weakly convective clouds. Hailstones are greater than 5 mm in diameter up to the size of "grapefruit", and they form in large thunderstorms and convective complexes (Figure 14). Graupel particles have densities near 0.1 to 0.8 $g\,ml^{-1}$, while hailstones have density approaching pure ice (0.92 $g\,ml^{-1}$). Marwitz (1972) recognized the different types of storms and attempted to categorize them as supercell (one large updraft), multicell, squall line, and so on. It is clear that the formation mechanism of hail requires strong updrafts to keep them aloft. The largest hailstones can have terminal velocities of approximately 50 $m\,s^{-1}$ which implies updrafts of similar magnitude (Pruppacher and Klett, 1997). The interactions between the dynamics and microphysics is complex and not completely understood. However, hailstorms can cause large amounts of property and crop damage, mostly resulting from extensive regions of modest 0.5 to 3 cm diameter hail. Changnon and Burroughs (2001) compared the US annual average of $445 million in damages the $1.9 billion caused by one storm (2001 dollar values).

Thin sections of hailstones reveal the presence of air bubbles of different size and concentration resulting from rejection of dissolved air as ice crystals grow from accreted supercooled drops. Drop size and concentration changes from place to place in the updraft environment; the bubble characteristics reflect these changes giving alternation regions of clear and bubbly ice. Further information on the growth process can be obtained by use of polarized

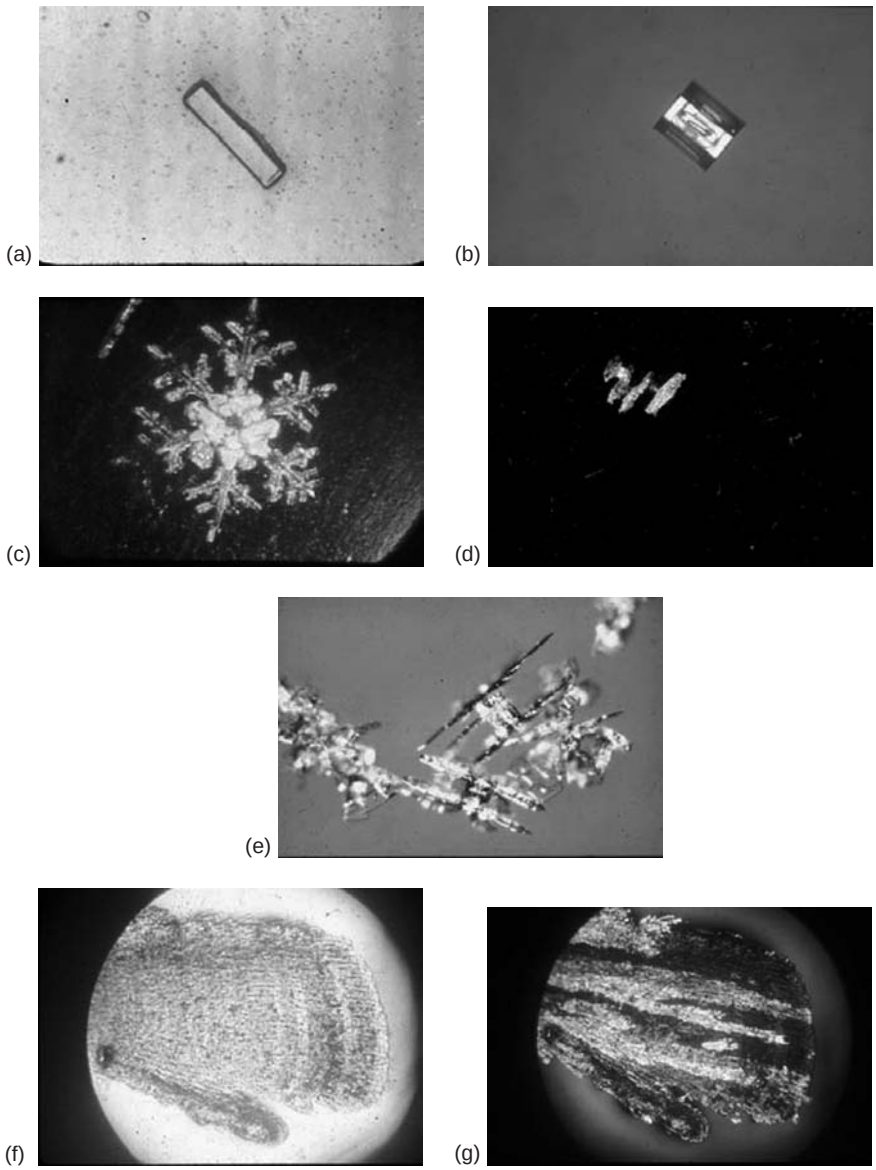

Figure 12 (a) Ice particles which formed in the atmosphere. (b) Growth is influenced by temperature, supersaturation and the accretion of cloud drops. light, distinguishing between wet growth when latent heat evolution is sufficiently rapid to prevent complete freezing and ice grows in to a liquid surface layer, and dry growth when supercooled drops are captured and freeze as individuals. Under the former conditions, large crystals are formed as shown by uniform color of regions of the thin section; in the latter case bubbles and small crystals may be formed. This may also occur under simultaneous accretion of mixed-phase ice and supercooled water drops. The correlation of crystals is complicated as it depends on several things, temperature, water and ice content, particle size distribution and fall velocity of the hailstone (Brownscombe and Hallett, 1967). Figure 14 shows thin sections of two stones. The first (Figure 14a, b) formed originally on a conical graupel particle. The second (Figure 14c, d) formed on a frozen raindrop, which grew first as graupel and then as a hailstone. The circular gaps around the core of the hailstone (Figure 14c) were regions grown as spongy ice, only partly frozen, during growth under high liquid-water content. Water was lost prior to collection and storage at low temperature. The contours of bubbles and changing ice size result from changing cloud conditions for growth. The

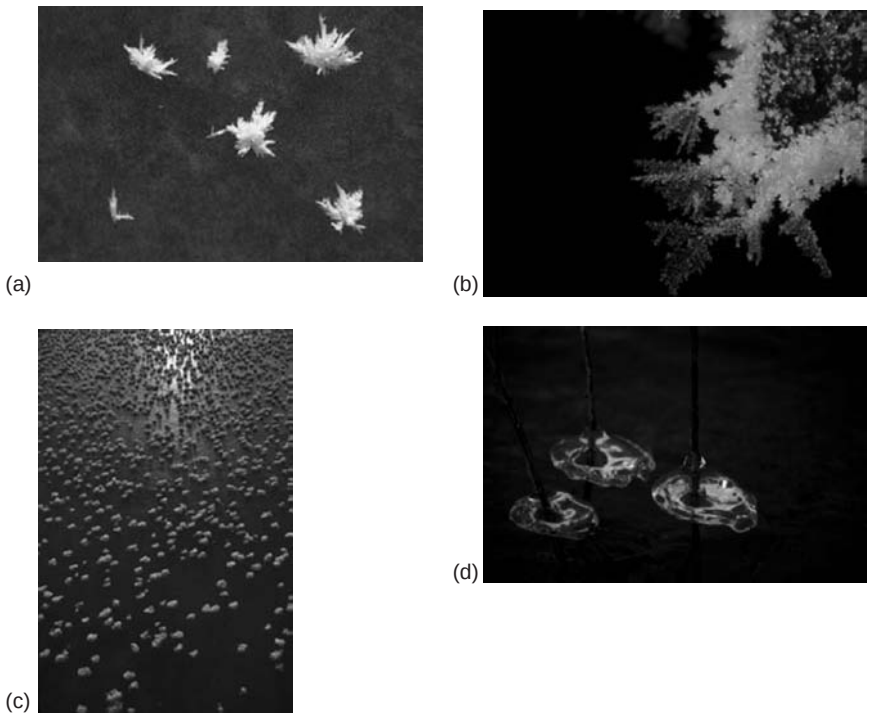

Figure 13 Examples of frost forming by radiative cooling with habit dependent on growth temperatures (a, b, and c) and ice boules formed over a stream by splashing of warmer water into cold air above (d) (© John Hallett). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

larger the hailstone, the larger the fall velocity, and the greater likelihood of its wet growth in high water content clouds.

CLOUD LIQUID-WATER CONTENT AND PRECIPITATION AS A FUNCTION OF TEMPERATURE

There have been several summaries of large data sets showing cloud properties as a function of temperature. Figure 15 shows how the cloud liquid-water content changes as a function of temperature (Gultepe and Isaac, 1997) for mid latitude stratiform clouds. Similar results were obtained by Feigelson (1978), Mazin (1995) and later again by Gultepe *et al.* (2002).

Similarly, precipitation amounts tend to be larger when the temperatures get warmer as shown in Figure 16 for some stations in the Mackenzie river valley (Isaac and Stuart, 1996). However, these relationships only hold for simple stratiform clouds. For precipitation from convective clouds, which often occur during the summertime in the same area, the amounts get smaller when the temperatures are cooler. Evidence is found for this in Figure 16 when the temperature gets warmer than $+10\,^{\circ}\mathrm{C}$. Isaac and Stuart (1992) came to the same conclusion in a study of Canadian precipitation-temperature relationships for different seasons.

Table 1 provides justification for why cloud water content and precipitation amount should depend on temperature. Warmer air has the capacity to hold more moisture and the potential for greater precipitation is thus enhanced. However, radiative influences may also be important in the precipitation-temperature relationship. For example, when convection occurs in the afternoon during the summertime, temperatures can drop because the incoming solar radiation is blocked.

CLOUD AND PRECIPITATION PARTICLE SIZE DISTRIBUTIONS

There have been many studies of the particle size distributions in clouds and in precipitation. Figure 17 shows results of averaging 2037 spectra averaged over 3 km in all liquid stratiform clouds found at temperatures between 0 and $-34\,^{\circ}\mathrm{C}$. The measurements were made using five different Particle Measurement System (PMS) probes (Knollenberg, 1981) and span a diameter range of a few microns to several millimeters. Of most relevance to hydrology is the particle size distribution of rain and snow at the surface. The early work of Marshall and Palmer (1948) and Gunn and Marshall (1958) assumed an exponential distribution of the

Figure 14 Hailstones. form:

$$N(D) = N_o \exp(-\Lambda D)$$

with $N_o = 8 \times 10^3\,\mathrm{m^{-3}\,mm^{-1}}$ ($\Lambda = 41R^{-0.21}$) for rain and $N_o = 3.8 \times 10^3 \quad R^{-0.87}\,\mathrm{m^{-3}\,mm^{-1}}$ ($\Lambda = 25.5R^{-0.48}$) for melted diameters of snow where R is in $\mathrm{mm\,h^{-1}}$.

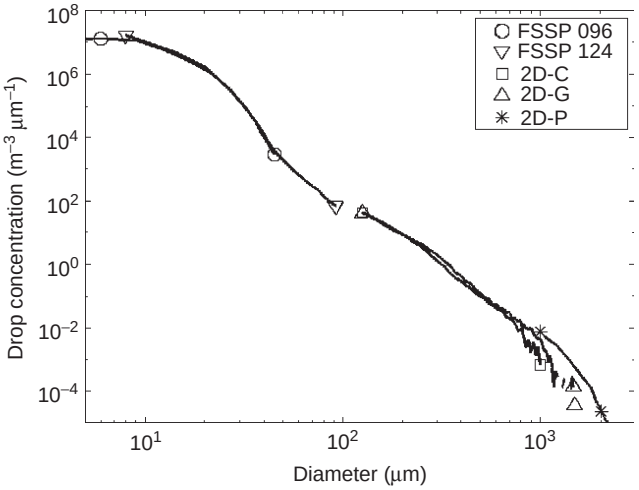

Figure 17 Results from averaging 2037 spectra made in all liquid Canadian winter clouds using an instrumented aircraft (Cober *et al.*, 2003) © 2003 by Environment Canada. Published by the American Institute of Aeronautics and Astronautics, Inc.

More recently, at least for raindrop-size distributions, both the gamma (Ulbrich, 1983) and lognormal distributions (Feingold and Levin, 1986) have been used. The gamma distribution is given as:

$$N(D) = N_o D^{\mu} \exp(-\Lambda D)$$

and it defaults to the exponential distribution when the curvature parameter, μ, goes to zero. The gamma distribution is a useful way of describing the raindrop size–distribution (e.g. Bringi *et al.*, 2003), but the coefficients depend on climate regime and type of rainfall (e.g. convective or stratiform). However, the older Marshall–Palmer parameterization is still being used and can give a reasonable first approximation (e.g. Sheppard and Joe, 1994).

Such distributions may only effectively describe extended data sets and thus are useful in a climatological sense. For specific short periods or small data sets, their use must be treated with caution because local turbulent regions may lead to particle sorting and physical processes of a specific scale (as the width of a cirrus trail) may lead to significant local deviations.

CLOUD SYSTEMS

The main purpose of this article is to describe cloud formation and the microphysical processes leading to precipitation. Other sections will handle storms and storm systems. However, Figure 18 shows the types of clouds and cloud systems that can generate precipitation around the world. In polar regions, as Figure 3 shows, little precipitation actually falls, and, what does comes from stratiform clouds and

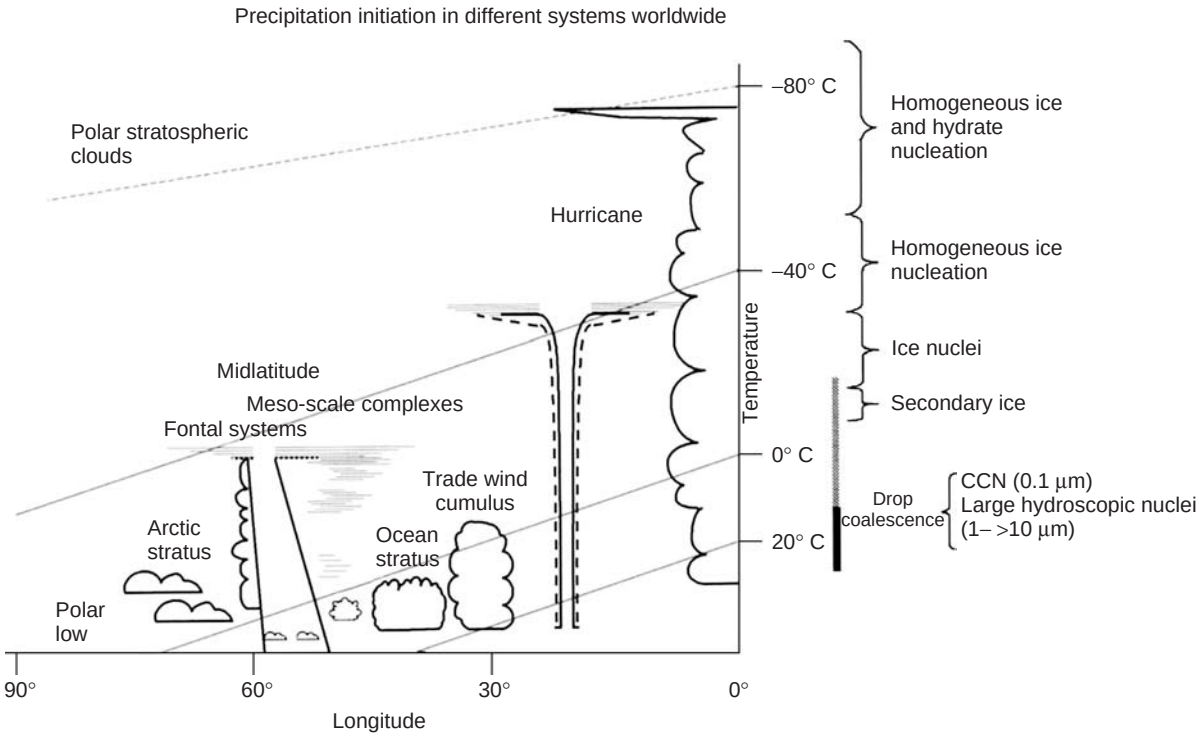

Figure 18 Examples of precipitation mechanisms, as a function of latitude and altitude, on a worldwide basis (Hallett and Isaac, 2001. © 2001 American Meteorological Society)

associated systems such as polar lows and frontal systems. Frontal systems and convective storms dominate the mid latitude belt, with the occasional hurricane. In the tropics, deep convective clouds and their associated systems account for the large amount of precipitation that falls within this latitude zone (see Figure 3). The dynamics of such systems is very complicated but obviously very important for cloud development and precipitation formation.

CONCLUDING REMARKS

The driving engine for most clouds systems is the latent heat release that occurs through phase changes. For example, for each mm of precipitation, $25\,\mathrm{W\,m^{-2}}$ of latent heat is released into the atmosphere. It is essential to know how such precipitation is formed from clouds in order to completely understand the energy cycle of the atmosphere. Our climate is particularly sensitive to cloud properties. For example, Slingo (1990) stated that the radiative forcing at the top of the atmosphere due to a doubling of carbon dioxide concentrations could be balanced by relatively modest increases of 15–20% in the amount of low clouds and 20–35% in liquid-water path, and by decreases of $\sim$ 15–20% in mean drop radius. Rotstayn (1999) suggested that a 1% increase in cloudiness, a 6% increase in liquid-water path, and a 7% decrease in droplet effective radius may result in a radiative forcing of about $-2.1\,\mathrm{W\,m^{-2}}$ in the heat budget of the atmosphere. In comparison, the Intergovernmental Panel on Climate Change (2001) estimated that the radiative forcing due to increases in greenhouse gases from preindustrial times to 1998 was $2.4\,\mathrm{W\,m^{-2}}$.

It should be emphasized that the greatest driving force for the atmospheric engine is generated in the tropics, since this is the region where cloud bases have the highest temperature and water contents aloft, and therefore most of the atmospheric latent heat is released in the convection occurring in this area. The transport of this energy away from the tropics drives the atmospheric system.

However, there are many uncertainties in how clouds and precipitation form. Hallett and Isaac (2001) summarized a Panel discussion at the 13th International Conference on Clouds and Precipitation (Reno, 2001), which considered this topic. We need to extend our knowledge of CCN for larger size particles, and determine the geographic variability of such particles. Our current knowledge of how ice forms in the atmosphere from ice nuclei to ice multiplication needs further study. The development of precipitation through the warm rain process also has gaps in our understanding. A better insight into the physical (particle growth) and dynamical (air motions) processes is required. We also need to gain more insight through studies

that compare model simulations to observations. Finally, we need a multidisciplinary approach to these questions because they require a balance between, theory, modeling, laboratory experimentation, instrument design and field observational work.

29: Atmospheric Boundary-Layer Climates and Interactions with the Land Surface

ALBERT AM HOLTSLAG[1] AND MICHAEL B EK[2]

[1] *Meteorology and Air Quality Wageningen University, Wageningen, The Netherlands*
[2] *National Centers for Environmental Prediction/Environmental Modeling Center, Suitland, MD, US*

The purpose of this article is to provide an overview of the relevant processes and interactions in the Atmospheric Boundary Layer (ABL) over land. Modeling principles for the ABL are summarized and discussed, including the formulation and role of the surface fluxes. It is shown that both the ABL and the coupled soil-vegetation-atmosphere system can be well represented in the well-defined cases examined. The interactions between the ABL and the land surface are illustrated with the role of soil moisture on boundary-layer cloud initiation. As such, a new analytical development is discussed and illustrated for the tendency of relative humidity at boundary-layer top. Typically, increased soil moisture leads to a higher potential for boundary-layer clouds, but in some cases, the largest potential for boundary-layer clouds is predicted over dry soils. For readers not familiar with atmospheric turbulence and meteorological definitions, some background is given as well.

INTRODUCTION

The characteristics of the Earth's surface strongly influence the motions and processes in the lower part of the atmosphere, known as the *Atmospheric Boundary Layer* (ABL). Usually, friction of the wind causes turbulence in the ABL, and this increases with the roughness of the surface. Over relatively warm surfaces, the ABL is heated from below, and convection may strongly amplify the environmental turbulence. On the other hand, over relatively cold surfaces, the presence of turbulence may vanish completely owing to the cooling of the ABL. Thus, the climate in the atmospheric boundary layer strongly depends on the presence of turbulence in response to the surface characteristics and the atmospheric flow above the ABL (*see* **Chapter 25, Global Energy and Water Balances, Volume 1**).

Turbulence directly impacts the transfer between the surface and the atmosphere of momentum, sensible heat, water vapor, ozone, and methane, among many other quantities. Turbulence also defines the mixing of properties inside the atmospheric boundary layer, the transfer of quantities between the boundary layer and the clear or cloudy atmosphere aloft, and the mixing inside clouds. It is characteristic that the surface temperature over sea is rather constant on the timescale of a day, while over land, the surface temperature may vary considerably owing to solar downward radiation and long-wave cooling of the surface. This has important implications for the turbulence and processes in the ABL (e.g. Stull, 1988).
