(Archie, 1942; Sen *et al.*, 1981), where σ_w [S m^{-1}] denotes the water electrical conductivity, and F [−] is a formation factor depending on the pore space geometry (porosity, tortuosity, effective pore/grain size), usually written in dependence on effective porosity, n_{eff} [−], and a so-called cementation exponent m [−] (for unconsolidated sands, typically $m \approx 1.3$, *see* e.g. Schön, 1996). The surface conductivity contribution in equation (8) may be expressed as

$$\sigma_{s,sat} = \frac{2\mu_s Q_s}{F\Lambda} \tag{10}$$

(Johnson *et al.*, 1986), where Λ [m] is an intrinsic measure of interconnected pore size, Q_s [C m^{-2}] is the surface ionic charge density, and μ_s [m^2 V^{-1} s^{-1}] is the effective ionic mobility in the electrical double layer around the charged surface. In general, ionic charge density and mobility depend on water chemistry, that is, on σ_w. The pore-size parameter Λ accounts for different surface and bulk tortuosity factors; its inverse is closely related to the surface area to pore volume ratio.

In general, σ may also describe induced electrical polarization (IP) phenomena attributed to ion-selective membrane effects in the pore space, in particular, associated with present clay minerals (e.g. Marshall and Madden, 1959; Vinegar and Waxman, 1984; Lesmes and Frye, 2001). Then, σ becomes a complex-valued quantity, σ^*, comprising real (σ') and imaginary (σ'') parts (or magnitude and phase). In the frequency range relevant for practical applications (typically <100 Hz), however, virtually only σ_s contributes to the imaginary part and, hence, σ'' allows direct access to internal surface characteristics. Importantly, σ_s generally depends on the applied measurement angular frequency ω [s^{-1}]. The relaxation times of transient IP processes directly correspond to the respective spatial scales at which these processes take place in the pore space. This leads to a dispersive behavior $\sigma_s(\omega)$ that contains important additional information for textural characterization (e.g. Kemna *et al.*, 2000; Lesmes and Morgan, 2001; Scott and Barker, 2003).

The dependence of real and imaginary conductivities on water saturation S is normally expressed as a simple power-law relation. For clay free formations, where only the electrolytic conductivity contributes to the real conductivity, it is

$$\sigma' \cong \sigma_{el} = \sigma_{el,sat} S^p \tag{11a}$$

(e.g. Archie, 1942). Here p [−] is the so-called saturation exponent with typically $p \approx 2$ (*see* e.g. Schön, 1996). For the imaginary conductivity, the corresponding relationship is

$$\sigma'' = \sigma''_{sat} S^q \tag{11b}$$

(e.g. Vinegar and Waxman, 1984), but recent studies (e.g. Ulrich and Slater, 2004) indicate that the saturation exponent of the imaginary conductivity, q [−], is significantly smaller than the saturation exponent of the real part (p). However, the saturation dependency of induced polarization is still an issue of current research (e.g. Titov *et al.*, 2004).

The relationships between structural, in particular textural, aquifer properties and the bulk electrical conductivity have motivated the attempt to assess hydraulic conductivity, K_h [m s^{-1}], or permeability, k [m^2], from geoelectrical measurements. Early approaches were based on the linear regression analysis of $\log\sigma - \log K_h$ correlations, which provides calibration functions valid for a particular set of

samples or field site (e.g. Mazáč *et al.*, 1985; Huntley, 1986). For instance, Heigold *et al.* (1979) found the field-scale empirical relation

$$\log K_h \approx -1.28 + 0.93 \log \sigma \tag{12}$$

(K_h in [m s^{-1}], σ in [S m^{-1}]) for the Niantic-Illiopolis aquifer in Illinois, USA. However, generally both a direct and an inverse relation between logσ and logK_h can be observed, depending on lithology type. In relatively clean sands, σ increases with increasing K_h since both properties are similarly controlled by porosity (dominance of σ_{el}). In clayey material, clay content takes over the governing role and, accordingly, an opposite σ-K_h relationship is found: σ increases but K_h decreases with increasing clay content (dominance of σ_s).

Recently, different empirical to semiempirical models were proposed for electrical k estimation (e.g. Börner *et al.*, 1996; de Lima and Niwas, 2000; Purvance and Andricevic, 2000; Slater and Lesmes, 2002). One approach (Börner *et al.*, 1996) is based on an observed direct relation between the surface area to pore volume ratio, A_p [m^{-1}], and σ'' (*see* Börner and Schön, 1991) in conjunction with a modified Kozeny–Carman model,

$$k \propto \frac{1}{F A_p^u} \tag{13}$$

where the formation factor F is estimated from measurements of σ_w. The exponent u [−] can be related to the fractal dimension of the pore surface (Pape *et al.*, 1987), that is, to soil/rock type. In contrast, the controlling influence on k might be attributed to a characteristic grain size, r_{gr} [m], rather than a characteristic pore size (such as A_p or Λ), by adopting a Hazen type model,

$$k \propto r_{gr}^w \tag{14}$$

with generalized exponent w [−], in conjunction with an empirically found inverse relation between r_{gr} and σ'' (Slater and Lesmes, 2002).

Geoelectrical Methods

With geoelectrical methods the subsurface bulk electrical conductivity σ, or resistivity $\rho = \sigma^{-1}$ [Ωm], is measured. Measurements are usually accomplished by injecting a DC, or quasi DC (low-frequency), electric current into the ground using a pair of electrodes and measuring the resultant voltage drop between another pair of electrodes (Figure 4). This defines a transfer resistance (or impedance, if also IP effects are considered) measurement, which contains information about a characteristic region of the underground, primarily depending on the measurement geometry (Figure 5). Accordingly, from a set of measurements with different geometry a model of the subsurface electrical conductivity distribution can be derived.

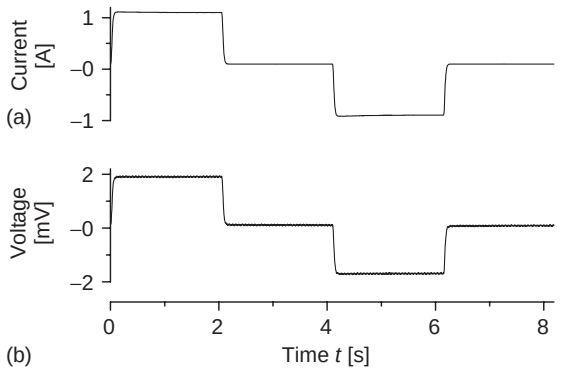

Figure 4 Typical signal waveforms in geoelectrical surveying: (a) injected square-wave current, and (b) observed voltage response after application of a low-pass filter to reduce power line noise

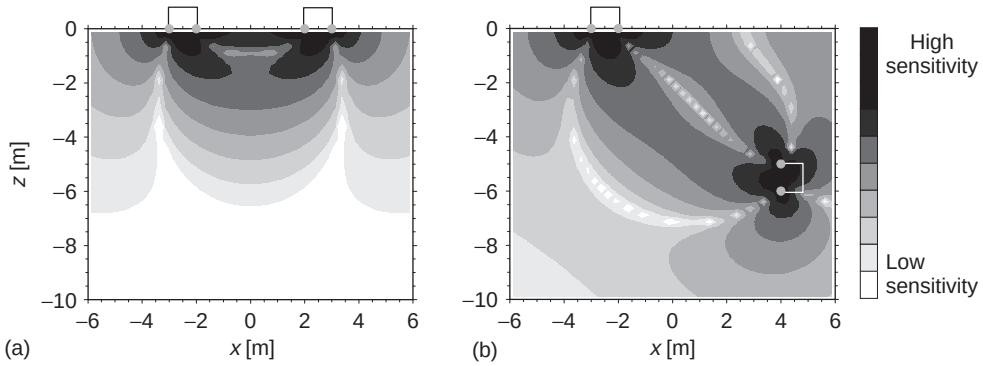

Figure 5 Sensitivity patterns for typical geoelectrical measurements using two separated electrode pairs for current injection and voltage measurement (so-called dipole–dipole configuration) assuming a homogeneous ground: (a) both electrode pairs placed at the surface, (b) electrode pairs placed at the surface and in a borehole, respectively. Grey circles indicate position of electrodes (Reproduced from Kemna, 1996, by permission of Landesamt fur Natur & Umwelt der Lander Schlesing-Holstain)

Early approaches were restricted in terms of the geometric parameterization of the underground as well as electrode placement. For example, in classic geoelectrical soundings (see e.g. Telford *et al.*, 1990) a multilayer earth model is assumed and only surface electrodes are used. However, with the advances in instrumentation and computational capabilities more flexible electrical imaging methods were developed, yielding high-resolution images of the subsurface electrical conductivity distribution based on surface and/or borehole measurements (for an overview, see Binley and Kemna, 2005). Following the terminology in medical imaging, this approach is nowadays usually referred to as electrical resistance (or resistivity) tomography (ERT).

ERT theory is based on the Poisson equation, which relates the electric potential, $\phi(\mathbf{r})$ [V], owing to any current sources to the underlying electrical conductivity distribution, $\sigma(\mathbf{r})$. For a point source (electrode) at the origin, with current strength I [A], it is

$$\nabla \cdot (\sigma \nabla \phi) = -I\delta(\mathbf{r}) \tag{15}$$

where δ denotes the Dirac delta function. For arbitrary 2D and 3D electrical conductivity models, usually finite element or finite difference methods are used to numerically solve the modeling (forward) problem defined by equation (15) subject to given boundary conditions (for an overview, *see* Hohmann, 1988). The ERT imaging (inverse) problem is inherently nonlinear, nonunique, and strongly ill-posed. However, in most imaging algorithms (e.g. Loke and Barker, 1995; LaBrecque *et al.*, 1996) nonuniqueness and ill-posedness are overcome by applying some sort of regularization, that is, imposing some constraints (such as smoothing) on the model. More recently, these approaches have been extended to also include IP effects in the interpretation (Oldenburg and Li, 1994; Kemna *et al.*, 2000).

Hydrogeological Applications

Geoelectrical methods have been extensively used for hydrogeological purposes. Early applications focused on the characterization of aquifers by means of geoelectrical soundings and subsequent hydrogeological interpretation of the derived electrical 1D models (e.g. Kosinski and Kelly, 1981), usually by taking hydraulic (borehole) data into account. Although correlations between, for example, electrical conductivity and hydraulic conductivity provided some calibration capability, these early applications were generally only of qualitative nature. However, with the improved understanding of soil/rock electrical signatures, today electrical-structural models are available that bear the potential for an improved quantitative aquifer characterization, in particular if applied in conjunction with high-resolution electrical imaging methods (Kemna *et al.*, 2004). With further development of these approaches, it may become possible to obtain, for example, images of *in-situ* hydraulic conductivity (for inverse modeling *see* **Chapter 156, Inverse Methods for Parameter Estimations, Volume 4**) with relatively high spatial resolution (*see* Figure 6), which obviously is of extreme practical relevance.

In addition to direct structure characterization, geoelectrical methods have been likewise proven to be efficient for the monitoring of subsurface flow and transport processes (*see* **Chapter 78, Models of Water Flow and Solute Transport in the Unsaturated Zone, Volume 2** and **Chapter 155, Numerical Models of Groundwater Flow and Transport, Volume 4**) when applied in a time-lapse mode. Earlier studies include the monitoring of groundwater flow by profiling or mapping the electrical response to an injected saline tracer, either from the surface (e.g. White, 1994; Morris *et al.*, 1996) or with the help of borehole electrodes (e.g. Bevc and Morrison, 1991). From the electrical response, for example, the effective groundwater flow direction and velocity can be determined. Using modern ERT methodology, the imaging of subsurface water or solute

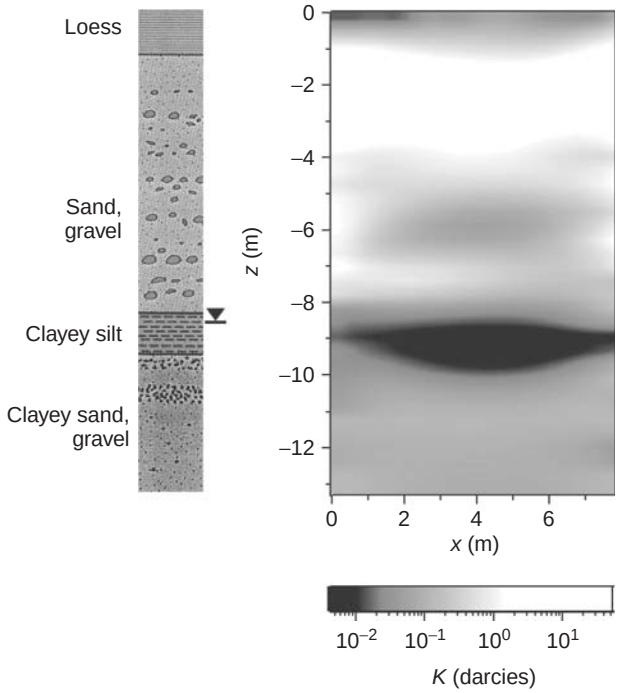

Figure 6 *In-situ* estimate of hydraulic permeability in a typical Quaternary environment (lithological setting shown on the left) as derived from cross-borehole electrical imaging results in conjunction with the application of a semiempirical electrical-hydraulic model according to equation (13) (Reproduced from Kemna *et al.,* 2004, by permission of Society of Exploration Geophysicists)

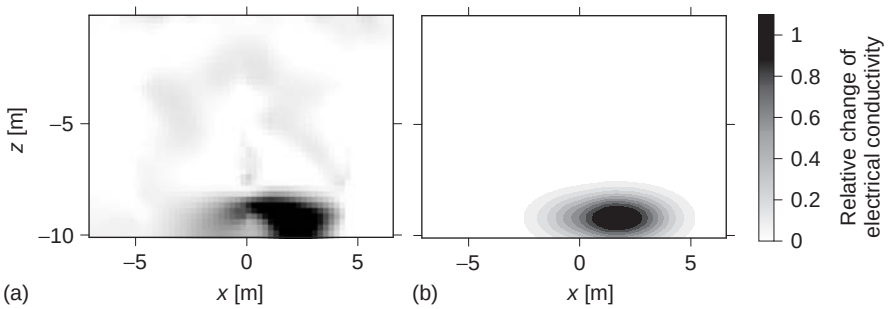

Figure 7 (a) ERT derived map of temporal electrical conductivity changes in the course of a tracer experiment conducted in a heterogeneous aquifer at the Krauthausen test site, Germany. (b) Corresponding result of an equivalent 3D advection-dispersion model fit, assuming a linear relation between relative electrical conductivity change and tracer concentration (Reprinted from Kemna *et al.*, 2002. © Copyright 2002, with permission from Elsevier)

plume movement is possible with high spatial resolution (e.g. Daily *et al.*, 1992; Slater *et al.*, 2000; Yeh *et al.*, 2002). Recently, it was demonstrated how cross-borehole ERT results in the course of a field tracer experiment can be used to quantify the variability of parameters relevant to flow and transport in heterogeneous aquifers (Kemna *et al.*, 2002) (for flow and transport parameters and models *see* **Chapter 152, Modeling Solute Transport Phenomena, Volume 4** and **Chapter 155, Numerical Models of Groundwater Flow and Transport, Volume 4**). By interpreting images of temporal electrical conductivity changes by means of equivalent transport models (Figure 7), longitudinal and lateral spreading of a tracer plume, as well as the degree of mixing and the heterogeneity of transport within the plume, can be quantified in terms of fitted equivalent dispersivities (Kemna *et al.*, 2002). The spatial variability of equivalent transport parameters contains information about the spatial structure of the flow field, which in turn can be used to infer information about the structure of the hydraulic conductivity field (e.g. Rubin and Ezzedine, 1997; Vanderborght and Vereecken, 2001) (*see* **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**).

ELECTROMAGNETIC AQUIFER CHARACTERIZATION

In electromagnetic (EM) methods, electromagnetic fields of various sources (e.g. controlled transmitter coils, radio transmitters, telluric currents) are used to investigate the electromagnetic properties of the subsurface. Numerous different approaches exist depending on the employed source type, the measurement principle (e.g. time domain vs. frequency domain), and the analyzed time/frequency range (*see* e.g. Telford *et al.*, 1990).

In this section, we will distinguish between low-frequency EM methods (typically 1–100 kHz), including frequency-domain and time-domain approaches, and the high-frequency ground-penetrating radar (GPR) method (typically 10–1000 MHz). Both methodological fundamentals as well as hydrogeological applications will be addressed. Since low-frequency EM methods primarily characterize the subsurface in terms of electrical conductivity, it is here again referred to Section "Electrical-hydrogeological relationships" where the basis of its hydrogeological interpretation is provided. In the GPR method, however, primarily the dielectric permittivity is analyzed and therefore in the corresponding section dielectric-hydrogeological relationships are likewise reviewed.

Low-Frequency Electromagnetic Methods

Frequency-domain Methods

A typical frequency-domain (FD) EM system consists of two coils (loops), a transmitter and a receiver coil (Figure 8). In the transmitter coil an alternating current (frequency typically ranging from 1 to 100 kHz) generates a magnetic field, the so-called primary field, H_p^* [A m^{-1}] (where $*$ denotes a complex quantity comprising real and imaginary parts). According to Faraday's induction law, the time-varying primary magnetic field induces a time-varying electric field in the earth. Owing to the conductive nature of the earth, this electric field is associated with time-varying electric currents, the so-called eddy currents, according to Ohm's law. These eddy currents in turn generate a magnetic field, the so-called secondary field, H_s^* [A m^{-1}], which is picked up by the receiver coil together with the primary field. In typical FD-EM methods the mutual coupling of such a two-coil system is measured, which can be described as the ratio of the secondary to primary magnetic fields. From this, information on the electrical conductivity distribution in the subsurface can be derived.

Maxwell's equations form the theoretical basis of the general EM problem. For the considered case of a two-coil system, however, an apparent electrical conductivity (i.e. the conductivity of an equivalent homogeneous half-space),

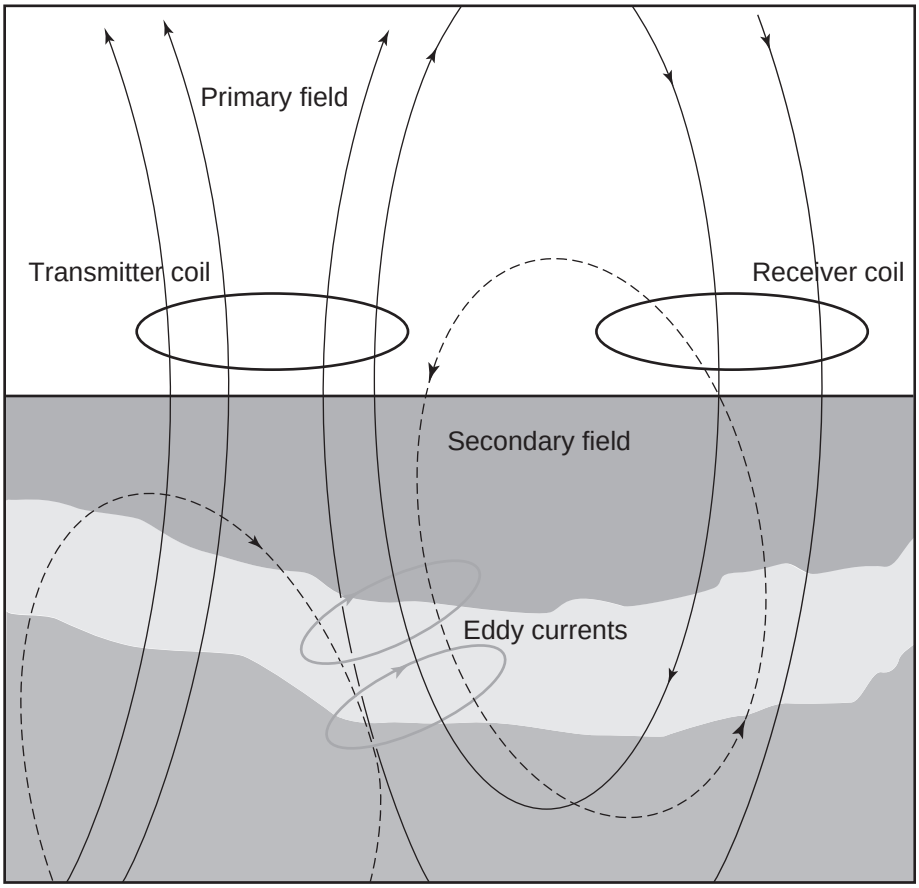

Figure 8 Measurement principle of a typical two-coil (loop–loop) frequency-domain EM system

σ_a [S m^{-1}], can be simply computed from the mutual coupling ratio H_s^*/H_p^* according to (McNeill, 1980a)

$$\sigma_a = \frac{4}{\omega\mu_0 r^2}\left(\frac{H_s^*}{H_p^*}\right)'' \tag{16}$$

if $\mu \approx \mu_0$ is assumed and

$$Q \equiv r\sqrt{\frac{\omega\mu_0\sigma}{2}} \ll 1 \tag{17}$$

where $''$ denotes the imaginary (quadrature) component, ω [s^{-1}] is the measurement angular frequency, $\mu_0 = 4\pi \cdot 10^{-7}$Vs A^{-1}m^{-1} the magnetic permeability of free space, μ [Vs A^{-1}m^{-1}] the subsurface magnetic permeability, r [m] the spacing between transmitter and receiver coils, Q [−] is the so-called induction number, and σ [S m^{-1}] an estimated maximum value for the subsurface electrical conductivity. The assumption of low induction numbers (equation (17)) is valid for most sediments and frequencies of commercially available EM systems operating in the low-frequency range.

While the interpretation of "apparent" electrical conductivities may be sufficient in certain situations, generally knowledge of the "true" electrical conductivity distribution in the subsurface is desired. This can be derived, however, by the application of inversion schemes similar to those used in geoelectrics, as outlined in Section "Geoelectrical methods", in conjunction with appropriate electromagnetic forward modeling routines (for an overview, *see* Oristaglio and Spies, 1999).

The induction number Q is closely related to another important parameter used in FD-EM methods, particularly for survey design, that is, the skin depth (e.g. Telford *et al.*, 1990)

$$\delta = \sqrt{\frac{2}{\omega\mu_0\sigma}} \tag{18}$$

[m]. The skin depth corresponds to the depth where the transmitted EM signal is reduced to e^{-1} of its original value at the surface; it is directly related to the exploration depth of a FD-EM survey. For a homogeneous earth, obviously $\delta = r/Q$. Equation (18) clearly shows the effect of both subsurface electrical conductivity and measurement frequency on the attenuation of EM fields. The more

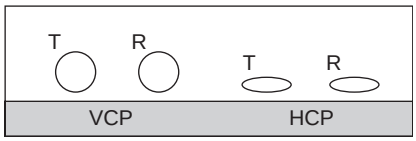

Figure 9 Vertical coplanar (VCP) and horizontal coplanar (HCP) orientations of a loop–loop EM system consisting of transmitter (T) and receiver (R) coils

conductive the earth, the stronger are the EM fields attenuated by Ohmic loss, and vice versa.

Besides the skin depth, also coil spacing and orientation are connected with the exploration depth. With increasing coil spacing, secondary field responses from greater depths are measured owing to the penetration characteristics of EM fields. For rigidly connected transmitter and receiver coils, two different system orientations are commonly used: horizontal coplanar (HCP) and vertical coplanar (VCP) (Figure 9). In the HCP orientation, the vertical component of the secondary field is measured; in the VCP orientation its horizontal component is measured. The horizontal component is more sensitive to the shallow subsurface than the vertical component. Approximate maximum exploration depths are 1.5 and 0.75 times the coil spacing for, respectively, HCP and VCP orientations (McNeill, 1980a).

Since the exploration depth of a FD two-coil system depends on measurement frequency as well as coil spacing and orientation, different surveying modes are possible. Many commercial systems operate in a wide frequency band in order to enable vertical soundings of the subsurface electrical conductivity via systematic frequency variation for a fixed measurement position at the surface. Alternatively, in order to map the electrical conductivity laterally the method is typically applied in a profiling mode by moving the system with fixed coil spacing along a transect while using a single measurement frequency. Via combination of both sounding and profiling modes, and also in conjunction with varying coil spacing, multidimensional imaging can be realized.

Besides the two-coil (loop–loop) configuration outlined above, there exist other FD-EM measurement approaches that utilize external (or far-field), either artificial or natural, sources as the primary field. In magnetotellurics (MT), for instance, natural ionospheric currents are used as external sources. Far-field artificial sources are primarily represented by radio transmitters originally operated for military communication or marine/aerial navigation purposes; they are used in the very-low-frequency (VLF), or radio-magnetotellurics (RMT), method. At the receiver side, in addition to coils picking up magnetic field components, also electrodes may be placed in the ground to measure electric field responses. Depending on the source type and which field components are measured, specific data processing techniques have been developed for the different approaches to infer information on the electrical conductivity distribution in the subsurface (for an overview, *see* Nabighian, 1991).

Importantly, EM methods solely based on magnetic field measurements do not require galvanic contact with the ground and thus bear inherent advantages over geoelectrical methods (*see* Section "Geoelectrical methods"). Accordingly, EM methods are widely used as an airborne reconnaissance method to enable a swift and relatively cheap mapping of the electrical conductivity distribution. Coils can be located either on a plane or helicopter, or on a rigid boom towed by the aircraft. Similarly, marine surveys are possible, where the coils are typically located on a cable suspended in the water or dragged along the seafloor. EM methods may also be superior to electrical methods in highly resistive environments (provided that induction effects are still significant), where high contact resistances at the electrodes often impede a deeper penetration of injected direct currents. In conductive environments, on the other hand, the attenuation of EM fields is relatively large and hence the use of electrical methods may be more advantageous.

Time-domain Methods

Time-domain electromagnetic (TD-EM) methods also use a transmitter and a receiver coil (Figure 10). A static primary magnetic field is generated by a steady current in the transmitter coil. When the current is sharply turned off, the associated abrupt change in the magnetic field induces an electromotive force in the ground, which gives rise to decaying eddy currents ("smoke rings") flowing in subsurface conductors. These currents in turn generate a secondary magnetic field, which is measured at the receiver coil and from which an "apparent" electrical conductivity can be calculated (McNeill, 1980b). By means of application of appropriate modeling and inversion routines, the "true"

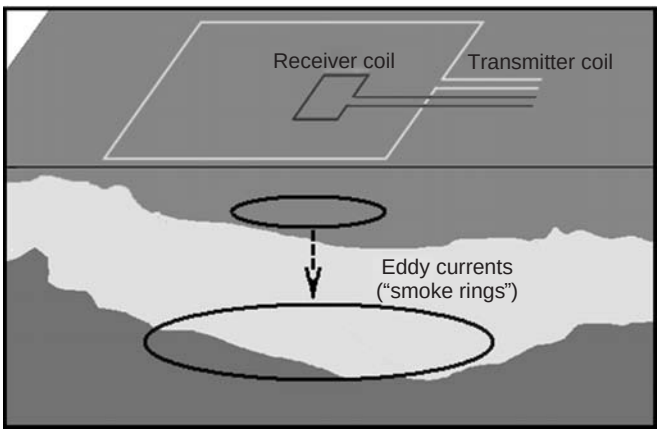

Figure 10 Layout of a typical time-domain EM survey showing induced electric currents in the subsurface

electrical conductivity distribution in the subsurface can also be obtained (Oristaglio and Spies, 1999).

Time-domain EM transmitter coils have relatively large dimensions (coils with an area of several $100\,m^2$ are not uncommon), whereas the receiver coils have smaller dimensions. Especially in urban areas, the signal-to-noise ratio is significantly improved by using small receiver coils. The receiver coil can be located inside the transmitter coil, at a certain distance, or the transmitter coil itself can be used as receiver. After the transmitter current is turned off, measurements may take several seconds. They are then repeated several times to increase the signal-to-noise ratio, each time with a different current polarity. This reduces the influence of polarization effects in the subsurface on the measured signal. TD-EM methods are typically used as a sounding tool by interpreting early and late-time responses, analogous to the spectral analysis in FD approaches.

Hydrogeological Applications

Since all EM methods aim to map the subsurface electrical conductivity distribution, they represent, in principle, an alternative to geoelectrical methods for all identified hydrogeological applications (*see* Section "Electrical aquifer characterization"). EM methods are typically preferred for investigations at a larger (e.g. aquifer) scale (e.g. Edet, 1991; Puranen *et al.*, 1999; Danielsen *et al.*, 2003). Under favorable conditions (little anthropogenic interference, presence of high-conductive dissolved solids in the groundwater, or presence of conductive contaminants/tracers), for instance, an image of the groundwater body or a contaminant plume can be obtained (e.g. Wynn, 2002).

Ground-Penetrating Radar

Ground-penetrating radar (GPR) is an EM pulse reflection method that is based on similar principles as reflection seismics (*see* Section "Seismic methods"). With GPR the travel time, like in conventional sonar and radar, and amplitude of high-frequency (10–1000 MHz) EM waves propagating from a transmitter antenna through the subsurface to a receiver antenna are measured. GPR is sensitive to changes in the dielectric permittivity and electrical conductivity, which cause reflection, refraction, and diffraction, as well as attenuation of the EM waves. Variations in these properties influence the measured travel times and amplitudes. Permittivity and electrical conductivity strongly depend on water content, salinity, porosity, grain size, and clay content of sediments, and therefore many subsurface structural characteristics can be detected by GPR. A benefit of GPR is its relatively high spatial resolution, as well as the possibility of on-line visualization of the measuring results.

Dielectric-Hydrogeological Relationships

Existing dielectric-hydrogeological relationships are based on either empirical, phenomenological, or some sort of mixing models (e.g. Shen *et al.*, 1985; Knoll, 1996; Hagrey and Müller, 2000). Empirical models mostly relate the volumetric water content, θ_v [−], to the relative dielectric permittivity (dielectric constant), ε_r [−], which is defined as $\varepsilon_r = \varepsilon/\varepsilon_0$, where ε [$As\,V^{-1}m^{-1}$] is the dielectric permittivity and $\varepsilon_0 = 8.854 \cdot 10^{-12} As\,V^{-1}m^{-1}$ its value in free space. For instance, the relation of Topp *et al.* (1980) is often applied:

$$\theta_v = -5.3 \cdot 10^{-2} + 2.9 \cdot 10^{-2}\ \varepsilon_r - 5.5 \cdot 10^{-4}\ \varepsilon_r^2 + 4.3 \cdot 10^{-6}\ \varepsilon_r^3 \qquad (19)$$

Volumetric mixing formulas relate the bulk permittivity of a multiphase mixture to the permittivities and volumetric fractions of its constituents. A general form is that of Lichtenecker and Rother (1931) (*see* e.g. Birchak *et al.*, 1974):

$$\varepsilon_b^\chi = \sum_i V_i\ \varepsilon_i^\chi \qquad (20)$$

where ε_b is the bulk relative permittivity, V_i [−] and ε_i are the volumetric fraction and relative permittivity, respectively, of the i-th constituent, and χ is an empirical constant accounting for the geometric shape of the solid matrix (grains). For $\chi = 0.5$, one obtains for a three-component mixture of matrix, water, and air a formula similar to the complex refractive index method (CRIM) (e.g. Shen *et al.*, 1985):

$$\sqrt{\varepsilon_b} = (1 - S)n\sqrt{\varepsilon_{air}} + Sn\sqrt{\varepsilon_w} + (1 - n)\sqrt{\varepsilon_m} \qquad (21)$$

with porosity n, saturation $S = \theta_v/n$, and ε_{air}, ε_w, and ε_m denoting the relative permittivities of air, water, and matrix, respectively. For $\varepsilon_w \approx 80$ and for example, $\varepsilon_m = 4$ (possible value for dry soil) and $S = 1$ (full saturation), equation (21) yields $\varepsilon_b \approx 4 + 28n + 48n^2$.

In general, the dielectric properties can be described by a frequency-dependent, complex dielectric permittivity, $\varepsilon^*(\omega)$, comprising real (ε') and imaginary (ε'') parts. The frequency dependence is taken into account by many phenomenological models such as the Cole–Cole model (Cole and Cole, 1941)

$$\varepsilon^*(\omega) = \varepsilon_\infty + \frac{\varepsilon_0 - \varepsilon_\infty}{1 + (i\omega\tau)^c} \qquad (22)$$

Here, ε_0 and ε_∞ represent the (real-valued) low and high-frequency asymptotes of ε^*, respectively, i denotes the imaginary unit ($i = \sqrt{-1}$), c [−] is the so-called Cole–Cole-exponent and τ [s] a characteristic relaxation time.

Measurement Principles

GPR utilizes short EM pulses of broadband dipole antennas that are emitted into the ground. The propagation velocity,

v [m s^{-1}], of the EM waves is directly related to the real part of the relative dielectric permittivity, ε'_r, via

$$v \approx \frac{c_0}{\sqrt{\varepsilon'_r}} \tag{23}$$

where $c_0 \approx 3 \cdot 10^8 \text{ms}^{-1}$ is the vacuum propagation velocity of EM waves and it is assumed that $\sigma \ll \omega\varepsilon_0\varepsilon'_r$ (with σ [S m^{-1}] being the DC electrical conductivity). Typically, dominant frequencies between 10 and 1000 MHz are used, corresponding to wavelengths, $\lambda = 2\pi v/\omega$ [m], in the range 0.1 to 10 m. The wavelength defines the maximum spatial resolution of GPR; layers smaller than $\lambda/4$ cannot be resolved (Jol, 1995). Obviously, a higher frequency provides a higher resolution.

Solving Maxwell's equations for the electric field strength, $\mathbf{E}^*$ [V m^{-1}], in case of an isotropic, homogeneous medium and sinusoidal time dependence exp (iωt) yields for the transversal plane wave traveling in vertical (z [m]) direction $\mathbf{E}^*(t) = \mathbf{E}_0^* \exp(\text{i}\omega t - \gamma^* z)$, where the complex propagation constant $\gamma^* \equiv \alpha + \text{i}\beta$ [m^{-1}] consists of an attenuation constant

$$\alpha = \frac{\omega}{c_0}\sqrt{\frac{\varepsilon'_r}{2}\left(\sqrt{1+\left(\frac{\sigma}{\omega\varepsilon'}\right)^2} - 1\right)} \tag{24}$$

and a phase constant

$$\beta = \frac{\omega}{c_0}\sqrt{\frac{\varepsilon'_r}{2}\left(\sqrt{1+\left(\frac{\sigma}{\omega\varepsilon'}\right)^2} + 1\right)} \tag{25}$$

(*see* e.g. Hagrey and Müller, 2000).

Equations (23) to (25) exhibit the dependence of the propagation behavior of the EM waves on material properties. Water is critical for the propagation in rocks because its dielectric constant ($\varepsilon'_r \approx 80$) is much higher than that of air ($\varepsilon'_r = 1$) and the solid matrix ($\varepsilon'_r \approx 4 \ldots 10$) (for typical values of different materials *see* e.g. Reynolds, 1997). The electrical conductivity is decisive for the attenuation and thus the exploration depth (skin depth), δ [m], defined as $\delta = 1/\alpha$ (cf. equation (18)). In high-conductive environments, the use of GPR is strongly limited (e.g. van Overmeeren, 1994).

The EM waves emitted by the GPR transmitter antenna into the ground are reflected and refracted at boundaries between regions (layers) with different complex impedance, $Z^* = \sqrt{\mu_0/\varepsilon^*}$ [Ω], leading to multiple waves associated with different subsurface raypaths that are recorded with the receiver antenna. Figure 11 shows the different wavepaths that can be identified for a typical GPR survey geometry with two antennas over a layered underground. The corresponding travel time curves are plotted in Figure 12.

The air wave propagates with the speed of light above the Earth's surface; it can be used as a reference to mark the beginning of the measurement. Directly at the surface, the ground wave propagates with the velocity v of the uppermost layer. The corresponding travel times for air and ground waves are, respectively, $t_{air} = x/c_0$ and $t_g = x/v$, where x [m] denotes the distance in horizontal direction. From simple ray theory, the travel time of the reflected wave is given as

$$t_r = \sqrt{\left(\frac{x}{v}\right)^2 + \left(\frac{2d}{v}\right)^2} \tag{26}$$

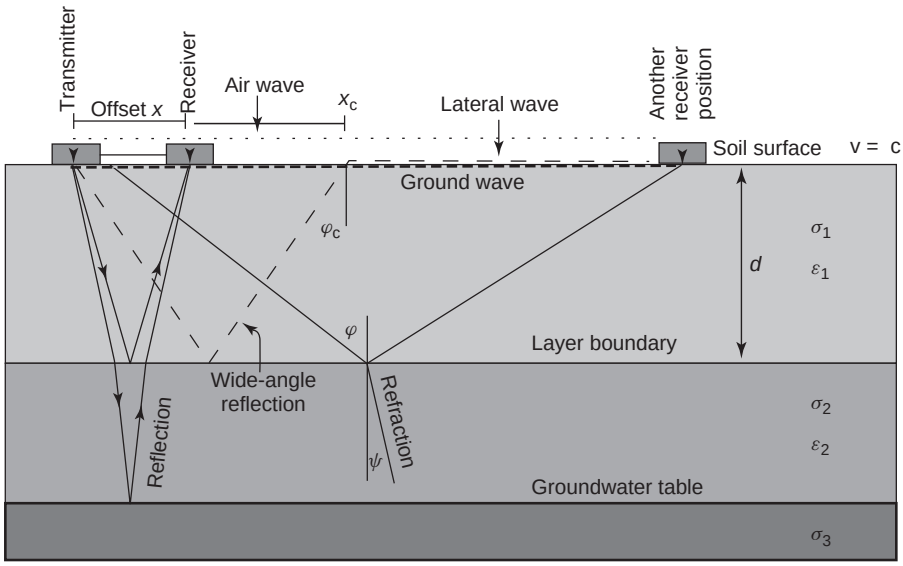

Figure 11 Typical GPR survey geometry showing the different waves that can be observed

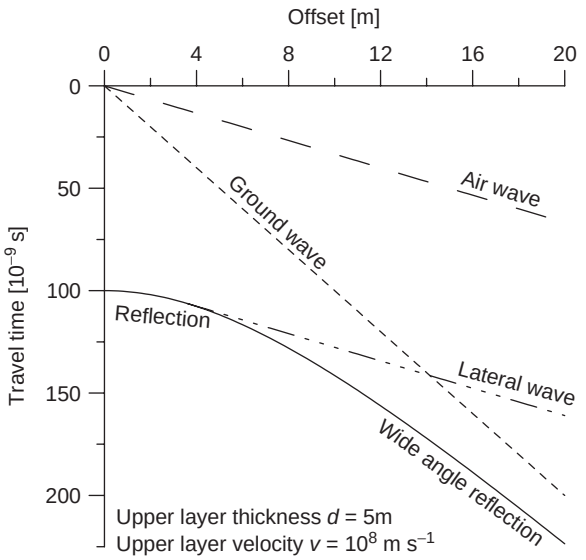

Figure 12 Travel time curves for the different waves shown in Figure 11 for a two-layer model with exemplary parameter values

where d [m] is the thickness of the uppermost layer. When a reflected, up-traveling wave encounters the surface at an angle $\varphi \geq \varphi_{\text{critical}} = \arcsin(v/c_0)$, the so-called lateral wave (*see* e.g. Huisman *et al.*, 2003) with travel time

$$t_l = \frac{x}{c_0} + \frac{2d}{v}\sqrt{1 - \left(\frac{v}{c_0}\right)^2} \tag{27}$$

can be observed, analogous to the head wave in refraction seismics.

The depth of discontinuities can be directly calculated from the corresponding reflection travel times (equation (26)) for given velocity values, which can be obtained from common midpoint (CMP) measurements (i.e. constant midpoint between transmitter and receiver antennas; *see* e.g. Reynolds, 1997). Another measurement mode is the constant-offset gather, where both antennas are moved with fixed separation. Because of the high pulse succession, quasi-continuous profiling is possible with moving antennas. Borehole surveys may include borehole-to-surface and/or borehole-to-borehole measurements (e.g. Binley *et al.*, 2002). Here, data may be collected in a zero-offset profiling mode (transmitter and receiver in different boreholes at equal depths) or in a multiple-offset gather (transmitter and receiver in different boreholes at different depths).

The general conversion of travel times into depths (migration) is equivalent to conversion procedures used in seismics. Prior to time-to-depth migration, however, the recorded signals must be corrected for possible errors caused by incorrect station geometry and zero time, geometric spreading, transmitter radiation pattern, transmitter amplitude, and high-angle raypaths (Peterson, 2001).

Hydrogeological Applications

One of the main applications of GPR is the estimation of water content in the unsaturated zone (e.g. Binley *et al.*, 2001, 2002; Alumbaugh *et al.*, 2002; Huisman *et al.*, 2002, 2003; Schmalz *et al.*, 2002; Schmalholz *et al.*, 2004) using proven petrophysical relationships. Variations in porosity and grain size likewise influence the propagation velocity of EM waves. Therefore, GPR can provide indications of changes in properties connected with textural or hydraulic parameters. Moreover, lithology information can be inferred; typically high-velocity zones correlate to sand and gravel layers, while low-velocity regions correlate to clay and silt layers. Peterson *et al.* (1999) derived 2D high-resolution images of porosity and electrical conductivity from radar tomography data at the Boise hydrogeophysical research site using the CRIM approach (equation (21)). Estimates showed a good agreement with corresponding data from neutron probe measurements.

The large contrast in dielectric permittivity between unsaturated and saturated zones also makes the groundwater table a common target in GPR surveys; it can be mapped quasi-continuously with high spatial resolution. Although structures below the groundwater table can be resolved (Figure 13), information from the saturated zone may be limited owing to the relatively high attenuation of EM waves in this region. However, GPR can be used to investigate various subsurface structures relevant to hydrogeology, such as sedimentary sequences, fractured or karstic zones, faults, and cavities (e.g. Benson, 1995).

The detection of subsurface contamination has also been objective of numerous GPR studies (e.g. Brewster and Annan, 1994; Greenhouse *et al.*, 1993). Contaminants have been found to be indicated by zones where radar reflections are weak or absent (Davis and Annan, 1989) or where additional reflections occur (Francisca and Rinaldi, 2001). Sauck *et al.* (1998) noted that owing to biogeochemical processes the electrical conductivity of hydrocarbon spills changes with time from resistive to conductive; these changes can be mapped with GPR.

Using GPR in a time-lapse manner, dynamic processes such as infiltration of surface water (*see* **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2** and **Chapter 150, Unsaturated Zone Flow Processes, Volume 4**) or spreading of a contaminant plume can be studied by mapping the associated changes in dielectric permittivity over time. Recent developments aim at combining GPR with other geophysical methods such as electrical resistivity tomography (Binley *et al.*, 2002).

COMBINED HYDROGEOPHYSICAL APPROACHES

Combined hydrogeophysical approaches aim at the improved characterization of subsurface structures or processes by using geophysical methods in conjunction with hydrogeological and/or hydrological data. These data are usually obtained from well bore measurements (*see* **Chapter 151, Hydraulics of Wells and Well Testing, Volume 4**) and therefore carry only limited spatial information. Most of the combined hydrogeophysical approaches require relationships between hydrogeological and geophysical properties. In this part, we will focus on aquifer systems although considerable work on combining geophysical with hydrogeological data is presently available in the vadose zone literature (e.g. Binley *et al.*, 2001; Alumbaugh *et al.*, 2002; Huisman *et al.*, 2002).

Earlier work in hydrogeophysics has focused on synthetic case studies showing the potential of using geophysical data for aquifer characterization. Rubin *et al.* (1992) for example presented a method to identify the permeability distribution in near-surface aquifers based on a hydrogeophysical inversion technique. They incorporated, in addition to sparsely sampled pressure and hydraulic conductivity data, densely sampled seismic data, derived from a reflection or tomography survey in combination with empirical relationships between seismic and hydraulic properties. The feasibility of their procedure is illustrated using a few synthetic case studies. Copty *et al.* (1993) showed that seismic information improved the hydraulic conductivity estimates even in cases where a random error was added to the seismic velocities. They proposed a Bayesian updating of the hydraulic conductivity field using seismic velocity-hydraulic conductivity-pressure relationships, thereby accounting for estimation uncertainty. Based on these findings, further studies were conducted on the joint use of geophysical and well bore data to characterize hydraulic properties of aquifers. Copty and Rubin (1995) used a stochastic procedure to incorporate seismic surface reflection data and well data into the identification of the log hydraulic conductivity field and the spatial distribution of lithofacies. This procedure was tested on a synthetic case made up of a geological section consisting of a series of sandy aquifers separated by clay layers. Hyndman *et al.* (1994) used a combination of seismic and tracer data to estimate spatial patterns of aquifer properties such as hydraulic conductivity and dispersivity (*see* **Chapter 155, Numerical Models of Groundwater Flow and Transport, Volume 4**) for two synthetic aquifers with the same seismic profile but with different hydraulic conductivity profiles in a hypothetical lithological cross section with two different images. Their proposed split inversion method (SIM) does not require knowledge on the relationship between seismic velocity and hydraulic conductivity but it assumes the existence of some relationship for large-scale lithological zones. This method was then used to estimate the lithological zonation of the Kesterson aquifer (San Joaquin Valley, California), the hydraulic conductivity of each zone, and its dispersivity (Hyndman and Gorelick, 1996). Hyndman and Gorelick (1996) showed that combining seismic and tracer data has the potential to provide high-resolution estimates of aquifer zonation and hydraulic properties. Hubbard *et al.* (1999) performed numerical analyses of synthetic case studies where the scale of the geophysical measurements (tomographic radar and seismics) was varied relative to the scale of hydraulic conductivity. Site-specific petrophysical models were used to relate hydraulic conductivity to either seismic or radar velocities. The study suggested that collection of a few tomographic profiles and interpretation of these profiles together with limited well bore data can provide information on the correlation structure of hydraulic conductivity.

In the last years, a few studies appeared that deal with real case studies. McKenna and Poeter (1995) used geological, geophysical, and hydrological data to identify hydrofacies and to define their spatial distribution for a field site located in Golden, Colorado. Hydrofacies are defined as homogeneous possibly anisotropic geological units being

hydrogeologically meaningful. They allow the construction of subsurface models with sharp interfaces in hydraulic conductivities. McKenna and Poeter (1995) used multiple-indicator, stochastic simulation conditioned on hard and soft information to produce realizations of hydrofacies geometries. Hard data are those data obtained in the vertical direction from wells whereas soft data are available between wells (e.g. geophysical data derived from surface or cross-borehole surveys). Each of these geometries then serves as zonation pattern for inverse flow modeling in order to discard implausible realizations and to characterize each zonation by a specific hydraulic conductivity value. Hyndman and Gorelick (1996) applied SIM to estimate the effective hydraulic conductivity of the observed lithologies at the Kesterson aquifer and the dispersivity value for the entire domain, as already outlined above. In their approach, they combined seismic, hydraulic, and tracer data using SIM. For the Kesterson aquifer, SIM adjusts in total six parameters (two seismic velocity parameters identifying three lithological classes with specific velocity, three hydraulic conductivities, and a regional value for the dispersivity) to best fit tracer data. A first step in the approach was to estimate seismic slowness (inverse seismic velocity) from available seismic cross sections obtained from well bore measurements. From these data, vertical and horizontal variograms for the region were derived. Sequential Gaussian simulation was used to develop multiple 3D conditional seismic slowness realizations. The SIM was then used to identify three lithological classes within each realization, each with a specific slowness value. The effective hydraulic conductivity was then estimated for each lithological zone such that observed tracer concentrations were optimally matched, and a value of dispersivity for the whole region was derived. The obtained results demonstrate that combining seismic and tracer data has the potential to derive structural information and hydraulic properties of aquifers.

Another interesting study was presented by Chen *et al.* (2001), who explored the possibility of using ground-penetrating radar and seismic tomography to estimate the hydraulic conductivity at the South Oyster site using a Bayesian approach. Their approach uses a-priori information on the hydraulic conductivity measured at selected wells using flowmeter technique. Geophysical data were only used at those wells where hydraulic conductivity was available. Correlation analysis showed positive correlations between GPR velocity and natural log conductivity of 0.68 and between seismic velocity and natural conductivity of 0.67. GPR attenuation and log conductivity appeared to be uncorrelated. To estimate log conductivity, a stochastic framework in which log conductivity, GPR velocity, GPR attenuation, and seismic velocity are considered as spatial random functions was adopted. Normal linear regression models are used to update conditional probability distribution functions (pdf) of seismic velocity, attenuation, and GPR velocity needed in the Bayesian likelihood approach using collocated hydrological (in this case hydraulic conductivity) and geophysical data. Chen *et al.* (2001) showed that especially velocity data hold potential in improving estimation of hydraulic conductivity even in cases where both hydraulic conductivity and geophysical tomography data vary in narrow ranges. Important for this approach is, however, the presence of correlations between the various properties. Hubbard *et al.* (2001) used a suite of methods such as surface GPR and seismic crosshole tomography, cone penetrometer, and borehole flowmeter to interpret subregional and local stratigraphy, to provide high-resolution hydraulic conductivity estimates and log conductivity spatial correlation functions. They derived horizontal and vertical intregal scales for hydraulic properties using a Bayesian approach (*see* e.g. Chen *et al.*, 2001) including tomographic data (e.g. seismic and radar velocity) and a-priori knowledge of the hydraulic conductivity pdf. Using first-order linear stochastic theory, the longitudinal dispersion coefficient of an inert solute plume in an aquifer with properties derived from the Oyster site was calculated. From this value, the longitudinal plume length was estimated and compared with visual evaluation of the plume length of a bromide plume observed at the Oyster site. Both length scales were found to be in reasonable agreement.

Gloaguen *et al.* (2001) estimated the water content of an unconfined sandy aquifer underlain by a 20 m thick clay layer using GPR. The 2D distribution of the saturated/unsaturated thickness was derived from a combination of GPR reflection, piezometric, and stratigraphic data using co-kriging. Once the piezometric levels and the clay layer depth were determined, travel times were used to compute the velocity field, which was then transferred to water content using the CRIM relation (equation (21)). From observed GPR attenuations and electrical conductivities observed in piezometer wells, porosity was determined using Archie's law (equation (9)).

OUTLOOK

Noninvasive characterization of aquifer properties and hydrological processes using geophysical methods will become more and more important in the next years. Geophysical methods in combination with hydrogeological and hydrological models and concepts may help to overcome some of the unresolved problems in subsurface research such as, for example, upscaling issues and characterization of space-time structures of subsurface properties and processes. This requires a better integration of hydrological, hydrogeological, and geophysical knowledge. In this article, research activities in the area of combined hydrogeophysical approaches were outlined, which represent a first step in tackling these unresolved problems. Further steps involve the development of data fusion techniques to

effectively integrate available information from the various sources, but also the development of novel technologies and methodologies with improved imaging and characterization capabilities. More recent methodological advances include, for instance, the surface nuclear magnetic resonance (SNMR) method – enabling direct access to subsurface water – and the magneto-electrical resistivity imaging technique (MERIT) – utilizing also magnetic fields of impressed electric currents (for an overview, *see* Yaramanci *et al.*, 2005). The establishment of hydrogeological test sites providing detailed information on geophysical, hydrological, and hydrogeological quantities is essential to develop and validate novel approaches.

149: Hydrodynamics of Groundwater

FRITZ STAUFFER

Swiss Federal Institute of Technology, Zurich, Switzerland

The mathematical formulation of problems of flow in aquifers is usually based on a formulation of the fluid mass balance, which has to be fulfilled at any location in the domain under consideration. A knowledge of the fluid mass flux through the saturated aquifer material, or the motion equation, is required. The resulting partial differential equation can be solved for a chosen flow domain, given parameters, and initial and boundary conditions. The solution results in the steady state or transient field of the piezometric head, from which the flux and the velocity fields may be expressed.

MOTION EQUATION FOR SATURATED FLOW, DARCY'S LAW

The Experimentally Derived Law

In 1856, Henri Darcy published the results of flow experiments with filter sands ('Les fontaines publiques de la ville de Dijon'). The experimental layout is shown, in a slightly modified form, in Figure 1.

A homogeneous sand column is built in a vertical tube with cross-sectional area A. The packing is completely saturated with water. Water flows with the discharge Q through the sand packing. At measurement stations P1 and P2, with elevations z_1 and z_2, the water pressure p_1 and p_2 is measured with the help of water manometers. The corresponding pressure heads are $p_1/(\rho g)$ and $p_2/(\rho g)$, where ρ is the water density and g is the gravitational acceleration. The experimental results by Darcy yielded the following empirical relationship (*Darcy's law*):

$$q = \frac{Q}{A} = K\frac{\Delta h}{\Delta l} \tag{1}$$

The area A comprises the complete cross-sectional area including the column. The symbol q is the specific discharge, which is the (volumetric) discharge per unit area, K is the hydraulic conductivity (that depends on the permeability of the material), h is the piezometric head, which can be interpreted as sum of pressure energy and potential energy per unit weight of water, Δh is the head difference, and Δl is the distance between the two locations P1 and P2. The piezometric head h is defined as:

$$h = z + \frac{p}{\rho g} \tag{2}$$

where z is level of the considered measurement location relative to an arbitrary datum. The water density ρ is taken as constant.

Darcy's experiment is the phenomenological foundation of the motion equation of a fluid in porous media (equation 1). It can be shown that the relationship holds even for upward flow, or when the flow direction is arbitrary. To relate the flux to a finite area A is equivalent to an averaging of the microscopic velocity over many pores. In fact, A has to be large enough in order to get representative results for the porous medium. The same principle holds for the measurement of pressure using manometers, since the result is an average over the contact area between the manometer and the porous medium, which comprises many pores. The length Δl is not the real flow path of a microscopic fluid particle, but the length of the trajectory of the specific flux. Obviously, postulating Darcy's law signifies the adoption of a macroscopic approach (to be presented below).

For a confined aquifer, the concept of piezometric head (equation 2) is illustrated in Figure 2. Consider a vertical piezometer tube with opening at the lower end, at location $\mathbf{x} = (x, y, z)$, where the prevailing water pressure is $p(\mathbf{x})$. The air pressure, p_a, within the piezometer, above the liquid level, is at zero atmospheric pressure, $p_{a,at}$. Assuming hydrostatic conditions, the water level in the piezometer

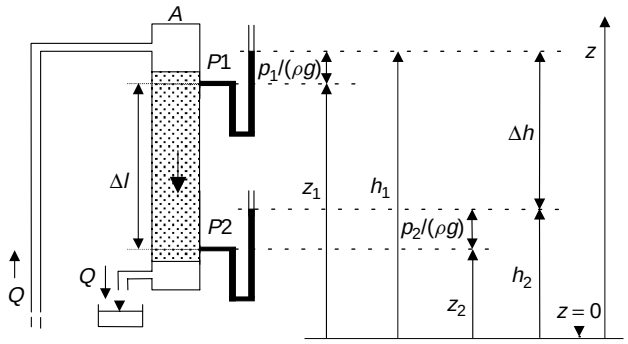

Figure 1 Schematic layout of darcy's experiment in a sand column (gray) with liquid manometers P1 and P2

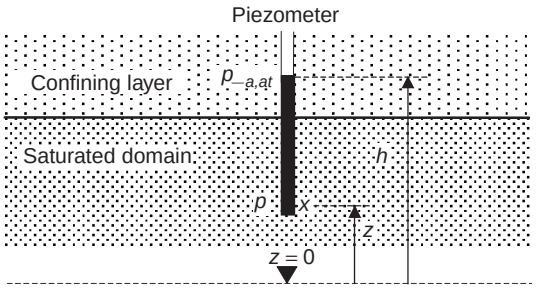

Figure 2 Concept of piezometric head h

reaches $h(\mathbf{x})$ according to equation 2, which holds for any liquid with the density ρ.

Typical values of hydraulic conductivity K (orders of magnitude) for unconsolidated sediments are listed in Table 1.

Although, as explained above, Darcy's law was proposed by Henri Darcy on the basis of experiments conducted in sand columns (thus limiting the law to one-dimensional flow of a homogeneous fluid in homogeneous porous media), it is possible to derive the motion equation from first principles of fluid mechanics. To achieve this goal, we start by considering the motion equation at a microscopic level, that is, at a point within the fluid that occupies the void space (section on Microscopic Consideration below), and then deriving the macroscopic law, that describes the flow in a porous medium domain, by averaging the microscopic motion equation over a representative elementary volume (REV, section on Macroscopic Consideration). An advantage of such an approach is that the derived law is applicable to the general case of three-dimensional flow in anisotropic inhomogeneous material of a variable density fluid.

Table 1 Typical values of hydraulic conductivity K and permeability k for various unconsolidated sediments

Sediment	K[m s^{-1}]	k[m^2]
Coarse gravel	10^{-2}	10^{-9}
Sandy gravel	10^{-3}	10^{-10}
Sand	10^{-4}	10^{-11}
Silt	10^{-6}	10^{-13}
Clay	10^{-9}	10^{-16}

Microscopic Consideration

Towards a physically based foundation and generalization of Darcy's law, a discussion may start with microscopic considerations (Figure 3). Theoretically, the fluid motion equation may be formulated for a microscopically small fluid volume within a pore. The flow problem may be formulated for the (complex) pore system with solid impermeable boundaries due to the grains. Inflow and outflow boundaries of the flow domain would be represented by prescribed head conditions.

Accordingly, a "microscopically" small fluid element in a pore is considered (Figure 3). On the basis of hydrodynamic considerations, the momentum balance equation for this fluid element is:

$$\rho\frac{\partial \mathbf{v}}{\partial t} + \rho\mathbf{v}\nabla\cdot\mathbf{v}\left(\equiv \rho\frac{\mathrm{d}\mathbf{v}}{\mathrm{d}}t\right) = \rho\mathbf{g} - \nabla p + \nabla\cdot\boldsymbol{\tau} \qquad (3)$$

where $\mathbf{v}$ is the fluid's velocity, $\boldsymbol{\tau}$ is the viscous stress tensor. The symbol ∇p of a scalar quantity p means gradient of p; this is a vector with components $\partial p/\partial x$, $\partial p/\partial y$, $\partial p/\partial z$, and $\nabla\cdot\mathbf{v}$ of a vector quantity $\mathbf{v}$ means the divergence, $\nabla\cdot\mathbf{v} = \partial v_x/\partial x + \partial v_y/\partial y + \partial v_z/\partial z$. The terms on the left-hand side in equation 3 signify the momentum increase per unit time and unit volume. They can be interpreted as inertia forces, caused by the temporal and the convective fluid acceleration. The terms on the right-hand side are the gravity force, the pressure gradient (= force due to pressure), and the friction, all related to a unit volume.

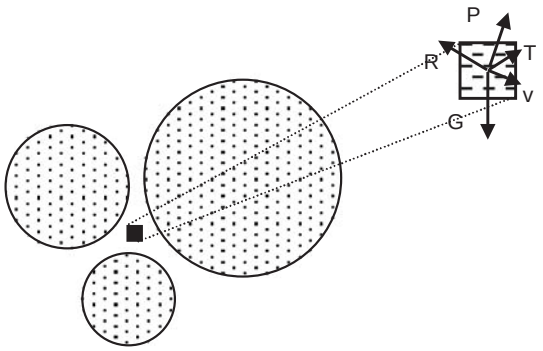

Figure 3 Microscopic approach: A small fluid element in a pore, with the acting forces per unit fluid volume inertia **T**, gravitation **G**, pressure gradient **P**, friction **R**, and the fluid velocity vector **v**

The relation between $\boldsymbol{\tau}$ and $\mathbf{v}$ is usually approximated by Newton's law:

$$\nabla \cdot \boldsymbol{\tau} = \mu \nabla^2 \mathbf{v} \tag{4}$$

where μ is the dynamic viscosity, and $\nabla^2\mathbf{v}$ of a velocity $\mathbf{v} = (v_x, v_y, v_z)$ is expressed as $\nabla^2\mathbf{v} = (\partial^2 v_x/\partial x^2 + \partial^2 v_x/\partial y^2 + \partial^2 v_x/\partial z^2, \partial^2 v_y/\partial x^2 + \partial^2 v_y/\partial y^2 + \partial^2 v_y/\partial z^2, \partial^2 v_z \partial x^2 + \partial^2 v_z/\partial y^2 + \partial^2 v_z/\partial z^2)$.

In cases with variable fluid viscosity μ, equation 4 may be valid approximately in an averaged sense. A property of the momentum equation 3 is that the variables $\mathbf{v}$, p, $\boldsymbol{\tau}$, and may be also the parameters ρ and μ are subject to more or less strong spatial variability within the pore space. The boundary condition along the solid boundaries within the complex pore system is $\mathbf{v} \cdot \mathbf{n} = 0$, where $\mathbf{n}$ denotes the unit outward normal vector normal to the solid walls, as is commonly assumed for flow near solid walls.

Macroscopic Consideration

The aim of a macroscopic consideration is to express averaged values of a microscopic quantity within a finite control volume (Figure 4), the size of which is chosen according to the requirement of obtaining stable averages. By averaging the spatial variability of the quantity within the control volume, we obtain a smoothed variation. Such a control volume is called *representative elementary volume, REV* (Bear, 1979). The average value is attributed to the center of the REV. The averaged form the microscopic momentum equation 3 is:

$$\left\langle \rho \frac{\partial \mathbf{v}}{\partial t} \right\rangle_{\mathrm{REV}} + \langle \rho \mathbf{v} \nabla \mathbf{v} \rangle_{\mathrm{REV}} = \langle \rho \mathbf{g} \rangle_{\mathrm{REV}} - \langle \nabla p \rangle_{\mathrm{REV}} + \langle \nabla \boldsymbol{\tau} \rangle_{\mathrm{REV}} \tag{5}$$

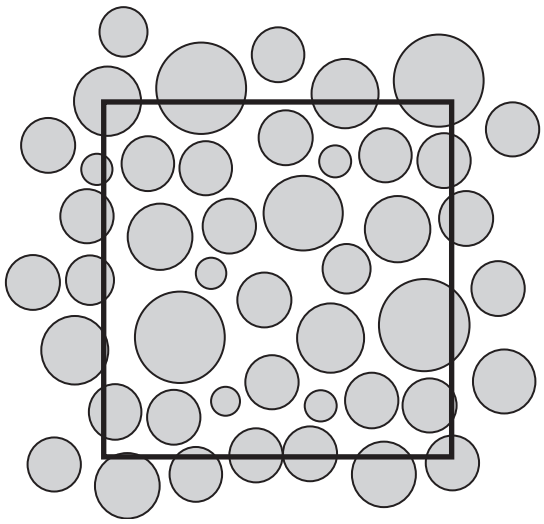

Figure 4 Concept of the representative elementary volume REV (within frame) with solid (gray) and fluid (white)

where $\langle\,\rangle_{\mathrm{REV}}$ means averaging over the REV. Equation 5 may be the starting point for the formulation of theories towards a theoretical foundation of Darcy's law, for example, after Bear and Bachmat (1991). After Matheron, (de Marsily, 1986), the linear form of Darcy's law is the consequence of the linear momentum balance provided the inertia terms are neglected.

Generalized Darcy's Law

The generally accepted result of the averaging procedure over the REV yields the generalized form of Darcy's law (Bear, 1979), which is the motion equation in a three-dimensional porous medium:

$$\mathbf{q} = -\frac{\mathbf{k}}{\boldsymbol{\mu}} \cdot [\nabla p - \rho \mathbf{g}] \tag{6}$$

The coefficient $\mathbf{k}$ is the permeability, which in general is a second order tensor. Typical values of permeability are listed in Table 1. Both fluid density ρ and dynamic viscosity μ may be space dependent. The values of p, ρ, and μ are averages over the REV.

Equation 6 allows a description of variable density flow (*see* **Chapter 157, Sea Water Intrusion Into Coastal Aquifers, Volume 4**), which may arise due to large temperature or large concentration gradients within the flow domain, where density differences may strongly affect the flow field. The latter is of special importance near coastal regions, or during the injection of water with high solute concentration into groundwater.

If the fluid density ρ is taken as constant within the considered flow domain, equation 6 can be expressed in the usual form, referred to as *Darcy's law*:

$$\mathbf{q} = -\mathbf{K} \nabla h \tag{7}$$

with the hydraulic conductivity tensor, $\mathbf{K}$, which relates to the permeability $\mathbf{k}$ as follows:

$$\mathbf{K} = \mathbf{k} \frac{g}{\nu} \tag{8}$$

and the piezometric head h (equation 2). The parameter ν is the kinematic viscosity with $\nu = \mu/\rho$. Given $\mathbf{k}$ and ν, the hydraulic conductivity $\mathbf{K}$ can be calculated, for example, for various temperatures affecting ν, using equation 8.

Applicability of Darcy's Law

Neglecting the inertia term is justified in most cases of ground water flow, due to the small groundwater velocities. A rough estimate of the ratio between the convective inertia term and the friction term within a single pore with scale d_{P} can be expressed by the Reynolds' number Re:

$$\frac{\rho \mathbf{v} \nabla \mathbf{v}}{\mu \nabla^2 \mathbf{v}} \approx \frac{v \dfrac{v}{d_{\mathrm{P}}}}{\nu \dfrac{v}{d_{\mathrm{P}}^2}} = \frac{v d_{\mathrm{P}}}{\nu} = Re \tag{9}$$

We may neglect the inertia terms compared to the friction term if *Re* is small. This means that creeping laminar flow conditions are required. The pore scale d_P might be best expressed by:

$$d_P = (k)^{1/2} \tag{10}$$

as suggested by Ward (Bear, 1979). For practical reasons, *Re* is usually taken as follows:

$$Re = \frac{qd}{\nu} \tag{11}$$

where d is a readily determined characteristic length of the pore space, for example, from sieve analysis of unconsolidated aquifer material as d_{10}, the grain size at 10% of the cumulative weight. The criterion for the applicability of Darcy's law is that *Re* is smaller than about 1 to 10 (Bear, 1979). In most ground water flow situations, this requirement is fulfilled. Exceptions may occur for flow at high gradient in aquifers, for example, near wells, or in macropore material.

Flow at higher Reynolds numbers is usually modeled by adding a correction term to the head gradient of the form aq^2 in Darcy's law according to Forchheimer (see Bear, 1979). A first order approximation of a more general motion equation was suggested by Chen *et al.* (2001) in the form:

$$-\rho J(\mathbf{q})\mathbf{q} + \mu\mathbf{q} = -\mathbf{k} \cdot [\nabla p - \rho\ \mathbf{g}] \tag{12}$$

where J is an operator. For $J(\mathbf{q}) = 0$ Darcy's law is obtained in its original form. For isotropic porous media, the first term reduces to $-\rho J(\mathbf{q}) = aq$.

Darcy's Law for Compressible Fluids

If variations of the fluid density, ρ, are only due to compressibility of the fluid, a potential after Hubbert (Bear, 1979) can be defined as follows:

$$h(\mathbf{x}) = z + \int_{p_0}^{p} \frac{\mathrm{d}p}{\rho(p)g} \tag{13}$$

with $p = p(\mathbf{x})$. This represents a generalization of the piezometric head for compressible fluids. Consider a piezometer according to Figure 2. Integrating the pressure profile $p(z)$ with fluid density $\rho(p)$, yields $h(\mathbf{x})$. Accordingly:

$$\nabla h = \frac{\partial h}{\partial p}\nabla p;\ \text{or}: \nabla p = \rho g \nabla h \tag{14}$$

and Darcy's law for compressible fluids becomes:

$$\mathbf{q} = -\frac{\mathbf{k}}{\boldsymbol{\mu}}\nabla h \tag{15}$$

Therefore, the relationship formally corresponds to equation 7.

The tensorial property of hydraulic conductivity, **K**, and permeability, **k**, is due to anisotropy effects. Anisotropy can arise, for example, due to stratification of heterogeneous aquifer.

Hydraulic Conductivity Tensor

Why are the tensors **K** and **k** symmetrical? This is shown for the example of **K**. Consider flow through the circular unit area with origin O (Figure 5) and normal unit vector $\mathbf{N} = (N_x, N_y, N_z)$. A hydraulic gradient $\mathbf{i} = (i_x, i_y, i_z)$ is present. Discharge is considered through the half-spherical area S, again with origin O, with an arbitrary surface element dS on S with normal unit vector $\mathbf{n} = (n_x, n_y, n_z)$. The hydraulic gradient in direction of **n** is $I(\mathbf{n}) = \mathbf{i} \cdot \mathbf{n} = n_x i_x + n_y i_y + n_z i_z$. Hydraulic conductivity in the direction of **n** is $K(\mathbf{n})$. The specific discharge d**q** through the surface element $dS(\mathbf{n})$ becomes:

$$\mathrm{d}\mathbf{q}(\mathbf{n}) = K(\mathbf{n})I(\mathbf{n})\mathbf{n}\,\mathrm{d}S(\mathbf{n}) \tag{16}$$

The component in direction of **N** is:

$$\mathrm{d}q(\mathbf{N}, \mathbf{n}) = K(\mathbf{n})I(\mathbf{n})\mathbf{n} \cdot \mathbf{N}\,\mathrm{d}S(\mathbf{n}) \tag{17}$$

The total discharge $q(\mathbf{N})$ through the half-spherical surface S is:

$$q(\mathbf{N}) = \int_S K(\mathbf{n})I(\mathbf{n})\mathbf{n} \cdot \mathbf{N}\,\mathrm{d}S \tag{18}$$

Choosing for **N** and **n,** the Cartesian directions x, y, and z and $i = 1$, the components of **K** are according to Table 2.

The integrals in Table 2 have to be evaluated over the surface area S. The expressions represent the discharge per unit area at a hydraulic gradient of one, and, therefore, the components of the tensor **K**. As shown in Table 2, the tensor is symmetric, provided $K(\mathbf{N}) = K(-\mathbf{N})$. This physical property of central symmetry is certainly fulfilled for porous media.

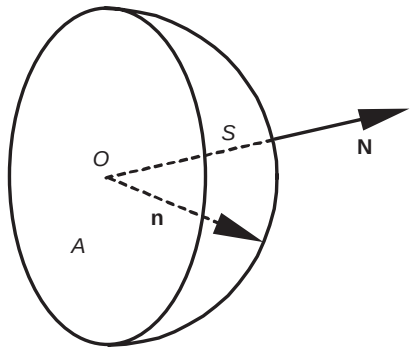

Figure 5 Circular unit area *A* with normal unit vector **N**, and half-spherical area *S* for direction-dependent hydraulic conductivity *K*

Table 2 Components of tensor **K**

	$\mathbf{i} = (1, 0, 0)$	$\mathbf{i} = (0, 1, 0)$	$\mathbf{i} = (0, 0, 1)$
$\mathbf{N} = (1, 0, 0)$	$K_{xx} = \int K(\mathbf{n}) n_x n_x \, dS(\mathbf{n})$	$K_{xy} = \int K(\mathbf{n}) n_x n_y \, dS(\mathbf{n})$	$K_{xz} = \int K(\mathbf{n}) n_x n_z \, dS(\mathbf{n})$
$\mathbf{N} = (0, 1, 0)$	$K_{yx} = \int K(\mathbf{n}) n_y n_x \, dS(\mathbf{n})$	$K_{yy} = \int K(\mathbf{n}) n_y n_y \, dS(\mathbf{n})$	$K_{yz} = \int K(\mathbf{n}) n_y n_z \, dS(\mathbf{n})$
$\mathbf{N} = (0, 0, 1)$	$K_{zx} = \int K(\mathbf{n}) n_z n_x \, dS(\mathbf{n})$	$K_{zy} = \int K(\mathbf{n}) n_z n_y \, dS(\mathbf{n})$	$K_{zz} = \int K(\mathbf{n}) n_z n_z \, dS(\mathbf{n})$

A symmetric tensor can be expressed by a symmetrical matrix, as for **K**:

$$\mathbf{K} = \begin{bmatrix} K_{xx} & K_{xy} & K_{xz} \\ K_{yx} & K_{yy} & K_{yz} \\ K_{zx} & K_{zy} & K_{zz} \end{bmatrix}; \qquad \text{with } K_{ij} = K_{ji} \tag{19}$$

According to the theorem for principal axes, a symmetric matrix can be transformed into a diagonal matrix $\mathbf{K}'$ by an orthogonal transformation, that is, by rotation of the coordinate system to the so called critical or principal axes x', y' and z':

$$\mathbf{K}' = \begin{bmatrix} K_{x'} & 0 & 0 \\ 0 & K_{y'} & 0 \\ 0 & 0 & K_{z'} \end{bmatrix} \tag{20}$$

The components $K_{m'}$ are the principal values of the tensor. The problem is identical to express the eigenvalues of the matrix requiring:

$$(\mathbf{K} - K'\mathbf{1}) \cdot \mathbf{e} = 0 \tag{21}$$

where **1** is the unit matrix, **e** is the unit eigenvector. The homogeneous Equation system 21 can be fulfilled if the determinant $det(\mathbf{K} - K'\mathbf{1})$ vanishes. The requirement leads to a characteristic polynomial of third degree with zero values equal to the eigenvalues $K_{x'}$, $K_{y'}$, and $K_{z'}$. These eigenvalues need to be positive for physical reasons. Furthermore, the sum of the diagonal components is constant in both coordinate systems:

$$K_{xx} + K_{yy} + K_{zz} = K_{x'} + K_{y'} + K_{z'} \tag{22}$$

Given the principal values $K_{x'}$, $K_{y'}$, and $K_{z'}$ the coefficients of the tensor **K** can be calculated as follows:

$$K_{ij} = K_{x'} \cos\alpha_{ix'} \cos\alpha_{x'j} + K_{y'} \cos\alpha_{iy'} \cos\alpha_{y'j} + K_{z'} \cos\alpha_{iz'} \cos\alpha_{z'j}; \quad i, j = x, y, z \tag{23}$$

K_{ij} can be interpreted as specific flux in direction i for a hydraulic gradient of 1 in direction of j. The functions $\cos(\alpha_{mn})$ are the direction-cosines between the directions m and n.

In the two-dimensional case, the directions of the principal axes x' and y' are determined by a single angle α (Figure 6). Together with the two principal components $K_{x'}$ and $K_{y'}$, the tensor is characterized by three parameters. In the three-dimensional case, we have three K-components and three angles.

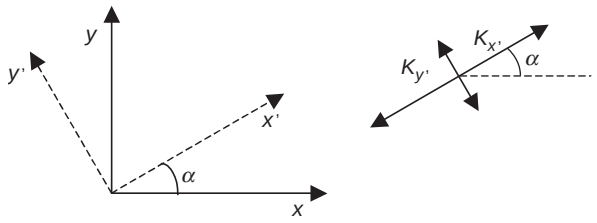

Figure 6 Coordinate system for the principal values for the hydraulic conductivity tensor $\mathbf{K}'$ in the two-dimensional case: Rotation by the angle α

Velocity

Based on the specific discharge $\mathbf{q}(\mathbf{x})$, the velocity vector $\mathbf{v}(\mathbf{x})$ can be determined by:

$$\mathbf{v} = \frac{\mathbf{q}(\mathbf{x})}{\phi(\mathbf{x})} \tag{24}$$

where ϕ is the porosity. The vector **v** is the average fluid velocity within the REV.

MASS BALANCE EQUATION FOR SATURATED FLOW

The formulation of the mass balance equation for saturated porous medium starts again with a microscopic consideration. For a microscopically small fluid volume without internal sources or sinks, it is required that (Figure 7):

$$\nabla \cdot (\rho \mathbf{v}) = -\frac{\partial \rho}{\partial t} \tag{25}$$

Basic element of the mass balance is the fluid mass flux $\mathbf{J} = \rho\mathbf{v}$ (= mass per unit area of fluid). The divergence of the mass flux equals the mass outflow minus the inflow per unit volume and unit time, and equals at the same time the change of fluid mass per unit time. Without sources and sinks, this mass change is due to fluid (and solid matrix) compressibility. Averaging equation 25 over an REV (Figure 4) yields:

$$\langle \nabla \cdot (\rho \mathbf{v}) \rangle_{\text{REV}} = \left\langle -\frac{\partial \rho}{\partial t} \right\rangle_{\text{REV}} \tag{26}$$

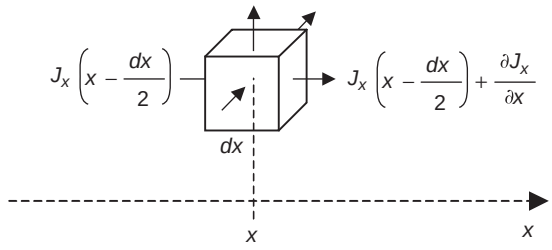

Figure 7 Microscopic volume element for the fluid mass balance with mass flux J_x in x-direction

Applying the averaging theorem (Whitaker, 1967), the balance equation is:

$$\langle \nabla \cdot (\rho \mathbf{v}) \rangle_{\mathrm{REV}} = \nabla \cdot \langle (\rho \mathbf{v}) \rangle_{\mathrm{REV}} + \frac{1}{V_0} \int_{A_{sf}} \mathbf{n} \cdot \mathbf{v} \, \mathrm{d}A \quad (27)$$

The surface area A_{sf} is the boundary between solid and fluid phase. The unit vector $\mathbf{n}$ is normal to this surface area at a particular point. Along the boundary, the velocity $\mathbf{v}$ vanishes. If the averaging is directly applied to the fluid phase f, the balance equation is:

$$\langle \nabla \cdot (\rho \mathbf{v}) \rangle_{\mathrm{REV}} = \nabla \cdot (\phi \langle \rho \mathbf{v} \rangle_{\mathrm{f}}) \quad (28)$$

The average mass flux $\langle \rho \mathbf{v} \rangle_{\mathrm{f}}$ can be written as:

$$\langle \rho \mathbf{v} \rangle_{\mathrm{f}} = \langle \rho \rangle_{\mathrm{f}} \cdot \langle \mathbf{v} \rangle_{\mathrm{f}} + \mathbf{J_d} \quad (29)$$

where $\mathbf{J}_{\mathrm{d}}$ is a dispersive mass flux caused by averaging the product of two variable quantities ρ and $\mathbf{v}$ within the REV. If the fluid density is constant, or can be considered as constant, at least within the REV, $\mathbf{J}_{\mathrm{d}}$ vanishes. The dispersive mass flux is usually neglected. The right-hand term of equation 26 can be written as:

$$\left\langle \frac{\partial \rho}{\partial t} \right\rangle_{\mathrm{REV}} = \frac{\partial}{\partial t} \langle \rho \rangle_{\mathrm{REV}} = \frac{\partial}{\partial t} (\phi \langle \rho \rangle_{\mathrm{f}}) \quad (30)$$

Equations 29 and 30 inserted in 26, with $\mathbf{q} = \phi \mathbf{v}$ and $\langle \rho \rangle_{\mathrm{f}} = \rho$ yields the macroscopic mass balance equation for a fluid of variable density in porous media:

$$\nabla \cdot (\rho \mathbf{q}) = -\frac{\partial (\phi \rho)}{\partial t} \quad (31)$$

For constant fluid density ρ the mass balance equation is:

$$\nabla \cdot \mathbf{q} = -\frac{\partial \phi}{\partial t} \quad (32)$$

and for constant density and porosity, it reduces to:

$$\nabla \cdot \mathbf{q} = 0 \quad (33)$$

If the fluid density depends on temperature T and solute concentration c, with $\rho(T, c)$, the mass change per unit time for constant porosity ϕ is:

$$\frac{\partial (\rho \phi)}{\partial t} = \phi \left(\frac{\partial \rho}{\partial T} \frac{\partial T}{\partial t} + \frac{\partial \rho}{\partial c} \frac{\partial c}{\partial t} \right) \quad (34)$$

If density variation is only due to fluid compressibility, the mass change per unit time is:

$$\frac{\partial (\phi \rho)}{\partial t} = \left(\rho \frac{\partial \phi}{\partial p} + \phi \frac{\partial \rho}{\partial p} \right) \frac{\partial p}{\partial t} \quad (35)$$

According to Hubbert's potential (equation 13) the change in pressure over time is:

$$\frac{\partial p}{\partial t} = \rho(p) g \frac{\partial h}{\partial t}$$

and therefore:

$$\frac{\partial (\phi \rho)}{\partial t} = \rho S_0 \frac{\partial h}{\partial t} \quad (36)$$

where S_0 is the called *specific storativity*, with:

$$S_0 = \left(\rho \frac{\partial \phi}{\partial p} + \phi \frac{\partial \rho}{\partial p} \right) g \quad (37)$$

Physically the specific storativity S_0 is the volume change of the fluid per unit volume of porous medium due to a unit increase or decrease in the piezometric head. It consists of two parts. The first part is due to a change in the pore volume, caused by deformation of the porous matrix. The second part is due to fluid compressibility. The latter can easily be assessed with the help of the fluid compressibility (compressibility of water: 4.810^{-10} Pa^{-1} for normal atmospheric conditions). In general, S_0 depends on fluid pressure, p. In practice, a constant value is usually applied for S_0.

The divergence of fluid mass flux can be further simplified by neglecting density differences within the REV, by assuming that at the macroscopic level, spatial changes are smaller than the temporal ones, by:

$$\nabla \cdot (\rho \mathbf{q}) = \rho \nabla \cdot \mathbf{q} \quad (38)$$

Therefore, the mass balance equation for compressible fluids and elastic matrix and an additional source/sink term, P, representing, for example, pumping, is, with Darcy's law (equation 7 inserted):

$$\nabla \cdot (\mathbf{K} \nabla h) + P = S_0 \frac{\partial h}{\partial t} \quad (39)$$

or in detail:

$$\frac{\partial}{\partial x}\left(K_{xx}\frac{\partial h}{\partial x}+K_{xy}\frac{\partial h}{\partial y}+K_{xz}\frac{\partial h}{\partial z}\right)+\frac{\partial}{\partial y}\left(K_{yx}\frac{\partial h}{\partial x}+K_{yy}\frac{\partial h}{\partial y}+K_{yz}\frac{\partial h}{\partial z}\right)+\frac{\partial}{\partial z}\left(K_{zx}\frac{\partial h}{\partial x}+K_{zy}\frac{\partial h}{\partial y}+K_{zz}\frac{\partial h}{\partial z}\right)+P=S_0\frac{\partial h}{\partial t} \tag{40}$$

For incompressible fluid and rigid matrix, it becomes (with $P = 0$):

$$\nabla \cdot (\mathbf{K}\nabla h) = 0 \tag{41}$$

If the porous medium is also isotropic, the balance equation is:

$$\nabla \cdot (K\nabla h) = 0 \tag{42}$$

If it is also homogeneous, we get the Laplace equation:

$$\nabla^2 h = \frac{\partial^2 h}{\partial x^2}+\frac{\partial^2 h}{\partial y^2}+\frac{\partial^2 h}{\partial z^2} = 0 \tag{43}$$

The specific storativity S_0 is of the order of $S_0 = 10^{-2}\,\mathrm{m}^{-1}$ for highly compressible clay material, and $S_0 = 10^{-7}\,\mathrm{m}^{-1}$ for rock material with small porosity (de Marsily, 1986). For sandy gravel aquifer material, S_0 is near $S_0 = 10^{-5}\,\mathrm{m}^{-1}$ (Domenico and Schwartz, 1990). The specific storativity is clearly increased if the porous medium contains a residual amount of trapped air bubbles.

FORMULATION OF FLOW PROBLEMS

The formulation of a flow problem consists of:

1. specifying the flow domain D, with boundary B;
2. specifying the appropriate fluid mass balance equation (continuity equation) with the dependent variable, for example, $h(\mathbf{x},t)$;
3. specifying the coefficients, for example, $\mathbf{K}(\mathbf{x})$, $S_0(\mathbf{x})$;
4. specifying the initial condition for transient flow problems;
5. specifying the boundary conditions at the boundary of the domain D.

Altogether, this defines a complete flow problem or flow model.

Initial Condition

The initial condition consists of the state of the dependent variable within the domain D at time $t = 0$:

$$h(\mathbf{x}, t=0) = h_0(\mathbf{x}); \quad \text{or} \quad p(\mathbf{x}, t=0) = p_0(\mathbf{x}); \quad \mathbf{x} \in D \tag{44}$$

Boundary Conditions

Along the complete boundary B, the flow conditions have to be formulated (specified or prescribed). Owing to the continuum principle, since the REV is not well defined directly on the boundary, the use of a finite REV raises a conceptual problem near the boundary. As an idealization, it is generally adopted that the average over the REV can be extrapolated to the boundary in order to obtain a continuous variable.

Direct Contact with Surface Water (Boundary B_1)

If an aquifer is in direct contact with a surface water body (like river, creek, canal, lake, etc.), the pressure can be expressed for the surface water body along the boundary B_1 (Figure 8). Assuming static conditions in the surface water body, the condition for the piezometric head is:

$$h(\mathbf{x}, t) = h_{\mathrm{B}_1}(\mathbf{x}, t); \qquad \mathbf{x} \in B_1 \tag{45}$$

The parameter $h_{\mathrm{B}_1}(\mathbf{x},\mathrm{t})$ is the water level of the surface water body, which can be transient. Mathematically speaking, this is a first type boundary condition (Dirichlet boundary condition).

Prescribed Flux Through Boundary (Boundary B_2)

If a prescribed flux $q_n(\mathbf{x},t)$, with $\mathbf{x} \in \mathrm{B}_2$, through the boundary is present at boundary B_2(see Figure 9), we have:

$$q_n(\mathbf{x}, t) = q_{\mathrm{B}_2}(\mathbf{x}, t); \quad \mathbf{x} \in B_2 \tag{46}$$

This corresponds to a second type boundary condition (Neumann boundary condition).

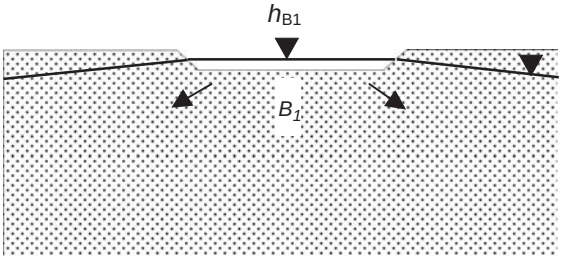

Figure 8 Boundary B_1: Direct contact of aquifer with a surface water body (schematic vertical cut)

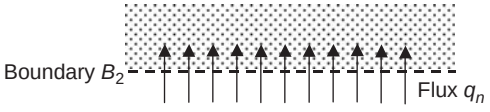

Figure 9 Boundary B_2: Prescribed flux q_n through a boundary

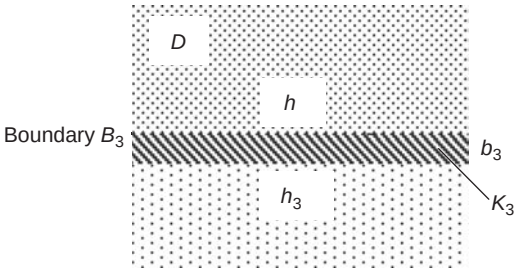

Figure 10 Semipermeable boundary B_3

A special case is the impermeable boundary, with $q_n = 0$ at boundary B_2, with the condition:

$$q_n(\mathbf{x}, t) = \mathbf{q}(\mathbf{x}) \cdot \mathbf{n} = \mathbf{K}(\mathbf{x}) \nabla h(\mathbf{x}) \cdot \mathbf{n} = 0; \qquad \mathbf{x} \in B_2 \tag{47}$$

which, for an isotropic hydraulic conductivity K, becomes:

$$\frac{\partial h}{\partial n}(\mathbf{x}) = 0; \qquad \mathbf{x} \in B_2 \tag{48}$$

Semipermeable Boundary (Boundary B_3)

Here, the flow domain is confined by a semipermeable layer of a porous medium with reduced permeability (Figure 10). Beyond this layer the hydraulic head is h_3. The hydraulic conductivity of the semipermeable layer is K_3, and the layer thickness is b_3.

According to Darcy's law, the specific flux through the boundary is:

$$q_n = K_3(\mathbf{x}) \frac{h_3(\mathbf{x}) - h(\mathbf{x})}{b_3}; \qquad \mathbf{x} \in B_3 \tag{49}$$

or:

$$(-\mathbf{K} \nabla h) \cdot \mathbf{n} = \frac{h_3(\mathbf{x}) - h(\mathbf{x})}{\sigma_3(\mathbf{x})}; \qquad \mathbf{x} \in B_3 \tag{50}$$

where $\mathbf{n}$ is a unit vector normal to the boundary. The factor $\sigma_3 = b_3/K_3$ is called *leakage coefficient*. The boundary condition (third type) is of mixed type (Cauchy boundary condition), with elements of first and second type. For isotropic hydraulic conductivity K, it becomes:

$$q_n = -K(\mathbf{x}) \frac{\partial h}{\partial n}(\mathbf{x}) = \frac{h_3(\mathbf{x}) - h(\mathbf{x})}{\sigma_3(\mathbf{x})}; \qquad \mathbf{x} \in B_3 \tag{51}$$

If the layer gets very permeable, $\sigma_3 \to 0$, and the present boundary condition reduces to one of prescribed head. For $\sigma_3 \to \infty$, the boundary is impermeable.

Groundwater Table as Boundary (Boundary B_4)

At the groundwater table, the pressure is, by definition, equal to atmospheric pressure, or relative pressure $p = 0$, or $h = z$. In the general case, the groundwater table is transient with $z_{GWT}(\mathbf{x},t)$ with $\mathbf{x} \in B_4$. Additionally, an areal recharge

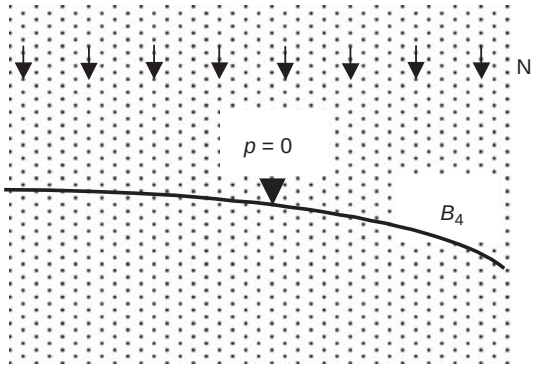

Figure 11 Groundwater table as boundary B_4 (schematic vertical section)

rate (fluid volume per unit area and unit time) $\mathbf{N}(\mathbf{x},t) = (0,0,-N)$ with $\mathbf{x} \in B_4$ may also be present (see Figure 11).

The problem consists of the fact that the boundary condition is known, but the location of the boundary is not known. Moreover, the boundary may be transient ("moving" boundary). Additional requirements are needed. The property that the relative water pressure at the groundwater table is zero, due to contact with air, can be represented by a function $F(\mathbf{x},t)$,

($F(\mathbf{x},t) = 0$, can be considered as the equation that describes the geometry of the boundary, Bear, 1979) with the condition for the water table:

$$F(x, y, z, t) = h - z = \frac{p}{\rho g} = 0; \qquad \mathbf{x} \in B_4 \tag{52}$$

The formulation of the condition $F(\mathbf{x},t) = 0$ can be accomplished by the material derivative:

$$\begin{aligned} \frac{DF}{Dt} &= \frac{\partial F}{\partial t} + \frac{\partial F}{\partial x}\frac{\partial x}{\partial t} + \frac{\partial F}{\partial y}\frac{\partial y}{\partial t} + \frac{\partial F}{\partial z}\frac{\partial z}{\partial t} = 0 \\ &= \frac{\partial F}{\partial t} + \frac{\partial F}{\partial x}u_x + \frac{\partial F}{\partial y}u_y + \frac{\partial F}{\partial z}u_z = 0 \\ &= \frac{\partial F}{\partial t} + \mathbf{u_F} \cdot \nabla F \end{aligned} \tag{53}$$

where $\mathbf{u_F}$ is the velocity of the groundwater table. The fluid mass balance condition at the moving groundwater table relative and normal to the surface $F(\mathbf{x},t) = 0$ requires (Figure 12):

$$\mathbf{q} \cdot \mathbf{n} - \mathbf{N} \cdot \mathbf{n} = \mathbf{u_F} \cdot \mathbf{n} \cdot \phi_e \tag{54}$$

where $\mathbf{n}$ is the unit vector normal to the surface $F = 0$, and ϕ_e is the effective (drainable) porosity. Therefore, the velocity of the groundwater table is expressed by:

$$\mathbf{u_F} = \frac{1}{\phi_e} \cdot (\mathbf{q} - \mathbf{N}) \tag{55}$$

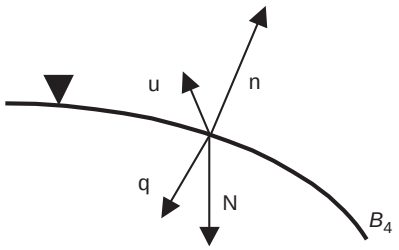

Figure 12 Specific flux vectors at the groundwater table (Boundary B_4)

Inserted in equation 53, the motion equation for the groundwater table is:

$$\frac{\partial F}{\partial t} + \frac{1}{\phi_e}[\mathbf{q} - \mathbf{N}]\nabla F = 0 \tag{56}$$

Together with equation 52 and Darcy's law for the principle axes of the tensor **K,** the condition for the 'moving' boundary B_4 gets:

$$\phi_e \frac{\partial h}{\partial t} = K_x \left(\frac{\partial h}{\partial x}\right)^2 + K_y \left(\frac{\partial h}{\partial y}\right)^2 + K_z \left(\frac{\partial h}{\partial z}\right)^2 - \frac{\partial h}{\partial z} \cdot (K_z + N) \tag{57}$$

This condition is nonlinear and has to be fulfilled simultaneously with the fluid mass balance equation.

Seepage Face Boundary (Boundary B_5)

A seepage face forms along an outlet surface (Figure 13), where water leaves the porous medium, gets in contact with the atmosphere, and seeps along the outlet surface. Assuming that the water thickness is negligible, the boundary condition at the seepage face between points D and E is:

$$p(\mathbf{x}) = 0; \quad \text{or:} \quad h(\mathbf{x}) = z; \quad \mathbf{x} \in B_5 \tag{58}$$

Contrary to the groundwater table (boundary B_4), the location of the seepage face is in principle known for a given boundary, with the exception of the upper point D, which is at the same time part of the free surface (boundary B_4).

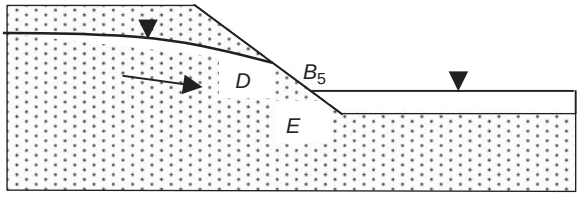

Figure 13 Seepage face along outlet surface (Boundary B_5)

FLOW IN EXTENDED THIN AQUIFERS

Flow of water in extended thin aquifers can be modeled as two-dimensional horizontal flow if the horizontal extension of the flow domain is much larger than the vertical. Usually, the following assumptions are adopted:

- The flow is horizontal. This means that vertical flux components are neglected.
- Water and porous matrix can be compressible. Therefore, the piezometric head is defined according to Hubbert's potential (equation 13).
- In the flow domain, no density effects due to temperature or concentration differences are considered.

By this formulation, a considerable simplification of the formulation of the flow problem is achieved. The flow domain not only reduces to the horizontal plane, but also the complicated motion equation 57 vanishes.

Flow in Confined Aquifers

The starting point for the formulation of the (macroscopic) mass balance equation within the aquifer is equation 39. For extended thin aquifers, the fluid mass balance is performed for a control volume (Figure 14), which extends over the complete thickness, H, of the aquifer. Aquifer bottom and top are taken as impermeable. Taking into account the fact that the aquifer may be more or less strongly heterogeneous, which leads to a spatial variability of the parameters **K**, and S_0, and the variable h. The size of the control volume has to that large, that stable average values are obtained. The integration of equation 39 over the control volume can be formulated as follows, with $P = 0$:

$$\iiint_{KV} \nabla \cdot (\mathbf{K}\nabla h)\, \mathrm{d}V = \iiint_{KV} S_0 \frac{\partial h}{\partial t}\, \mathrm{d}V \tag{59}$$

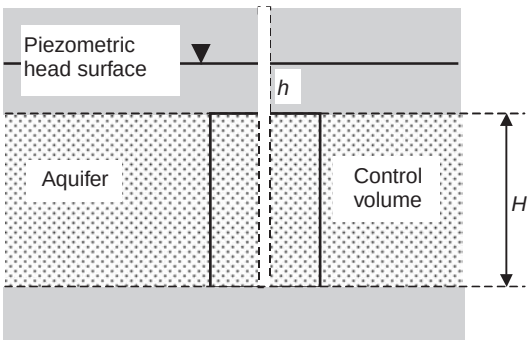

Figure 14 Control volume for an extended thin aquifer

Applying Gauss' law to the left-hand side of equation 59 leads to:

$$\iiint_{KV} \nabla \cdot (\mathbf{K}\nabla h)\,\mathrm{d}V = \iint_{A} (\mathbf{K}\nabla h)\mathbf{n}\,\mathrm{d}A = Q_{x2} - Q_{x1} + Q_{y2} - Q_{y1} \quad (60)$$

where $\mathbf{n}$ is the unit vector normal to the surface A. The surface A is the complete surface of the control volume. The terms Q_i are the horizontal fluxes through the vertical surfaces A_i. Vertical fluxes are not present. Assuming a horizontal bottom and top surface of the control volume leads to:

$$H \cdot \langle \nabla \cdot (K\nabla h) \rangle = \nabla \cdot (H\mathbf{q}) = H \cdot \left\langle S_0 \frac{\partial h}{\partial t} \right\rangle \quad (61)$$

where $\langle\rangle$ means averaging over the control volume. The term $\mathbf{q}H = Q'$ is the horizontal flux per unit width, with components in the direction $\mathbf{i}$:

$$Q'_i = H\ q_i = \frac{H}{A_i} \iiint_{A_i} (\mathbf{K}\nabla h)\mathbf{i}\,\mathrm{d}A \quad (62)$$

The horizontal flux $\mathbf{Q}'$ per unit width may be modeled by the approach in analogy to Darcy's law:

$$\mathbf{q}H = -H\mathbf{K}_{\mathbf{eq}}\nabla\langle h \rangle \quad (63)$$

where K_{eq} is the equivalent hydraulic conductivity, valid for the control volume. The expression $H\mathbf{K}_{\mathrm{eq}} = \mathbf{T}$ is called *transmissivity* $\mathbf{T}$. This coefficient is, in general, again a symmetrical second order tensor. For isotropic condition in the horizontal plane, it reduces to a scalar quantity $T = KH$. Assuming, furthermore, that the temporal volume changes within the control volume can be written as:

$$H \left\langle S_0 \frac{\partial h}{\partial t} \right\rangle = H S_0 \frac{\partial \langle h \rangle}{\partial t} = S \frac{\partial \langle h \rangle}{\partial t} \quad (64)$$

we get the flow balance equation for an extended thin aquifer, including a source/sink term, $P(x, t)$, with $h = \langle h \rangle$ of the form:

$$\nabla \cdot (\mathbf{T}\nabla h) + P = S \frac{\partial h}{\partial t} \quad (65)$$

The coefficient $S = HS_0$ is the storativity for confined aquifers. The storativity, S, is dimensionless and can be interpreted as *water volume change in the control volume per unit horizontal area of the aquifer at a unit increase of the piezometric head*. Typical values are around $S = 10^{-5}$ for sandy gravel material. If water and the porous matrix are taken as incompressible, it reduces to $S = 0$. In this case, the equation describes a pseudosteady state. In transient flows, time dependence is introduced via the boundary conditions.

For anisotropic porous media, $\mathbf{T}$ is a tensor, and the flow balance equation becomes (in detail):

$$\frac{\partial}{\partial x}\left(T_{xx}\frac{\partial h}{\partial x}\right) + \frac{\partial}{\partial x}\left(T_{xy}\frac{\partial h}{\partial y}\right) + \frac{\partial}{\partial y}\left(T_{yx}\frac{\partial h}{\partial x}\right) + \frac{\partial}{\partial y}\left(T_{yy}\frac{\partial h}{\partial y}\right) + P = S\frac{\partial h}{\partial t} \quad (66)$$

and for isotropic T:

$$\frac{\partial}{\partial x}\left(T\frac{\partial h}{\partial x}\right) + \frac{\partial}{\partial y}\left(T\frac{\partial h}{\partial y}\right) + P = S\frac{\partial h}{\partial t} \quad (67)$$

and for constant isotropic T:

$$T\left(\frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial y^2}\right) + P = S\frac{\partial h}{\partial t} \quad (68)$$

If flow is additionally at steady state, we get:

$$\frac{\partial^2 h}{\partial x^2} + \frac{\partial^2 h}{\partial y^2} + \frac{P}{T} = 0 \quad (69)$$

The flow balance equation can easily be extended to include leaky aquifers (Figure 15). A confined aquifer is connected with a lower (l) and/or an upper (u) aquifer by semipermeable layers of hydraulic conductivity K_{l} and K_{u} and of thickness b_{l} and b_{u}. The piezometric head in the lower and upper aquifers is h_{l} and h_{u}.

The vertical fluxes q_{vl} and q_{vu} can be expressed by Darcy's law and by introducing leakage coefficients, σ_{l} and σ_{u}:

$$q_{\mathrm{vl}} = K_{\mathrm{l}} \cdot \frac{h_{\mathrm{l}} - h}{b_{\mathrm{l}}} = \frac{h - h_{\mathrm{l}}}{\sigma_{\mathrm{l}}}$$
$$q_{\mathrm{vu}} = K_{\mathrm{u}} \cdot \frac{h_{\mathrm{u}} - h}{b_{\mathrm{u}}} = \frac{h - h_{\mathrm{u}}}{\sigma_{\mathrm{u}}} \quad (70)$$

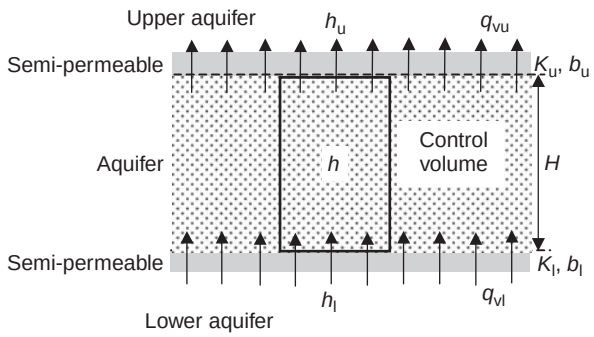

Figure 15 Leaky confined aquifer: control volume

Therefore the flow balance equation for a leaky confined aquifer is:

$$\nabla \cdot (\mathbf{T}\nabla h) + \frac{h_\mathrm{l} - h}{\sigma_\mathrm{l}} + \frac{h_\mathrm{u} - h}{\sigma_\mathrm{u}} = S\frac{\partial h}{\partial t} \qquad (71)$$

Flow in Unconfined Aquifers

In unconfined aquifers (Figure 16), the upper limit of the flow domain is given by the groundwater table, whose location may be transient. The bottom of the aquifer is at the level $z_\mathrm{l}(\mathbf{x})$, which does not need to be horizontal. The flow balance equation is formulated for a control volume with its center at location $\mathbf{x}$; it extends from the bottom to the groundwater table. Therefore, the control volume is transient. According to Dupuit's assumption, the elevation of the groundwater table can be approximated by the average piezometric head $h(\mathbf{x})$ within the control volume.

Contrary to the confined case, an additional volume change occurs within the control volume due to the vertical movement of the groundwater table and due to a possible areal replenishment rate N (Volume per unit horizontal area and unit time). A rise in the groundwater table elevation, h_{GWT}, causes an increase in the water volume by ΔV, and *vice versa*. This can be stated, per unit horizontal area and unit time, as follows:

$$\phi_\mathrm{e}\frac{\partial h_{GWT}}{\partial t} \approx \phi_\mathrm{e}\frac{\partial h}{\partial t} \qquad (72)$$

where ϕ_e is the effective (drainable) porosity, which is the part of the total pore volume, which can be filled or drained. Thus the flow balance equation for unconfined aquifers becomes, including a source/sink term P:

$$\nabla \cdot (\mathbf{T}\nabla h) + N + P = S\frac{\partial h}{\partial t} \qquad (73)$$

where S is the storativity of the unconfined aquifer. It is composed of a portion due to compressibility of water and porous matrix, and the effective porosity, which is in fact dominant. The storativity, S, for unconfined aquifer is the volume change of water per unit horizontal area and unit rise of the groundwater table. Typical values are around $S = 0.1$ to 0.2 for sandy gravel aquifers. Obviously the values are larger than those for confined conditions.

The transmissivity depend on the thickness $H(x, t)$, which, for unconfined aquifers, is:

$$H(\mathbf{x}, t) = h(\mathbf{x}, t) - z_\mathrm{l}(\mathbf{x}) \qquad (74)$$

Therefore, the transmissivity $T(\mathbf{x}, h(\mathbf{x}, t), t)$ depends on the level $h(\mathbf{x}, t)$ of the groundwater table, and the flow balance equation becomes nonlinear. If the transient changes in the piezometric head, $h(\mathbf{x}, t)$, can be neglected, compared to the thickness, H, the balance equation becomes linearized.

A leaky unconfined aquifer can be considered in a fashion similar to that of the confined case. The flow balance equation for a lower (l) leaky aquifer with leakage coefficient σ_l becomes:

$$\nabla \cdot (\mathbf{T}\nabla h) + N + \frac{h_\mathrm{l} - h}{\sigma_\mathrm{l}} = S\frac{\partial h}{\partial t} \qquad (75)$$

A frequent application of this concept is the consideration of the interaction between surface water and groundwater (Figure 17). Let an unconfined aquifer be directly connected with a surface water body. Clogging of the bottom of the surface water body (river, creek, lake, etc.) by fine sediments may cause the establishment of a semipermeable layer. This relates to the part of the aquifer beneath a (rather wide) river and an underlying (relatively) thin aquifer, as Figure 17 shows portions of the phreatic aquifer with no direct contact with surface water. Moreover, for this part, there is no replenishment rate N where there is a semipermeable layer. Such a situation can be treated using equation 75 by replacing h_l and σ_l by h_SW and σ_SW., and by setting $N = 0$. Even without a clogging layer, a leakage coefficient may be present. This may be due to the vertical flow components, which lead to a level difference between h (average head in control volume below surface water body) and h_SW (surface water level). Moreover it can happen that the leakage coefficient depends on the surface water level, $h_\mathrm{SW}(t)$. This may be the case when the lateral banks of the surface water body are more permeable than the bottom, thus leading to higher infiltration or exfiltration rates for higher surface water levels, h_SW.

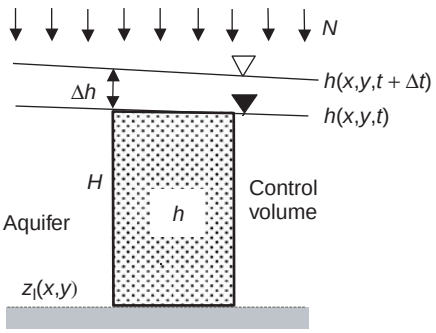

Figure 16 Unconfined aquifer: Control volume

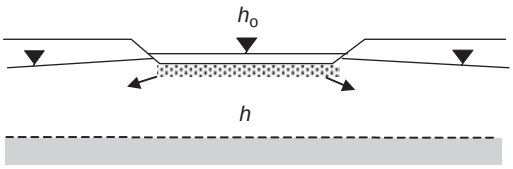

Figure 17 Direct infiltration from surface water to groundwater

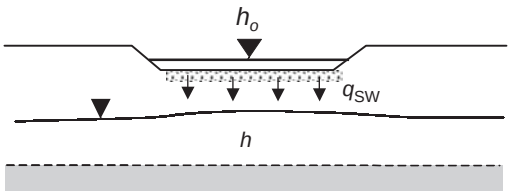

Figure 18 Groundwater table below the bottom of a surface water body

If the hydraulic conductivity, K_{SW}, of the semipermeable layer of the surface water decreases, the leakage coefficient of this layer increases and the groundwater table may, finally, fall below the bottom of the surface water body (Figure 18). An unsaturated domain establishes itself between surface water and the groundwater table. The flux through the bottom of the surface water body is now determined by h_{SW}, K_{SW} and the water pressure below the semipermeable layer. Such a situation is best modeled by replacing N in equation 75 by an areal recharge rate $q_{SW}(\mathbf{x}, t)$ within the surface water area.

Initial and Boundary Conditions

The formulation of the flow problem in extended thin aquifers, again, needs the definition of the flow domain D, of the flow balance equation for the dependent variable $h(\mathbf{x}, t)$, of the coefficients (e.g. T, S, $N(\mathbf{x}, t)$), of the initial condition $h(\mathbf{x}, t) = 0 \in D$, and of the boundary conditions. The coefficients $T(\mathbf{x})$, $S(\mathbf{x})$, and $N(\mathbf{x}, t)$ have to be defined within the complete flow domain D. Additionally, the levels of the aquifer bottom, $z_l(\mathbf{x})$, and top $z_u(\mathbf{x})$ have to be specified.

Direct Contact with Surface Water (Boundary B_1)

The aquifer is in direct contact with a surface water body along the boundary B_1. This leads to the boundary condition (first type) similar to equation 45:

$$h(\mathbf{x}, t) = h_{B_1}(\mathbf{x}, t); \qquad \mathbf{x} \in B_1 \tag{76}$$

Prescribed Flux Q' Through Boundary (Boundary B_2)

The prescribed flux $\mathbf{Q}'$ per unit width (second type boundary condition) is similar to equation 46:

$$\mathbf{Q}'(\mathbf{x}, t) \cdot \mathbf{n}(x, t) \equiv Q_n(\mathbf{x}, t) = -\mathbf{T} \cdot \nabla h \cdot \mathbf{n} = Q_{n,B_2}(\mathbf{x}, t); \quad \mathbf{x} \in B_2 \tag{77}$$

where $\mathbf{n}$ is the unit vector normal to the boundary. For an impermeable boundary, we get for isotropic T:

$$Q_n(\mathbf{x}, t) = -T \frac{\partial h}{\partial n} = 0; \text{ or : } \quad \frac{\partial h}{\partial n} = 0; \quad \mathbf{x} \in B_2 \tag{78}$$

Semipermeable Boundary (Boundary B_3)

If a surface water body represents a boundary, and is connected via a semipermeable layer with an aquifer, it can be idealized for a vertically integrated flow according to Figure 19:

$$Q_n(\mathbf{x}, t) = -\mathbf{T} \cdot \nabla h \cdot \mathbf{n} = \frac{h_3(\mathbf{x}, t) - h(\mathbf{x}, t)}{\sigma_3(\mathbf{x}, t)}; \qquad \mathbf{x} \in B_3 \tag{79}$$

where σ_3 is again a leakage coefficient.

Simple Example for Flow Problem Formulation

Consider a flow domain in an unconfined isotropic aquifer, according to Figure 20. The flow balance equation is

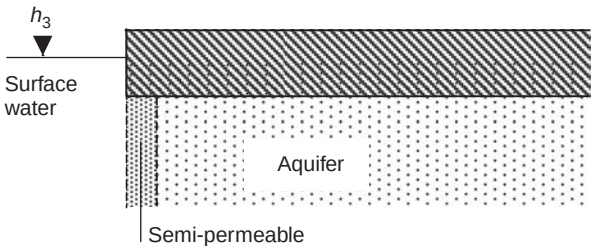

Figure 19 Semipermeable boundary B_3: Idealization

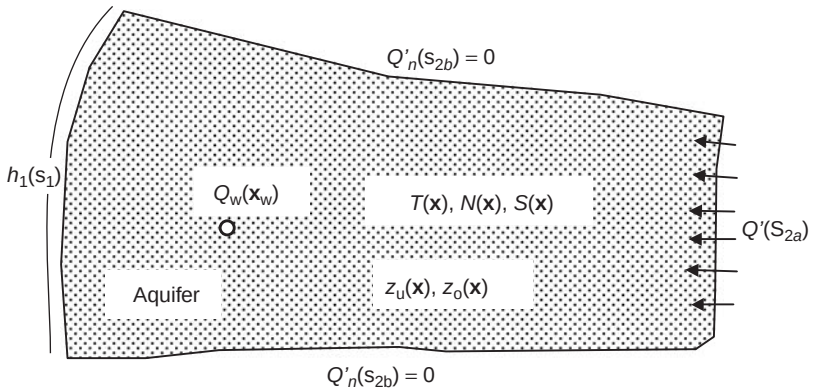

Figure 20 Example of an extended unconfined thin aquifer with a pumping well

given by equation 67. The transmissivity T is calculated with the help of the equivalent hydraulic conductivity, $K_{eq}(\mathbf{x})$, and the thickness, $H(\mathbf{x}, t) = h(\mathbf{x}, t) - z_l(\mathbf{x})$. Therefore, the aquifer bottom levels, $z_l(\mathbf{x})$, have to be provided as well. The values for $K_{eq}(\mathbf{x})$ may be determined by pumping tests in boreholes or wells. Either interpolated, distributed, or geologically motivated zonal values for K_{eq} can be provided. The replenishment rate is $N(\mathbf{x}, t)$. This rate is essentially the precipitation rate minus the evapotranspiration rate and the surface runoff and can be estimated by using hydrological methods. The boundary conditions along the boundaries are as follows. The aquifer is in direct contact with a river with a water level $h_1(\mathbf{s}_1)$. This defines a first type boundary condition along the river. At the opposite boundary, a prescribed distributed flux, $Q'(\mathbf{s}_{2a})$, is given. The lateral boundaries are impermeable, with $\partial h/\partial n(\mathbf{s}_{2b}) = 0$. The effect of a pumping well with pumping rate Q_w at location $\mathbf{x}_w$ is considered in the source/sink term P. The initial condition is $h(\mathbf{x}, t = 0) = h_0(\mathbf{x})$, which may be based on interpolated head measurements at a given time.

150: Unsaturated Zone Flow Processes

JOHN R NIMMO

United States Geological Survey, Menlo Park, CA, US

Water flow in the unsaturated zone is greatly influenced by unsaturated hydrostatics (water content, energy, pressure, and retention) and by unsaturated hydrodynamics (diffuse flow and preferential flow). Important multiphase processes include the transport of gases, nonaqueous liquids, and solid particles. Numerous means are available for determination of unsaturated conditions and properties, both measurement (of moisture state, water retention, and dynamic characteristics) and through various formulas and models that are mostly empirical in nature, but in some cases incorporating insight into unsaturated-zone physical processes. Applications to practical problems include models and techniques relating to distributions of water and energy, fluxes at the land surface, inputs, outputs, and fluxes within the unsaturated zone, all of which are frequently complicated by heterogeneity and preferential flow. Further scientific advance requires new measurement techniques and theoretical constructs that more adequately represent the important physical processes within practical modeling schemes.

INTRODUCTION

The unsaturated zone, sometimes called the *vadose zone* or *zone of aeration*, plays several critical hydrologic roles. As a storage medium, it is a zone in which water is immediately available to the biosphere. As a buffer zone between the land surface and aquifers below, the unsaturated zone is a controlling agent in the transmission of contaminants and aquifer-recharging water. As an accessible body of material in which physical and chemical processes may be relatively slow, it is a place where wastes are emplaced to isolate them from significant exchange with other environmental components. Thus, the flow processes that occur in the unsaturated zone substantially contribute to a wide variety of hydrologic processes.

Scientifically, the unsaturated zone is highly complex and must be studied with an interdisciplinary approach. There is much variety in its natural constituents: soils, rocks, water, air, plants, animals, and microorganisms. Modern hydrology must consider interactions not only among these constituents themselves, but also with a wide variety of contaminants, including pesticides, fertilizers, irrigation wastewater, manure, sewage, toxic chemicals, radioactive substances, bacteria, mine wastes, and organic liquids.

This article first describes in a fundamental way the physical basis of phenomena that strongly relate to unsaturated flow. The next section presents techniques for obtaining quantitative values of properties that influence unsaturated flow, by direct measurement and by indirect means. The third major section describes some of the main hydrologic applications related to flow in the unsaturated zone.

PHENOMENA OF UNSATURATED ZONE FLOW

Water resides in an unsaturated porous medium along with air and solids, as Figure 1 illustrates. The usual tendency is for water to cling to solid surfaces, in films, and in curved air–water interfaces as shown. Hydrological processes involve movement of any of these materials. Thus, transport in an unsaturated medium is always a case of multiphase transport, though the term "multiphase" is used mainly for cases where gas, solid, or multiple-liquid phases are considered.

Various materials comprise the solid fabric of the unsaturated zone, including soil, stones, porous rock, and organic matter. A common distinction is between particulate, or granular, media in which particles are separate from each other, and consolidated or lithified media in which they are joined.

Basic features of soil and rock relevant to flow in the unsaturated zone include texture, structure, and

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

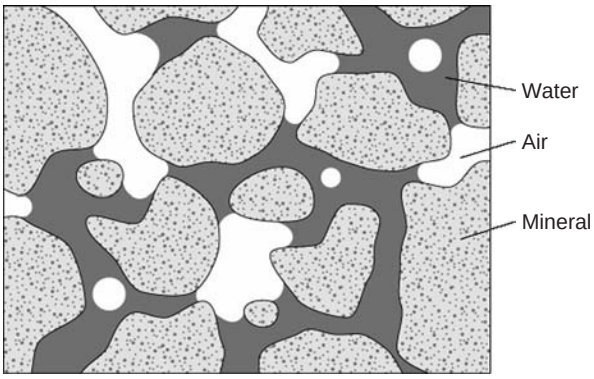

Figure 1 Microscopic cross-sectional view of a hypothetical unsaturated medium. Few intergrain contacts appear because these contacts are essentially points in three-dimensional space, and mostly do not lie in the two-dimensional plane of this figure

the content of mineral and nonmineral constituents (*see also* **Chapter 147, Characterization of Porous and Fractured Media, Volume 4**). Texture, applied to a granular medium, refers to particle-size distribution. Structure refers to the arrangement of the solid components of the medium. Essential structural considerations include porosity, aggregation, cementation, and macropores. Structure is often considered alongside texture as a primary determinant of the pores of the medium.

This section considers unsaturated-zone flow phenomena through progressive increases in complexity as elaborated in Table 1. It concludes with a discussion of multiphase flow, with explicit attention to the transport of materials other than liquid water.

Unsaturated Hydrostatics

Water Content, Energy, and Pressure

The most basic measure of the water is volumetric water content, symbolized θ or θ_w, defined as the volume of water per bulk volume of the medium. An alternative is the mass-basis (or gravimetric) water content θ_m, the mass of water per mass of solid. These are related by the formula

$$\theta_w = \frac{\rho_b}{\rho_w}\theta_m \quad (1)$$

where ρ_b is the bulk density and ρ_w is the density of water. In general, the volumetric water content is most useful because its range has a clearly defined maximum at the medium's porosity, ϕ, and it relates easily to visualizations of intrapore geometry as in Figure 1.

Water is held in an unsaturated medium by forces whose effect is expressed in terms of the energy state of the water, force being the negative gradient of energy. The energy is usually expressed as a potential, taken as energy per unit volume. For an incompressible bulk material like water, the energy per unit volume can equivalently be considered as a pressure. Gravitational energy can be treated essentially as it is for saturated modes of fluid transport. The matric potential or pressure, which often is the only other significant type of energy determining the chief water transport processes in an unsaturated medium, arises from the interaction of water with a rigid matrix ("matric" being the adjective form of "matrix"). Sometimes this quantity is called *capillary potential* or *pressure*. Matric pressure may be thought of as the pressure of the water in a pore of the medium relative to the pressure of the air, in other words, the pressure difference across an air–water interface. When a medium is unsaturated, the water generally is at lower pressure than the air, so the matric pressure is negative. Another term is "suction", the negative of matric pressure. Many problems are simpler with the expression of matric pressure in head units.

Matric pressure is often thought of in relation to surface tension and capillary phenomena, especially in the range near saturation. A pore with water can be compared to a thin capillary tube with one end immersed, as in Figure 2.

Table 1 Levels of complexity considered in unsaturated flow

Type of flow	Phenomena	Mathematical description	Relevant features and properties of medium	Typical applications
Static (no flow)	All forces (on water) balance	Hydrostatic equation	Water retention	Available water for plants; basis for understanding
Steady	Flow driven by unchanging force field	Darcy's law	Hydraulic conductivity	Long-term averages
Unsteady – diffuse	Continuity, and force field affected by dynamic conditions	Darcy's law and continuity equation (combined as Richards' equation)	Hydraulic conductivity and water retention	Stable flow in media whose pore sizes approximate grain sizes
Preferential	Flow concentrated in pathways that differ in character from the bulk medium	Unknown; diverse alternatives in current use	Macropores, layer contrasts, propensity for unstable flow	Flow in media with significant nonuniformities; unstable flow

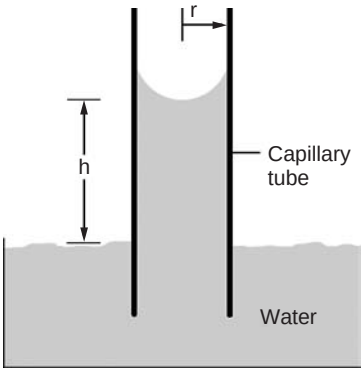

Figure 2 Capillary rise in a tube of circular cross section

The curvature of the air–water interface is inversely related to the water pressure: tighter curvature is associated with smaller pores and with more negative matric pressure. To quantify the relation between the tube radius and matric pressure ψ, consider the pressure in the water just below the curved air–water interface, which equals ψ. For the static situation, upward and downward forces balance. The downward force is the pressure acting on the area of the air–water interface, $\psi\pi r^2$. The upward force results from surface tension σ, the force per unit length of the air–water interface, acting on a circumference of the inner wall of the tube. For the case where the air–water interface is perfectly tangent to the tube wall, this force is $2\pi r\sigma$. Equating these forces gives

$$\psi = -\frac{2\sigma}{r} \tag{2}$$

Pores in natural media are not perfectly cylindrical, but the same relation applies if it is understood that r represents an effective pore radius. The relation given in equation (2) is useful in picturing what happens within a pore and in modeling unsaturated hydraulic properties.

Where the three phases come together, the angle between the air–water interface and the air–solid interface, measured through the water, is the contact angle. This angle depends on the materials. If the solid has much greater attraction to the liquid than to the air, it is highly wettable and the contact angle can be essentially zero, as assumed in the derivation of equation (2). If the solid has much greater attraction to the air, the material is nonwettable and would have a contact angle near 180°. Intermediate cases have intermediate values of contact angle, and some materials are difficult to classify as wettable or nonwettable. For a nonzero contact angle, formulas like (2) are modified by multiplying the force associated with surface tension by the cosine of the contact angle.

When the medium is so dry that water does not fill pores, but adheres in thin films to the solid matrix, the concepts of surface tension and capillarity are not so directly applicable, and the forces of adhesion establish the matric pressure. One can think of a capillary component of matric pressure that dominates when the medium is wet, and an adhesive component that dominates when it is dry.

Water Retention

If the matric pressure is close to zero, air–water interfaces are broadly curved, nearly all pores are filled, and the water content is high. If matric pressure is much less than zero, the interfaces are more tightly curved, they can no longer go across the largest pores, and the pores have less water in them. Thus, greater water content goes with greater (less strongly negative) matric pressure.

The relation between matric pressure and water content, called a *water retention* curve, depends on the medium. Larger pores empty first as the water content decreases. A medium with many large pores will have a retention curve that drops rapidly to low water content at high matric pressures. Conversely, a fine-pored medium will retain much water even at low matric pressures, and so will have a flatter retention curve. Figure 3 shows a typical retention curve for a sandy soil. The curve is far from linear and covers 5 orders of magnitude in ψ. This enormous range is difficult to work with and requires multiple measurement techniques. In most cases, investigators measure and plot only a portion of the range, usually at the wet end.

Considering the drying of soil from saturation, θ in Figure 3 stays high until a particular ψ value where it starts to decline. This ψ is called the *air-entry value*. By the capillary hypothesis, it exists because the largest

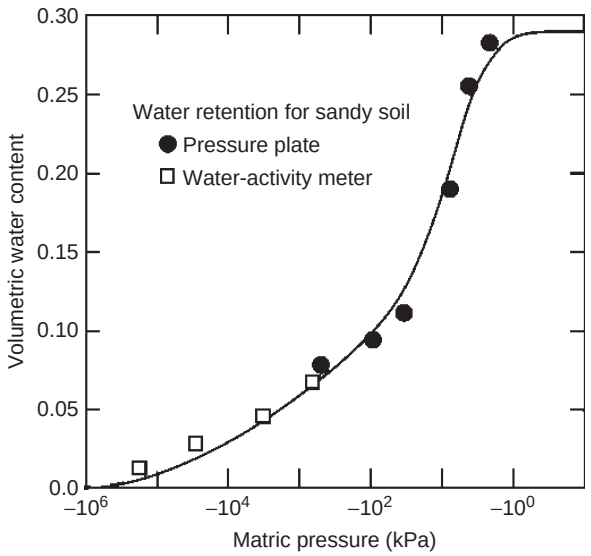

Figure 3 A retention curve for a sandy soil from the amargosa desert research site (Andraski, 1996). The points are measurements by two different methods and the smooth curve is a fit of the model of Rossi and Nimmo (1994)

fully wet pore of the medium will stay filled until the air–water pressure difference exceeds the equivalent ψ value of capillary rise. In natural media the air-entry value is usually poorly determined, as the decline in θ with ψ starts gradually, beginning at ψ nearly equal to zero. Artificial porous media, however, can be made in such a way that many pores are close to the size of the largest pore, so that air entry is a sharp and sudden phenomenon.

The maximum θ value of the curve usually is not equal to ϕ but rather something less, because at $\psi = 0$, trapped air occupies some of the pore space. At the other end, the curve goes to $\theta = 0$ at a ψ value of about -10^6 kPa.

In a granular medium, the particle-size distribution or texture relates in a general way to the pore-size distribution, as larger particles may have larger pores between them. Texture thus is a major influence on the retention curve. Additionally, the structure of the medium, especially as related to such features as aggregation, shrinkage cracks, and biologically generated holes, substantially influences the retention curve.

At low matric pressures, few pores are filled and a large fraction of the total water is in thin films. These films are thinner at lower matric pressures, with less energy for holding water onto the solid medium. At high matric pressures thicker films can be important, as when the medium is nearly saturated except for fractures and other large pores. If the films are thick enough, water in them may be free to flow. Tokunaga and Wan (1997) have measured film thicknesses of tens of microns at matric pressures between -0.1 kPa and 0.

The retention relation is strongly hysteretic: when measured as the medium wets, water content is less for a given matric pressure than it is when measured as the medium dries. Figure 4 shows a typical example. The outer curves, starting from extreme wet or extreme dry conditions, are called *main drying* and *main wetting* curves. The curves

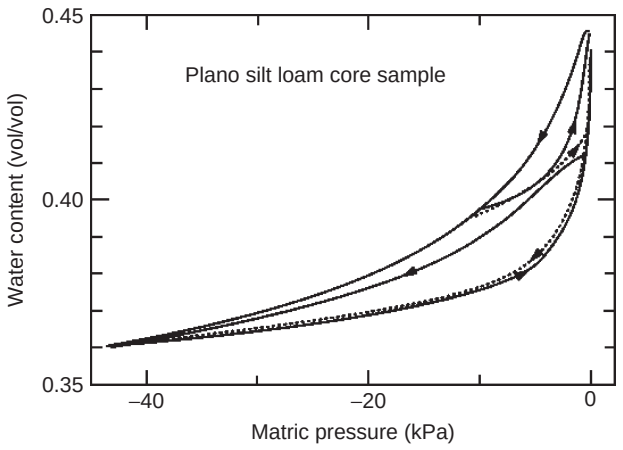

Figure 4 Hysteretic water retention in a soil core sample, data of Nimmo and Miller (1986)

starting from intermediate water contents are called *drying* and *wetting scanning* curves. Of course, there are whole families of possible scanning curves, starting from different points. Scanning curves that start on main curves are called *primary scanning* curves, those that start on primary scanning curves are secondary scanning curves, and so forth. Unsaturated zone investigations frequently neglect hysteresis, not always justifiably.

Several mechanisms cause $\theta - \psi$ hysteresis, the main one in fairly wet media being the Haines jump mechanism, illustrated in Figure 5. Unlike capillary tubes, pores in natural media are not uniform in effective diameter. The pore throats, which control the ψ at which pores empty and therefore determine the drying curve, are smaller than the pore bodies, which control the ψ at which pores fill and determine the wetting curve. As the medium dries and ψ decreases, water retreats gradually as the air–water interface becomes more curved. At the narrowest part of the pore throat, this surface can no longer increase curvature by gradual amounts, so in what is called a *Haines* jump, it retreats suddenly to narrower channels elsewhere in the nearby pore space. An analogous phenomenon occurs during wetting, when the decreasing interface curvature cannot be supported by the diameter of the pore at its maximum. Hysteresis occurs because the drying and wetting Haines jumps occur at different ψ values. Some of the pore space, where the movement of the interface is always gradual, is not subject to hysteresis. The amount of such nonhysteretic pore space varies with the pore geometry of the medium, and thus is one phenomenon that makes the degree of hysteresis vary among media. Other mechanisms include contact angle hysteresis, which is not well understood because contact angles within pores are difficult to measure, and adsorptive hysteresis, which may be quite significant near the dry end of the moisture range.

As explained below in connection with gas transport, natural media do not usually become fully saturated, even at $\psi = 0$. Some amount of air normally gets trapped in the form of bubbles enclosed by water, typically occupying 10 to 30% of the pore space. Thus, the main drying curves in Figures 3 and 4 have a maximum θ that is less than ϕ. Sometimes, though, the medium may be saturated long enough for all trapped bubbles to dissolve. On drying, the retention curve would then start from $\theta = \phi$, as illustrated by the data in Figure 6. This is called a *first* (or initial or primary) *drying* curve. One natural phenomenon likely to involve a first drying curve is the decline of a water table after a long time at a high level.

Temperature, because it affects surface tension and other relevant properties, significantly affects the retention relation. Increasing temperature means that less water will be held at a given matric pressure. This effect can be quantified using the gain-factor model of Nimmo and

Miller (1986) or the enthalpy-based model of Grant and Salehzadeh (1996).

Basic Unsaturated Flow

In conventional unsaturated flow theory, two types of factors determine water flux: driving forces (chiefly gravity and matric pressure gradients) and properties of the medium. The matric forces sometimes greatly exceed the gravitational force. Other forces may be significant for driving flow under some conditions, as when temperature gradients are significant, or when there are physical barriers to the movement of solutes. The medium properties of chief importance are the water retention relation and the hydraulic conductivity.

Unsaturated flow has its basic mathematical expression in Darcy's law, which states that the flux density q is proportional to the driving force. The proportionality constant is the hydraulic conductivity K. For the case of

one-dimensional flow driven by gravity and matric pressure gradients, Darcy's law can be expressed as

$$q = -\frac{K(\theta)}{\rho g}\left[\frac{\mathrm{d}\psi}{\mathrm{d}z} + \rho g\right] \tag{3}$$

where ρ is the density of water, g is the acceleration of gravity, and z is upward distance. The conversion factor $1/\rho g$ is shown here explicitly so that this expression can be used directly with ψ in SI pressure units such as kPa, and K in velocity units such as m/s. In head units, ρg (the weight of water per unit volume) equals dimensionless unity and ψ takes dimensions of length.

K of the medium depends on the whole set of filled pores, especially the size, shape, and connectedness of filled channels. The retention relation and the history of the moisture state determine what pores are filled. In unsaturated media, as illustrated by the measurements in Figure 7, K depends very strongly on the water content. As water content decreases, the large pores, which make by far the greatest contribution to K, empty first. Then, not only are there fewer filled pores to conduct water, but they are smaller and therefore less conductive because there is more viscous friction. With fewer pores filled, the paths of water flowing though the medium become more tortuous. When the soil is quite dry, few pores are filled, and the water moves mainly through poorly conducting films adhering to particle surfaces. These factors combine to reduce hydraulic conductivity by several orders of magnitude as the soil goes from saturation to typical field-dry conditions.

Other factors also can influence hydraulic conductivity. Matric pressure is relevant though its main effect is indirect, through influence on θ. Temperature affects K through its influence on viscosity and other factors. Microorganisms can reduce K by constricting or obstructing channels though the pores. Chemical activity can similarly reduce K if precipitates form. It can also influence K by affecting the cohesion of particles and hence the structure of the medium.

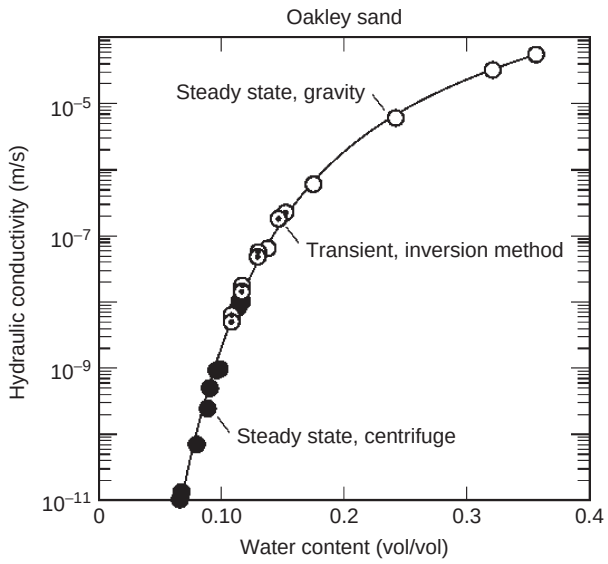

Figure 7 Hydraulic conductivity for a sandy soil (Oakley sand), measured by three methods

Unsteady Diffuse Flow

When unsaturated flow is transient (nonsteady), as it generally is, the flow itself causes the water content to change throughout the medium, which leads to continuously changing hydraulic conductivity and driving forces. These interacting processes, first described by Buckingham (1907), can be accommodated mathematically by combining the equation of continuity

$$\frac{\partial\theta}{\partial t} = -\frac{\partial q}{\partial z} \tag{4}$$

with Darcy's law (3) to get Richards' (1931) equation, which for one-dimensional vertical flow within a medium in earth gravity can be written

$$C\frac{\partial\psi}{\partial t} = \frac{1}{\rho g}\frac{\partial}{\partial z}\left[K\frac{\partial\psi}{\partial z}\right] + \frac{\partial K}{\partial z} \tag{5}$$

where C is the differential water capacity, a property of the medium defined as $\mathrm{d}\theta/\mathrm{d}\psi$. It is also possible to formulate this equation in terms of θ (Sposito, 1986). The equation can be solved numerically in the general case (e.g. Lappala *et al.*, 1987). Analytical solutions have also been developed (e.g. Salvucci, 1996), though these require simplifying assumptions that are not directly applicable to most situations of unsaturated flow. Richards' equation does not adequately represent all circumstances of unsaturated flow, for example, at wetting fronts and flow instabilities (Stonestrom and Akstin, 1994; DiCarlo, 2004). Some of these are discussed below in connection with unstable flow.

An alternative formulation of unsteady unsaturated flow depends on a property called *hydraulic diffusivity* or *soil-water diffusivity*. This is based on the fictional but useful assumption that the flow is driven by gradients of water content rather than potential. Richards' equation (5) without the gravitational term can be transformed into

$$\frac{\partial\theta}{\partial t} = \frac{\partial}{\partial z}\left[D(\theta)\frac{\partial}{\partial z}(\theta)\right] \tag{6}$$

where

$$D(\theta) = K(\theta)\frac{\mathrm{d}\psi}{\mathrm{d}\theta} \tag{7}$$

is the hydraulic diffusivity (Childs and Collis-George, 1950). $D(\theta)$ is a property of the medium dependent on θ and its history. Advantages of this formulation include that: (i) $D(\theta)$ can be easier to measure than $K(\theta)$ and

$\theta(\psi)$; (ii) the typical increase of $d\psi/d\theta$ with decreasing θ compensates in part for the decline in K with decreasing θ, so that in the field D usually varies less than K; and (iii) many mathematical techniques for solving equation (6) have previously been developed for diffusion applications.

Preferential Flow

Preferential Paths

Flowpaths that permit fast movement, whether because of their character (e.g. large pore diameter) or their present state (e.g. high water content) are called *preferential paths*. Such a path may be a single pore (i.e. a macropore), a connected series of pores, or a group of adjacent pores acting in parallel. These paths are common in natural porous media with significant heterogeneity, such as surface soils and fractured rock. Flow in preferential paths transports water and contaminants much faster than would be predicted from bulk medium properties and Richards' equation. Another important effect of preferential flow is that a relatively small fraction of the subsurface medium interacts with contaminants, which limits adsorption and other attenuating processes. Three basic types of preferential flow (Figure 8) are (i) macropore flow, caused by flow-enhancing features of the medium; (ii) funneled (or deflected or focused) flow, caused by flow-impeding features of the medium; and (iii) unstable (or fingered) flow, caused by temporary flow-enhancing conditions of parts of the medium.

Macropores, distinguished from other pores by their larger size, greater continuity, or other attributes, conduct preferential flow under conditions such as extreme wetness. Common macropores include wormholes, root holes, and fractures. Where macropore flow occurs, flow through the remainder of the medium may be called *matrix flow*. When macropores are filled, flow through them is fast. When macropores are empty, they constitute a barrier to matrix flow and there may be essentially no flow through the macropores themselves. In some conditions, however, there may be significant film flow along macropore walls (Su *et al.*, 2003). Macropores that are partly filled provide a variety of possibilities for the configuration and flow behavior of water.

Funneled flow commonly occurs with contrasting layers or lenses, where flow deflected in direction becomes spatially concentrated. The local increase in water content causes a corresponding increase in hydraulic conductivity and flux. In field experiments in a sandy soil, Kung (1990) found that the flow became more preferential with depth (Figure 9). At about 6-m depth, the flow was moving through less than 1% of the whole soil matrix. Although this medium had no significant observable macropores, preferential flowpaths were the dominant pattern. The main feature causing this preferential flow was "... an interbedded soil structure with textural discontinuities and inclined bedding planes". Considering Kung's work and others', Pruess (1998) noted that because funneling results from horizontal impediments and can produce very rapid flow "... we have the remarkable situation that unsaturated seepage can actually proceed faster in a medium with lower average permeability".

Unstable variations in flow and water content, even within a uniform portion of the medium, can increase flow rates considerably (Wang *et al.*, 2003). A typical case has a layer of fine material above coarse material. Downward-percolating water does not immediately cross

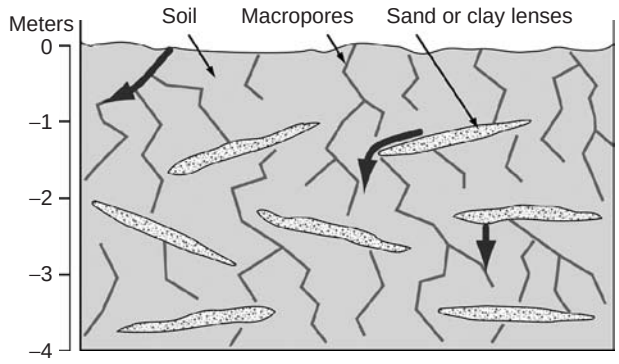

Figure 8 Three basic types of preferential flow. Arrows indicate narrow regions of faster flow than their surroundings. Macropore flow occurs through channels created by aggregation, biotic activity, or similar causes. Funneled flow occurs when flow is deflected by heterogeneities of the medium so as to create zones of higher water content and greater K. Unstable flow can be generated at layer boundaries such as the bottom of a sand lens at right, where flow into the lower layer moves in the form of highly wetted fingers separated by regions of relatively dry soil. the interface into the coarse material. When water pressure builds up significantly at the interface, water may break through into the coarse medium at only a few points. The material near individual points of breakthrough becomes wetter and hence much more conductive. For some time thereafter, additional flow into the coarse material moves in the few "fingers" that are already wet (Figure 10). Between fingers, the medium can be relatively dry. In addition to textural contrasts, hydrophobicity (water repellency) and air trapping may contribute to flow instability. Layer boundaries may interrupt preferential flowpaths. There may also be processes that homogenize preferential flow, though such effects have been little studied.

In virtually every unsaturated-zone transport problem, it is essential to assess the prevalence of preferential flow and the flow mechanisms that might be active. One approach is to evaluate the features of a particular site that might cause macropore, funneled, or unstable flow. Another is to collect and evaluate evidence from observed water or solute distributions that cannot easily be explained without hypothesizing preferential flow.

Quantification of Preferential Flow

One straightforward way of quantitatively treating preferential flow is by representing preferential flowpaths with discrete pathways whose geometry and water content, with appropriate laminar-flow expressions, predict the flow rate through the part of the medium they occupy. Usually this is impossible because the position, number, shape, orientation, and connectedness of pathways are unknown.

Conceptually opposite to the discrete pathway approach is the widely used equivalent-medium approach. The key assumption is that the effective hydraulic properties of a large volume of the medium are equivalent to the average properties of a homogeneous granular porous medium. The effective hydraulic properties then can be applied directly in numerical simulators employing Darcy's law and Richards' equation. The main advantage of the equivalent-medium approach is that the many existing theories, models, and techniques developed for diffuse flow in granular media can be applied to preferential flow. This approach is only valid if certain conditions are met. The medium must be representable as a continuum (Bear, 1979, p. 28–31), but this requirement is difficult to satisfy in macroporous media with flow inhomogeneities at relatively large scales. Representative volumes may necessarily be so large that only a small fraction of the assumed volume is participating in the flow. Modeled transport velocities then may greatly underestimate the actual velocities. In practice, an adjustment of the effective porosity of the equivalent granular medium is commonly done to compensate for such effects, though this adjustment will not produce accurate predictions if, as expected, the degree of preferential flow depends strongly on the degree of saturation. The

equivalent-medium approach also is inadequate where it is essential to have knowledge of the individual flowpaths.

Unstable flow complicates the quantification in at least two ways that do not apply to macropore or funneled flow: (i) unstable flow is not tied to particular permanent features of the medium; and (ii) the preferentiality of unstable flow changes dynamically (e.g. unstable flowpaths commonly grow wider as flow progresses through them). Theories of unstable flow in terms of scaling and other concepts, have been developed for example, by Raats (1973), Parlange and Hillel (1976), Glass *et al.* (1989), Selker *et al.* (1992), Wang *et al.* (1998), Eliassi and Glass (2002), and Jury *et al.* (2003).

Multimodality

A family of approaches that rely on a conceptual partitioning of water or pore space into portions with different flow rates and behaviors may more realistically represent flow that includes preferential paths than do traditional unsaturated-flow models. Models used in these approaches have names such as "dual-porosity" and "dual-modality". The concept of mobility, that is, how easily certain system components (in particular, water and contaminants) move within different parts of the medium, is frequently used in defining and characterizing these approaches.

The simplest of these models assume matrix flow to be negligible, so that all flow is preferential flow. Given the nonlinear nature of unsaturated flow, the difference in conductance between, say, a wormhole, and an interparticle space between clay or silt grains, may be several orders of magnitude. For practical purposes this may constitute a mobile–immobile distinction. Other models assume the matrix to be permeable but with different properties and possibly different modes of flow than the portion of the medium that has preferential flow.

The degrees of possible mobility cover a continuum, and truly immobile water is unlikely. Some models postulate three degrees of effective mobility, for example, mesopores in addition to micropores and macropores (Luxmoore, 1981). A closer approach to a continuum of mobility is that of Griffioen *et al.* (1998).

Solute transport occurs in both diffuse and preferential modes. **Chapter 152, Modeling Solute Transport Phenomena, Volume 4** describes important phenomena, many of which are as relevant in unsaturated as saturated media.

Multiphase Flow

The transport of water and solutes is often considered independently of other fluids or solids. But normally, more than one phase is transported in an unsaturated medium. Besides the liquid water, air and other gases, there may be nonaqueous liquids that need to be considered as separate phases, and there may be solid particles that are free to move. Multiphase flow is a common element of contamination problems because many contaminants are nonaqueous, for example, volatile vapors, organic liquids (oils, solvents, etc.), colloids, and microorganisms.

For gases and nonaqueous liquids, it is often helpful to use the concept of permeability to represent the flow-influencing property of the solid matrix independently of the fluid. This relates to K according to

$$k = \frac{K\mu}{\rho g} \tag{8}$$

where k (dimensions L^2) is the permeability, μ is the viscosity (dimensions $ML^{-1}T^{-1}$), and ρ (ML^{-3}) is the density of the fluid. Darcy's law (3) takes the form

$$q = -\frac{kk_r(\theta)}{\mu}\left[\frac{d\psi}{dz} + \rho g\right] \tag{9}$$

where k_r is relative permeability, a dimensionless factor needed to account for the θ dependence in an unsaturated medium. Ideally, a medium has the same k for any fluid. This independence is not absolute because fluid properties other than μ and ρ, such as those related to slip effects (described below) or other non-Newtonic phenomena, can affect the flow, and some fluids cause structural changes that affect k.

Transport of Gases

Lacking the strong intermolecular forces of a liquid, individual gas molecules move nearly independently. Gas in the unsaturated zone commonly extends over large distances without being blocked by liquid, forming a continuous gas phase. Unlike solutes in liquid, the minority components within a gaseous mixture tend to mix completely at the molecular level, and to move in the same way as any other gas molecules. The more independent motion of the molecules also makes gases less viscous than liquids. Gas is highly compressible, which complicates some transport phenomena while making possible some useful measurement techniques. Gas flow exhibits slip, also called the *Klinkenberg* effect. Even the gas molecules closest to surfaces are free to move, and, unlike the essentially stationary boundary molecules of liquids, will have a net motion in the direction of the bulk flow of gas. This makes the permeability to gas somewhat greater than one would expect from measurements of the liquid permeability. Gas molecules dissolve in liquids. Like other solutes, gases differ in solubility. Carbon dioxide is much more soluble than nitrogen or oxygen. Gases also interact in chemical or biological reactions, of great importance in some contamination and restoration problems.

Strictly speaking, there is viscous friction between gas and adjacent liquid, so moving liquid tends to drag gas with it, and vice versa. Usually this friction is so much smaller than other driving forces that it can be ignored.

Gas flow is then independent of liquid flow, and often described by a separate implementation of Darcy's law. The gas pressure takes the place of matric pressure. Gas flow is often slow because the driving forces are small. When components of the gas are of comparable density, gravity is not a major driving force, and, unlike water driven by differences in matric pressure, in gases there normally is no mechanism to sustain large pressure gradients. Therefore convection is often not as important as other mechanisms, especially diffusion. In a gas, the molecules of a minority component move more easily than they would in a liquid, because of the lesser intermolecular cohesion. This causes greater diffusion. Dispersion, on the other hand, still depends largely on convective flow rates, and so is not necessarily greater in a gas. In contrast to solute transport, therefore, diffusion of gases is normally more important than dispersion. The diffusion coefficient for two gases in a porous medium is directly related to the diffusion coefficient for the gases in a free space, but also depends on such factors as pore size, tortuosity, and continuity.

Gas is trapped if it resides in bubbles or pockets from which every possible path to the outside of the medium goes through liquid or solid. Air easily becomes trapped during wetting, wherever a pore is slower than its neighbors to fill with water. Once the pore is surrounded by water, air within it is trapped. Stonestrom and Rubin (1989b) found experimentally during the drying and wetting of two different soils that some amount of air was trapped whenever θ was greater than about 70% of the porosity. A medium that has been "saturated" by ordinary means usually has a significant fraction of its pore space occupied by trapped bubbles of air within certain pores. Sometimes the word "satiated" is used for this condition, to reserve "saturated" for the case when there is strictly no gas in the pores. In general, though, "saturation" means that the medium has finished absorbing water by the wetting process it has been subjected to. This normally results in a matric pressure of zero, with trapped air. Trapped air bubbles change size with matric pressure in accordance with Boyle's law. They also shrink as gas dissolves or expand as it comes out of solution. The quantity of trapped air is easy to determine at saturation because all air present is trapped; measurement of volumetric water content subtracted from the porosity will indicate volumetric trapped air content. For the amount of air trapped at saturation, Mualem (1974) proposed a rule of thumb based on empirical observations, that 10% of the pore space will be occupied by trapped air. In general, this will vary with the medium, rate of wetting, water content before wetting, and other factors, and can far exceed the 10% guideline.

Transport of Nonaqueous Liquids

Liquids such as oils and organic solvents that do not easily dissolve in water are retained and transported within a porous medium in some of the same ways as water, but with crucial differences. Being a phase separate from water, they are often called *nonaqueous phase liquids*, or NAPLs. Hess *et al.*, (1992) and Essaid *et al.*, (1993) give examples of how fluid contents can be observed and measured and their distributions simulated at a site of oil contamination of groundwater.

To a first approximation, nonaqueous liquids obey the laws of surface tension and viscous flow, just like water. Liquids such as oils typically have a weaker tendency to cling to solid surfaces than does water. Thus, they are a relatively nonwetting phase, and they exist mainly in blobs or interconnected shapes within the pores of the medium, separated from the particle surfaces by a layer of water (Figure 11). With enough nonaqueous liquid present, it also can form a continuous phase across significant distances within the medium. Then its transport may be described using the permeability form of Darcy's law (9). Otherwise, the nonaqueous liquid is present mainly as isolated blobs, around which water flows as it flows around solid particles. Dillard *et al.*, (1997) show how such factors as the nature of the K distribution can affect oil transport in the subsurface.

Nonaqueous liquid transport often must be considered in combination with other modes. Many liquids volatilize significantly, so the resulting vapor moves in gaseous form. Nonaqueous liquids normally dissolve significantly and undergo transport also as a solute. These modes of transport are less affected by the degree of continuity of the nonaqueous phase than is the liquid transport mode.

Transport of Particles

Small solid particles can move through the subsurface in response to a complex set of factors. These particles include bacteria and other microorganisms as well as nonliving colloids such as rock fragments, mineral precipitates such

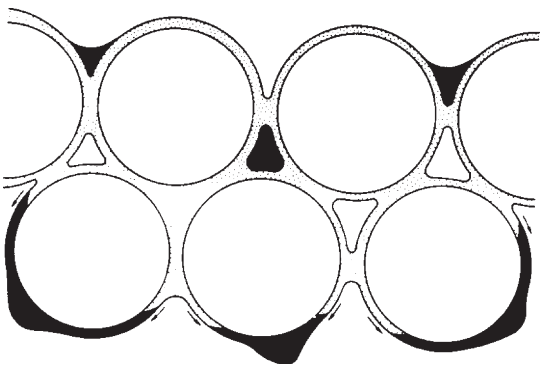

Figure 11 Four phases present in an artificial medium made of glass spheres. In this cross-sectional diagram, stippled areas are water, black areas are nonaqueous liquid, and white areas within the circles are solid glass and elsewhere are air (Reproduced from Schwille, 1988 by permission of Lewis Publishers (Chelsea, MI, USA))

as iron oxides and carbonates, weathering products such as clay minerals, macromolecular components of dissolved organic carbon such as humic substances, and microemulsions of nonaqueous liquids.

Mobile particles play several roles in practical unsaturated zone problems. (i) They themselves are sometimes contaminants. (ii) They act as carriers of any contaminants that sorb onto them, overriding the intrinsic transport characteristics of those contaminants. This complicates solute transport problems, especially when the solutes of interest adsorb onto the colloids and the colloids are more mobile than the solute. (iii) They can be naturally present or artificially introduced agents (typically bacteria) that break down organic contaminants and other compounds into other substances whose presence may be more desirable. (iv) Their presence and possible redistribution within the pore space can affect hydraulic conductivity or other transport properties.

Mechanisms of particulate transport include convection, advection, and adsorption, as for solutes, and other mechanisms (Harvey and Garabedian, 1991). Adsorption depends strongly on the composition of the medium, generally increasing with additional clay and decreasing with additional organic matter. Another mechanism of great importance is straining, the blocking of further motion by pores that are smaller than the particles themselves. For microbiological organisms such factors as death and reproduction also must normally be considered.

In unsaturated media, there are additional mechanisms that can make particle transport more complex than in saturated media (DeNovio *et al.*, 2004). The movement is strongly retarded as water content decreases, leading to a sometimes useful assumption that through the soil there is little motion except when the medium is nearly saturated. Particles can be removed from mobile fluid through mechanical filtration by films as well as by small pore spaces. Besides the reasons for water itself and solutes to move much more slowly at lower water contents, there is also a strong tendency for solid particles to adsorb onto the air–water interface (Wan and Wilson, 1994), as illustrated in Figure 12. This adsorption may be stronger than the adsorption onto the soil matrix itself. This effect also means that when the pores are all filled with water except for some amount of trapped air, that air may significantly retard the transport.

The mobility of inorganic colloids in the subsurface is controlled by chemical interactions between colloids and immobile matrix surfaces, and by hydrological and physical factors. Changes in aqueous chemistry can cause colloids to aggregate or to disaggregate. Higher ionic strengths, for example, usually favor colloid aggregation. This affects mobility because in general larger, aggregated particles are less mobile. Particles can be released into subsurface water as a result of mechanical grinding of mineral surfaces. Hydrodynamic forces associated with increases in flow rate can dislodge colloids.

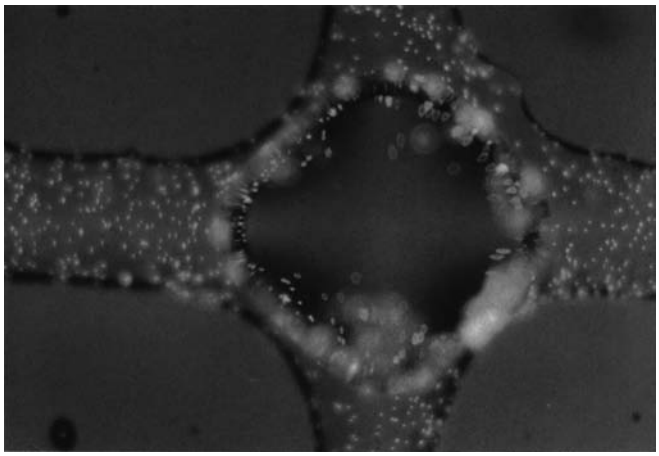

Figure 12 Microscopic cross-sectional view of hydrophobic latex particles in water in artificial pores (Wan and Wilson, 1994). The main pore body, the intersection between the two perpendicular pores, is about 200 μm across. The latex particles (light-colored dots) are 1 μm in diameter. A large air bubble occupies most of the main pore. Some of the particles are adsorbed on the air-water and water-solid interfaces (Reproduced from Wan and Wilson, 1994 by permission of American Geophysical Union). DETERMINATION OF UNSATURATED CONDITIONS AND PROPERTIES

Moisture State

Water has many distinctive properties – volatility, density, molecular and nuclear structure, and electrical and thermal properties – that lend themselves to measurements indicating the amount of water present in a porous medium. The basic gravimetric method is to dry soil in an oven until the weight is constant, so that the difference between that weight and the initial wet weight indicates how much water was in the soil. This is often used as the standard for calibrating other methods.

Several methods in widespread use are minimally disruptive. X-ray or γ-ray attenuation can indicate water content in space and time: the more water, the less the beam intensity coming out of the medium. This effect is sometimes used tomographically to produce a two-dimensional map of water content in a cross section of the medium. Neutron scattering is commonly used for monitoring water content as a function of depth in the field. This method is based on the relative effectiveness of the various components of the wet soil in slowing neutrons. Because of the conservation of energy and momentum, a neutron passing through matter

is slowed down most effectively by collisions with particles that are about the same size as itself. In soil, essentially the only particles that are the size of a neutron are the hydrogen nuclei in water molecules. A probe that includes both a source of fast neutrons and a detector of slow neutrons registers more counts in wetter soil. Commercially available equipment has a neutron source and detector housed in a cylindrical probe that can be lowered to various depths in a lined hole, to obtain measurements as a function of depth. Another way to monitor water content over a period of time in the lab or field is by measurement of the dielectric constant of the medium, usually by time-domain reflectometry (TDR) (Topp *et al.*, 1980). Liquid water has a much greater dielectric constant than other constituents of soil or rock, so this effect can indicate the amount of water present within the volume sensed. For most applications, TDR electrodes in the form of metal rods are inserted into the soil. Various geometries of electrodes are possible, including a coaxial cylinder for laboratory use with core samples. A less common method is to measure electrical conductivity (e.g. Sheets and Hendricks, 1995), which increases with water content. This principle can be applied tomographically (e.g. Daily *et al.*, 1992) for observing two- or three-dimensional details of changing water distributions in the field. Ground penetrating radar (e.g. Eppstein and Dougherty, 1998) can also be applied directly or tomographically.

The most direct measurement of matric pressure is by a tensiometer. In firm contact with the porous medium, this device allows for equilibration of pressure between the water in unsaturated pores and the water in a larger chamber where a gauge or transducer reads the pressure (Figure 13). The key feature is the porous membrane that contacts the soil. In order to assure a continuous liquid water pathway from the pore water to the chamber water, this membrane must remain totally saturated. Thus, it must have an air-entry value beyond any ψ value to be measured, and must not be allowed to dry out. There is a basic ψ limit of about -80 kPa, below which ordinary tensiometers fail because of runaway bubble formation, though Miller and Salehzadeh (1993) have shown that devices that remove dissolved air can extend this range.

Other methods are available for media drier than -80 kPa and for easier application when less accuracy is acceptable. Some of these are based on the humidity of the air in soil pores. A low (strongly negative) matric pressure increases the pore water's effectiveness for absorbing water molecules out of the vapor in the soil air, resulting in a lower relative humidity. The effect is slight, however; a 0 to -1500 kPa matric pressure range corresponds to a 100 to 99% range in relative humidity. Psychrometers (Andraski and Scanlon, 2002) and chilled-mirror devices (Gee *et al.*, 1992) are both used to measure humidity for this purpose. Another class of methods uses an intermediary porous medium of known retention properties. Examples include

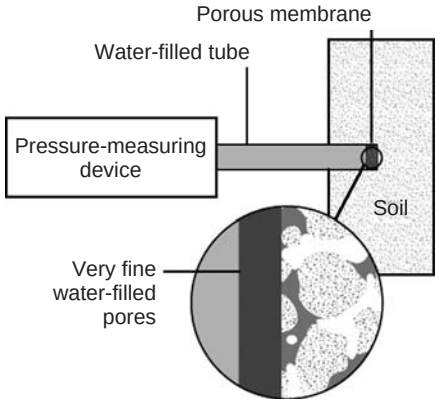

Figure 13 Schematic diagram of a tensiometer in contact with soil for matric pressure measurements. The pressure measuring device can be an electrical transducer, a manometer, or other pressure gauge. The porous membrane is often porous ceramic or sintered metal, or one of various other materials intended for use as filters. Especially in field applications, the membrane is often shaped as a tube or cup rather than a disk, to have greater contact area with the soil

gypsum blocks, nylon fabric, and filter paper (Scanlon *et al.*, 2002). This medium is placed in contact with the medium to be measured so that the matric pressure becomes equal in both. Then the water content of the intermediary medium is measured by other means (usually electrical conductivity, thermal diffusivity, or mass) and translated into a matric pressure using the known properties. Often the retention curve of the intermediary medium is not known directly, but rather a calibration relation between matric pressure and the measured quantity (e.g. electrical resistance) is known.

Water Retention

Measurement

Any system that makes independent simultaneous measurements of water content and matric pressure can indicate water retention relations. Additionally, there are methods specifically intended to measure this property. Many of these use a large porous membrane, often ceramic, to permit equilibration of water pressure between the porous medium on one side of the membrane and bulk water on the other. The pressure of this bulk water (and hence the pore water pressure) is controlled, as is the air pressure in the medium, in order to control its matric pressure. Pressure or suction chambers that do this use the principle of water-equilibration through a membrane of the sort used in tensiometers as in Figure 13. The pressure, or less commonly the volume of water, is adjusted through a planned sequence, and paired values of matric pressure and water content (one of them controlled and the other measured) represent the retention curve.

Estimation

Because various nonhydraulic properties of a medium, especially particle-size distribution, correlate in some way with water retention but are considerably easier to measure, models have been developed for estimating water retention from these. The basis is that the water retention curve of a medium depends directly on its pore-size distribution, which is related to the particle-size distribution. In a randomly packed medium, intergrain pores are expected to be larger where the particles are larger. Arya and Paris (1981) developed a widely used model based on this principle, using capillary theory and particular assumptions about the effective radii of capillaries to be associated with particular sizes. Models of this type often work reasonably well for sandy media. In general, however, the correlation between particle and pore size does not hold. For example, increasing fine-particle content, especially with clay particles, usually correlates in soils with increasing aggregation and more numerous macropores. Adding clay to sand can increase rather than decrease the number of large pores. More recent models (e.g. Rieu and Sposito, 1991; Nimmo, 1997) extend their applicability to more types of media with the use of additional information such as aggregate-size distributions.

Another way of estimating water retention without measuring it is with statistically calibrated pedotransfer functions such as the Rosetta model (Schaap, 1999). The basis for these is not a principle like the correlation of pore and particle size, but rather a database of measured water retention and other properties for a wide variety of media. Given a medium's particle-size distribution and other properties such as organic matter content, a model of this type can estimate a retention curve with good statistical comparability to known retention curves of other media with similar nonhydraulic properties. The foundation in empirical data helps to compensate for such effects as the increase in large pores with increasing clay. The accuracy and reliability of these models are limited, however. They sometimes, but not always, produce acceptable estimates. Without any retention measurements for the medium in question, it is usually impossible to know if the model result is a good representation of the retention curve or not.

Hysteresis models have been developed to represent the entire set of hysteretic moisture relations from a partial data set. The most widely used is that of Mualem (1974), which yields a complete set of scanning curves given both drying and wetting main curves. Other models require greater or lesser amounts of data. The model of Nimmo (1992), for example, requires the main drying curve and two points of the main wetting curve. In general, less stringent data requirements lead to modeled results of less reliability.

Empirical Formulas for Water Retention

Whatever method is used to determine a water retention curve, it is frequently convenient to express it as a parametric empirical formula. This helps in providing interpolation or extrapolation of data, in giving a smooth, continuous form that is easy to work with mathematically, and in representation of the curve with a few (typically 2 to 5) parameter values. Among the most widely used empirical formulas are that of Brooks and Corey (1964)

$$\theta = (\theta_{\max} - \theta_{\min}) \left[\frac{\psi}{\psi_b} \right]^b + \theta_{\min} \tag{10}$$

where ψ_b, b, and $\theta_{\min}$ are fitted empirical parameters and $\theta_{\max}$ is the maximum value of θ; and that of van Genuchten (1980)

$$\theta = (\theta_{\max} - \theta_{\min}) \left[\frac{1}{1 + \left(\frac{\psi}{\psi_c} \right)^{\nu}} \right]^{\mu} + \theta_{\min} \tag{11}$$

where ψ_c, ν, μ, and $\theta_{\min}$ are fitted empirical parameters. Representations as simplified as these have shortcomings. For example, the Brooks and Corey curve works poorly in the wettest portion of the retention curve, and the van Genuchten in the driest. Numerous alternatives have been published, with advantages for particular applications or types of media. Some of these are based on different mathematical formulas, for example, the lognormal distribution (Kosugi, 1994), which has advantages in understandability of the significance of its parameter values. Others are formed by combining formulas by addition (Ross and Smettem, 1993) or by joining different functions that each apply in a different portion of the range. For example, Ross *et al.* (1991) developed an equation for realistic representation in the dry range, Rossi and Nimmo (1994) for the whole range from oven-dryness to saturation, and Durner (1994) for bimodality of pore-size distribution.

Dynamic Characteristics

Measurement of K and D

The most accurate measurements of hydraulic conductivity are by steady-state methods. One way is to establish constant (though not necessarily equal) pressures of water at two opposing faces of a porous medium, measure the flux density, and calculate K using Darcy's law (Mualem and Klute, 1984). Another is to force water through at a constant and known flux density, which lets the matric pressure become uniform in part of the sample, then to compute K from the known flux density and force of gravity (Childs and Collis-George, 1950). With gravity as the main driving force, steady-state measurements are possible only for the high K values of fairly wet soil. Centrifugal force makes possible the accurate measurement of K at low water contents (Nimmo *et al.*, 2002b).

There are many techniques for measuring unsaturated hydraulic conductivity using unsteady flow. One of these is the instantaneous-profile or unsteady drainage flux method (Hamilton *et al.*, 1981). It is useful in both the laboratory and the field. This method is based on a determination, within a medium in which unsteady flow has been established, of both the flux density and the matric pressure gradient, from water contents in space and time, and from matric pressure measurements at a given instant of time after the application of water. Another alternative for laboratory applications uses flow driven by evaporation. There are various indirect and inverse methods – a wide variety of situations where available data describing water flow over time can provide information for an estimation of K or D (Hopmans *et al.*, 2002). The tension infiltrometer method is in widespread use for field applications. This method uses the measured infiltration rate as a function of time for water applied at controlled ψ values as data to calculate the unsaturated hydraulic properties. It is often implemented as an inverse method, as discussed further below. Garnier *et al.* (1997) have developed a transient flow method for the more difficult case of soils that swell as water content increases. Infiltrometer methods are useful in field applications (e.g. Smettem *et al.*, 1995; Vandervaere *et al.*, 2000a; Vandervaere *et al.*, 2000b). Water is supplied at a known or measured rate, generally through a flow-restricting membrane or crust to establish unsaturated flow, and measurements of the changing moisture state in the soil are used with the flow rate to estimate unsaturated K.

Diffusivity methods also give K if the water retention relation is known. Typically, these methods are easier but less accurate than direct K measurements. One family of techniques examines the water content distribution within a medium whose water content is changing with inflow. Another popular technique for diffusivity is the one-step outflow method (Gardner, 1956; Doering, 1965) in which a sample in a pressure chamber with an outflow membrane is suddenly exposed to a step increase in air pressure. This forces water out through the membrane as the matric pressure and water content decrease. Measurements of the rate of outflow permit an estimation of $D(\theta)$, normally to within about 1 order of magnitude. Various refinements of the method and alternative methods of calculation have been developed (e.g. Passioura, 1977; Valiantzas and Kerkides, 1990; Etching and Hopmans, 1993). Multistep techniques have also been developed in recent years (van Dam *et al.*, 1994). These resemble the one-step outflow method, but are conducted through a series of small pressure-change steps instead of one large one.

Determination of saturated K can be important in the unsaturated zone because frequently there are localized zones of saturation and also because this property is sometimes used in estimating other hydraulic properties. A straightforward method uses the flow rate measured with a constant applied head gradient, much like the analogous method for unsaturated K. It is also possible to supply water to a soil column from a source with a level that falls as the water is used up, the falling-head method for saturated K. A falling head, where the water level can be related to the cumulative flux, is more useful for saturated than for unsaturated properties because the water content does not change with the applied pressure. Saturated K is easier to measure than unsaturated K but it has unique difficulties. One is the fact that gaps between a soil sample and a retainer wall will fill with water, possibly becoming rapid-flow channels that lead to an indication of K much greater than the actual K of the soil. This is not usually a problem for unsaturated measurements because large gaps desaturate when the matric pressure is even slightly less than zero. Another problem in a saturated K measurement is that because of air trapping the soil is not really saturated and its water content may be poorly determined. For these and other reasons, measured values of saturated K frequently have poor reliability and may have little relation to observed field phenomena that would seem to occur at saturation.

To determine permeability for a gas, a straightforward flow-measuring apparatus can be used with soil samples in a laboratory for accurate results but with considerable effort (Stonestrom and Rubin, 1989a). Field methods (Weeks, 1978; Baehr and Hult, 1991; Shan, 1995) normally rely on measurements of pressure variations at points within the medium in response to pressure changes imposed elsewhere in the medium.

Estimation of K

Property transfer models can be useful for estimating K, as for water retention. Usually, these use water retention, not particle-size distribution, as the more easily measured type of data from which unsaturated K is calculated. If a transfer from particle size to K is needed, such a model may be combined with a water retention property transfer model like that of Arya and Paris (1981), though reliability is likely to be markedly reduced because the particle-size distribution is less directly related to K.

Capillary theory provides an interpretation of the pores in the medium that relates to both K and retention. Purcell (1949) was the first to use it to quantitatively relate these two properties, using the assumption that pores are equivalent to a bundle of capillary tubes of different sizes, with a particular size distribution for a given medium. The drying retention curve relates to the effective radius at which pores empty and the capillary formula (2) quantifies this radius in terms of ψ. Because larger pores empty first, for a given ψ, pores smaller than the radius corresponding to ψ are considered filled. Poiseuille's law gives the effective conductance of a filled capillary, and an integration of such conductances for all filled pores leads to an estimate of K for that ψ value (and its corresponding θ). In effect, this is a summation of contributions from

each size of filled pore, weighted by the abundance of that size, to give a number assumed proportional to K. Multiplication by a matching factor, quantified using a single known value of K, gives the $K(\theta)$ or $K(\psi)$ curve. In practice, the matching factor is often based on saturated K, though in general this is a poor choice because saturated K depends primarily on the very largest pores of the medium, which have little relevance to $K(\theta)$ over most of the θ or ψ range (Nimmo and Akstin, 1988). Choices of how the model handles issues such as pore length, connectedness, and tortuosity lead to different versions of this sort of model (e.g. Childs and Collis-George, 1950; Burdine, 1953). The version of Mualem (1976) has become widely used because it is mathematically easy to work with and gives estimates as good as or better than others. Mualem and Dagan (1978) and Hoffmann-Riem *et al.*, (1999) have developed schemes for generalizing this class of models. More recent developments include the incorporation of angular pore geometry (Tuller *et al.*, 1999), which allows a pore of given size to form a continuum of sizes of effective water flow conduit, rather than restricting it to the circular-capillary states of complete fullness or complete emptiness. Network and percolation-theory models have also been developed but have not come into widespread use.

As in the case of water retention, completely empirical formulas can represent unsaturated K. Gardner (1958), for example, used a formula of the form

$$K(\theta) = A\exp(-\alpha\theta) \tag{12}$$

where A and α are fitted empirical parameters. Such formulas have greater simplicity and sometimes lead to more realistic curve shapes than formulas developed for combined representation of K and water retention as described below. The α parameter in (12) is widely used in developing and applying other models, such as analytical solutions of Richards' equation.

Combined Estimation of K and Water Retention

A direct combination of an empirical formula for water retention into a capillary theory formulation of unsaturated K can yield a convenient analytical formula for $K(\theta)$, and facilitate the combined treatment of water retention and unsaturated K. For example, the Brooks and Corey (1964), van Genuchten (1980), or lognormal (Kosugi, 1999) model can be inserted into the Burdine (1953) or Mualem (1976) model. The combination of the van Genuchten and Mualem models results in the formula

$$K(\psi) = K_{\mathrm{m}}\frac{\left\{1-\left(\frac{\psi}{\psi_c}\right)^{\nu-1}\left[1+\left(\frac{\psi}{\psi_c}\right)^{\nu}\right]^{-\mu}\right\}^2}{\left[1+\left(\frac{\psi}{\psi_c}\right)^{\nu}\right]^{\mu/2}} \tag{13}$$

where K_{m} is the matching factor computed from a known (ψ, K) point. Leij *et al.* (1997) give a tabulation and evaluation of formulas that result from such combinations. Use of such formulas is central to pedotransfer-function models for coordinated estimation of water retention and K. As in the water-retention application of pedotransfer functions described above, these provide a particularly easy way to estimate the hydraulic properties needed for a Richards-equation analysis, though likewise with problems of poor and unknown reliability.

Translation of parameter values from one model to another, that is, for a given medium finding the values for one model's parameters directly from the parameter values previously estimated for a different model (Morel-Seytoux *et al.*, 1996; Morel-Seytoux and Nimmo, 1999), is a convenience where the retention curve is known only in terms of one particular parameterization, and an application requires another. In order to give a unique conversion, a specific equivalence criterion must be chosen. This can, for example, be the invariance of a relevant property like capillary drive (a single-number combination of retention and conductive properties related especially to infiltration rates).

Inverse approaches can yield hydraulic property values in a variety of situations and experiments, as explained in detail in **Chapter 156, Inverse Methods for Parameter Estimations, Volume 4**. The basic idea is that a forward model (e g. Richards' Equation), which can compute output conditions (θ or ψ as a function of space and time) using given properties (water retention and unsaturated K), can be used in an algorithm that does the inverse of this. That is, given a set of measured output conditions, the algorithm determines values of the properties that would most closely simulate the measured conditions. Those values then have effectively been determined, and can be used in the forward model. Conditions such as water content as a function of space and time frequently are easier to measure than the properties of the medium. One way of inverse modeling is to use a forward model with manual or automated trial-and-error: guess the property values, compute outputs, compare with observation, revise estimated property values, and try again. Many particular field or lab situations, for example, the one-step or multistep outflow method, are suitable for unsaturated hydraulic property estimation by inverse approaches (Hopmans *et al.*, 2002). Frequently, the transient ψ values from one or more tensiometers installed in the sample are used as data in addition to the outflow rate as a function of time.

Scaling provides another way of determining unsaturated properties from limited data, relating them from place to place or from one medium to another (Miller, 1980). In a wet medium, surface tension is the main phenomenon associated with retention, and viscosity with conductivity. These are drawn together in the surface-tension viscous-flow

(STVF) similitude model of Miller and Miller, (1956). One way for two media to be similar is for one of them to be geometrically a direct magnification of the other by a scale factor λ. For natural media, the point-to-point correspondence is not exact; the particles of Miller-similar media can be repositioned, and they do not have to be exact scale replicates, as long as they are statistically equivalent for the purpose at hand. If two media are Miller-similar, if surface tension controls water retention, and if viscous flow laws determine K for a given geometrical configuration, the unsaturated hydraulic properties of one medium can be directly determined from those of the other using the known value of λ. The value of ψ in one medium differs by a factor of λ from that in the other. Water content, being a ratio of volumes, is the same in each. Thus, the retention curve $\theta(\psi)$ of one similar medium equals $\theta(\lambda\psi)$ of the other. Because of the radius-squared factor for conductivity in Poiseuille's law, $K(\theta)$ for similar media is different by a factor of λ^2. Warrick *et al.*, (1977) relaxed some of the Miller–Miller criteria, opening up new field applications by showing the relaxed criteria to be useful for relating properties from one sample to another. Porosity, for example, does not have to be identical for Warrick-similar soils. Whenever a set of media can be considered similar with known values of λ, knowledge of hydraulic properties for one of the media permits calculation of the properties of all. Recent applications of this sort include those of Rockhold *et al.*, (1996) and Nimmo *et al.*, (2002a).

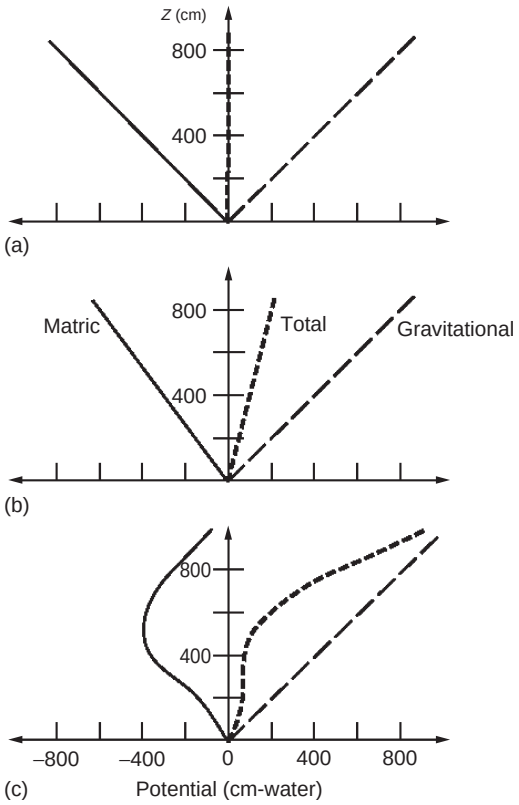

Figure 14 Profiles of matric, gravitational, and total potential for idealized situations of (a) static water, (b) steady downward flow, and (c) unsteady flow. The water table is at $z = 0$

APPLICATIONS TO DISTRIBUTIONS AND FLUXES

This article emphasizes the presence and movement of water within the unsaturated zone. **Chapter 146, Aquifer Recharge, Volume 4** considers the fluxes from the unsaturated zone into the saturated zone. **Chapter 152, Modeling Solute Transport Phenomena, Volume 4** and **Chapter 153, Groundwater Pollution and Remediation, Volume 4** consider the fluxes of other substances, for the evaluation of which the flux of water is usually the first consideration.

Distributions of Water and Energy

The distribution of water with depth at a given time depends on the energy state (based on components including matric and gravitational potential), wetting/drying history, and dynamics of the water itself. If there is no flow, one can infer that the gradient of total potential is zero, so if the matric and gravitational components are the only significant ones, they add to a constant total potential. Figure 14(a) shows this type of hydrostatic profile for the case where a water table is present. Since the matric pressure in this case is linear with depth and the water content is controlled by the water retention properties of the medium, for a uniform unsaturated zone, the water content profile (not shown in Figure 14) then mimics the shape of the water retention curve. The previous history of the unsaturated zone would dictate whether a wetting or drying retention curve would apply. In general, there is significant trapped air when the medium is close to saturation; thus, it frequently is appropriate to consider a repeat-cycle curve rather than a first drying curve. Given time, approximate versions of such a hydrostatic profile may develop in portions of a profile where water movement is negligible. If water flows vertically downward at a steady rate in a homogeneous medium, the total gradient must be constant, but the matric pressure does not cancel out the gravitational potential, as illustrated in Figure 14(b). At many locations this situation probably never develops, but some locations, especially where the unsaturated zone is thick, may commonly have constant potential or an approximation to it. Darcy's law applies directly in field situations where flow is steady, though steadiness in nature is often temporary or approximate. In the general case of unsteady flow, the matric pressure profile cannot be determined so simply, and may take on an irregular form like the example in Figure 14(c).

The uppermost part of the water distribution profile is sometimes described in relation to field capacity, defined as the water content of a soil profile when the rate of downward flow has become negligible two or three days after a major infiltration (SSSA, 1997). An essential assumption for use of the field capacity concept is that soil, when wetted to a high water content, loses water by drainage at a declining rate that does become negligible. This concept is used in agriculture to indicate the wettest soil conditions that need to be considered for plant growth, and sometimes is mentioned in hydrologic investigations, for example, as related to soil moisture storage. Elements of the definition of field capacity are imprecise and require subjective judgment, for example, in deciding what is negligible. Field capacity is implicitly associated with the entire soil profile through the root zone, including preferential flow characteristics and, especially, flow-retarding layers that enable layers above them to retain a high water content. Thus, it is not appropriate to consider the field capacity of an individual soil sample or a point within the unsaturated zone. Because it is based on distinct intervals of major infiltration and major drainage, the concept of field capacity is most applicable in field plots that are periodically wetted to a high degree, as by annual snowmelt, flood, or monsoons; especially in applications where only approximate quantification or rules of thumb are required. This concept does not work well in rocky or fracture-dominated media that retain significant water only briefly, on land where water application is consistently erratic, or in applications requiring exactness, repeatability, or validity at multiple scales of observation.

In a portion of the unsaturated zone immediately above the water table, it may happen that all pores are filled with water, held by capillary forces. The depth interval that is saturated but above the water table is called a *capillary fringe*. In a hydrostatic profile, this corresponds to a flat portion of the retention curve between saturation and an air-entry pressure. As in other cases of saturation within the unsaturated zone, there is likely to be significant trapped air, though not an air phase that is continuous through the medium. Some media will not have a significant capillary fringe because their retention characteristics have the air-entry pressure at essentially zero. These media, including materials with significant fractures or other macropores, are more common than is apparent from databases and literature surveys of measured water retention, because, historically, most measurements have been done on samples that have been repacked from mechanically disturbed material. Repacking often destroys the large pores that would otherwise lead to a zero air-entry pressure. Caution must also be invoked in applying the capillary fringe concept where the water table fluctuates. The hydrostatic equilibrium required for a capillary fringe may take considerable time to establish, given typically small values of unsaturated K. Furthermore, soil-water hysteresis would make for a different capillary fringe with a falling than with a rising water table.

Fluxes at the Land Surface

Input

Infiltration is the downward movement of water through the land surface. Because osmotic, thermal, and other modes of driving water flow are usually negligible, water is driven into the soil mainly by gravity and ψ gradients. If the soil is dry near the surface the ψ gradients usually dominate gravity. When the soil is very wet to some depth, gravity may become the major driving force. The usual case is that water infiltrates faster at the start and slows down as a zone of increased water content develops at the surface and grows. Figure 15 shows actual infiltration rates i [$\mathrm{L\,T^{-1}}$] varying over time in four soil columns. If water at the surface is abundantly available but not under significant pressure, infiltration occurs at the infiltration capacity, a rate determined only by the soil, not by the rate of application or

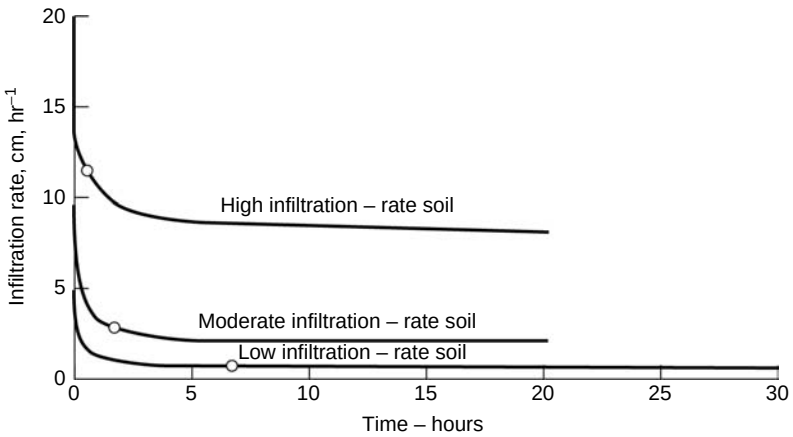

Figure 15 Measured infiltration rates over time for three soil columns

other factors. If water arrives at the surface faster than the infiltration capacity, excess water ponds or runs off. Like hydraulic conductivity, infiltration capacity is not single-valued for a given medium but varies with water content and other conditions. If water arrives at a rate less than the infiltration capacity, the water may immediately infiltrate. The infiltration rate then is determined by the rate of application. This article addresses the issue of what happens when the soil limits the infiltration rate, requiring attention to the infiltration capacity not only as the key element for quantifying i under that condition but also as the criterion that determines whether that condition exists. Conditions that complicate the ideal conception of infiltration include: variation of application rate with time, spatial variability of soil and surface properties, water repellency of the soil, air trapping, and variations of temperature.

Richards' equation (5) can be applied to infiltration processes. But the phenomena involved, especially with water contents, pressures, and fluxes sharply changing in time and space, make this difficult or inappropriate. Most studies use instead a formulation specifically tailored for infiltration, generally with more specific assumptions. Some of these formulations are based on a conceptualization of the physics of infiltration while others are more purely empirical.

The Green and Ampt model of infiltration assumes uniform properties of the medium, a perfectly sharp wetting front at depth L, a constant matric pressure ψ_o at the land surface, a uniform initial water content θ_i, a uniform water content θ_w behind the wetting front, and a value of matric pressure ψ_{wf} at the wetting front that remains fixed even as the front moves downward. Gravity may be included, or, in a simplified form of the model, assumed negligible. The mathematical formulation of the model comes from expressing the infiltration rate in two different ways – by Darcy's law and by the computed change in water storage – and setting them equal to each other. This leads to the depth of the wetting front being

$$L(t) = \left(2K\frac{\Delta\psi}{\Delta\theta}t\right)^{1/2} \tag{14}$$

and the infiltration rate

$$i = \Delta\theta\frac{\mathrm{d}L}{\mathrm{d}t} = \Delta\theta\left(\frac{K\dfrac{\Delta\psi}{\Delta\theta}}{2t}\right)^{1/2} \tag{15}$$

where $\Delta\theta = \theta_w - \theta_i$ and $\Delta\psi = \psi_o - \psi_{wf}$. Analogous formulas can be derived for the case where gravity is not negligible. The inverse proportionality of i to the square root of time appears frequently in infiltration formulas. The natural decline of the infiltration rate as the soil gets wetter correlates in the model with the declining driving force as the constant $\Delta\psi$ is stretched over an increasing depth interval. Mathematically, this works out to square-root-of-time behavior. The Green–Ampt model gives a direct quantification of infiltration with simple formulas for the basic character of infiltration under common circumstances. But, of course, it does not give specific details of the infiltration process. Generally, one must infer a value of ψ_{wf} from other known facts concerning the infiltration; the fact that ψ_{wf} cannot be measured severely limits the use of this model in a predictive manner. The Green–Ampt assumptions are most likely to be satisfied in uniform, coarse-textured soil with simple structure.

Philip (1957) presented mathematical solutions to the problem of infiltration under fewer restrictions than required by Green and Ampt. Philip assumed that the medium properties and the initial water content are uniform, and that the water content at the land surface is held at a fixed water content greater than the initial water content. Starting with a form of Richards' equation, he derived

$$i = \frac{1}{2}\mathrm{S}t^{-1/2} \tag{16}$$

where S is a soil hydraulic property called the *sorptivity* (dimensions $\mathrm{L\,T^{-1/2}}$), which indicates the relative tendency for the medium to absorb infiltrating water. For the case where gravity is significant, Philip developed a series solution that can be approximated for short times by the truncation

$$i = \frac{1}{2}\mathrm{S}t^{-1/2} + A \tag{17}$$

where A is an empirical parameter whose value approaches saturated K after a long time. Philip's model has been tested against measurements, notably by Davidson *et al.* (1963), who found good agreement with the model in terms of both preservation of the shape of the wetted profile, and of the rate of its downward movement. Yet, it would be exactly true only for certain unlikely restrictions on the unsaturated hydraulic conductivity and the ponding of infiltrating water. Furthermore, most cases of infiltration are in heterogeneous soils with nonuniform water content and variable water application, in which the Philip model would give approximate results at best.

Empirical formulas for infiltration have been used where the relevant soil hydraulic properties are not necessarily known. Gardner and Widtsoe (1921) used an exponential formula expressed by Horton (1940) as

$$i = i_c + (i_o - i_c)\exp(-\alpha t) \tag{18}$$

where i_o is the initial infiltration rate, i_c is the rate of infiltration after it becomes steady, and α is an empirical constant that depends on the soil. Holtan (1961) proposed an empirical formula useful for the early stages of infiltration, based on a power law function of the effective yet-unused water-holding capacity of the upper part of the soil profile:

$$i = i_c + a\left[ML_l - \int_0^t i\,dt\right]^n \qquad (19)$$

where i_c, a, and n are constants, and M is the air-filled soil porosity down to a specified depth L_l (ideally to a known impeding layer).

Output

The term exfiltration is occasionally used to indicate water fluxes out of the soil at the land surface, though mostly these processes are discussed in terms of evapotranspiration. As a whole, evapotranspiration is usually treated as a surface or micrometeorological problem, though certain critical unsaturated-zone processes are involved, especially for the evaporation, or bare-soil, component.

When the soil is wet enough, plenty of water is available at the surface so that atmospheric conditions control the evaporation rate. When the soil is too dry to supply water at the maximum rate the atmosphere will absorb it, the soil properties will control the evaporation rate. Thus, there are at least two cases to consider: the atmosphere-dominated "constant-rate" phase during which the transport mechanisms of the soil are ignored, and the soil-dominated "declining-rate" phase during which atmospheric effects are ignored. If the second phase persists long enough, the soil may become so dry that water transport within it is primarily in the form of vapor rather than liquid. This defines a third phase, in which the evaporation rate is slow and may be nearly constant. The initial atmosphere-dominated phase typically lasts a few hours to a few days after irrigation or rainfall. As with infiltration, there is a moisture state criterion based on local conditions and properties that separates atmosphere-dominated and soil-dominated flow. Gardner and Hillel (1962) have quantitatively treated the question of when the atmosphere-dominated phase ends. The overall reduction of evaporation rate with time can be considered in terms of self-mulching; after a bare-surface soil has dried to a certain extent, a layer with very small θ forms at the surface. The low hydraulic conductivity of this layer limits the rate of flow of water from the soil below it to the land surface, thus limiting evaporation (Buckingham, 1907).

During the soil-dominated phase, to roughly estimate the average evaporation rate, the problem can be approached with Richards' equation, assuming that the system is isothermal, vapor does not flow, gravity is negligible, diffusivity is constant, and the soil is a semi-infinite slab uniformly wet at the beginning. The problem then falls into the same class as the gravity-free infiltration problem. The solution for evaporative flux density goes as the inverse square root of time, just as in typical assessments of infiltration rate.

Water resource applications often require values of total evapotranspiration, including treatment of atmospheric conditions in addition to the unsaturated-flow phenomena considered here. Infiltration minus evapotranspiration is often taken as the net input of water to the subsurface. A second major hydrologic application is the evaporation of water from the saturated zone. Capillary forces can draw water up from the water table to depths from which it supplies the evaporative process. This can be a substantial loss mechanism from a water-table aquifer, especially where the unsaturated zone is thin. Various quantitative treatments of these effects have been developed, for example, by Ripple *et al.* (1972).

Fluxes Within the Unsaturated Zone

Redistribution

After water has infiltrated, it redistributes, driven by gravity, matric pressure gradients, and possibly other forces. Figure 16 illustrates water content distributions at various times during and after infiltration, in a mechanically disturbed soil and in a soil with intact natural structure. Redistribution continues until conditions are such that all forces balance out. Equivalently, the water may be considered to progress toward a state of minimal (and uniform) total energy of the earth–water–air system, that is, equilibrium.

In an idealized case of homogeneous soil and perfectly sharp wetting fronts, the redistributing water content profile may take the shape of an elongating rectangle. If there are no losses to evaporation or anything else, the rectangle will maintain the same area as it evolves. This picture of redistribution may be approximated to various degrees in real media, for example, as in Figure 16(d). Many factors cause deviations from the ideal, including layers that retard the flow, and preferential flow and lateral heterogeneity that advance the downward movement of a portion of the water, thereby blunting the rectangular sharpness of the wetting front. Greater K above than below the wetting front may cause water to accumulate in the lower portions of the wetted zone, distorting the rectangle laterally.

Normally, hysteresis strongly influences redistribution because the wetting front progresses downward according to the wetting curves of water retention and conductivity, whereas θ in the upper portions of the wetted zone decreases according to the drying curves. Because a drying retention curve has greater θ for a given ψ, water contents remain higher in the upper portions than they would if there were no hysteresis. Thus, one important consequence of hysteresis is to hold more water near the land surface where it is accessible to plants.

After unsteady infiltration, a pattern of variations in water content with depth becomes established as alternations of surface wetness and surface dryness move downward by gravity. Matric pressure gradients move water from wet to dry, both upward and downward, so as the pattern of θ variation moves downward, wet zones become drier and dry zones wetter. Thus, variations are damped out with depth.

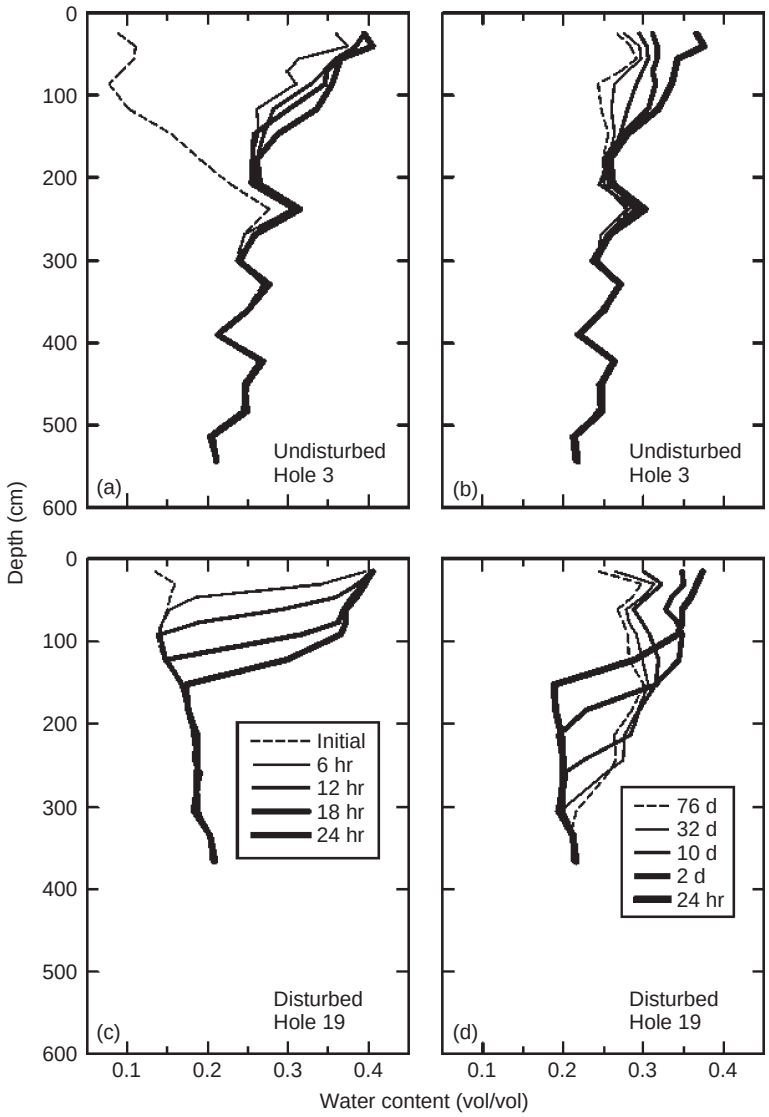

Figure 16 Measured water distributions during and after 24 h of flood infiltration in (c,d) a disturbed, relatively homogeneous soil in a landfill and (a,b) an adjacent undisturbed soil, on the snake river plain in Idaho (Nimmo *et al.,* 1999). Evaporation was inhibited by an impermeable cover at the land surface

Gravity takes on greater relative importance as the variations decrease. In a thick unsaturated zone, a region may develop in which gravity is the only significant driving force, as illustrated in Figure 2 of **Chapter 146, Aquifer Recharge, Volume 4**. Approximating the periodic infiltration of water with a sinusoidally varying flux, Gardner (1964) estimated the depth at which θ variations would become negligible. For a periodicity of one year and typical values of D, the profile would become damped within a few meters of the surface. An important application of this is in Darcian methods for estimating aquifer recharge rates as discussed in **Chapter 146, Aquifer Recharge, Volume 4**.

Usually the above considerations would need to be adjusted or reinterpreted with attention to preferential flow. There is not yet a widely accepted quantitative theory for this. Qualitatively, a major effect of preferential flow is to permit more rapid movement of water to significant depths. This would occur primarily under very wet conditions, and would be followed in the redistribution process by a slower flow of water into the regions between preferential flow channels.

Effects of Layering

Layers that contrast in hydraulic properties impede vertical flow by various mechanisms. (i) When water moves down from a coarse to a fine layer, as from coarse sand to silt, if both layers are near saturation, the fine layer has smaller hydraulic conductivity; therefore, flow slows when it reaches the fine layer. If, however, the coarse layer is

nearly saturated but the fine layer is initially fairly dry, at first the flow may be temporarily accelerated while the flow is dominated by the sorptive nature of the fine medium, which tends to suck water out of the coarse material. (ii) Where a fine layer overlies a coarse layer, water moving downward is impeded under many conditions. When coarse material is dry, it has an extremely small hydraulic conductivity; thus it tends not to admit water into the pores and exhibits a somewhat self-perpetuating resistance to flow. Water breaks into the coarse layer if the pressure at the layer contact builds to the point that the water-entry pressure (the minimum water pressure needed to fill an empty pore) of some of the large pores is exceeded. This can generate flow instabilities, as discussed previously. Stable or not, water flow into the pores of the coarse medium increases that medium's hydraulic conductivity. With equal ψ values across the layer boundary, which is necessary for water not to accumulate at the boundary, unsaturated K of the coarse layer is often less than that of the fine layer. Stable or diffuse flow through layers where fine overlies coarse is slower than it would be if both layers had the properties of the fine medium. Miller and Gardner (1962) demonstrated this effect experimentally.

Layer thickness can influence the long-term tendency of downward flow in other ways. An important case is where a granular medium overlies fractured bedrock. If the fractures are not microscopically narrow and the rock is otherwise impermeable, the bedrock admits water only under nearly saturated conditions. The thinner the layer of granular material, the more easily it becomes saturated down to the depth of the bedrock and hence the more frequently it generates deep percolation. This more frequent saturation at the layer boundary increases the fraction of average precipitation that flows into the bedrock and possibly into the aquifer as recharge.

A common phenomenon in layered media is the accumulation of water in a region of the unsaturated zone to the point where it becomes saturated, even though there is unsaturated material between that region and the saturated zone. Because this phenomenon usually results from an impeding layer on which excess water is perched, it is called *perching*. It may be a temporary or a nearly permanent feature, depending on the nature of the medium, the prevailing hydrologic conditions, and the effect of artificial modifications. The high water content of a perched zone causes greater hydraulic conductivity and potentially faster transport through the three-dimensional system. The main effect is not a direct increase in vertical flow because the increase in effective vertical hydraulic conductivity is offset by a diminished vertical hydraulic gradient within the perched water. (Vertical flow within and below the perched water cannot be faster than the vertical flow above the perched water or the perched water would have drained.) Horizontally, however, there may be greatly increased flow (e.g. Nimmo *et al.*, 2002c). New and different processes may significantly affect contaminant transport in a perched zone. Reduced aeration, for example, may affect biochemical processes. At the scale of the entire stratified vadose zone, perching may significantly increase anisotropy. For considerable horizontal distances the hydraulic conductivity might be as great as $1\,\mathrm{cm\,s^{-1}}$ or more, as for a saturated gravel. At the same time, however, vertical flow might be limited by an unsaturated layer having vertical hydraulic conductivity 10 or more orders of magnitude less, as for rock with unfilled fractures.

Layering strongly influences the direction of flow within the unsaturated zone. The flow is often assumed to be predominantly vertical because (i) with a continuous air phase in the pores, buoyancy does not counteract gravity as it does in the saturated zone, and (ii) whatever the effect of other forces, gravity acts vertically. Some vertical flow continues even where impeding layers cause substantial perching and horizontal diversion. Horizontal flow can be especially important in sloping or laterally heterogeneous media. Horizontal flow under nearly saturated conditions, called *interflow*, may be substantial near the land surface during storms. In thick unsaturated zones where adjacent layers contrast sharply, horizontal flow can have great importance even in arid climates.

CONCLUSION

Unsaturated flow is complicated by the significance of multiple phases. At least three drastically different substances – water, air, and solid mineral – are critical to its nature and quantification. Unsaturated flow phenomena are extremely sensitive to the proportions of those phases, especially the fluid phases, as natural variations in the proportion of water and air can cause a property like hydraulic conductivity to vary over many orders of magnitude.

Many of the features that make saturated zone hydrology difficult – for example, opacity of the subsurface, heterogeneity, complex geometry on small and large scales – are all the more influential when properties vary so drastically, for example, K at a given point in space varying by orders of magnitude. As a result of these complications, unsaturated zone hydrology is subject to a greater degree of inexactness than most fields of quantitative physical science. Often, even factor-of-10 accuracy is difficult to achieve. This means that in many presentations of analyses and model predictions, the precision of the mathematical results goes far beyond what is justified by sparseness or poor quality of the data that support those results, and also beyond what is justified by applicability of the models and concepts. Evaluation of uncertainty depends much on hard-to-quantify conceptual uncertainty.

Given only 100 years since quantitative physical theory was first applied to unsaturated flow, understanding has

developed considerably. In the early twenty-first century, it is still developing rapidly and maturing. Further advancement in response to scientific and societal needs requires new measurement techniques to obtain more and higher quality data, and new theoretical constructs that more adequately represent the important physical processes within practical modeling schemes.

151: Hydraulics of Wells and Well Testing

PHILIPPE RENARD

University of Neuchâtel, Neuchâtel, Switzerland

Well testing and well hydraulics play a major role in applied hydrogeology. While well hydraulics aims at modeling the groundwater behavior in response to a perturbation – such as pumping – in a well, well testing aims at using these models in an inverse approach to infer the properties of the aquifer or of the well itself. The history of well hydraulics and well testing started in 1863 with Dupuit, who developed the first analytical solution to model radial flow to a well in steady state. In 1935, Theis published the most important analytical solution. The Theis solution assumes that the aquifer is confined, bidimensional, homogeneous, and isotropic. Subsequently, numerous models have been developed with the aim to enlarge the domain of applications. This article presents a brief review of these various models and describes their behavior in terms of drawdown and log derivative of the drawdown. The log derivative is used as a tool to help in the identification of the most appropriate model when analyzing field data.

INTRODUCTION

Well hydraulics is the part of groundwater hydraulics (*see* **Chapter 149, Hydrodynamics of Groundwater, Volume 4**) that deals specifically with aquifer response to hydraulic perturbations in a well. Well tests are field tests in which the hydraulic response is measured and analyzed. Well hydraulics and well testing are intimately related since they respectively solve the direct and the inverse problem. As any inverse problem (*see* **Chapter 156, Inverse Methods for Parameter Estimations, Volume 4**), the well-test interpretation suffers from nonuniqueness. Usually this is solved by assuming a very simple model with a very small number of parameters as compared to the number of field observations. The problem is then over-determined and has a unique solution when a model has been chosen. The difficulty is to identify the model that best represents reality. Often, different models will show the same type of response and they will not be distinguishable (e.g. unconfined aquifer and double porosity aquifer). In addition, the measurements may not be sufficient to see all the typical phases of a given model, either because the very early phase is too rapid and is not recorded or conversely the late phase is not recorded because the test does not last long enough. This long introductory remark highlights the fact that despite the relatively large number of models that are available, the practitioner will always be confronted with the dilemma of a nonunique interpretation.

Since groundwater is mainly extracted by wells and well testing represents the main field method for determining the hydraulic properties of the subsurface, much research has been conducted in this area. We can trace the first publication on well hydraulics to Dupuit (1863), who proposed the first series of analytical solutions to steady-state flow to a well in idealized confined or unconfined aquifers. Since then, there has been a continuous and parallel development of analytical models and well-testing procedures. This is reflected by the numerous books published, both in the fields of hydrogeology (Batu, 1998; Butler, 1998; Dawson and Istok, 1991; Hantush, 1964; Kruseman and Ridder, 1992; Lebbe, 1999; Lee, 1999; Walton, 1996) and petroleum engineering (Bourdet, 2002; Earlougher, 1977; Horne, 1995; Raghavan, 1993; Streltsova, 1988).

The aim of this article is to provide an introduction to this field. The article is not intended to be used as a manual or to be exhaustive. Rather, it includes some of the most important historical findings with sufficient details to permit the reader to apply the techniques and understand the basic concepts and equations. Additional aspects are covered in a cursory manner, simply to direct the reader to pertinent sources of information. Some aspects have arbitrarily been

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

left aside such as anisotropy, pulse tests, sinusoidal tests, horizontal wells, and so on.

The article is organized in five sections. The first section presents an overview of well-testing procedures and interpretation methodologies. The second introduces the basic equations of groundwater flow to a well in an ideal confined aquifer as well as the steady-state solution for such a case. The third considers the Theis solution for the transient regime in the ideal confined aquifer. The fourth reviews different nonidealities that can affect the response of an aquifer to pumping in a well. The last briefly considers some other types of hydraulic perturbations.

WELL TESTING

Well tests are conducted with two major objectives. One is to determine the properties of geological formations for a broad range of applications from groundwater exploration to waste-disposal-site evaluation. The other objective is to evaluate the hydraulic properties of the production well itself in order to design the exploitation scheme (depth of the pump, pumping rate) or to evaluate the well efficiency.

The fundamental principle of well testing is the imposition of a hydraulic perturbation in the well and monitoring the aquifer response. Testing procedure may be classified according to the type of perturbation, and to the type and location of response monitoring. Note that the typology is not mutually exclusive.

- *Single well test*: The perturbation and the monitoring are conducted in the same borehole.
- *Interference test*: The perturbation and the monitoring are conducted in separate boreholes.
- *Pumping test*: The aquifer is perturbed by pumping. It can either be a single well test or an interference test. Generally the pumping rate is constant, but variable-pumping-rate tests can also be interpreted. An *injection test* is similar to a pumping test, but water is injected rather than being extracted.
- *Step-drawdown test*: A single well test with a series of successive constant pumping rates.
- *Buildup or recovery test*: It follows a pumping test. After the pump has been stopped, the recovery to the initial level is observed, either in the pumping well or in observation wells.
- *Constant head test*: The head is maintained constant and the water discharge is recorded in the perturbation well. Head changes can be recorded in observation boreholes.
- *Slug test*: The perturbation is a sudden modification of the head in the well, the response is the head variation in the well itself or in observation boreholes.
- *Packer test*: It can be any of the above tests, but it is conducted in an interval of the well isolated with the help of packers. The packers are inflatable or mechanical and allow testing a distinct zone within a well.

Once data – time series of pressures or heads and/or discharge rates – have been recorded from one of the above tests, the interpretation procedure follows fours steps.

- *Data preprocessing*. The data are converted into adequate units, outliers and trends are removed.
- *Model identification*. A conceptual and mathematical model is chosen based on the geological information available and based on a qualitative analysis of the data.
- *Parameter identification*. The physical parameters of the model are obtained by fitting the theoretical response to the observed response. This is a typical inverse problem (*see* **Chapter 156, Inverse Methods for Parameter Estimations, Volume 4**).
- *Quality control*. The adequacy of the model must be checked. A statistical analysis of the discrepancies between the model and the data is conducted in order to test the validity of the interpretation.

While standard well-test analysis used to be based on manual type curve matching or straight-line analysis, the methodology is now mostly computerized for all the four above introduced steps. As a consequence, new methods have been intensively developed in the last twenty years. The benefits of interactive graphics and data handling with computers are obvious. Computerized analysis has allowed handling large data sets directly recorded in the field with electronic pressure gauges and data acquisition systems. Moreover, it has allowed the introduction of the systematic use of the logarithmic derivative of the drawdown as a tool for model identification (Bourdet *et al.*, 1989). Numerical Laplace inversion has broaden the range of models that would be tedious to program otherwise (Dougherty, 1989; Moench and Ogata, 1984). Numerical convolution has allowed interpretation of continuously variable pumping rate test. Automatic model fitting with different optimization algorithms became also possible (McElwee, 1980; Rosa and Horne, 1991), opening the way to a more objective model fitting as well as to a statistical analysis of the results. Finally, computerized data analysis has also allowed the application of general purpose or specifically developed numerical models (*see* **Chapter 155, Numerical Models of Groundwater Flow and Transport, Volume 4**) to interpret field data (Lavenue and de Marsily, 2001; Lebbe, 1999; Pinder and Bredehoeft, 1968), or to forecast the impact of wells on aquifers.

With the expansion of personal computing technology, a large number of well test analysis software has been developed both in the groundwater and petroleum engineering fields. Some of them are freely available through various institutional or academic internet sites (`http://water.usgs.gov/nrp/gwsoftware/`,

http://water.usgs.gov/software/, **http://www.kgs.ukans.edu/Datasale/suprpump.html**, **http://home.olemiss.edu/~acheng/software/index.html**) or under commercial licenses **http://www.scisoftware.com/products/cat_pump_test/cat_pump_test.html**. Amongst other commercial software, and based on the author's experience, one of the best available software package from the petroleum engineering field is Saphir (**http://www.kappaeng.com/Saphir/index.asp**).

THE IDEAL CONFINED AQUIFER

Groundwater-Flow Equation Around a Well

Following Dupuit (1863), we consider an idealized aquifer (Figure 1a). The aquifer is assumed to be infinite in lateral extent, fully confined (no recharge or leakage), two dimensional (large extension compared to its thickness), having a homogeneous transmissivity and storativity. At time zero, pumping starts at a constant rate in the well. If we assume that the heads are constant in space prior to pumping, the flow field will be radial (Figure 1b). All flow lines will converge toward the well as straight lines. If we consider a cylinder of radius r centered on the well, the total water flux $Q(r)$ [L^3T^{-1}] flowing through the cylinder is given by multiplying the area of the cylinder by the specific discharge calculated according to Darcy's law. This yields the following:

$$Q(r) = -2\pi r T \frac{\partial h}{\partial r} \tag{1}$$

where T [L^2T^{-1}] is the transmissivity of the aquifer (hydraulic conductivity multiplied by the aquifer thickness). Since the aquifer is fully confined, and since the water is only slightly compressible, the mass conservation of water between two cylinders during a time interval can be expressed as

$$\frac{\partial Q}{\partial r} = -2\pi r S \frac{\partial h}{\partial t} \tag{2}$$

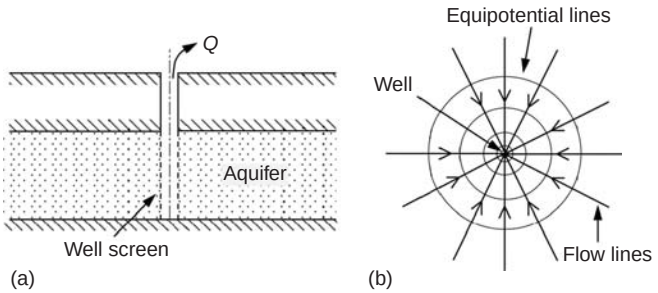

Figure 1 Schematic illustration of an idealized confined aquifer (a) and radial converging flow (b) to a fully penetrating pumping well in such aquifer

with S[−] representing the storage coefficient and t the time. Combining equations (1) and (2) yields

$$\frac{1}{r}\frac{\partial h}{\partial r} + \frac{\partial^2 h}{\partial r^2} = \frac{S}{T}\frac{\partial h}{\partial t} \tag{3}$$

Equation (3) is linear, and has been derived by assuming for didactic reasons that the heads were constant prior to pumping. But this is not a necessity. In general, equation (3) will be written instead in terms of drawdown s [L], defined as the difference between the head h_0 as it would have been without pumping minus the actual head h in the aquifer during pumping (Figure 2).

$$s(t) = h_0(t) - h(t) \tag{4}$$

While h is the solution to equation (3) with complex boundary and initial conditions, s is another solution with much simpler initial and boundary conditions.

It is important to note that when an aquifer is unconfined, the previous equations are not rigorously valid. They can only be applied if the saturated thickness is large compared to the drawdown. Other equations, which are nonlinear, were derived by Dupuit, under additional simplifying assumptions but are of limited applicability. In the following, we restrict ourselves to the case of confined aquifers unless we specify otherwise.

The Dupuit–Thiem Solution in Steady State

Once again, following Dupuit (1863), we consider the case in which flow to a well is in dynamic equilibrium, that is, steady state. The pumping rate Q is constant and the head in the aquifer varies in space but not in time. Under this assumption, the flow $Q(r)$ through any cylinder must be identical to the pumping rate Q. Hence, we can directly integrate equation (1), and making use of the definition of the drawdown to find

$$s(r) = -\frac{Q}{2\pi T}\ln(r) + A \tag{5}$$

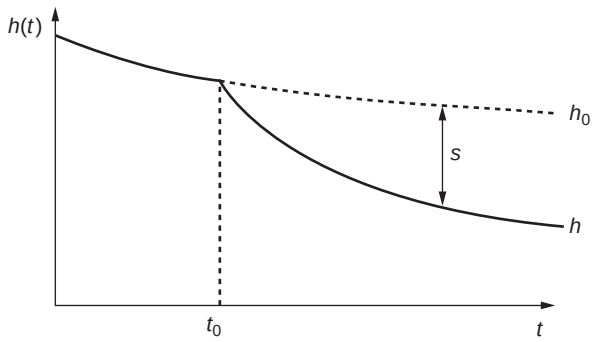

Figure 2 Definition of the drawdown

A is a constant of integration. To eliminate A, Dupuit defines rather arbitrarily a radius R at which the head h_0 is not affected by the pumping. A better technique was proposed by Thiem (1906) who considered the drawdown difference $s_1 - s_2$ between two observations points located at distance r_1 and r_2 from the pumping well. This yields

$$T = \frac{Q}{2\pi(s_2 - s_1)} \ln\left(\frac{r_1}{r_2}\right) \tag{6}$$

Equation (6), known as the *Thiem's formula*, allows determination of the transmissivity T of an aquifer from a constant pumping rate field experiment. Thus, one only has to measure the drawdown difference between two piezometers, and make sure that the difference remains constant and to calculate T with equation (6). Despite that this equation has been derived under steady state assumptions, we will show in Section Relation between Jacob and Thiem solutions that it is also valid for transient conditions for homogeneous aquifers. However, in practice, it should be applied with great care, as the calculated transmissivity is strongly affected by heterogeneities as we will discuss in Section Heterogeneous aquifers.

THE THEIS SOLUTION

The Theis (1935) solution considers the same geometry as the Dupuit–Thiem solution, but under transient-flow regime. It is the most important analytical solution for well hydraulics because most other transient models tend towards it either for early or late times. Therefore, it can often be used even if the underlying assumptions are not fully satisfied.

Assumptions and Solution

The Theis model assumes that the aquifer is confined, infinite, homogeneous, and isotropic; the well is fully penetrating the aquifer, the well has a negligible radius and is 100% efficient; the pumping rate Q is constant. The initial condition is set to zero drawdown everywhere within the aquifer prior to pumping.

$$s(r, t = 0) = 0 \tag{7}$$

The boundary conditions consist of zero drawdown at infinity and a fixed flux equal to the pumping rate at the well.

$$\lim_{r\to\infty} s = 0 \tag{8}$$

$$\lim_{r\to 0} 2\pi T r \frac{\partial s}{\partial r} = -Q \tag{9}$$

The solution of equation (3) subject to initial and boundary conditions (7–9) yields the Theis solution

$$s = \frac{Q}{4\pi T} E_1\left(\frac{r^2 S}{4tT}\right) \tag{10}$$

E_1 is the exponential integral function. Written in dimensionless form the Theis solution is

$$s_D = \frac{1}{2} E_1\left(\frac{r_D^2}{4t_D}\right) \tag{11}$$

where s_D, r_D, and t_D represent respectively the dimensionless drawdown, dimensionless radius, and dimensionless time defined as

$$s_D = \frac{2\pi T}{Q} s, \quad r_D = \frac{r}{r_W}, \quad t_D = \frac{Tt}{r_W^2 S} \tag{12}$$

with r_W being the radius of the well. Note that the logarithmic derivative of the drawdown is as follows (Chow, 1952):

$$\frac{\partial s_D}{\partial \ln(t_D)} = t_D \frac{\partial s_D}{\partial t_D} = \frac{1}{2} \exp\left(-\frac{r_D^2}{4t_D}\right) \tag{13}$$

Equation (11) describes how the drawdown evolves in time and space as a function of transmissivity and storativity of the aquifer and as a function of the pumping rate. Since Bourdet *et al.* (1983), equation (11) together with its logarithmic derivative, equation (13), are usually plotted in log–log scale as a function of t_D/r_D^2. It shows that the drawdown increases with time and decreases with radial distance (see Figure 3a). The derivative tends toward a constant value of 0.5 for late time. The spatio-temporal behavior of the cone of depression shows that the shape of the cone is created very quickly, and then the cone moves downward.

Compression Zone and Radius of Investigation

An important question in well hydraulics and well testing is the definition of the volume of aquifer that is affected by pumping and influences the drawdown behavior. For that purpose, it is useful to calculate the flux of groundwater through a cylinder centered on the well, having a radius r_D. This flux, normalized by the pumping rate, is

$$q_D = \frac{q(r_D)}{Q} = \exp\left(-\frac{r_D^2}{4t_D}\right) \tag{14}$$

Figure 4 shows the behavior of equation (14), three zones are distinguishable and evolve with time. At small radial distances, the normalized flux is close to 1. This indicates that the flux is equal to the pumping rate; the aquifer simply transfers water to the well. At infinity, the flux is close to

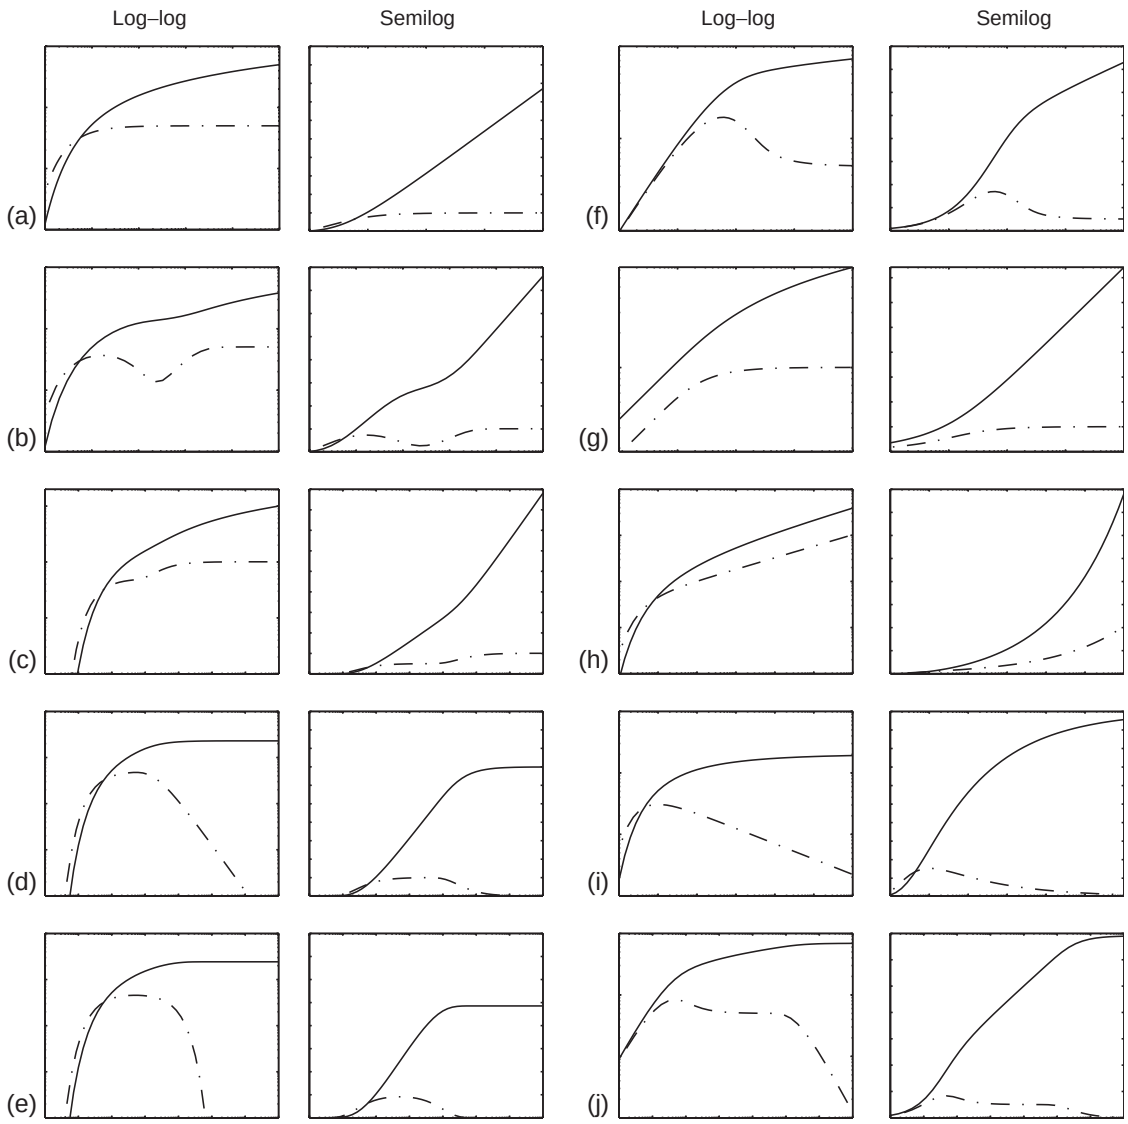

Figure 3 A synthesis of some typical drawdown behaviors in response to constant pumping rate. The drawdown (solid line) and the log derivative (dashed line) are plotted as a function of time in double-logarithmic or semilogarithmic scale. (a) Theis model: confined ideal aquifer. (b) Unconfined, or double porosity aquifer. c) Confined aquifer with a no-flow boundary. (d) Confined aquifer with a constant head boundary. (e) Leaky aquifer: Hantush and Jacob (1955) model. (f) Single well test with well-bore storage and possibly skin effects. (g) Single vertical fracture having an infinite conductivity. (h) General Radial-Flow model with $n < 2$. (i) General Radial-Flow model with $n > 2$. (j) Single well test with well-bore storage, infinite acting radial flow and constant head boundary (Reproduced from Gringarten *et al.* (1974), by permission of American Geophysical Union)

zero. There, the aquifer is not yet active. At intermediate distances, the fluxes vary from 0 to 1; water is mobilized from the compaction of aquifer and elastic expansion of the water itself. This is the so called *compression zone*, which propagates with time.

The radius of investigation of a pumping test is a concept introduced by Dupuit. It was defined as the radius beyond which the drawdown is zero. For the Theis solution, which never predicts drawdown to be strictly zero, there are several possible and arbitrary definitions depending on what is considered as being a negligible drawdown. An elegant possibility is to define the radius of investigation as the radius such that the rate of increase in drawdown with time is maximal (Van Poolen, 1964). Using this definition and calculating the distance at which the second temporal derivative of the drawdown is zero, one finds the simple result:

$$r_{\mathrm{D}}^{i} = 2\sqrt{t_{\mathrm{D}}} \quad \text{or} \quad r^{i} = 2\sqrt{\frac{Tt}{S}} \tag{15}$$

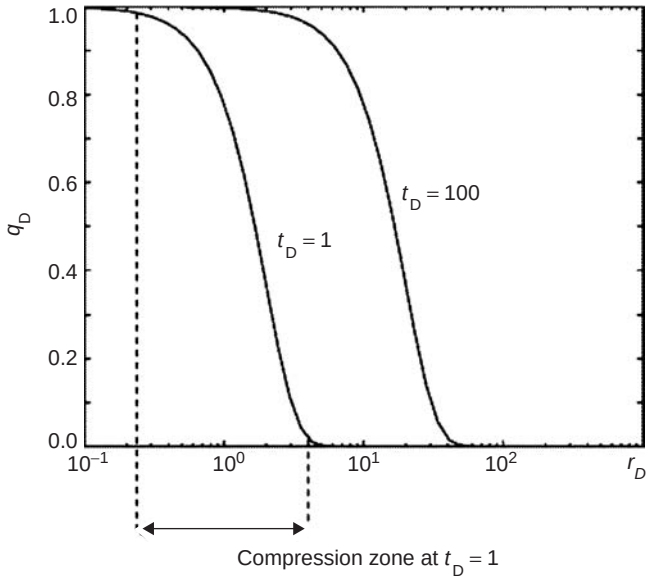

Figure 4 Normalized groundwater flux as a function of radial distance from the well and time

Most alternative definitions of the radius of investigation yield similar equations, being functions of the square root of dimensionless time, but with scaling factors varying from 1.5 to 4.3. All these definitions illustrate the arbitrariness of the concept, but interestingly they all locate the radius of investigation within the compression zone.

More recently, the question of the extension of the investigation domain during a pumping test has been formulated in the framework of spatial filtering functions and heterogeneous transmissivity fields (Beckie, 2001; Oliver, 1993). These authors found that the investigation area is more or less an ellipse that encloses the pumping and the observation wells, but the influence of the heterogeneities within this ellipse is not spatially uniform.

Approximation of the Exponential Integral Function

Applying equations (10) or (11) for well-test interpretation or to design exploitation schemes requires the use of the exponential integral function. It is generally directly available in most mathematical software but, if necessary, it can be calculated with a polynomial and rationale approximations (Abramowitz and Stegun, 1970). For small x, the approximation is

$$\begin{aligned} &0 \le x \le 1 \\ &E_1(x) = -\gamma - \ln(x) + a_1 x + a_2 x^2 \\ &\qquad + a_3 x^3 + a_4 x^4 + a_5 x^5 + \varepsilon \\ &|\varepsilon| < 210^{-7} \end{aligned} \tag{16}$$

with γ being the Euler constant and

$$\begin{aligned} &\gamma = 0.57721566 \quad a_2 = -0.24991055 \quad a_4 = -0.00976004 \\ &a_1 = 0.99999193 \quad a_3 = 0.05519968 \quad\quad a_5 = 0.00107857 \end{aligned} \tag{17}$$

For large x, the approximation is

$$\begin{aligned} &1 \le x \le \infty \\ &E_1(x) = \frac{1}{xe^x}\left(\frac{x^4 + a_1x^3 + a_2x^2 + a_3x + a_4}{x^4 + b_1x^3 + b_2x^2 + b_3x + b_4}\right) + \varepsilon \\ &|\varepsilon| < 210^{-8} \end{aligned} \tag{18}$$

with

$$\begin{aligned} a_1 &= 8.5733287401 \quad & a_2 &= 18.0590169730 \\ a_3 &= 8.6347608925 \quad & a_4 &= 0.2677737343 \\ b_1 &= 9.5733223454 \quad & b_2 &= 25.6329561486 \\ b_3 &= 21.0996530827 \quad & b_4 &= 3.9584969228 \end{aligned} \tag{19}$$

Asymptotic Behavior: the Jacob Solution

Equation (16) shows that the exponential integral $E_1(x)$ tends toward $-\gamma - \ln(x)$ when x tends toward 0. In practice, when the dimensionless number t_D/r_D^2 is greater than 10, the Theis solution can be approximated by a simple logarithmic function. This is the so-called Jacob's approximation of the Theis solution (Cooper and Jacob, 1946).

$$s_D \approx \frac{1}{2}\left[\ln\left(\frac{4t_D}{r_D^2}\right) - \gamma\right] \quad \text{or} \quad s \approx \frac{2.30Q}{4\pi T}\log\left(\frac{2.25tT}{r^2S}\right) \tag{20}$$

Note that when equation (20) is valid, the logarithmic derivative of the drawdown becomes constant.

$$\frac{\partial s_D}{\partial \ln(t_D)} = t_D\frac{\partial s_D}{\partial t_D} = \frac{1}{2} \quad \text{or} \quad \frac{\partial s}{\partial \ln(t)} = \frac{Q}{4\pi T} \tag{21}$$

This relation is used to analyze data sets. One calculates the logarithmic derivative of the measured drawdown and plots it as function of time. When the derivative becomes constant, it indicates that the drawdown has reached a logarithmic asymptote. In petroleum engineering literature, the interval of the data set that shows a constant derivative is identified as the *Infinite Acting Radial Flow* (IARF). During this period of time, one can use safely the logarithmic approximation (18) to interpret the data. If the derivative does not remain constant, the logarithmic approximation cannot be used.

Relation Between Jacob and Thiem Solutions

When Jacob's approximation is valid in two observation boreholes located at distances r_1 and r_2 from the pumping well, we can use equation (20) to calculate the drawdown

difference between the two piezometers. The result is a constant value

$$s_2 - s_1 = \frac{Q}{2\pi T} \ln\left(\frac{r_1}{r_2}\right) \tag{22}$$

which is identical to what Thiem predicted using the steady-state assumption (equation 6).

Interpretation of a Pumping Test with the Theis Solution

The original method was based on the graphical superposition of the Theis type curve with the observed data on two log–log sheets of paper. Nowadays, many software will contain algorithms that apply the Theis method, but we believe that, here, it is useful to illustrate how the interpretation procedure can easily be implemented with any spreadsheet, graphical, or mathematical software. As a preliminary remark, note that equation (20) can be written as

$$s = a \log\left(\frac{t}{t_0}\right) \tag{23}$$

with

$$a = \frac{2.30Q}{4\pi T} \tag{24}$$

$$t_0 = \frac{r^2 S}{2.25T} \tag{25}$$

a has the dimension of length [L], t_0 has the dimension of time [T]. A plot of the measured drawdown s as function of the log of time will show a straight line with a slope a for late time. t_0 will be the value of t for which $s = 0$. We can therefore very easily read the values of a and t_0 from the graph (Figure 5a). A simple interpretation procedure is then:

1. Plot the drawdown measured in the field and its logarithmic derivative as a function of time on the same semilog scale graph.
2. Estimate roughly on the graph the slope a of the straight line, or read the value of the derivative when it stabilizes, it is $a/2.3$. In the example shown in Figure 5(a), we find a slope of about 1.75 m.
3. Read the time t_0 by extrapolating the straight line to the intercept with the horizontal axis, that is, where $s = 0$. In the example, we find $t_0 = 3.5\,10^2$ s.
4. Calculate with the spreadsheet or mathematical software the theoretical drawdown and derivative using the values of a and t_0.

$$s = \frac{a}{2.3} E_1\left(\frac{0.5625t_0}{t}\right) \tag{26}$$

$$\frac{\partial s}{\partial \ln(t)} = \frac{a}{2.3} \exp\left(-\frac{0.5625t_0}{t}\right) \tag{27}$$

   If the exponential integral is not directly available you can use equations (16) and (18). Superpose the theoretical drawdown and derivative on the graph previously done.
5. Improve the fit iteratively by modifying the values of a and t_0 and by visual inspection on your graph or by using a nonlinear least-square algorithm. It is possible to switch (by using the graphical options of the plotting software) from a semilog to a log–log plot if one wants to represent the final plot in log–log scale but this is not required. In our example, the final fit is shown in Figure 5(b).

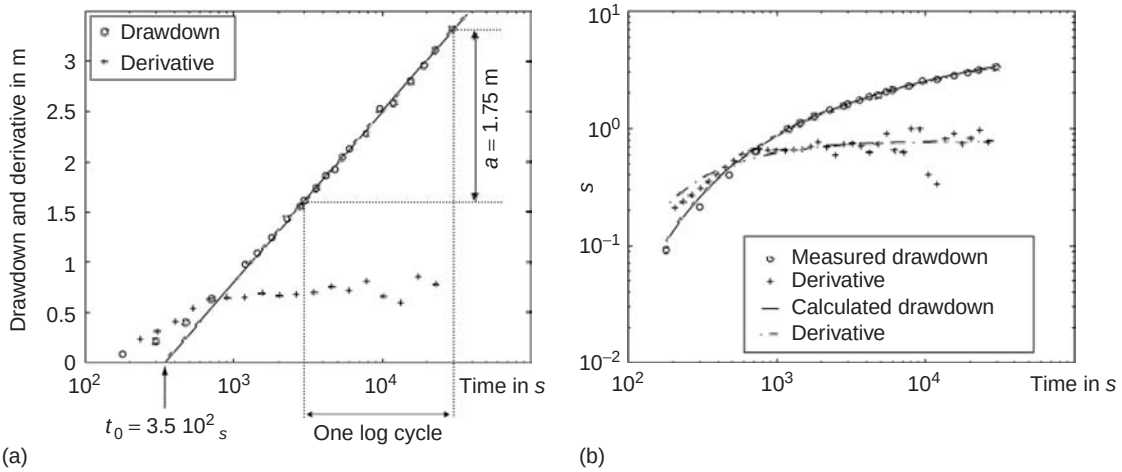

Figure 5 Example of an interpretation of a data set with Theis method. (a) semilog plot of the drawdown and log derivative of a data set, identification of the constant a and t_0. (b) Superposition of the data with the model after automatic fitting

6. Should the fit be acceptable (both drawdown and derivative), the transmissivity T and the storativity S of the aquifer can be estimated with:

$$T = \frac{2.30Q}{4\pi a} = 0.183\frac{Q}{a} \tag{28}$$

$$S = \frac{2.25Tt_0}{r^2} \tag{29}$$

NONIDEALITIES

Heterogeneous Aquifers

What is the validity of the assumption of homogeneity? What is the meaning of the transmissivity obtained from a pumping test interpreted with Theis or Jacob solutions when the aquifer is heterogeneous? Meier *et al.* (1998) conducted a numerical study to investigate these questions. They simulated numerically the flow to a well in a series of heterogeneous aquifers. They considered that the transmissivity field is heterogeneous (Figure 6a) while the storativity is kept constant. They imposed a constant rate in the well and calculated the drawdowns in several piezometers (Figure 6b) using a finite element code. The numerical experiment is repeated for different types of transmissivity fields.

The main conclusion from this study is that the apparent transmissivity, estimated from the slope of the Jacob's straight line, of the transmissivity fields that they investigated is almost identical in all observation wells even if the heterogeneity in transmissivity is important. In these cases, the apparent transmissivity is very close to the uniform-flow effective transmissivity of the heterogeneous media (*see* **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**). However, the straight lines are shifted from one observation well to the next (Figure 6b), and therefore the estimated storativities vary within several orders of magnitude. The apparent heterogeneity in storativity is only a consequence of the heterogeneity in transmissivity. When interpreting a well test, such apparent heterogeneity in estimated storativity may be used as an indicator of the degree of heterogeneity of the transmissivity field. Furthermore, when many observation wells are available the geometric mean of the estimated storativity can be used as an estimator of the real storativity (Sánchez-Vila *et al.*, 1999). A consequence of the shift of the straight lines between observation wells due to heterogeneity, is that the Thiem method that only accounts for drawdown difference between two points will be strongly biased depending on the location of the points. This effect is illustrated by a laboratory experiment in a sand tank filled with a spatially variable pattern of different sands (Silliman and Caswell, 1998). They show that the application of the Thiem formula provides estimates of hydraulic conductivities that are extremely variable and that can be significantly lower (even negative) or higher than the local hydraulic conductivities.

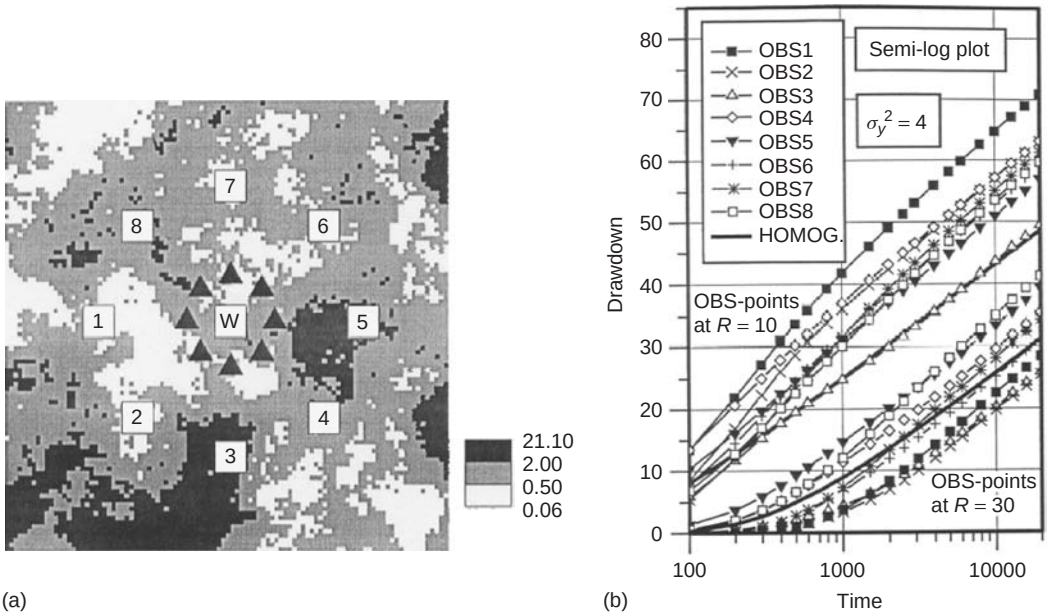

Figure 6 Effect of heterogeneity. (a) Example of a simulated map of transmissivity for a multilognormal field. The W indicates the location of the pumping well. The triangles and the squares indicate the location of two series of observation wells. (b) Calculated drawdown in all the observation points. The line labeled HOMOG represents the calculated drawdown for the equivalent homogeneous medium (Reproduced from Meier *et al.,* 1998 by permission of American Geophysical Union)

In steady state, an interesting result is provided by Dagan (1982), who shows that the expected value of the hydraulic head in a heterogeneous aquifer follows the usual Dupuit solution (equation 5). Dagan also provides approximations for the variance of the head and shows how it is influenced by the heterogeneity of transmissivity and pumping rate.

Partially Penetrating Wells

When the well does not fully penetrate the aquifer (Figure 7a), the flow field around the well has a vertical component. Hantush (1961) showed that in such a case the drawdown tends toward the classical Theis solution when

- the piezometer is located at a distance which is larger than one and a half times the thickness of the aquifer;
- or the observation well is screened over the complete thickness of the aquifer.

When the piezometer is close to the pumping well, the drawdown is affected by the partial penetration depending on the respective location of the well screen and the piezometer (Figure 7b). The late time asymptote is a Jacob straight line whose slope is the same as for a fully penetrating well. A common mistake is to use the screened interval thickness to obtain the hydraulic conductivity, while the real thickness of the aquifer should be used (if it is known).

Bounded Aquifers

When the aquifer is not infinite, the drawdown is affected by the presence of boundaries. There are two typical cases: the presence of a river recharging the aquifer (constant head boundary) and the presence of an impervious geological boundary (no flow boundary).

If we assume that all the other assumptions from Theis are still valid, then the solution to these two problems is obtained by the application of the superposition principle and the theory of images. The concept is that the boundary is mathematically equivalent to the presence of an imaginary well located on the opposite side of the boundary. For the case of a no flow boundary, the image well is a pumping well, while for the case of a constant head boundary, the image well is an injection well (Figure 8).

Using this theory, the solution for both cases is

$$s = \frac{Q}{4\pi T} E_1\left(\frac{r^2 S}{tT}\right) + \beta \frac{Q}{4\pi T} E_1\left(\frac{r_i^2 S}{tT}\right) \qquad (30)$$

with r_i being the distance between the observation well and the imaginary well, $\beta = 1$ for a no-flow boundary and $\beta = -1$ for a constant head boundary.

For the case of a no-flow boundary, the behavior of the drawdown is illustrated in Figure 3(c). It is characterized by a doubling of the late time slope. Two segments of straight line in semilog scale can be seen. The first one corresponds to the Jacob approximation before the drawdown is affected by the boundary. The second straight line corresponds to the superposition of the pumping well and the boundary. Figure 3(d) illustrates the constant head boundary case. The drawdown stabilizes because of recharge from a river; the derivative decreases continuously and follows a straight line on a log–log plot.

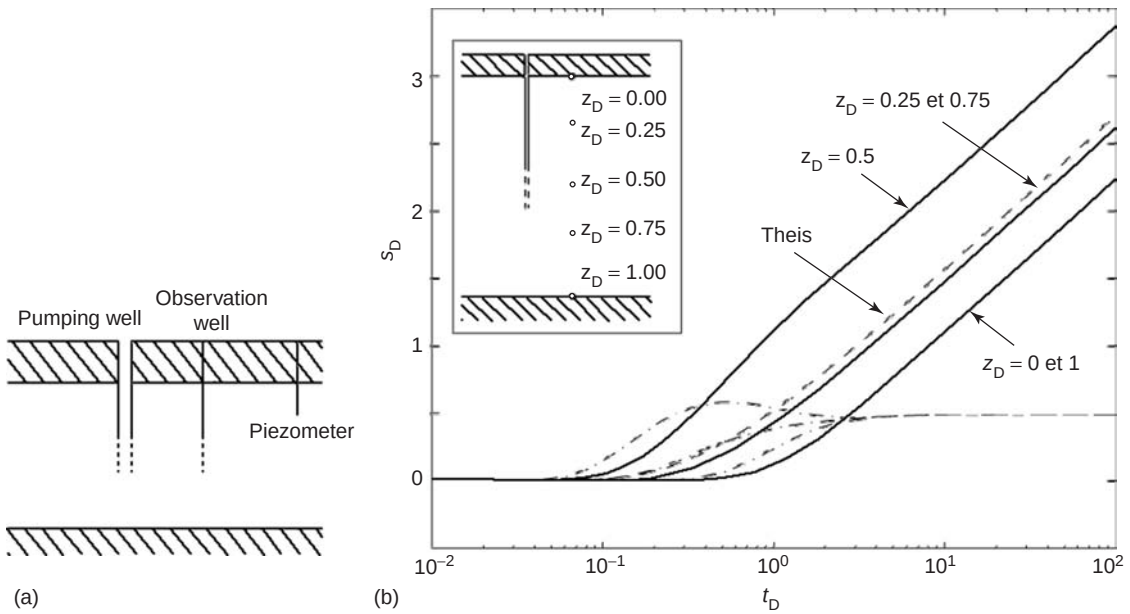

Figure 7 Schematic section through a confined aquifer partially penetrated by a pumping well. (b) Type curves of Hantush's solution for partial penetration in semilog scale for the geometrical configuration illustrated in the figure

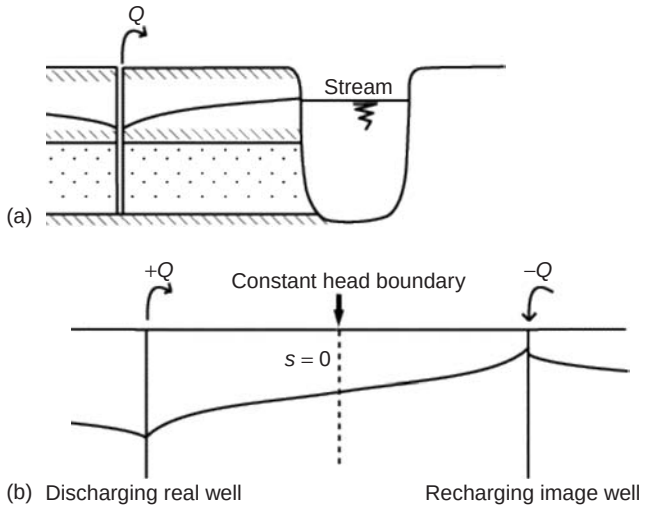

Figure 8 Schematical representation of a confined aquifer bounded by a constant head boundary

Equation (30) implicitly assumes that the constant head is imposed throughout the whole thickness of the aquifer (Figure 8). A recent model considers a more realistic setup that accounts for the geometry of the riverbed (width compared to aquifer thickness) and an imperfect hydraulic connection between the river and the aquifer (Butler *et al.*, 2001). This model allows propagation of drawdown beneath a partially penetrating stream. The type curves of predicted drawdown range from the fully penetrating stream case (equation 30) to the Theis solution (equation 11) as a function of aquifer geometry and stream leakance: streambed hydraulic conductance multiplied by the square of the streamed width divided by the transmissivity of the aquifer below the stream.

Equation (30) can be extended for multiple boundaries. When the boundaries fully penetrate the aquifer, analytical solutions are obtained by the application of image theory. The analytical solution is then the sum of a series of drawdowns resulting from pumping and injection wells located according to the geometry of the boundaries. If one of these boundaries is a constant head boundary, the drawdown stabilizes to a constant value and a steady state is reached for late times. Closed expressions for these asymptotic values are useful, for example for the design of pumping schemes. For a single constant head boundary, the late time asymptote is

$$s = \frac{Q}{2\pi T} \ln\left(\frac{2L}{r_0}\right) \tag{31}$$

with L being the distance between the well and the boundary and r_0 the radius of the well.

In the case of the closed rectangular system shown on Figure 9, the late time asymptote is obtained with the

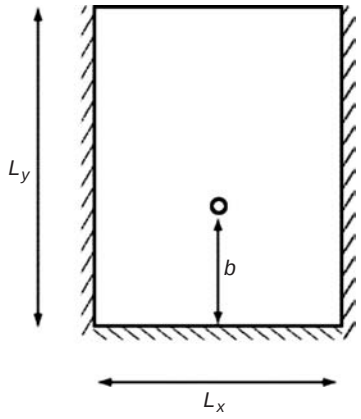

Figure 9 Geometry of a simplified rectangular system with a pumping well, three no flow boundaries and one constant head boundary

Perrochet approximation

$$s = \frac{Q}{2\pi T} \ln\left(\frac{e^{2\pi\frac{L_x - b}{L_y}}}{2\pi}\frac{L_y}{r_0}\right), \frac{L_x}{L_y} > \frac{1}{2}, \frac{3L_x}{4} > b > \frac{L_x}{4} \tag{32}$$

with relative errors less than 1%.

When b = 0, the asymptote becomes

$$s = \frac{Q}{\pi T} \ln\left(\frac{e^{\pi\frac{L_x}{L_y}}}{2\pi}\frac{L_y}{r_0}\right) \tag{33}$$

Variable Pumping Rate

As a starting point, suppose that the pumping rate is constant with a value Q_1 for $0 < t < t_1$ and then the pumping rate is suddenly increased to a value Q_2 at the time $t = t_1$. Assuming that all the other Theis assumptions are valid, the drawdown during the first phase of the test can be expressed with the Theis solution:

$$s = \frac{Q_1}{4\pi T} E_1\left(\frac{r^2 S}{4Tt}\right) t < t_1 \tag{34}$$

Because of the linearity of the groundwater flow equation for a confined aquifer, we can apply the principle of superposition in time and the drawdown in the second phase is simply the sum of the drawdown due to pumping Q_1 from $t = 0$ and the drawdown due to the pumping rate difference $Q_2 - Q_1$ starting at $t = t_1$.

$$s = \frac{Q_1}{4\pi T} E_1\left(\frac{r^2 S}{4Tt}\right) + \frac{Q_1 - Q_2}{4\pi T} E_1\left(\frac{r^2 S}{4T(t - t_1)}\right) t > t_1 \tag{35}$$

We can generalize this idea to a continuously varying pumping rate $Q(t)$:

$$s = \frac{Q(0)}{4\pi T} E_1\left(\frac{r^2 S}{4Tt}\right) + \frac{1}{4\pi T}\int_0^t \left.\frac{\partial Q}{\partial t}\right|_\tau E_1\left(\frac{r^2 S}{4T(t-\tau)}\right) \mathrm{d}\tau \qquad (36)$$

Leakage Through the Confining Layer

Often aquifers are not fully confined, and receive a significant inflow from adjacent beds. Hantush and Jacob (1955) developed the first analytical solution for this situation. Their model considers a confined aquifer overlain by an aquitard and another aquifer (Figure 10). They assume that the pumped aquifer is recharged from the unpumped aquifer through the aquitard. The pumped aquifer is an ideal homogeneous isotropic and infinite two-dimensional aquifer. The flow is assumed to be vertical in the aquitard, there is no storage in the aquitard, the head remains constant in the unpumped aquifer, and the flow remains horizontal in the aquifer. The analytical solution to this problem contains a new dimensionless number related to the aquitard property:

$$\frac{r}{B} = r\sqrt{\frac{k'}{Te'}} \qquad (37)$$

with e' the thickness of the aquitard and k' its hydraulic conductivity. Figure 3(e) shows the typical behavior of the drawdown calculated with the Hantush and Jacob model. After following the Theis solution at early time, the drawdown stabilizes and the derivative drops very fast. If the aquitard is impermeable or very thick or if the observation point is very close to the pumping well, that is, r/B is small, then the solution reaches a plateau at very late time. Conversely, if the aquitard is highly permeable or very thin, or if the observation well is located at a great distance from the pumping well, that is, r/B is large, then the drawdown rapidly stabilizes to a constant value:

$$s_D = K_0\left(\frac{r}{B}\right) \qquad (38)$$

with K_0 the modified Bessel function of the second kind and of the zeroth order.

Later on, improved solutions accounting for storage in the aquitard, complex multilayer systems were developed (Hantush, 1960; Neuman and Witherspoon, 1972). These solutions provide the basic theory allowing indirect testing of low permeability formations.

Unconfined Aquifer

Unconfined aquifers are commonly encountered in well-test analysis. However, radial flow to a well in such an aquifer is a complex physical and mathematical problem. The water table will decline during pumping and therefore the domain for which the equations have to be solved is not constant. Furthermore, the saturated zone is in direct hydraulic relation with the unsaturated zone (Figure 11) and finally, even if the aquifer is horizontal, there is a vertical component of the flow in the vicinity of the pumping well. A complete analytical solution for the saturated–unsaturated system was derived by Kroszynski and Dagan (1975). The main conclusion of their work is that, even if it is more exact to make a complete saturated–unsaturated analysis, the difference in the position of the calculated water table is small if we compare the prediction made by the complete model with the prediction made by a model that does not take into account the unsaturated zone.

The approach most often used is based on the concept of a delayed water-table response. It was initiated by Boulton (1954) and developed by Neuman (1972, 1974). The typical behavior of the drawdown is shown in Figure 3(b). There are three typical stages. In the early time, the drawdown follows a Theis type curve corresponding to the release of water from elastic storage. Then, there is a transition with a flattening of the curve and a hole in the derivative.

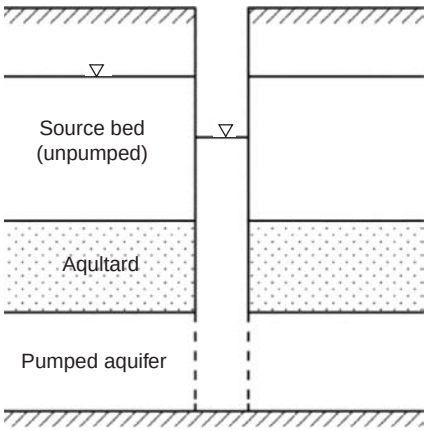

Figure 10 Schematic of Hantush–Jacob model

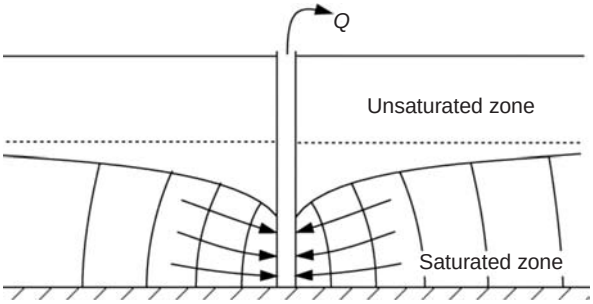

Figure 11 Radial flow to a well in an unconfined aquifer

For late time, the drawdown follows a second Theis curve corresponding to the release of water from the drainage of the unsaturated zone. The derivative becomes a constant. One of the latest model developed for unconfined aquifers is an extension of the Boulton and Neuman models for a large diameter well and partially penetrating the aquifer (Moench, 1997, 1998).

Well-bore Storage Effect

When the radius of the pumping well is large it contains a significant amount of fluid (Figure 12a). During early times, the aquifer's contribution to the total discharge is small (Figure 12b). Most of the water is pumped from the well itself. Later, the aquifer's contribution becomes dominant. Papadopulos and Cooper (1967) developed a model of this situation. Their model is identical to the Theis model for the governing equation, initial condition, and boundary condition at infinity. The difference is the boundary condition at the well that account for finite well radius and water storage in the well. This additional concept requires the definition of an additional dimensionless parameter, the well-bore storage coefficient:

$$C_{\mathrm{D}} = \frac{r_c^2}{2r_{\mathrm{W}}^2 S} \tag{39}$$

with r_c being the radius of the casing and r_{W} the radius of the well screen. Figure 3(f) shows a typical behavior of the drawdown in the pumping well. The main characteristic of this type curve is that for early times, the asymptote is a straight line with unit slope in the log–log plot:

$$s_{\mathrm{w}} = \frac{Q}{\pi r_c^2} t \tag{40}$$

The logarithmic derivative follows the same straight line of unit slope. During this period, when the drawdown and derivative follow the same line, the well-bore storage effect is dominant. This is followed by a transition where the derivative departs from the straight line and makes a hump. For late times, the derivative stabilizes and the behavior is dominated by the aquifer contribution. The drawdown tends toward the Jacob's solution. Note that later on, boundary effects can affect the solution. For example Figure 3(j) shows the same type of behavior with an additional constant head boundary that stabilizes the drawdown for the late time and shows a drop of the derivative.

Skin Effect

The drawdown in the pumping well can be strongly affected by the skin effect, that is, the existence of a zone of lower hydraulic conductivity than the aquifer in the immediate vicinity of the well (Figure 13). This zone of low hydraulic conductivity may be due to poor well development, deposition of particles or development of bacterial films. Also, increased hydraulic conductivity in the immediate vicinity of the well is possible and is accounted for in the theory but have less impact on the drawdowns in the well.

The concept of skin effect was introduced by van Everdingen (1953). Later, Agarwal *et al.* (1970) developed a solution including both well-bore storage and skin effect. To quantify the skin effect and assuming steady state, it is simple to show that the additional drawdown s_{D} in the well due to a cylinder of radius r_s and having a transmissivity T_s is

$$s_{\mathrm{D}} = \frac{Q}{2\pi T}\sigma \tag{41}$$

with σ being the skin factor:

$$\sigma = \left(\frac{T - T_S}{T}\right) \ln\left(\frac{r_s}{r_{\mathrm{w}}}\right) \tag{42}$$

Note that σ is positive if the well is clogged ($T_s < T$) and negative for the opposite case. The early time

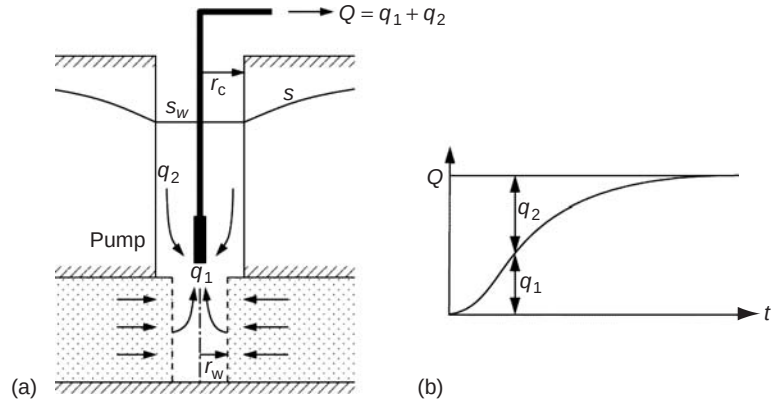

Figure 12 Schematic of the well-bore storage effect

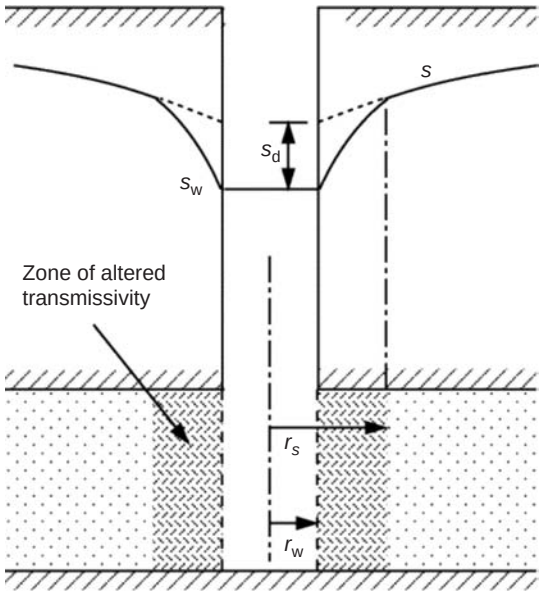

Figure 13 Finite thickness skin model

behavior of the solution of Agarwal *et al.* is identical to the Papadopulos–Cooper solution (1967). The late time asymptote is a straight line (on semilog plot) parallel to Jacob's straight line but shifted by σ.

$$s_D = \tfrac{1}{2}[\ln(4t_D) - \gamma] + \sigma \tag{43}$$

As with the Theis model, the late time data allows unique identification of the transmissivity of the aquifer from the slope of the straight line, or from the value of the logarithmic derivative. However, the position of the line is both a function of storativity and of the skin effect. It is therefore impossible to determine both the storativity and the skin effect with a single well test.

An other important feature of the Agarwal solution is that the shape of the type curves are identical for all type curves having the same value of the product $C_D e^{2\sigma}$ when $\sigma > 0$, and $C_D e^{2\sigma} > 10^3$. Furthermore the shape of these type curves (see Figure 3f) is identical to the original Papadopulos–Cooper type curves only accounting for well-bore storage effects. In practice, this means that the effect of well-bore storage and skin effect are not distinguishable.

Quadratic Head Losses

In the model of Agarwal *et al.* the drawdown in the pumped well increases linearly with Q. However, based on field observations, Jacob (1947) indicates that the drawdown in a pumping well generally increases as a function of the square of the flow rate (Figure 14a).

$$s = AQ + BQ^2 \tag{44}$$

This additional head loss can strongly affect the drawdown in the borehole and therefore its efficiency. The additional drawdown is attributed to inertial or turbulent flow occurring in the zone just outside the well, through the well screen and in the casing (Rorabaugh, 1953). This additional drawdown is commonly referred to as the quadratic head losses or the nonlinear head losses in the well. The *nonlinear head-loss coefficient* B allows quantifying the importance of this effect. In petroleum engineering, this phenomenon is mainly described for gas well testing and is modeled with a rate dependent skin effect. In practice, to evaluate the importance of these head losses, a step-drawdown test is conducted. At first, the well is pumped at a given flow rate for a given amount of time (Figure 14b); subsequently the flow rate is modified and applied for another given duration; then again the flow rate is changed and and so on. Usually the minimum number of steps is three, allowing to identify the nonlinear head-loss coefficient and to check the adequacy of equation (44). The interpretation of such step-drawdown tests relies on the late time asymptote and on the superposition principle (Eden and Hazel, 1973; Hantush, 1964). Some attempts have been made to include the inertial term in a transient solution

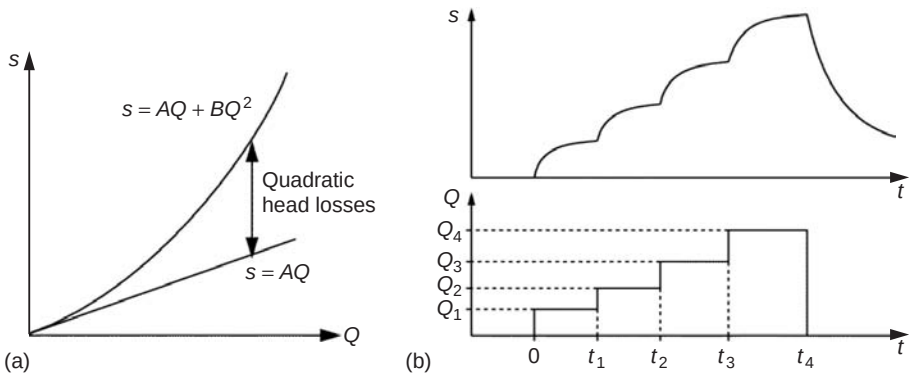

Figure 14 (a) Drawdown in the well as a function of the discharge rate. (b) A step-drawdown test

(Chachadi and Mishra, 1992), but the analytical approach is not yet fully convincing as it does not respect the continuity of heads throughout the well screen. The most promising approach used to date is numerical. It includes the inertial term within the aquifer and has been applied to a deep fractured aquifer (Kohl *et al.*, 1997).

The Double Porosity Model

In 1960, Barenblatt and his coworkers introduced a revolutionary concept:

> "Unlike in classical fluid flow theory, for each point in space, not one hydraulic head but two, h and h', are introduced. The head h represents the average head in the fractures in the neighborhood of the given point, whereas [...] h' is the average head in the matrix in the neighborhood of the given point" (Barenblatt *et al.*, 1960). This concept forms the foundation of the double porosity approach. In their article, Barenblatt *et al.* assumed that the storativity of the fractures was negligible. Warren and Root (1963) introduced a storativity for the fractures and developed a model, which is still used today.

The formulation of the double porosity models (see Figure 15) is based on two coupled standard groundwater flow equations (one for the fracture, one for the matrix) with an exchange term. The hydraulic conductivity and the specific storage coefficient are defined separately for each media. To simplify the system of equations, Warren and Root assume that the water moves from matrix blocks to fractures, but not from matrix block to matrix block. It is furthermore assumed that the flow rate between the matrix and the fractures is proportional to the hydraulic conductivity of the matrix, to the hydraulic head differences between the two systems, and to a geometrical factor depending on the size and the shape of the matrix blocks. This is the so-called pseudosteady state assumption of Warren and Root.

A typical drawdown curve is shown in Figure 3(b). It has a sigmoidal shape. During early time, the water is pumped from storage in the fractured system, the matrix does not affect the flow. In the intermediate times, water is released from the matrix while the drawdown in the matrix is small compared to drawdown in the fractures. During the late time, the drawdown in the matrix approaches the drawdown in the fractures and the aquifer behaves like a single porosity aquifer with the combined property of the matrix and the fractures. The log derivative shows a typical depression before it stabilizes to the constant value indicating that the drawdown reached the late time Jacob's straight line.

More recently, the model of Warren and Root has been extended to account for well-bore storage and skin effect (Bourdet and Gringarten, 1980). Another modification of the model is to account for transient flow within the matrix to the fractures (Boulton and Streltsova, 1977). In this model, the head distribution is solved within the blocks and therefore it is necessary to assume a given shape for the blocks. Boulton and Streltsova consider a representation of the fractured medium as alternating layers of matrix rocks and fractures. Once again, the resulting type curves show the typical sigmoidal shape and depression in the logarithmic derivative.

General Radial-Flow Model

The General Radial-Flow (GRF) model (Barker, 1988) is a generalization of radial-flow equations to any flow dimension n that includes the specific cases of linear flow ($n = 1$), usual cylindrical flow ($n = 2$), and spherical flow ($n = 3$), it extends as well to noninteger-flow dimensions for intermediate cases (see Figure 16). The beauty of this model is that it provides a unique solution for a large range of possible behaviors with only one additional parameter (the flow dimension n). In subsequent publications, the GRF model was extended to include well-bore storage, skin effects, and double porosity (Hamm and Bideaux, 1996). The solution of the standard GRF model (without skin, well-bore storage and double porosity) with a constant pumping rate in an infinite medium is

$$s_D = \frac{r_D^{2-n}}{\Gamma\left(\frac{n}{2}\right)}\Gamma\left(\frac{n}{2} - 1, \frac{t_D}{4r_D^2}\right) \tag{45}$$

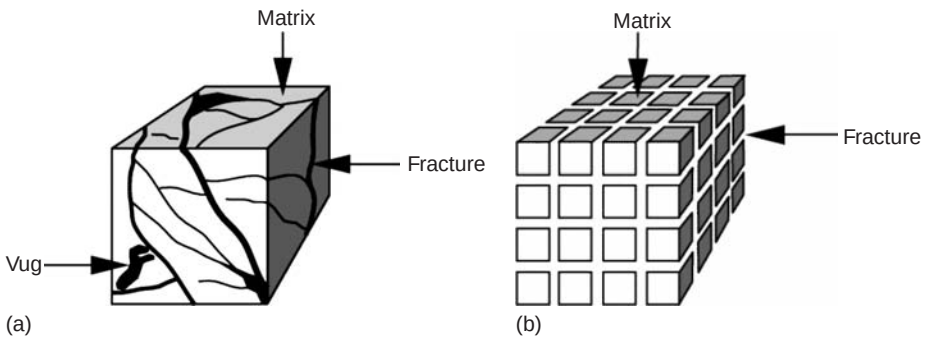

Figure 15 A fractured block illustrating the double porosity concept (Adapted from Cinco-Ley, 1996)

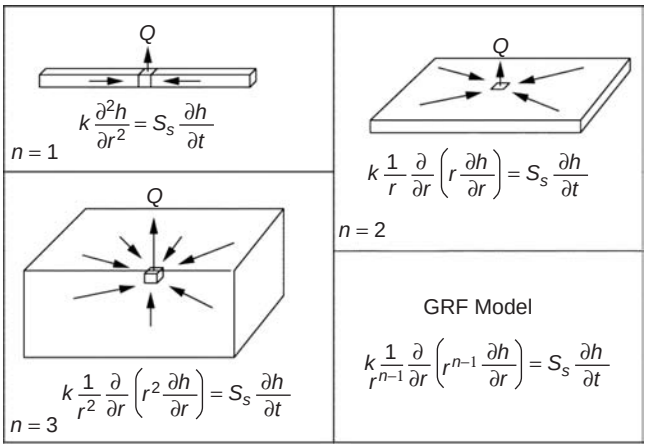

Figure 16 Concept of radial flow in 1, 2, 3, and generalization to n dimensions

with n being the flow dimension, $\Gamma(x)$ the gamma function, and $\Gamma(a, x)$ the incomplete gamma function. Figure 3(h) and Figure 3(i) show two examples of drawdown for $n < 2$ and $n > 2$ respectively. A typical characteristic of the GRF model is that the log derivative of the drawdown follows a straight line with a slope of $1 - n/2$ in the diagnostic plot. When $n = 2$, the GRF model converges toward the Theis solution, and the log derivative becomes constant for late time (0 slope). Barker suggests that the fractional-flow dimension may be related to the observed fractal properties of fracture networks. However, the diffusivity of the GRF model remains equal to k/S_s even when the flow dimension is fractional. An alternative analytical model based on a fractal network of fractures has been proposed by Chang and Yortsos (1990). Both models have been compared with numerical simulations in fracture networks. Acuna and Yortsos (1995) show that the model of Chang and Yortsos agrees with drawdowns simulated on artificially generated fractal networks (e.g., Sierpinski carpets). More recently, Jourde *et al.* (2002) show that fractional-flow dimension may even appear on a Euclidian network by using a network of pipes simulating a network of pseudorandom orthogonal fractures.

Individual Fractures

A more specific situation is the case of an individual fracture intersected by the well and acting as a drain in a larger porous aquifer. Several models have been developed for this type of configuration (Gringarten, 1982). The case of the drawdown in a well intersecting a vertical fracture of infinite conductivity and finite length is illustrated in Figure 3(g) (Gringarten *et al.*, 1974). A 0.5 slope for the drawdown and the derivative characterizes this solution at early time on a log–log plot.

OTHER HYDRAULIC PERTURBATIONS

Recovery Test

Head recovery after a pumping test can be modeled using the superposition principle. When the aquifer is confined, from a mathematical point of view, the end of pumping is equivalent to continuing pumping and simultaneously injecting the same amount. This implies that the drawdown can be calculated by adding drawdown due to pumping plus drawdown due to a simultaneous injection at the same location. In the case of the Theis assumptions, the solution for the recovery is therefore

$$s_{\mathrm{D}} = \frac{1}{2}E_1\left(\frac{r_{\mathrm{D}}^2}{4(t_{\mathrm{P}} + t_{\mathrm{R}})}\right) - \frac{1}{2}E_1\left(\frac{r_{\mathrm{D}}^2}{4t_{\mathrm{R}}}\right) \qquad (46)$$

where t_{R} is the dimensionless time since the recovery started and t_{P} is the dimensionless production time. Equation (46) is exact and can be used to analyze a data set and to estimate both T and S. An asymptotic solution is however often used. When both exponential integrals, in equation (46), can be approximated by a logarithmic function, one finds the late time asymptote:

$$s_{\mathrm{D}} = \frac{1}{2}\ln\left(\frac{t_{\mathrm{R}} + t_{\mathrm{P}}}{t_{\mathrm{R}}}\right) \quad \text{or} \quad s = \frac{2.30Q}{4\pi T}\log\left(\frac{t_{\mathrm{r}} + t_{\mathrm{p}}}{t_{\mathrm{r}}}\right) \qquad (47)$$

with t_{r} being the time since the beginning of the recovery and t_{p} the production time. This approximation allows rapid interpretation of late time recovery by constructing a semilog plot of the drawdown versus the log of the ratio $(t_{\mathrm{r}} + t_{\mathrm{p}})/t_{\mathrm{r}}$, denoted as the Horner time in the oil industry. Although, the slope is then proportional to the transmissivity, the storativity cannot be estimated. Another alternative to interpret recovery data has been proposed by Agarwal (1980). He found that if the recovery time is replaced by a corrected time t_a:

$$t_a = \frac{t_{\mathrm{p}}t_{\mathrm{r}}}{t_{\mathrm{p}} + t_{\mathrm{r}}} \qquad (48)$$

The interpretation is thus greatly facilitated. One can apply the standard interpretation models above described for constant rate pumping tests, including the log derivative for model identification. Note, however, that the approach is not valid for bounded aquifers.

Constant Head Test

In some situations, the artificial perturbation imposed in the well is not a constant discharge or recharge rate but a constant head. Under these circumstances, the aquifer responds by a groundwater discharge at a variable rate into the well, and a variation of head within the aquifer.

Both perturbations can be modeled. Considering an ideal confined aquifer, the standard analytical solution for the discharging rate in the well is the solution of Jacob and Lohman (1952). Mishra and Guyonnet (1992) indicate that using the drawdown normalized by the discharge rate allows field data to be interpreted with the usual Theis model. The discharge rate in the well can be evaluated with excellent accuracy using the Perrochet approximation:

$$q_D = \frac{q}{2\pi T s_0} = \frac{1}{\ln(1 + \sqrt{\pi t_D})} \tag{49}$$

with s_0 being the imposed drawdown at the well and with relative error less than 1% over the range $10^{-4} < t_D < 10^{12}$.

Additional solutions for the constant head case accounting for boundaries and transient effects are available in Murdoch and Franco (1994).

Constant head situations are naturally encountered in artesian aquifers. Constant head tests offer a useful alternative to pumping tests since they minimize the effect of well-bore storage and therefore reduce the required duration of a test. Another advantage is that constant head tests can be carried out when the maximum admissible drawdown may be limited. This can be the case when the hydraulic conductivity is small.

Slug Test

The slug test method (Hvorslev, 1951) was developed to rapidly estimate aquifer transmissivity. The principle involves instantaneously perturbing the water level in a well by an injection or an extraction of a known volume of water (Figure 17). After the perturbation, the water levels are recorded in the well or in a piezometer until they stabilize.

Depending on the geometry and type of aquifer, several analytical solutions can be used for slug-test data interpretation. Practical recommendations concerning the design and the performance of slug tests as well as a compendium of available analytical solutions is available in Butler (1998). Recent contributions include a detailed analysis of inertial effects, given the rapid and often oscillatory behavior of the head in the borehole itself (McElwee and Zenner, 1998; Zurbuchen *et al.*, 2002). From a general point of view, slug tests are very interesting because they take much less time to carry out than pumping tests or constant head tests and require less equipment. Consequently, they are cheaper to conduct. One can therefore perform a large number of slug tests in an aquifer in order to characterize the spatial distribution of hydraulic conductivities (see e.g. Mas-Pla *et al.*, 1997). Slug tests also allow testing low permeability formations that may not be tested within a reasonable period of time using pumping test techniques. The main disadvantage of slug tests is that the radius of investigation is much smaller than for a pumping test. As a consequence, they are much more strongly influenced by skin effects or local heterogeneities around the well (Butler and Healey, 1998). Another drawback of this technique is that it is difficult to estimate the storativity coefficient with sufficient certainty.

152: Modeling Solute Transport Phenomena

JACOB BEAR

Department of Civil and Environmental Engineering, Technion – Israel Institute of Technology, Haifa, Israel

The article presents the conceptual and well-posed mathematical models that describe the transport of solutes, or chemical species, in porous media, as encountered when considering the transport of dissolved salts and contaminants in aquifers. The various modes of transport: advection dispersion and diffusion are discussed and incorporated in the models. Solute sources are also incorporated in the models, including adsorption and an introduction to reactive transport. We shall emphasize that the fluid's velocity, and in unsaturated flow, also the fluid's saturation is required as input information to any solute transport problem. However, the model of flow problem that provides this information is discussed in ***Chapter 149, Hydrodynamics of Groundwater, Volume 4****. Unsaturated flow models are discussed in* ***Chapter 150, Unsaturated Zone Flow Processes, Volume 4****. The case of solute transport with variable density is not included, as it is presented in* ***Chapter 157, Sea Water Intrusion Into Coastal Aquifers, Volume 4****. More about chemical and biological reactions is presented in* ***Chapter 153, Groundwater Pollution and Remediation, Volume 4****.*

INTRODUCTION

The water *quality* aspect is essential in the management of any water resources system, in parallel to that of water *quantity*. In fact, in many parts of the world, with the increased demand for water and with the intensification of water utilization, the quality of water in the sources often deteriorates to the extent that it becomes the limiting factor in the development and management of the water resources system. Even under pristine conditions, ground water in springs, rivers, and aquifers always contains dissolved matter, especially dissolved salts. Sometimes, the concentration of solutes is such that the water is unfit for certain purposes, for example, for irrigation or for drinking. Unfortunately, too often, water contains (dissolved) *pollutants, or contaminants,* which are produced and released to the environment by human activities at ground surface, whether intentionally or not. Note that to emphasize the negative, often hazardous to human health, aspects of certain dissolved materials, or *chemical species* in solution, we usually refer to them as *pollutants* or *contaminants* rather than as merely *solutes.* In this article, we shall use these terms interchangeably. In **Chapter 155, Numerical Models of Groundwater Flow and Transport, Volume 4**, we consider salinization of ground water associated with the phenomenon of seawater intrusion into coastal aquifers.

Although the processes of water *salinization* and *contamination* occur in both surface and ground water, special attention should be devoted to their occurrence in aquifers, because of the very slow velocity of ground water, and the capacity of the solid matrix to adsorb and absorb pollutants, and then release them over prolonged periods of time. Cleanup of a contaminated aquifer (and the vadose zone) is much more lengthy and costly.

Certain chemical species in groundwater may chemically interact with other species, and/or with the solid matrix. Others may undergo biological transformations. In this article, these processes are briefly introduced.

The issue of ground water pollution, including sources of pollutants, quality standards, and regulations, is presented in **Chapter 153, Groundwater Pollution and Remediation, Volume 4**. Here, we shall focus only on the models that describe the *transport*, that is, the movement, accumulation, and transformation of solutes in ground water.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

The entire discussion will be at the *macroscopic* level, that is, the level at which the porous medium comprising the aquifer is regarded as a *continuum*, and the behavior of the aquifer system is described in terms of state variables that represent *intrinsic phase averages* of their corresponding *microscopic* ones over a Representative Average Volume (REV) (e.g. Bear, 1972; Bear and Bachmat, 1990). The objective of constructing and solving such models is to enable planners and managers to predict future changes in the concentration of solutes, in response to planned management decisions. Such predictions are required in connection with aquifer management, in dealing with aquifer pollution and remediation techniques (*see* **Chapter 153, Groundwater Pollution and Remediation, Volume 4**), and in the use of tracers. The subjects of protecting ground water resources against pollution, and monitoring the movement of solutes in aquifers are discussed in **Chapter 153, Groundwater Pollution and Remediation, Volume 4**.

FLUXES

We consider the transport of a contaminant (= a chemical species) within a fluid phase that occupies the entire void space. Three modes of transport will be considered: advection, diffusion, and dispersion.

The quantity of the chemical species in solution will be represented as concentration (expressed as mass of species per unit fluid phase volume).

Advective Flux – Macroscopic Level

The (macroscopic) *advective flux*, $\mathbf{J}^{\gamma}_{\text{adv}}$, of a chemical γ-species (= mass of γ per unit area of fluid per unit time), is expressed in the form:

$$\mathbf{J}^{\gamma}_{\text{adv}} = \mathbf{V}c^{\gamma} \tag{1}$$

where c^{γ} denotes the concentration of the considered γ-species, and $\mathbf{V}$ denotes the (mass-averaged) velocity of the fluid phase, described by Darcy's law (*see* **Chapter 149, Hydrodynamics of Groundwater, Volume 4** for saturated flow and **Chapter 150, Unsaturated Zone Flow Processes, Volume 4** for unsaturated and multiphase flow).

Per unit area of porous medium, the macroscopic advective flux is expressed by $\theta\mathbf{J}^{\gamma}_{\text{adv}} = \theta\mathbf{V}c^{\gamma}$, where θ denotes the volumetric fraction of the fluid (with $\theta = \phi =$ porosity for saturated flow).

Diffusive Flux

Diffusive Flux – Microscopic Level

We consider the *(microscopic) diffusive flux*, $\mathbf{j}^{\gamma}_{\text{diff}}$ of a γ-species. A fluid phase is, usually, composed of a number of *chemical species*, each made up of a large number of identical molecules (ions, atoms, etc.) that are in constant random motion. The *solvent* is considered as one of the chemical species. At the *microscopic level*, that is, at a point *within* the fluid that occupies the void space (or part of it), each extensive quantity (mass, momentum, energy) of a chemical species, or of a phase, present in a given domain, may be regarded as a *continuum*. At the microscopic level, an extensive quantity of a chemical species at a (microscopic point) is the average of that quantity over the individual molecules of that species within a microscopic representative elementary volume centered at that point.

Let $\rho^{\gamma}(\equiv c^{\gamma})$ and $\mathbf{V}^{\gamma}$ denote the density and velocity of a γ-species *at the microscopic level*. The flux of the γ-species (= mass per unit area of fluid per unit time) is given by $\rho^{\gamma}\mathbf{V}^{\gamma}$. Because $\mathbf{V}^{\gamma}$ is not known, we express this flux as the sum of two fluxes:

$$\rho^{\gamma}\mathbf{V}^{\gamma} \equiv \rho^{\gamma}\mathbf{V} + \rho^{\gamma}(\mathbf{V}^{\gamma} - \mathbf{V}) \equiv \rho^{\gamma}\mathbf{V} + \mathbf{j}^{\gamma}_{\text{diff}},$$
$$\mathbf{j}^{\gamma}_{\text{diff}} \equiv \rho^{\gamma}(\mathbf{V}^{\gamma} - \mathbf{V}) \tag{2}$$

that is, an advective flux (at the microscopic fluid velocity $\mathbf{V}$), $\rho^{\gamma}\mathbf{V}$, and a *diffusive flux*, $\mathbf{j}^{\gamma}_{\text{diff}}$, at a velocity relative to the latter, both at the microscopic level.

A *binary fluid*, is composed of two chemical species, a *solute*, γ, and a *solvent*, δ. In such a fluid, the (microscopic mass) flux of molecular diffusion is expressed by *Fick's law of molecular diffusion*:

$$\mathbf{j}^{\gamma}_{\text{diff}} \equiv \rho^{\gamma}(\mathbf{V}^{\gamma} - \mathbf{V}) = -\rho\mathcal{D}^{\gamma\delta}\nabla\omega^{\gamma} \tag{3}$$

where $\omega^{\gamma}(\equiv\rho^{\gamma}/\rho)$ denotes the mass fraction of γ, and $\mathcal{D}^{\gamma\delta}$ (a scalar often assumed to be independent of c^{γ}) is the *coefficient of molecular diffusion* (dims. L^2/T) of a γ-species in a fluid phase containing a second species, δ. The diffusive flux of the δ-species, is given by

$$\mathbf{j}^{\delta}_{\text{diff}} = \rho^{\delta}(\mathbf{V}^{\delta} - \mathbf{V}) = -\rho\mathcal{D}^{\delta\gamma}\nabla\omega^{\delta} \tag{4}$$

with $\mathcal{D}^{\gamma\delta} = \mathcal{D}^{\delta\gamma}$. For a homogeneous fluid, $\nabla\rho = 0$, and, therefore,

$$\mathbf{j}^{\gamma}_{\text{diff}} = -\mathcal{D}^{\gamma\delta}\nabla c^{\gamma} \tag{5}$$

Another form of the diffusive flux is

$$\mathbf{j}^{\gamma}_{\text{diff}} = -\frac{\hat{\rho}^2}{\rho}M^{\gamma}M^{\delta}\mathcal{D}^{\gamma\delta}\nabla n^{\gamma} \tag{6}$$

where $\hat{\rho}$ is the total *molar density* of the fluid (= number of moles of fluid per unit volume of fluid), n^γ is the *molar fraction* of γ, $\rho^\gamma/\hat{\rho} = n^\gamma M^\gamma + n^\delta M^\delta$, and $\omega^\gamma = n^\gamma M^\gamma/(n^\gamma M^\gamma + n^\delta M^\delta)$. More generally, the diffusive flux is driven by a gradient in the *chemical potential* (Denbigh, 1981), $\mu^\gamma = \mu^\gamma(p, n^\gamma, T)$. It then takes the form:

$$\mathbf{j}^\gamma_{\text{diff}} = -\frac{\hat{\rho}^2}{\rho RT} n^\gamma \mathcal{D}^{\gamma\delta} \nabla \mu^\gamma \big|_{p,T} = \left(\frac{\hat{\rho}^2}{\rho RT} n^\delta \mathcal{D}^{\delta\gamma} \nabla \mu^\delta \big|_{p,T} \right) \tag{7}$$

where R and T denote the universal gas constant and the temperature, respectively. Typical values of $\mathcal{D}^{\gamma\delta}$ at 25 °C, for a solute in an aqueous phase, are in the range of $5\text{–}100 \times 10^{-6}\,\text{cm}^2\,\text{s}^{-1}$. For example, for Ca^{2+} : $\mathcal{D}^{\gamma\delta} = 7.9 \times 10^{-6}\ \text{cm}^2\,\text{s}^{-1}$, for K^+ : $\mathcal{D}^{\gamma\delta} = 30 \times 10^{-6}\,\text{cm}^2\,\text{s}^{-1}$, for Cl^- : $\mathcal{D}^{\gamma\delta} = 20.3 \times 10^{-6}\,\text{cm}^2\,\text{s}^{-1}$. Typical values for a dilute chemical component in the air are: for water vapor: $\mathcal{D}^{\gamma\delta} = 2.2 \times 10^{-1}\ \text{cm}^2\,\text{s}^{-1}$, for TCE vapor: $\mathcal{D}^{\gamma\delta} = 7.8 \times 10^{-2}\text{cm}^2\,\text{s}^{-1}$. Correlations for $\mathcal{D}^{\gamma\delta}$ for a broad range of compounds, as a function of temperature and pressure, are given by Poling *et al.* (2000). Fick's law, equation (3), is also valid, as an approximation, for the diffusive flux of a γ-species in a *multicomponent system*, as long as the other component, δ, is the solvent, and all components, except δ and γ, are dilute. Another case for which Fick's law holds is when all components are dilute, except for the δ-component. Then, since $\Sigma_{(\gamma)} \mathbf{j}^\gamma_{\text{diff}} = 0$, we have

$$\begin{aligned} \mathbf{j}^\lambda_{\text{diff}} &= -\rho \mathcal{D}^{\lambda\delta} \nabla \omega^\lambda, \lambda \neq \delta \\ \mathbf{j}^\delta_{\text{diff}} &= -\sum_{\gamma(\neq\delta)} \mathbf{j}^\gamma_{\text{diff}} = \sum_{\gamma(\neq\delta)} \rho \mathcal{D}^{\gamma\delta} \nabla \omega^\gamma \end{aligned} \tag{8}$$

Lichtner (1996) presents an expression for the diffusive mass flux of an ionic species in a dilute aqueous solution that is electrically neutral; it is used for modeling the transport of multiple ionic species.

Diffusive Flux – Macroscopic Level

The expression for the macroscopic diffusive flux of a species is obtained by averaging the microscopic one over the appropriate REV, or by employing some *homogenization* technique. In the passage from the microscopic equation to its macroscopic counterpart, the configuration of the solid–fluid interface surface, and conditions on it, affect the transformation of the (local) gradient of concentration into a gradient of the average concentration (which is the state variable at the macroscopic level).

Bear and Bachmat (1990), who use volume (REV) averaging, obtained an expression for the *macroscopic* form of Fick's law for a chemical γ-species in a constant density fluid that occupies part of the void space (volumetric fraction θ), in the form:

$$\mathbf{J}^\gamma_{\text{diff}} \equiv \overline{\mathbf{j}^\gamma_{\text{diff}}} = -\mathcal{D}^\gamma \mathbf{T}^*(\theta) \cdot \nabla c^\gamma = -\boldsymbol{\mathcal{D}}^{*\gamma}(\theta) \cdot \nabla c^\gamma \tag{9}$$

where $c^\gamma (\equiv \overline{c^\gamma})$ denotes the component's concentration at the macroscopic level, and $\boldsymbol{\mathcal{D}}^{*\gamma}(\theta) (\equiv \mathcal{D}^\gamma \mathbf{T}^*(\theta))$, a second rank symmetric tensor, is the coefficient of molecular diffusion within a fluid phase *in a porous medium*. Note that $\mathbf{J}^\gamma$ denotes the flux of γ per *unit area of fluid within a porous medium cross-section*. For brevity, we have dropped the superscript δ in $\mathcal{D}^\gamma(\theta)$, and the overbar in the averaged concentration. The symbol $\mathbf{T}^*(\theta)$, a second rank symmetric tensor, represents the *tortuosity* of the porous medium (e.g. Bear and Bachmat, 1990). In an isotropic porous medium, the components, T^*_{ij} of the tortuosity tensor, may be represented as $T^*\delta_{ij}$, in which $T^*(<1)$ is a scalar tortuosity, and δ_{ij} is the ijth component of the *Kronecker delta,* with $\delta_{ij} = 1$ for $i = j$, $\delta_{ij} = 0$ for $i \neq j$.

For a fluid of variable density, the macroscopic diffusive flux of a γ-component is

$$\mathbf{J}^\gamma_{\text{diff}} = -\rho \boldsymbol{\mathcal{D}}^{*\gamma}(\theta) \cdot \nabla \omega^\gamma \tag{10}$$

where all variables and the coefficient are at the macroscopic level and the flux is per unit area of fluid in the porous medium cross-section.

The tortuosity of a phase is a macroscopic geometrical coefficient that expresses the effects of the microscopic surface that bounds that phase on the diffusive flux. As such, it depends on the configuration of the phase within the void space. In unsaturated flow, each of the tortuosity components is a function of the saturation. In an isotropic porous medium, Millington (1959) suggests:

$$\mathrm{T}^*(\theta) = \frac{\theta^{7/3}}{\phi^2} \tag{11}$$

Dispersive Flux

We start from the empirical observation (in field and laboratory experiments) that as an initially sharp interface between two miscible fluids (i.e. the same fluid, but with a jump in concentration of dissolved matter) is being displaced, say, in uniform flow, a transition zone is created between the two fluids. Across it, the concentration of the solute gradually varies from that of one fluid to that of the other (Figure 1). As flow continues, the width of this transition zone increases. Similarly, if a certain porous medium sub-domain initially contains a certain amount of a solute that can be used as a (conservative) *tracer*, and flow takes place in that porous medium domain, the zone occupied by the tracer will grow continuously, both in the direction of the flow, and transversely, that is, normal to it. These spreading phenomena cannot be predicted by using Darcy's law that describes the *averaged* flow, especially noting the spreading perpendicular to the direction of the (local) averaged flow, and the ever-growing zone occupied by the solute-labeled fluid.

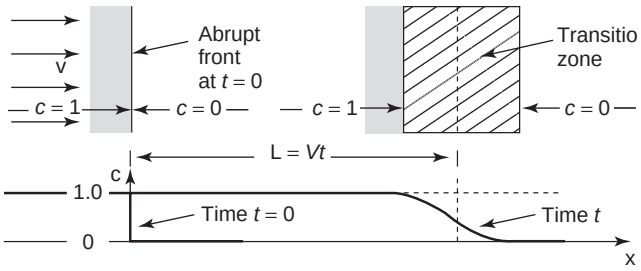

Figure 1 Longitudinal spreading of an initially sharp interface

The spreading phenomenon in a porous medium domain, as described above, is called *hydrodynamic dispersion* (or *miscible displacement*). It is an unsteady, *irreversible process* (in the sense that the initial solute distribution cannot be obtained by reversing the direction of the flow) in which the mass of a solute continuously "mixes" with the nonlabeled portion of the moving fluid.

The phenomenon of dispersion may be demonstrated also by a laboratory column experiment in which a steady flow of water takes place at a constant discharge, Q. The column contains a homogeneous porous material. At $t = 0$, tracer-marked water, at $c = 1.0$ (e.g. water with NaCl at a concentration that is sufficiently low so that the effect of density variations on the flow pattern is negligible), starts to displace the indigenous unmarked water ($c = 0$) in the column. Figure 2, called a *breakthrough curve*, shows the measured tracer concentration, $c = c(t)$, in the effluent leaving the column. In the absence of dispersion, the breakthrough curve would take the form of the dashed line shown in this figure. This would be indicative of the movement of a persistent sharp front between the labeled and unlabeled fluids. In reality, due to hydrodynamic dispersion, the breakthrough curve will take the form of the *S*-shaped curve shown as a solid line in the figure.

The above observations cannot be explained on the basis of the average flow velocity. We must refer to what happens at the *microscopic level*, namely, inside the REV. There, we observe velocity variations in both magnitude and direction across any pore cross-section (even when the averaged flow

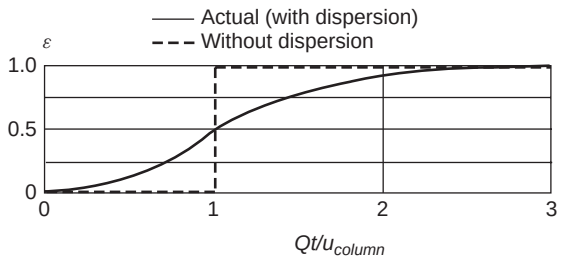

Figure 2 Breakthrough curve in one-dimensional flow in a column of homogeneous porous material

is uniform), and between flow paths. We recall that even in a straight circular capillary tube, we have a parabolic distribution of fluid velocity (see any text on fluid mechanics), with zero velocity at the (stationary) solid surface, and a maximum velocity at the center of the tube. Because of the shape of the interconnected pore space, the (microscopic) streamlines deviate from the mean direction of flow. Altogether, the velocity at the microscopic level varies in magnitude and direction from point to point within the fluid present in the void space. As a consequence, any initial cloud of closely spaced tracer particles will spread out, with each fluid particle traveling along its own microscopic streamline, and the shape and of the initial cloud will gradually change; the fluid volume occupied by the cloud will continuously grow. This phenomenon is referred to as *mechanical dispersion*, where the term "mechanical" is used to remind us that this part of the spreading is due to fluid mechanical phenomena, and "dispersion" is just another word for "spreading". The two basic factors that produce mechanical dispersion are, therefore, (i) *flow* and (ii) the *presence of a pore system* through which the flow takes place. Obviously, to observe spreading, we need a variation in concentration of the tracer (= identifiable particles).

Velocity variations alone cannot explain the ever-growing width (normal to the direction of flow) of a plume of tracer-labeled fluid particles originating at a point source. In order to explain the observed spreading, especially transverse to the flow direction, we must refer to an additional phenomenon that takes place in the void space, namely, *molecular diffusion.* Molecular diffusion of a chemical species in a fluid (see section "Diffusive Flux"), due to concentration gradients inside the void space, produces an additional flux of the species' particles (at the microscopic level) from regions of higher concentrations to those of lower ones, especially normal to the microscopic streamlines. This flux is relative to the advective one, produced by the fluid's velocity. This diffusive flux tends to equalize the concentration along every microscopic stream tube and (mainly) normal to it, between adjacent stream tubes. The phenomenon of diffusion, combined with the randomness of the streamlines, explains the observed ever-growing extent of transverse dispersion.

Thus, the deviations in solute concentration within a fluid from those obtained by assuming advection only (at the average velocity), are due to two simultaneous phenomena: (i) variations in the microscopic velocity of the phase, with respect to the averaged velocity, accompanied by variations in (microscopic) concentration, and (ii) molecular diffusion. In this way, molecular diffusion contributes to the dispersive flux. This contribution is in addition to the diffusive flux *at the macroscopic level*, as described by (the averaged) Fick's law, say equation (9). The latter is the only flux that takes place when the averaged velocity is zero.

Molecular diffusion turns dispersion, even in purely laminar flow, into an irreversible phenomenon. Irreversibility is exhibited, for example, by the growing width of a transition zone around an initially sharp tracer front in uniform flow, as the direction of the flow is reversed.

We use the term *hydrodynamic dispersion* to denote the spreading (at the macroscopic level) that results from both mechanical dispersion and molecular diffusion. Because molecular diffusion is a relatively slow process, its overall effect on dispersion is more significant at low velocities. We refer to the flux that causes mechanical dispersion (of a chemical species) as *dispersive flux*. It is a *macroscopic flux* that expresses the effect of the microscopic variations of velocity and solute concentration in the vicinity of a considered point.

Bear (1972, p. 232) showed that the average (over an REV), macroscopic flux (in terms of mass per unit area of fluid in the porous medium cross-section per unit time), $\overline{c\mathbf{V}}$, of the local, microscopic, advective flux of a chemical species, $c\mathbf{V}$, at a (macroscopic) point in a porous medium domain, can be obtained from (Figure 3):

$$\overline{cV} \equiv \overline{(\overline{c} + c^o)\left(\overline{\mathbf{V}} + \mathbf{V}^o\right)} = \overline{\overline{c}\,\overline{\mathbf{V}}} + \overline{c^o\overline{\mathbf{V}}} + \overline{\overline{c}\mathbf{V}^0} + \overline{c^o\mathbf{V}^0} \tag{12}$$

where $\boldsymbol{x}$ and $\boldsymbol{x}'$ denoting the center of the REV and a point within it, respectively, $\overline{\mathbf{V}}(\mathbf{x}, t)$ and $\overline{c}(\mathbf{x}, t)$ denote the (intrinsic phase) averages of the fluid's velocity and of the concentration, assigned to the center, $\mathbf{V}^o(\mathbf{x}', t; \mathbf{x})$ and $c^o(\mathbf{x}', t; \mathbf{x})$, denote the deviations from the above average values, respectively, at a point $\boldsymbol{x}'$, with $\overline{\mathbf{V}^o} = 0$ and $\overline{c^o} = 0$. The intrinsic phase average is defined as:

$$\overline{e}(\mathbf{x}, t) = \frac{1}{\mathcal{U}_{0\alpha}} \int_{\mathcal{U}_{0\alpha}(\mathbf{x},t)} e(\mathbf{x}', t; \mathbf{x})\, \mathrm{d}\mathcal{U}_\alpha(\mathbf{x}'),$$

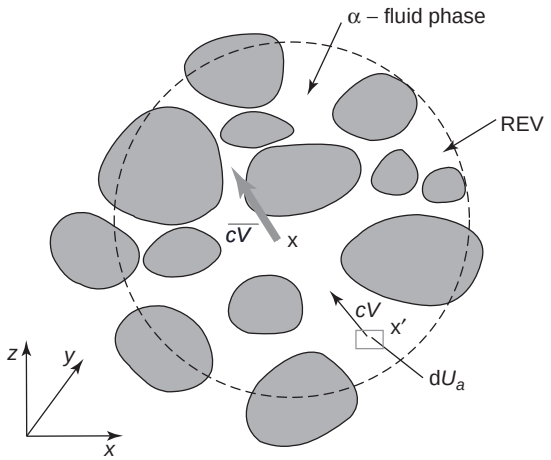

Figure 3 Nomenclature for averaging over an REV. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

$$\mathcal{U}_{0\alpha} = \theta_\alpha(\boldsymbol{x}, t)\mathcal{U}_0 \tag{13}$$

From equation (12), we obtain:

$$\overline{cV} = \overline{c}\,\overline{\mathbf{V}} + \overline{c^o\mathbf{V}^0} \tag{14}$$

From this equation, it follows that the average flux of a component at a point in a porous medium domain (= center of an REV) is equal to the sum of two macroscopic fluxes:

- An *advective flux*, $\overline{c}\,\overline{\mathbf{V}}$, expressing the mass of the component carried by the fluid, at the latter's average velocity, $\overline{\mathbf{V}}(\mathbf{x}, t)$.
- A flux, $\mathbf{J}_{\text{disp}}$ ($\equiv\overline{c^o\mathbf{V}^0}$), that results from the variation of c and $\mathbf{V}$ within the REV for which the considered point, $\boldsymbol{x}$, serves as a center. This flux is the flux referred to earlier as "mechanical dispersion". We refer to it as *dispersive flux*.

Investigations over a period of about five decades, starting around the mid-1950s (e.g. de Josselin de Jong, 1958; Saffman, 1959; Nikolaevskii, 1959; Bear, 1961; Scheidegger, 1961; Bear, 1972; Bear and Bachmat, 1990), led to the conclusion that the dispersive flux (per unit area of fluid) can be expressed as a Fickian-type law in the form:

$$\mathbf{J}_{\text{disp}}(\equiv\overline{c^o\mathbf{V}^0}) = -\mathbf{D}\cdot\nabla\overline{c}, \quad J_i^* = -D_{ij}\frac{\partial\overline{c}}{\partial x_j} \tag{15}$$

where $\mathbf{D}$, is the *coefficient of mechanical* (or *advective*) *dispersion*, and $\mathbf{J}_{\text{disp}}$ $^\circ\mathbf{J}$.

The coefficient of dispersion, $\mathbf{D}$, is a second rank symmetrical tensor, that is, $D_{ij} = D_{ji}$, $i, j = 1, 2, 3$. As such, it has *three principal directions*. Using these directions as Cartesian coordinate axes, x_1, x_2, x_3, the coefficient of dispersion takes the matrix form:

$$\mathbf{D} = \begin{pmatrix} D_{x_1x_1} & 0 & 0 \\ 0 & D_{x_2x_2} & 0 \\ 0 & 0 & D_{x_3x_3} \end{pmatrix} \tag{16}$$

In equation (16), $D_{x_1x_1}$ is called *coefficient of longitudinal dispersion*, while $D_{x_2x_2}$ and $D_{x_3x_3}$ are called *coefficients of transverse dispersion*.

Several authors (e.g. Nikolaevskii, 1959; Bear, 1961; Scheidegger, 1961; Bear and Bachmat, 1967, 1990) have derived the following expression for the relationship between the components D_{ij} of $\mathbf{D}$ and microscopic porous medium configuration, flow velocity, and molecular diffusion:

$$D_{ij} = a_{ijkm}\frac{\overline{V}_k\overline{V}_m}{\overline{V}}f(Pe, \delta), \quad Pe = \frac{L\overline{V}}{D_{\text{diff}}} \tag{17}$$

where $\overline{V}(\equiv|\overline{\mathbf{V}}|)$ is the magnitude of the average velocity, and Pe is a Peclet number, with L denoting a characteristic

length of the pores, for example, hydraulic radius, D_{diff} denoting the coefficient of molecular diffusion, and δ is some geometrical pore characteristics. The Peclet number expresses the ratio between the rates of transport of the considered component by advection and by diffusion. Bear and Bachmat (1967) suggested relationships for $f(Pe, \delta)$. In practice, we use $f(Pe, \delta) \simeq 1$. Henceforth, we shall omit the averaging symbols on c and $\mathbf{V}$.

The coefficients a_{ijkm} (dims. L) are components of a fourth rank tensor, **a**, called the *dispersivity of the porous medium*. It expresses the effect, on solute transport, of the microscopic configuration of the interface between the considered fluid phase and all other phases within the REV. In a saturated system, this interface is that between the fluid and the solid. When a fluid occupies only part of the void space, each of the dispersivity components depends on the volumetric fraction of the fluid, θ.

In a three-dimensional space, the dispersivity, **a**, has 81 a_{ijkm}-components. However, because of various symmetry considerations (Bear, 1961; Scheidegger, 1961), all but 36 components are zeros. In an *isotropic porous medium*, only 21 nonzero components remain. They, in turn, depend only on *two* parameters: a_L and a_T, called the *longitudinal* and *transversal dispersivities* of the porous medium, respectively. The value of a_L is of the order of magnitude of a length that characterizes the heterogeneous configuration of the phase within the REV (e.g. a typical grain size in saturated flow). Laboratory column experiments (e.g. de Josselin de Jong, 1958; Bear, 1961) have shown that a_T is 8 to 24 times smaller than a_L.

For an *isotropic porous medium*, we can express the components of the dispersivity tensor in terms of a_L and, a_T in the form:

$$a_{ijkm} = a_T \delta_{ij} \delta_{km} + \frac{a_L - a_T}{2} \left(\delta_{ik} \delta_{jm} + \delta_{im} \delta_{jk} \right) \quad (18)$$

where δ_{ij} are components of the Kronecker delta.

For an *anisotropic porous medium*, for example, a medium made up of a large number of thin layers normal to the axis of symmetry, the dispersivity can be expressed in the form:

$$\begin{aligned} a_{ijkm} = {} & a_I \delta_{ij} \delta_{km} + a_{II} \left(\delta_{ik} \delta_{jm} + \delta_{im} \delta_{jk} \right) \\ & + a_{III} \left(\delta_{ij} h_k h_m + \delta_{km} h_i h_j \right) \\ & + a_{IV} \left(\delta_{ik} h_j h_m + \delta_{jk} h_i h_m + \delta_{im} h_j h_k + \delta_{jm} h_i h_k \right) \\ & + a_V h_i h_j h_k h_m \end{aligned} \quad (19)$$

where a_I, a_{II}, a_{III}, a_{IV}, a_V are five independent parameters and $\boldsymbol{h}$ is a unit vector directed along the axis of symmetry.

By combining equations (17) and (18), we obtain

$$a_{ijkm} = a_T V \delta_{ij} + (a_L - a_T) \frac{V_i V_j}{V} \quad (20)$$

In the special case of uniform flow, say $V_x \equiv V_1 = V \neq 0$, $V_y = V_z = 0$, equation (20) reduces to $D_{11} = a_L V$, $D_{22} = D_{33} = a_T V$, $D_{ij} = 0$, for $i \neq j$.

In equations (12–15), we have shown how the dispersive flux and the coefficient of dispersion are obtained by averaging the advective flux over the domain occupied by a fluid within an REV. Usually we assume that within the void space, the fluid adheres to the wall, a condition that determines the velocity distribution within the fluid. However, under certain conditions, for example, when the solute is an anion or a cation repelled from a charged solid surface, near which the fluid's velocity is small, the average velocity of the fluid that carries the solute is, higher than when the solute is nonionic. As a consequence, the average advective flux of the solute will be higher, and so will the coefficient of dispersion, which is proportional to the average velocity. This phenomenon is called *ion exclusion* (Gvirtzman and Gorelick, 1991).

Another phenomenon (*size exclusion*) that may affect the magnitude of the coefficient of dispersion is when the molecules comprising the solute are large, to the extent that they are excluded from entering certain pores, or from getting close to the solid. As a consequence, they are carried by a higher average velocity than that of the fluid; this results in a higher coefficient of dispersion.

Total Flux

By combining the three modes transport – advection, dispersion, and diffusion – we can write the total macroscopic flux (*per unit area of a fluid phase*) of a γ-species as

$$\begin{aligned} \mathbf{J}^{\gamma}_{\text{total}} &= c^{\gamma} \mathbf{V} + \mathbf{J}^{\gamma}_{\text{diff}} + \mathbf{J}^{\gamma}_{\text{disp}} = c^{\gamma} \mathbf{V} - \mathbf{D}_h \cdot \nabla c^{\gamma}, \\ \mathbf{D}_h &= \mathbf{D} + \mathcal{D}^{*\gamma} \end{aligned} \quad (21)$$

where $\mathbf{D}_{\text{h}}$ is called the *coefficient of hydrodynamic dispersion*.

Macrodispersion

The phenomenon of dispersion was shown to be a consequence of the heterogeneity of the porous medium *at the microscopic level*, due to the presence of a solid matrix and a void space within the REV. A grain or pore diameter, or the hydraulic radius of the pore space, may serve as examples of a scale of heterogeneity at such level. This heterogeneity produces the velocity variations that take place at the microscopic level. The macroscopic level of description, obtained by averaging over an REV, and the dispersive flux, were introduced as a means for circumventing the need to know the details of the velocity distribution and of other transport features at the microscopic level.

Phenomena of transport take place within a *macroscopic* porous medium domain that may be homogeneous or heterogeneous with respect to the relevant macroscopic geometrical parameters of the porous medium, for example, porosity and permeability. In fact, *all subsurface domains encountered in practice are very heterogeneous*. This heterogeneity plays a dominant role in subsurface transport. We face a situation similar to that which is encountered at the microscopic level, namely, that the detailed information about the spatial variation of the relevant parameters is not available. At the microscopic level, we overcome the lack of information about the (pore scale) heterogeneity by averaging, employing the REV concept. Dispersion was introduced as a consequence of this averaging. An averaging, or smoothing, approach may also be applied (conceptually) to macroscopic level heterogeneities. As a result of this averaging, a new continuum is obtained for describing the porous medium and the phenomena that take place in it. We refer to it as the megascopic *level*.

As in the passage from the microscopic level to the macroscopic one, a new representative elementary volume is needed in order to perform the averaging/smoothing. We shall refer to such a volume as the Representative Macroscopic Volume (abbreviated as RMV). The characteristic size, l^*, of this volume, is constrained by $d^* \ll l^* \ll L$, where d^* is a length characterizing the macroscopic heterogeneity that we wish to smooth out, and L is a length characterizing the considered porous medium domain. The length scale of heterogeneity at the megascopic level is much larger than that corresponding to the macroscopic one.

Similar to what happens during microscopic-to-macroscopic smoothing, the (unknown) information about the heterogeneity at the macroscopic level appears at the megascopic one in the form of various coefficients that reflect the effect of the spatial variability of macroscopic level geometrical parameters (e.g. permeability and porosity) on the transport phenomena.

The total flux of a chemical component at the megascopic level can be obtained by averaging the macroscopic total flux of that component over an RMV. We obtain:

$$\overline{\overline{\theta \mathbf{J}^{\gamma}_{\text{total}}}} = \overline{\overline{c^{\gamma}\mathbf{q}}} + \overline{\overline{\theta\left(\mathbf{J}^{\gamma}_{\text{diff}} + \mathbf{J}^{*\gamma}\right)}} \approx \overline{\overline{c^{\gamma}}}\,\overline{\overline{\mathbf{q}}} + \overline{\overline{\hat{c}^{\gamma}\hat{\mathbf{q}}}}$$

$$\overline{\overline{\hat{c}^{\gamma}\hat{\mathbf{q}}}} \gg \overline{\overline{\theta\left(\mathbf{J}^{\gamma}_{\text{diff}} + \mathbf{J}^{*\gamma}\right)}}$$

$$\overline{\overline{e}}(\mathbf{x}, t) = \frac{1}{\overline{\overline{\mathcal{U}_0}}} \int_{\overline{\overline{\mathcal{U}_0}}} \overline{e}(\mathbf{x}', t; \mathbf{x})\, \mathrm{d}\overline{\overline{\mathcal{U}_0}}\left(\mathbf{x}'\right) \tag{22}$$

where the double bar over a macroscopic value indicates an average over an RMV (= megascopic volume, $\overline{\overline{\mathcal{U}_0}}$), and the hat symbol (ˆ) denotes the deviation of a macroscopic value of a quantity at any point within an RMV, from its average over the RMV. We note that the flux on the left-hand side of equation (22) (and hence all other fluxes) is *per unit area of porous medium*. The total megascopic flux is made up of two fluxes: an advective flux that carries the macroscopic concentration at the megascopic velocity, and a dispersive flux, due to the variations of the macroscopic specific discharge within an RMV. We have assumed that this latter flux is much larger than the average of the flux of hydrodynamic dispersion, that is, sum of the dispersive and diffusive fluxes at the macroscopic level.

Altogether, the total flux is, again, the sum of an advective flux and a dispersive one. There is no analogy here to the diffusive flux, as we have neglected it. At very low velocities, we may not neglect the average of the macroscopic diffusive flux. We usually *assume* that a Fickian-type dispersion law can be employed to describe also the dispersive flux at the megascopic level. A *macrodispersivity*, A_{ijkm}, can be defined in the same way as the dispersivity that was defined in equation (16). Bear (1979), and Bear and Verruijt (1987), while developing the vertically integrated mass balance equation for a component of a phase within an aquifer, suggested an expression for macrodispersivity. In an isotropic porous medium, the macrodispersivity reduces to a scalar. Gelhar (1976) and Gelhar *et al.* (1979) analyzed the dependence of macrodispersion on permeability variations.

To summarize, dispersion and macrodispersion are analogous phenomena, in that both are consequences of velocity variations that are due to heterogeneity, but at different scales. Dispersion arises from velocity variations within the void space, caused by the presence of the solid surfaces. Macrodispersion is caused by variations in the permeability and porosity at the macroscopic level. In both cases, the total flux can be expressed as a sum of an advective flux and a (mechanical) dispersive one, written at the respective levels. The structure of the coefficient of dispersion is the same in both cases, and so is the relationship between the coefficient of dispersion, the dispersivity, and the average velocity. The selection of which one to use in a particular case depends on the scale of the problem, that is, the *scale of heterogeneity*. The latter depends on the *scale of the problem*. Field experiments and model calibration seem to indicate that the longitudinal dispersivity is of the order of magnitude of 1/10 of the size of the *domain of interest,* although it should level off at some sufficiently large domain size. In practice, the transverse dispersivity is usually approximated as about 1/10 of the longitudinal one. Obviously, these are merely orders of magnitude and may be used as initial or preliminary estimates. In each particular case, the actual value should be determined by some model calibration, or parameter estimation procedure.

Apart from the different magnitude of the dispersivity to be employed, the expressions for advective and dispersive fluxes, equations (1) and (15–20) are assumed to remain

valid also when we model field conditions. The species mass balance equation discussed below is also the same at both scales.

MASS BALANCE EQUATION

Each of the flux equations discussed in the section "Fluxes", say, equation (21) involves two variables: the flux, $\mathbf{J}^{\gamma}_{\text{total}}$, and the (average) concentration, c^{γ}. To solve for these variables, the required additional equation is the balance equation for the mass of the considered species. We shall continue to discuss a fluid phase at a volumetric fraction θ; for saturated flow, we replace θ by the porosity, ϕ.

Fundamental Mass Balance

The general balance equation and the balance equation for the mass of a fluid phase are discussed in detail in **Chapter 149, Hydrodynamics of Groundwater, Volume 4**. To facilitate the discussion here, let us summarize this subject by introducing the general mass balance equation for any extensive quantity, E, *considered as a continuum*, having a density (= mass per unit volume of a continuum) e. For a finite domain, $\mathcal{U}_0$, bounded by a surface S, and for a finite period of time, Δt, this balance takes the form:

$$\left\{\begin{array}{c}\text{Quantity of } E\\ \text{accumulating}\\ \text{in } \mathcal{U}_o\\ \text{during } \Delta t\end{array}\right\} = \left\{\begin{array}{c}\text{Net quantity of}\\ E \text{ entering } \mathcal{U}_o\\ \text{through } \mathcal{S}\\ \text{during } \Delta t\end{array}\right\} + \left\{\begin{array}{c}\text{Net production}\\ \text{of } E\\ \text{in } \mathcal{U}_o\\ \text{during } \Delta t\end{array}\right\} \tag{23}$$

When writing the above equation for a small volume around a point in a fluid continuum, and letting both $\mathcal{U}_0$ and Δt shrink to zero, we obtain the balance equation for E in the form of the *partial differential equation*:

$$\frac{\partial e}{\partial t} = -\nabla \cdot e\mathbf{V}^E + \rho\Gamma^E \tag{24}$$

in which ρ denotes the mass density of that continuum, $\mathbf{V}^E$ denotes the velocity of the E-continuum, and Γ^E denotes the rate of net production of E, per unit mass of the continuum. Another form of equation (24) is

$$\frac{\partial e}{\partial t} = -\nabla \cdot (e\mathbf{V} + \mathbf{J}^E) + \rho\Gamma^E, \mathbf{J}^E = e(\mathbf{V}^E - \mathbf{V}) \tag{25}$$

in which $\mathbf{V}$ and $\mathbf{J}^E$ are the (mass averaged) velocity and the diffusive flux of E, respectively.

Equation (25) may be regarded as the most general balance equation for any extensive quantity E of a phase in a porous medium *at the microscopic level*. To obtain its *macroscopic* counterpart, we average it over the phase occupying part (volumetric fraction θ) of an REV. We obtain (Bear and Bachmat, 1990):

$$\frac{\partial \theta\overline{e}}{\partial t} = -\nabla \cdot \theta(\overline{e}\,\overline{\mathbf{V}} + \mathbf{J}^E + \mathbf{J}^{*E}) - \frac{1}{\mathcal{U}_o}\int_{\mathcal{S}} [\mathbf{e}(\mathbf{V} - \mathbf{u}) + \mathbf{j}^E] \cdot \mathbf{n}\, \mathrm{d}S + \theta\overline{\rho\Gamma^E} \tag{26}$$

where $\mathcal{U}_o$ is the volume of the REV, S is the (microscopic) surface that bounds the phase inside $\mathcal{U}_o$, $\boldsymbol{u}$ is the velocity of S, $\boldsymbol{n}$ is the outward vector normal to S, and $\mathbf{J}^E$ and $\mathbf{J}^{*E}$ denote the dispersive and (macroscopic) diffusive fluxes of E.

For example, for $e = c^{\gamma}$ = (mass) concentration of a γ-species, equation (26) becomes

$$\frac{\partial \theta\overline{c^{\gamma}}}{\partial t} = -\nabla \cdot \theta(\overline{c^{\gamma}}\,\overline{\mathbf{V}} + \mathbf{J}^{\gamma} + \mathbf{J}^{*\gamma}) - f^{\gamma} + \theta\overline{\rho\Gamma^{\gamma}}$$
$$\mathbf{J}^{*\gamma} = -\rho\mathbf{D} \cdot \nabla\overline{\omega^{\gamma}}, \quad \mathbf{J}^{\gamma} = -\rho\boldsymbol{\mathcal{D}}^{*\gamma} \cdot \nabla\overline{\omega^{\gamma}} \tag{27}$$

in which $f^{\gamma}(= (1/\mathcal{U}_o)\int_{\mathcal{S}} [c^{\gamma}(\mathbf{V} - \mathbf{u}) + \mathbf{j}^{\gamma}_{\text{diff}}] \cdot \mathbf{n}\, \mathrm{d}S)$ is a *source* term that expresses the net rate of transfer of mass by advection and diffusion, of γ from the considered fluid phase, across S, to all other phases within the REV (e.g. by adsorption on the solid and/or diffusion into another fluid phase), per unit volume of porous medium. When the surface, S, is a *material surface* with respect to the fluid, the transfer is by diffusion only. The term $\theta\overline{\rho\Gamma^{\gamma}}$ denotes another source of γ mass, due to production of γ *within* the phase (e.g. by chemical reactions, decay, or degradation). In equation (27), we note the expressions for the dispersive and diffusive fluxes.

Note that the values of θ and $\overline{\mathbf{V}}$ are obtained from the solution of the corresponding flow model. When the fluid's density depends on concentration, the flow and the solute transport models have to be solved simultaneously.

In what follows, we shall discuss the two kinds of sources of γ that appear in the mass balance equation (27).

Sources Due to Injection and Pumping

Let the considered fluid be injected at M isolated *points,* $\mathbf{x}^m$, at rates R^m_{ext} (dims. L^3/T), and known concentrations c^m_{ext}, and let the fluid be pumped at N isolated *points* at rates Q^n (dims. L^3/T) at the unknown concentration, $\overline{c^{\gamma}}$. The net source of solute mass is then expressed as

$$\theta\overline{\rho\Gamma^{\gamma}} = \sum_{(m)} R^m_{\text{ext}}(\mathbf{x}^m, t)\delta(\mathbf{x} - \mathbf{x}^m)\mathrm{c}^{\gamma}_{\text{ext}}(\mathbf{x}^m, t) - \sum_{(n)} Q^n(\mathbf{x}^n, t)\delta(\mathbf{x} - \mathbf{x}^n)\overline{c^{\gamma}}(\mathbf{x}^n, t) \tag{28}$$

where $\delta(\mathbf{x} - \mathbf{x}^m)$ denotes the *Dirac delta function* (dims. L^{-3}), with $\delta = 1$ for $\mathbf{x} = \mathbf{x}^m$, $\delta = 0$ for $\mathbf{x} \neq \mathbf{x}^m$.

Sources Due to Decay and Degradation

For radioactive decay, with λ denoting the decay coefficient, the source term takes the form:

$$\theta\overline{\rho\Gamma^\gamma} = -\theta\lambda\overline{c^\gamma} \tag{29}$$

The minus sign indicates that we have here a sink.

For an adsorbed component (see discussion in the next section) that undergoes radioactive decay, the source term takes the form:

$$\theta\overline{\rho\Gamma_s^\gamma} = -\lambda_s F \tag{30}$$

where F denotes the mass of the component per unit mass of solid, and λ_s is the coefficient of decay on the solid.

For any other decay or degradation phenomena of a considered component, we can replace λ in equation (29) by the degradation rate constant, k_f. For an adsorbed component, we replace λ by k_s in equation (30).

Without the averaging symbols, and for a fluid of constant density, equation (27) can be rewritten in the form:

$$\begin{aligned}\frac{\partial\theta c^\gamma}{\partial t} &= -\nabla\cdot\theta(c^\gamma\mathbf{V} + \mathbf{J}^\gamma + \mathbf{J}^{*\gamma}) - f^\gamma + \theta\rho\Gamma^\gamma \\ \mathbf{J}^{*\gamma} &= -\mathbf{D}\cdot\nabla c^\gamma,\ \mathbf{J}^\gamma = -\boldsymbol{\mathcal{D}}^{*\gamma}\cdot\nabla c^\gamma\end{aligned} \tag{31}$$

Sources Due to Adsorption

Adsorption (the opposite of *desorption*): It is the phenomenon of accumulation of a chemical species (= *adsorbate*) present in a liquid that occupies the void space, or part of it, on the solid matrix (= *adsorbent*) at the liquid-solid interface. This phenomenon is caused by the attraction of a species to the surfaces of the solid, or by reactions of the species in the liquid with the solid.

When the considered adsorption process is sufficiently fast, so that *chemical equilibrium* may be assumed to prevail, we can use of the thermodynamic relationship, called *adsorption isotherm*. This is a function that relates the quantity of a species adsorbed on the solid, to its quantity in the liquid phase that occupies the void space (or part of it), *at a fixed temperature*, under conditions of (chemical) equilibrium between the two quantities.

The concept of *adsorption isotherm* assumes that the amount of the species on the solid is solely a function of the concentration of the adsorbed species in the fluid close to the solid surface. This assumption fails when there is only one involved species in the fluid. It is also valid when there are more species, but their concentrations do not change appreciably in time. Otherwise, a more complicated analysis is required to determine the concentrations of all of the various species that are involved. Here, we consider only surface complexation.

The primary driving forces for adsorption are (i) the *lyophobic* (= solute disliking) nature of the solute, relative to the solvent that hosts it, (ii) high *affinity* of the solute for the solid, due, for example, to electrical attraction, (iii) *van der Waals attraction,* that is, intermolecular *forces* of attraction between molecules of the solid and those of the adsorbed species, and (iv) *chemisorption*, that is, chemical interaction between the solid and the adsorbed species. However the most significant factor is the degree of solubility of the dissolved species.

In certain porous media, the solid matrix itself is porous, with *much* smaller pores (i.e. with very low permeability). A soil made up of porous aggregates may serve as an example. Under such conditions, an adsorbate must first diffuse *into* the small pores of the aggregates, and then adsorb on their (very large) surface area. We refer to such phenomenon as *absorption*.

When adsorption of a chemical species in solution takes place, the total mass of the former is *partitioned* between the solution and the solid matrix. Any increase in the quantity of the species on the solid is accompanied by an appropriate increase in its quantity in the liquid, and vice versa.

We use the symbol F to denote the mass of the species (= adsorbate) adsorbed on the solid (= adsorbent), per unit mass of the latter (units: kg kg^{-1}, moles kg^{-1}). The isotherm for a given adsorbate–adsorbent pair can be directly obtained by performing a batch adsorption experiment.

When adsorption is the only interphase transfer mechanism, the term f^γ in equation (27) takes the form:

$$f^\gamma \equiv f^\gamma_{f\to s} = -f^\gamma_{s\to f} = \rho_b \left.\frac{\mathrm{d}F}{\mathrm{d}t}\right|_{\text{ads}} \tag{32}$$

where $\rho_b(\equiv(1-\phi)\rho_s)$ denotes the *bulk density of the solid matrix*. However, this rate is unknown.

Under the equilibrium assumption, we can eliminate the rate of interphase exchange due to adsorption, by writing and summing up the balance equations for the considered species in the fluid phase and on the solid. The macroscopic balance equation for the considered species on the solid can be obtained from equation (31), in which θc^γ is replaced by $\theta_s\rho_s F(\equiv\rho_b F)$, and assuming that no flux of the considered species takes place within the solid phase and/or on its surface. The resulting mass balance for the species on the solid surface, takes the form:

$$\frac{\partial}{\partial t}\rho_b F = -f^\gamma_{s\to f} + \rho_b\Gamma^\gamma_s \tag{33}$$

where $\rho_b\Gamma^\gamma_s$ is the rate of production of the species mass on the solid surface, per unit volume of porous medium. By summing up the two balance equations for the considered component, we obtain the *mass balance equation for the*

component in the porous medium as a whole, in the form:

$$\frac{\partial(\theta c^\gamma + \rho_b F)}{\partial t} = -\nabla \cdot \theta(c^\gamma \mathbf{V} - \mathbf{D}_h \cdot \nabla c^\gamma) + \theta\rho\Gamma^\gamma + \rho_b \Gamma_s^\gamma \tag{34}$$

in which appropriate expressions should replace the two source terms, for example, equation (28) through equation (30).

Equation (34) contains the two variables, $c^\gamma(\mathbf{x}, t)$ and $F(\mathbf{x}, t)$. By assuming equilibrium conditions, we can make use of an appropriate *isotherm* that relates c^γ to F. For example, we may use the linear *Freundlich isotherm*:

$$F = K_d c^\gamma \tag{35}$$

to obtain the mass balance equation for the species in the porous medium as a whole, in terms of a single variable, c^γ, in the form:

$$\frac{\partial(\theta c^\gamma + \rho_b F)}{\partial t}\left(\equiv \frac{\partial \theta R_d c^\gamma}{\partial t}\right) = -\nabla \cdot \theta(c^\gamma \mathbf{V} - \mathbf{D}_h \cdot \nabla c^\gamma) + \theta\rho\Gamma^\gamma + \rho_b \Gamma_s^\gamma \tag{36}$$

in which $R_\mathrm{d} = 1 + \rho_b K_d/\theta$ is called the *retardation coefficient* (discussed below). We note that this coefficient (>1) indicates the partitioning between the solute in solution and that on the solid. For saturated flow, we replace θ by ϕ. Equation (36) is applicable also to water in the unsaturated zone, as we assume that water is the (= wetting fluid) that is everywhere adjacent to the solid surface, albeit at some places as a very thin film, and that diffusion of the species is possible even through this very thin film.

When equilibrium cannot be assumed, the rate of transfer in both *balance equations* is expressed in terms of an appropriate rate transfer expression. Typically, this expression takes the form:

$$f_{f\to s}^\gamma = \alpha(Ac^\gamma - BF), \quad A, B = \text{coefficients} \tag{37}$$

For example, we may write the model in the form of the three equations:

$$\begin{aligned} \frac{\partial \theta c^\gamma}{\partial t} &= -\nabla \cdot \theta(c^\gamma \mathbf{V} - \mathbf{D}_h \cdot \nabla c^\gamma) + \theta\rho\Gamma^\gamma - f_{f\to s}^\gamma \\ \frac{\partial \rho_b F}{\partial t} &= f_{f\to s}^\gamma + \rho_b \Gamma_s^\gamma \\ f_{f\to s}^\gamma &= Ac^\gamma - BF, \quad A, B = \text{coefficients} \end{aligned} \tag{38}$$

which have to be solved simultaneously for $f_{f\to s}^\gamma$, $c^\gamma(\mathbf{x}, t)$ and $F(\mathbf{x}, t)$.

Retardation To understand the concept of *retardation*, R_d, appearing in equation (36), we consider one-dimensional solute transport in a homogeneous saturated porous medium domain, with and without any sources, except adsorption. The corresponding balance equations, respectively, are

$$\phi\frac{\partial c^\gamma}{\partial t} = -\nabla \cdot \phi\left(c^\gamma \frac{\mathbf{V}}{R_d} - \frac{\mathbf{D}_h}{R_d} \cdot \nabla c^\gamma\right), \quad R_d = 1 + \frac{\rho_b K_d}{\phi}$$

$$\phi\frac{\partial c^\gamma}{\partial t} = -\nabla \cdot \phi(c^\gamma \mathbf{V} - \mathbf{D}_h \cdot \nabla c^\gamma) \tag{39}$$

We note that both equations are similar, except that in the first equation, the average fluid velocity *seems* to be $\mathbf{V}/R_d$, and the coefficient of hydrodynamic dispersion seems to be reduced to $\mathbf{D}_h/R_d$. We recall that (except when velocities are very low) the major component of $\mathbf{D}_h$ is the coefficient of mechanical dispersion, $\mathbf{D}$, which is proportional to $\mathbf{V}$. Thus, under the assumption of equilibrium adsorption, described by a linear isotherm, the effect of adsorption is to retard the advance of the component (as part of it is adsorbed to the solid); the mean movement of the contaminant is at the reduced, or retarded velocity, $\mathbf{V}/R_d$. At the same time, spreading occurs as if the coefficient of mechanical dispersion is also reduced by the factor R_d, along with the coefficient of molecular diffusion in a porous medium. Figure 4 shows the phenomenon of retardation.

The same phenomenon of retardation exists also in the more general relations between c^γ to F.

Sources Due to Volatilization

Although the focus in this article is on saturated flow, as we have done earlier, by using θ instead of ϕ to indicate the volumetric fraction of a phase in a multiphase system, we add now the case of the unsaturated zone with two fluid phases: a gas, g, and a liquid, l, in which a considered chemical species can volatilize through the fluid-gaseous phase (microscopic) interface. The reason is that volatile organic compounds (VOC's) are often encountered as contaminants in the unsaturated zone. The considered volatile (superscript v) contaminant is a VOC that is present

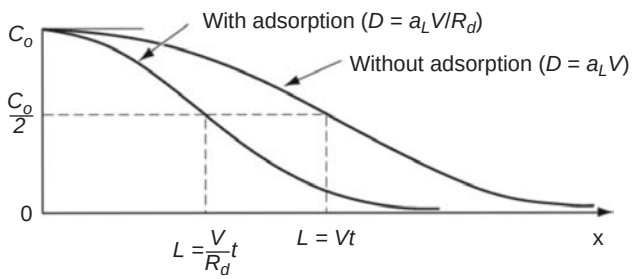

Figure 4 Retardation

as a vapor component in the gaseous phase (saturationS_g) at concentration c_g^v, in the aqueous liquid (saturationS_l) at concentration c_l^v, and as an adsorbate (linear isotherm, $F = K_d c_l^v$) on the solid at concentration F^v. The partitioning of v between the gas and the liquid is assumed to obey *Henry's law*

$$H \equiv \mathcal{H}_{g,l}^v = \frac{c_g^v}{c_l^v} \tag{40}$$

To generalize, we assume that the considered component also undergoes a first order decay, with rate coefficients, λ_g, λ_l, λ_s, in the gas, liquid, and solid phases, respectively. We shall assume that no sources and sinks are present in the considered domain, except that gas is extracted from the void space at a volumetric rate Q_g (= volume of gas per unit volume of porous medium). We shall disregard the presence of water vapor as a component in the gas, and of dissolved air as a component in the liquid. Because of the assumption of equilibrium partitioning, the three balance equations that describe the spatial and temporal concentration distributions of the VOC in the two fluid phases and on the solid, can be combined into a single mass balance equation for the component in the porous medium as a whole, in the form:

$$\begin{aligned}\frac{\partial}{\partial t}\left[\phi\left(S_l + S_g\mathcal{H} + \frac{\rho_b K_d}{\phi}\right)c_l^v\right] \\ = -\nabla\cdot\phi[S_g\mathcal{H}(c_l^v\mathbf{V}_g - \mathbf{D}_{gh}\cdot\nabla c_l^v) + S_l(c_l^v\mathbf{V}_l - \mathbf{D}_{lh}\cdot\nabla c_l^v)] \\ - \phi\left(\lambda_l S_l + \lambda_g S_g\mathcal{H} + \frac{\lambda_s\rho_b K_d}{\phi}\right)c_l^v - Q_g\mathcal{H}c_l^v\end{aligned} \tag{41}$$

This is a single mass balance equation, in the single variable, c_l^v.

Sources Due to Chemical Reactions

Chemical reactions may occur among species in solution in a fluid, that is, at the microscopic level. Each reaction has its own rate. When the characteristic time required for a reaction is much smaller than that for advection and diffusion, we consider the reaction as an *equilibrium reaction.* Otherwise, the reaction is referred to as a *kinetic reaction.* For homogeneous reactions, that is, ones that occur *within* a phase, it is usually assumed that the deviations in the thermodynamic state within the REV are sufficiently small such that the same form of the microscopic rate law can be used at the macroscopic level.

A chemical reaction can be described by a *stoichiometric* equation. The general form of a stoichiometric equation is

$$\nu^A\mathrm{A} + \nu^B\mathrm{B} + \cdots \longrightarrow \nu^P\mathrm{P} + \nu^Q\mathrm{Q} + \cdots \tag{42}$$

in which A,B,... denote *reactant* species, P,Q,...denote *product* species and the $\nu^{\gamma'}$s (>0) denote *stoichiometric coefficients*. For a reversible reaction, we replace the symbol $\rightarrow$ by $\rightleftharpoons$. For the reaction described by equation (42), the *rate of reaction,* R_r (in moles per second in a given volume of solution), is expressed in the form:

$$\begin{aligned}R_r &= -\frac{1}{\nu^A}\frac{\mathrm{d}[A]}{\mathrm{d}t}\bigg|_{c.r.} = -\frac{1}{\nu^B}\frac{\mathrm{d}[B]}{\mathrm{d}t}\bigg|_{c.r.} = \cdots \\ &= \frac{1}{\nu^P}\frac{\mathrm{d}[P]}{\mathrm{d}t}\bigg|_{c.r.} = \frac{1}{\nu^Q}\frac{\mathrm{d}[Q]}{\mathrm{d}t}\bigg|_{c.r.} = \cdots \\ \frac{\mathrm{d}[A]}{\mathrm{d}t}\bigg|_{c.r} &\equiv \frac{1}{M^A}\frac{\mathrm{d}c^A}{\mathrm{d}t}\bigg|_{c.r.}\end{aligned} \tag{43}$$

in which "c.r" denotes "chemical reaction", [A] denotes *molar concentration*, and M^A denotes the molar mass of A.

A reversible reaction can also be described by the stoichiometric equation

$$\sum_{(\gamma)}\nu^\gamma\mathcal{M}^\gamma \rightleftharpoons 0 \tag{44}$$

in which $\mathcal{M}^\gamma$ is a chemical symbols of the respective γ-species, and the ν^γ's are their corresponding stoichiometric coefficients. In this form of the stoichiometric equation, $\nu^\gamma < 0$ for a reactant and $\nu^\gamma > 0$ for a product. The rate of reaction is, then, given by:

$$R_r = \frac{1}{\nu^\gamma}\frac{\mathrm{d}[\gamma]}{\mathrm{d}t}\bigg|_{c.r.} \tag{45}$$

Often, the rate of the reaction for equation (42) is expressed as

$$R_r = k[A]^{\lambda^A}[B]^{\lambda^B}\cdots[P]^{\lambda^P}[Q]^{\lambda^Q}\cdots \tag{46}$$

with, in general, $\nu^\gamma \neq \lambda^\gamma$. For the reaction, $A + B \rightarrow C$, the reaction rate may be given, for example, by $R_r = -d[A]/\,\mathrm{d}t|_{c.r.} = k[A][B]$ – a *second order rate law*.

When a γ-species participates in several chemical reactions that cause its concentration within the fluid phase to increase (or decrease), we express the strength of the source (= rate of production) of that γ-species in the (macroscopic) balance equation, say equation (31), by:

$$\theta\rho\Gamma^\gamma = \sum_{(j)}\frac{\mathrm{d}c^\gamma}{\mathrm{d}t}\bigg|_{j\text{th hom.chem.react.}} = \theta M^\gamma\sum_{(j)}\nu_j^\gamma R_{rj} \tag{47}$$

in which R_{rj} is the reaction rate of the jth homogeneous chemical reaction in the fluid and ν_j^γ is the stoichiometric coefficient of the γ-species in the jth reaction. This rate of production is in addition to the rates of production resulting from other sources.

INITIAL AND BOUNDARY CONDITIONS

The solution of any of the balance equations for the mass of a solute requires initial and boundary conditions. Initial conditions involve the specification of the value of the concentration, $c = c(\mathbf{x}, t)$, at all points $\mathbf{x}$ of the domain at the initial time, $t = 0$.

General Boundary Conditions

The boundary conditions for solute transport models, at the macroscopic level, are based on the following two principles:

- At every point on a boundary, there exists no discontinuity in the concentration as the boundary is crossed from the considered domain to its vicinity. However, under certain conditions that are consequences of the various assumptions that underlie the model, we are forced to violate this condition in order to achieve a better approximation of a real situation.
- In the absence of sources and sinks of a considered solute on the boundary, which is the usual case, the component normal to the boundary of the total flux of that solute, with respect to the (possibly moving) boundary, undergoes no jump as the latter is crossed:

For a boundary surface that is also a *material surface* with respect to the solid, $(\mathbf{V}_{\text{solid}} - \mathbf{u}) \cdot \mathbf{n} = 0$, the condition of flux continuity can be written in the form:

$$[\![(c\mathbf{q}_r - \theta \mathbf{D}_h \cdot \nabla c)]\!]_{1,2} \cdot \mathbf{n} = 0, \mathbf{q}_r \equiv \theta(\mathbf{V}_{\text{fluid}} - \mathbf{V}_{\text{solid}}) \tag{48}$$

where $\mathbf{q}_r$ is the specific discharge of the fluid, relative to the solid, as described by Darcy's law, $\mathbf{n}$ denotes the unit vector normal to the boundary, moving at the velocity $\mathbf{u}$, and 1,2 denote the internal and external sides of the boundary, respectively. The values of $\mathbf{V}_{\text{fluid}}$ and θ are assumed known from the flow model.

For equation (48) to serve as a condition for c on a boundary, information on what happens on the external side of the latter (here, on c and ∇c) must be known as *a function of space and time*. Let us present a number of particular cases. We shall assume that all boundaries, except the phreatic surface (= water table), are stationary and material surfaces with respect to the solid.

Boundary of Prescribed Concentration

When the value of $c(\mathbf{x}, t)$ is prescribed as a known function, $f^1 = f^1(\mathbf{x}, t)$, at all points of a boundary segment, due to phenomena that take place on the external side of the latter, independent of what happens within the domain, the boundary condition is

$$c(\mathbf{x}, t) = f^1(\mathbf{x}, t) \tag{49}$$

This is a *first kind* or *Dirichlet boundary condition*.

Boundary of Prescribed Flux

When phenomena occurring on the external side of a boundary impose a known *total* flux of the considered component, $f^2 = f^2(\mathbf{x}, t)$, normal to a boundary segment, at all points of the latter, *regardless* of what happens within the considered domain itself, the condition takes the form:

$$(c\mathbf{q}_r - \theta \mathbf{D}_h \cdot \nabla c) \cdot \mathbf{n} = f^2(\mathbf{x}, t) \tag{50}$$

where the specific discharge (relative to the solid) $\mathbf{q}_r$ can be expressed by Darcy's law. As always, for saturated flow, we replace θ by ϕ. This is a *third kind*, or *Cauchy boundary condition*. A special case is an impervious boundary, where $f^2(\mathbf{x}, t) \equiv 0$, and $\mathbf{q}_r \equiv 0$. The boundary condition then reduces to a *second kind* or *Neumann boundary condition*.

Boundary Between Two Porous Media

Along such a boundary, we assume the existence of discontinuities in all solid matrix characteristics. Two conditions must be satisfied along such a boundary:

$$c|_1(\mathbf{x}, t) = c|_2(\mathbf{x}, t)$$
$$[c\mathbf{q}_r - \theta \mathbf{D}_h \cdot \nabla c]|_1 \cdot \mathbf{n} = [c\mathbf{q}_r - \theta \mathbf{D}_h \cdot \nabla c]|_2 \cdot \mathbf{n} \tag{51}$$

Since $[\mathbf{q}_r]|_1 \cdot \mathbf{n} = [\mathbf{q}_r]|_2 \cdot \mathbf{n}$, $[c]|_1 = [c]|_2$, the second equation can be written as

$$[\theta \mathbf{D}_h \cdot \nabla c]|_1 \cdot \mathbf{n} = [\theta \mathbf{D}_h \cdot \nabla c]|_2 \cdot \mathbf{n} \tag{52}$$

Boundary with a Body of Fluid

We consider a stationary boundary between a porous medium domain (denoted by *pm*) and a body of fluid (denoted by *fb*), for example, a lake or a river, assumed to be a "well mixed" domain, that is, at a *known uniform* concentration of the considered component, say, c''. The two domains are assumed to be in good hydraulic contact. The condition of no-jump (across the boundary) in the normal component of the total flux of the considered component, takes the form:

$$(c''\mathbf{V})_{fb} \cdot \mathbf{n} - [c\mathbf{q}_r - \phi \mathbf{D}_h \cdot \nabla c]|_{pm} \cdot \mathbf{n} = 0 \tag{53}$$

However, this boundary introduces an inconsistency in the case of no-flow across the boundary. An improvement,

introduced by adding a "buffer zone" (Bear and Bachmat, 1990), leads to the condition:

$$(c'' - c|_{pm})(\mathbf{q}_r \cdot \mathbf{n} + \alpha^*) = -\phi \mathbf{D}_h \cdot \nabla c|_{pm} \cdot \mathbf{n} \quad (54)$$

where α^* is a *transfer coefficient*, such that $\alpha^*(c'' - c)$ represents the sum of diffusive and dispersive fluxes through the transition zone. Equation (54) introduces a concentration jump on the boundary. This is a consequence of introducing the transition zone and the "well mixed zone" approximation.

Phreatic Surface with Accretion

The phreatic surface, defined in **Chapter 149, Hydrodynamics of Groundwater, Volume 4**, as the *surface at every point of which the water pressure is atmospheric*, serves as the upper boundary of the saturated domain. The condition for flow on this boundary is also presented there. Here, we shall discuss only the condition for the solute transport model.

The shape of the phreatic surface is defined by the equation $F = F(x, y, z, t) = 0$, with

$$F(x, y, z, t) \equiv h(x, y, z, t) - z = 0, \quad \mathbf{n} = \frac{\nabla F}{|\nabla F|},$$

$$\mathbf{u} \cdot \nabla F = -\frac{\partial F}{\partial t} \quad (55)$$

in which h denotes the piezometric head and $\mathbf{u}$ is the speed of displacement of the phreatic surface. Basically, the condition is one of continuity of the normal flux of the considered component across the boundary. As is usually done in groundwater hydrology, we neglect the details of the movement of water through the unsaturated zone above the phreatic surface, say at the *residual water volumetric fraction*, θ_{wr}, and consider only some mean value of natural replenishment, **N**, infiltrating at ground surface and reaching the phreatic surface as accretion, or *natural replenishment*. Let c' denote the concentration of the infiltrating water. The condition of equality of solute flux across the phreatic surface takes the form:

$$\phi[c(\mathbf{V} - \mathbf{u}) - \mathbf{D}_h \cdot \nabla c] \cdot \mathbf{n} = c'(\mathbf{N} - \theta_{wr}\mathbf{u}) \cdot \mathbf{n} \quad (56)$$

in which we may insert $F = h(x, y, z, t) - z$, and use equation (55) to express **n** and **u.**

Seepage Face

The seepage face as a boundary is discussed in **Chapter 149, Hydrodynamics of Groundwater, Volume 4**. The condition is based on equality of normal solute flux:

$$(\phi c\mathbf{V} - \phi \mathbf{D}_h \cdot \nabla c)|_{pm} \cdot \mathbf{n} = (c\mathbf{V})|_{env} \cdot \mathbf{n} \quad (57)$$

Since $c|_{pm} = c|_{env}$, $(\phi \mathbf{V})|_{pm} \cdot \mathbf{n} = \mathbf{V}|_{env} \cdot \mathbf{n}$, the condition of equation (57) reduces to

$$\mathbf{D}_h \cdot \nabla c|_{pm} \cdot \mathbf{n} = 0 \quad (58)$$

COMPLETE MATHEMATICAL MODEL

The mathematical statement, or *model*, of a multiphase flow problem, combined with the model of transport of a single chemical component, possibly with first order decay, adsorption, and volatilization, consists of the following parts:

- A mathematical description of the configuration of the surface that bounds the porous medium problem domain.
- A list of the dependent variables. These are the concentrations, c_α^γ of the considered γ-species within all fluid phases present in the system. In the case of adsorption, F^γ is included in the list of state variables. For the flow model, depending on the number of fluid phases that are in motion, we may add such variables as piezometric heads, pressures, saturations, and so on.
- Flux equations for the mass of the considered fluid phases. Darcy's law is often employed.
- Mass balance (partial differential) equations for the relevant fluid phases.
- Mass and momentum (partial differential) balance equations for the solid, when the latter is deformable.
- Mass balances (partial differential) equations that describe of the considered γ-species within all fluid phases present in the system and on the solid. These balance equations may contain source terms that correspond to decay, adsorption, and volatilization of the considered species.
- Dispersive and diffusive flux equations for the mass of the considered species
- Constitutive equations for the fluid phases, for the solid (in the case of a deformable solid), and for the γ-species. These include also thermodynamic relationships that describe the partitioning of the γ-species between adjacent phases under equilibrium conditions, or transfer functions for nonequilibrium conditions.
- Expressions for the various external sources and sinks (for the mass of fluid phases and the mass of the considered species).
- Statement of initial conditions for each of the relevant balance equations.
- Statement of boundary conditions for each of the relevant balance equations.
- Numerical values, or functional relationships for all the coefficients that appear in the various balance equations and constitutive relations included in the model.

The number of variables that describe the state of the system is usually large. To obtain a closed set of equations, within the framework of a *well-posed problem*, we need an equal number of equations. However, the number of *primary variables* (or *degrees of freedom*) of the problem, is much smaller. The number of partial differential equations of balance that has to be solved is then equal to the number of the primary variables. All other variables are obtained from the known values of the selected primary variables, using the remaining equations. Bear and Nitao (1995) present a detailed discussion on primary variables in modeling phenomena of transport in porous media.

The case of flow and solute transport with variable density is presented in **Chapter 157, Sea Water Intrusion Into Coastal Aquifers, Volume 4**, in connection with seawater intrusion into coastal aquifers.

153: Groundwater Pollution and Remediation

WALT MCNAB, FRED HOFFMAN AND BRENDAN DOOHER

Environmental Restoration Division, Lawrence Livermore National Laboratory, Livermore, CA, US

Contamination of groundwater resources by a variety of anthropogenic pollutants from both point and non-point sources represents a key global environmental problem. Contaminant species of concern include solvents, fuel hydrocarbons, heavy metals, pesticides, nitrate, and radionuclides. Groundwater contamination reflects local physical hydrogeological considerations but also the inherent properties of the contaminants. An understanding of the factors controlling contaminant behavior in the subsurface is a necessary prerequisite to exploring possible remedial solutions. These factors include the partitioning processes that govern the distribution of contaminant species between the aqueous phase, the solid phase (including adsorption onto soil particle surfaces), the gas phase, and, in some cases, nonaqueous phase liquids. Chemical and biological transformation processes also impact the behavior of different types of subsurface contaminants. The designs of passive and active groundwater remediation approaches often reflect consideration of one or more of these factors; however, the efficacy of most methods is often most closely dependent upon the physical characteristics of the subsurface environment, such as the distribution of hydraulic conductivity.

INTRODUCTION: SOURCES OF GROUNDWATER CONTAMINATION

Human interest in groundwater has historically reflected water supply concerns, which are widely recognized as a major problem facing human civilization as the global population continues to increase. In recent decades, groundwater contamination has been recognized as a substantial threat to the viability of this resource worldwide. Because of the relatively slow rates of recharge and fluid migration through the subsurface environment, and because of the vast potential for exposure of subsurface materials to sources of pollution, groundwater contamination represents a critical societal–environmental resource problem. Examples of typical groundwater contaminants include industrial chemicals (solvents, fuels, heavy metals, radionuclides), agricultural chemicals (fertilizers, pesticides, nitrate), and municipal wastes (fecal coliform, nutrients, nitrate, disinfectants, detergents). The 25 most frequently detected groundwater contaminants at hazardous waste sites in the United States as of the mid-1990s (National Research Council, 1994) are listed in Table 1. The list is composed of predominantly organic solvents and compounds associated with petroleum products and manufacturing and inorganic contaminants, such as heavy metals, from industry and mining. The list does not include what has recently become a ubiquitous groundwater contaminant in the United States, the gasoline additive methyl-*tert*-butyl-ether (MTBE), nor does it include perchlorate, ClO_4^-, used in the manufacture of rocket propellants and road flares, which is also only now gaining scrutiny as a contaminant of concern. Often, the emergence of such "new" groundwater contaminants reflects issues such as inadequate monitoring technologies and incomplete analysis of already available monitoring data, in addition to the simple introduction of new chemicals (Mackay and Smith, 1993).

The entry points of pollutants into the environment may be distinguished as point sources or nonpoint sources. Examples of point sources include leaking underground pipes and tanks, accidental or deliberate spill events, and seepage from disposal pits and landfills. Such sources threaten groundwater resources directly at the point of entry, where transport processes may subsequently facilitate migration. Nonpoint sources include such examples as aerial and ground spraying of pesticides, urban precipitation runoff, or the cumulative effect of numerous point sources, such as in large industrial areas. These nonpoint sources threaten regional water resources on a larger scale. In a

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

Table 1 The 25 most frequently detected ground-water contaminants at hazardous waste sites (Reprinted with permission from (Alternatives for Ground Water Cleanup). © (1994) by the National Academy of Sciences, courtesy of the National Academies Press, Washington, D.C)

Rank	Compound	Common sources
1	Trichloroethylene	Dry cleaning; metal degreasing
2	Lead	Gasoline (prior to 1975); mining construction material (pipes); manufacturing
3	Tetrachloroethlylene	Dry cleaning; metal degreasing
4	Benzene	Gasoline; manufacturing
5	Toluene	Gasoline; manufacturing
6	Chromium	Metal plating
7	Methylene chloride	Degreasing; solvents; paint removal
8	Zinc	Manufacturing; mining
9	1,1,1-Trichloroethane	Metal and plastic cleaning
10	Arsenic	Mining, manufacturing
11	Chloroform	Solvents
12	1,1-Dichloroethane	Degreasing; solvents
13	1,2-Dichloroethane	Transformation product of 1,1,1-trichloroethane
14	Cadmium	Mining; plating
15	Manganese	Manufacturing; mining; occurs in nature as oxide
16	Copper	Manufacturing; mining
17	1,1-Dichloroethene	Manufacturing
18	Vinyl chloride	Plastic and record manufacturing
19	Barium	Manufacturing; energy production
20	1,2-Dichloroethane	Metal degreasing; paint removal
21	Ethylbenzene	Styrene and asphalt manufacturing; gasoline
22	Nickel	Manufacturing; mining
23	Di(2-ethylhexyl)phthalate	Plastics manufacturing
24	Xylenes	Solvents; gasoline
25	Phenol	Wood treating; medicines

Note: This ranking was generated by the agency for toxic substances and disease registry using ground-water data from the National Priorities List of sites to be remediated under CERCLA. The ranking is based on the number of sites at which the substance was detected in ground water. (National Research Council, 1994).

1984 report, the United States Office of Technology Assessment (Office of Technology Assessment, 1984) produced a guide for categorizing the different potential sources of contamination:

- *Category I: Sources designed to discharge substances.* Subsurface percolation (e.g. septic tanks and cesspools); injection wells (for hazardous wastes and nonhazardous wastes, such as for brine disposal and drainage, and nonwastes, such as enhanced oil recovery, artificial recharge, solution mining, and *in situ* mining), and land applications (e.g. spray irrigation with wastewater and by-products such as sewer sludge).

- *Category II: Sources designed to store, treat, and/or dispose of substances discharged through unplanned release.* Landfills (industrial and municipal sanitary), open dumps including illegal dumping, residential (or local) disposal, surface impoundments, waste tailings, materials stockpiles, graveyards; animal burial sites, aboveground and underground storage tanks, open burning and detonation sites, and radioactive disposal sites.

- *Category III: Sources designed to retain substances during transport or transmission.* Pipelines, materials transport, and transfer.

- *Category IV: Sources discharging as consequences of other planned activities.* Irrigation practices (e.g. return flow), pesticide applications, fertilizer applications, animal feeding operations, de-icing salts applications, urban runoff, percolation of atmospheric pollutants, mining and mine drainage (both surface and underground mine-related).

- *Category V: Sources providing conduit or inducing discharge through altered flow patterns.* Production oil and gas wells, geothermal and heat recovery wells, water supply wells, and other types of wells (monitoring wells, exploration wells, construction/excavation borings).

- *Category VI: Naturally occurring sources whose discharge is created and/or exacerbated by human activity.* Groundwater–surface water interactions, natural leaching, saltwater intrusion/brackish water upconing (or intrusion of other poor-quality natural water).

Reducing the threats to groundwater resources posed by these sources of pollution is a major challenge facing hydrologists, hydrogeologists, engineers, and planners. An understanding of the problem of groundwater contamination – and the responses taken with respect to it – consists of three basic elements: the physical and chemical factors

that influence the behavior of contaminants in the subsurface, the risk posed by the contaminants to human health and the environment, and the steps that can be taken to mitigate that risk in some form. This article explores each of these elements in turn.

CONTAMINANT FATE AND TRANSPORT CONCEPTS AND PROCESSES

When liquid contaminants are released at the ground surface, they are transported primarily downward through the vadose (unsaturated) zone by a combination of gravity, density, and capillary forces. When contaminants reach the groundwater (the saturated zone), they may dissolve or be further diluted and are then transported by the moving groundwater (Figure 1) at rates dependent on the hydraulic gradient and the hydraulic conductivity and porosity of the subsurface geologic materials, as well as by physiochemical factors which may retard the movement of the contaminant. Because of the complex nature of the subsurface environment, groundwater contamination is a difficult and expensive problem to characterize and remediate. This is true for porous media, which this article addresses, as well as for the special cases of fractured rock and fractured porous rock media, which will not be considered further (refer to Sahimi, 1995) (*see* **Chapter 147, Characterization of Porous and Fractured Media, Volume 4**).

In addition to physical heterogeneities in the subsurface environment that affect groundwater flow and hence contaminant migration pathways, chemical heterogeneities also exist within the subsurface that will profoundly affect the behavior of contaminants. In the case of organic solvents and fuels, these include the possible presence of separate-phase liquids, the preferential partitioning of contaminants onto solid-phase materials in the aquifer matrix such as natural organic matter, and the existence of distinct biogeochemical microenvironments where contaminants may undergo chemical or microbially mediated degradation reactions. For inorganic contaminants such as metals and radionuclides, precipitation reactions that occur in response to changes in pH or redox conditions can immobilize contaminants, along with partitioning of solutes onto aluminosilicate or metal oxide mineral surfaces.

Partitioning Processes

Mass Transfer Between Aqueous Phase and NonAqueous Phase Liquids

Organic groundwater contaminants range in solubility from being infinitely soluble in water (e.g. ethanol) to being essentially insoluble (e.g. dioxins, high molecular weight aliphatic hydrocarbons); many common organic contaminants are water-soluble to some extent (Table 2). Low-solubility compounds are often introduced into the subsurface as nonaqueous phase liquids, or NAPLs (otherwise referred to as separate-phase liquids). The partitioning of mass between the aqueous phase and NAPL is a critical issue because measurable health effects associated with consumption of some organic contaminants by humans, animals, and plants may occur at very low concentrations (part-per-billion levels), so that even sparingly soluble compounds may pose a substantial environmental threat, and because these contaminants entrapped in the subsurface may serve as continuous sources of aqueous-phase contamination over long periods. The primary factor controlling the solubility of NAPL components in water is the electrical charge distribution across the molecule, or polarity, quantified by the dipole moment. Water molecules, because of the geometric orientation of the constituent oxygen and hydrogen atoms, have a high dipole moment compared to other liquids of similar molecular weight and thus will have a much higher affinity for one another than for lower dipole moment molecules. This results in a segregation of water molecules from the lower dipole moment molecules.

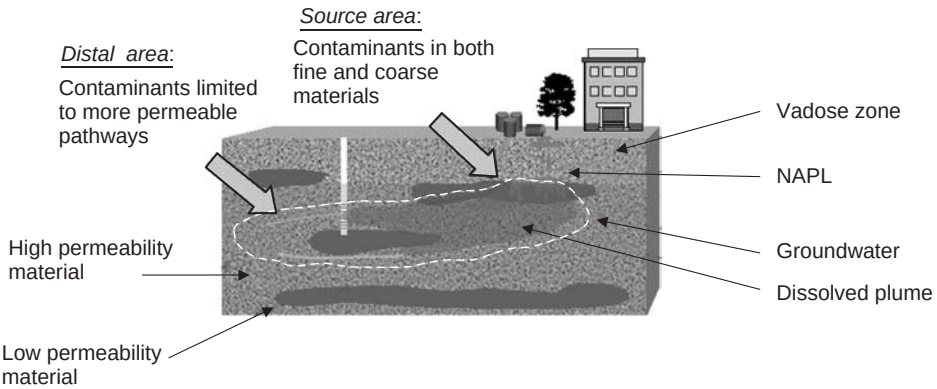

Figure 1 Conceptual release scenario for a NAPL penetrating the unsaturated zone and impacting underlying groundwater. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Table 2 Physical properties and cleanup levels of selected common organic groundwater contaminants

Compound	Density ($gm\,cm^{-3}$)[a]	Water solubility ($mg\,L^{-1}$)[b]	Vapor pressure (mm Hg)[b]	Henry's constant ($atm \cdot m^3\,mol^{-1}$)[b]	US EPA MCL ($\mu g\,L^{-1}$)[c]
Trichloroethylene	1.61	1100	58	9.1×10^{-3}	5
Tetrachloroethlylene	1.4	150	18	2.6×10^{-2}	5
1,1,1-Trichloroethane	1.33	1500	123	1.4×10^{-2}	200
1,2-Dichloroethane	1.25	8520	64	9.8×10^{-4}	5
Chloroform	1.48	8200	151	2.9×10^{-3}	80[d]
Benzene	0.88	1750	95	5.6×10^{-3}	5
Toluene	0.87	54	28	6.4×10^{-3}	1000
Chlorobenzene	1.11	466	117	3.7×10^{-3}	100
Pentachlorophenol	1.98	14	1.1×10^{-4}	2.8×10^{-6}	1
Napthalene	0.96	32	0.23	1.2×10^{-3}	–

Moreover, NAPLs cannot readily displace water in unsaturated soils by capillary effects because water generally exhibits a higher affinity for mineral surfaces than the organic liquids. As a result, NAPLs will often reside within larger pore spaces unoccupied by water. Under such circumstances, discontinuous bodies of NAPL may reside in the vadose zone, unable to migrate. Such NAPL bodies may slowly dissolve into the aqueous phase, acting as local contamination sources for a considerable period of time.

Aside from solubility considerations, the density of a NAPL, in comparison to that of water, is also an important consideration with regard to the fate of sparingly soluble contaminants in the environment. A number of common organic contaminants are characterized by densities greater than that of water (e.g. chlorinated halocarbons such as PCE and TCE), while others, particularly petroleum hydrocarbons, are significantly less dense than water (Table 2). Heavier-than-water organic liquids are referred to as DNAPLs (dense nonaqueous phase liquids), while lighter-than-water organic liquids are LNAPLs (light nonaqueous phase liquids). NAPLs will tend to float on top of the water table in an unconfined aquifer, whereas DNAPLs will tend to sink into the saturated zone. Different remediation strategies must be utilized for cleaning up these two classes of liquid-phase contaminants in the environment.

Mass Transfer Between Aqueous and Gas Phases

Lighter, volatile organic contaminants, either entrapped within the vadose zone or floating on the water table, may volatilize directly into the gas phase in unsaturated pore spaces. The volatility of a compound is indicated by its vapor pressure, which is the partial pressure of a vapor in equilibrium with its pure liquid state. Vapor pressures for some common organic contaminants are listed in Table 2. Many common organic contaminants are characterized by relatively high vapor pressures and are commonly referred to as volatile organic compounds (VOCs).

When organic compounds are dissolved in the aqueous phase (i.e. in soil water or groundwater), partitioning of mass between the aqueous phase and the soil gas phase is commonly modeled by Henry's law, which states that, at constant temperature, the vapor pressure of a compound is equal to the compound's mole fraction in the aqueous phase times a constant,

$$P_a = h_a X_a \tag{1}$$

where P_a is the vapor pressure of substance a, h_a the respective Henry's constant, and X_a the mole fraction of a in solution. This relationship is applicable in the ideal case of an infinitely dilute solute, where solute–solvent interactions are independent of concentration, so that Henry's law is most applicable when the solute concentration is fairly dilute. Henry's law constants for some common organic contaminants are given on Table 2.

Mass Transfer Between the Aqueous and Solid Phases

Mass transfer phenomena between the solid and aqueous phases include adsorption/desorption of dissolved species onto solid surfaces as well as dissolution or precipitation of mineral phases. These so-called water-rock interactions occur in response to a groundwater solution that is in chemical disequilibrium with solid materials in the aquifer, often the result of transport mechanisms bringing in a suite of solutes originally in equilibrium with a particular mineral assemblage into a portion of an aquifer system containing different minerals. Water-rock interactions are very significant with regard to groundwater contamination. For example, the continuous partitioning of solutes between the aqueous and solid phases can result in depletion of the aqueous solute at the leading edge of a migrating plume

and enrichment at the trailing edge, leading to an overall retardation of plume movement.

Adsorption reactions include a number of mechanisms, including complexation of metals onto mineral surfaces or the hydrophobic partitioning of organic contaminants onto organic materials present in the soil. Many common mineral phases found in geological materials tend to develop surface charges as a result of ionic substitution reactions in crystal lattices or crystal edge protonation/deprotonation reactions. These phenomena are especially prevalent in aluminosilicate clay minerals, which generally develop negative surface charges as a result of lattice substitution, and metal oxyhydroxides such as ferrihydrite, $Fe(OH)_3$, which develop variable surface charges (negative or positive) as a result of protonation/deprotonation reactions that are pH-dependent. Cations and anions in solution tend to redistribute in the vicinity of the mineral surface to satisfy charge imbalances. For ionic contaminants such as dissolved metals, this redistribution can take the form of chemical bonding to the mineral surface (either directly, or via hydrated complexes) or residence in a diffuse layer of ions near the surface (Sposito, 1989).

In contrast to ionic species, sparingly soluble (i.e. "hydrophobic") organic compounds generally exhibit a high affinity for naturally occurring solid-phase organic matter (e.g. cellulose, lignins, kerogen, and humic acids) present in soils rather than for charged mineral phases. Dissolved organic compounds tend to adsorb onto such materials either because of unfavorable free energy costs associated with remaining in solution or because of van der Waals or other weak electrostatic forces (Schwarzenbach *et al.*, 1993). In essence, adsorption of hydrophobic organic compounds to soil organic material is more a matter of the incompatibility of nonpolar compounds with water, rather than a direct attraction to the soil organic material (Westall, 1987). The tendency of an organic compound to partition onto natural organic matter may be gleaned from its organic carbon partition coefficient, or K_{oc}, which reflects the degree of nonpolarity, or hydrophobicity, of the compound and thus tends to correlate with the solubility of the compound (Table 2).

A simple model that is often employed for quantifying the adsorption of dissolved species onto a solid surface is based upon a distribution coefficient, or K_d:

$$K_d = \frac{C_s}{C_w} \tag{2}$$

where C_s is the sorbate concentration associated with the sorbent, typically in mol/kg, and C_w the aqueous concentration, typically in mol/L. For hydrophobic organic compounds in aquifers characterized by abundant solid-phase organic material, the K_d can be estimated as the product of the K_{oc} and the fractional organic carbon content of the sediments. For inorganic species, a variety of molecular adsorption models exist to quantify relationships between the adsorbate (the sorbed species) and the adsorbent (the solid surface), including the so-called diffuse double-layer model, which assumes that the adsorbent surface is a uniform plane of uniform charge density and that the adsorbate ions are point sources that interact with the adsorbent surface through electrostatic forces. Other approaches seek to quantify adsorption through the definition of conditional equilibrium constants (Sposito, 1989).

The same mechanisms responsible for the partitioning of contaminant species onto solid materials may also result in adsorption of these same species onto suspended colloidal particles, which are fine (nanometer to micron-size) particles of clay minerals, metal hydroxides, or organic material. This phenomenon is potentially important from an environmental viewpoint because some contaminants which would normally be expected to exhibit very low mobility in the subsurface as a result of adsorption might be transported over long distances (McCarthy and Zachara, 1989). For example, colloidal transport may be the likely explanation for the apparent migration of plutonium, a radionuclide that strongly sorbs to mineral surfaces, over hundreds of meters at the United States Department of Energy's Nevada Test Site (Kersting *et al.*, 1999).

In addition to adsorption reactions, the mobility of a variety of inorganic contaminants may be substantially influenced by precipitation and dissolution reactions (Stumm and Morgan, 1996; Parkhurst and Appelo, 1999). These types of reactions will occur when transport processes bring together a solution chemistry and a mineral assemblage that are not in mutual thermodynamic equilibrium. Disequilibrium provides the driving force for mineral precipitation reactions once a particular mineral phase becomes supersaturated in a solution. Conversely, a state of thermodynamic undersaturation in a solution with respect to a given mineral phase will provide a driving force for dissolution of mineral phases that may be present within aquifer material. For example, in the phenomenon of acid mine drainage, oxygenated rainwater in contact with iron sulfide-rich mine tailings oxidizes the iron and sulfide components, yielding a solution dominated by H^+, SO_4^{2-}, and metal cations. The effluent solution migrates into the subsurface where it reacts with carbonate minerals such as calcite, $CaCO_3$, that are unsaturated in acidic waters to produce secondary mineral phases not originally present in the aquifer, such as gypsum, $CaSO_4 \cdot 2H_2O$. Further downgradient, as carbonate dissolution reactions mitigate the acidity of the mine tailings effluent, iron hydroxide mineral phases such as ferrihydrite, $Fe(OH)_3$, become supersaturated and precipitate out of solution. This can provide sorption sites for dissolved metals such as lead, copper, or zinc.

A summary of the susceptibility of important metal and radionuclide groundwater contaminants to various mineral equilibria and adsorption constraints is shown in Table 3.

Table 3 Selected metals and radionuclides and potential water-rock interaction effects

Species	Water-Rock Interactions[a]
Lead	Low solubility of lead hydroxyl carbonates and phosphate, adsorption onto soil minerals and organic matter, coprecipitation with manganese oxide.
Chromium	Cr(VI), typically as CrO_4^{2-}, exists under oxidizing conditions and is highly mobile. Reducing conditions yield Cr(III), which is less mobile, generally precipitating as $Cr(OH)_3$ or coprecipitating with iron hydroxide phases.
Zinc	Mobility is limited at slightly to fairly alkaline pH values by formation of carbonate and hydroxide mineral phases and sorption to soil minerals.
Arsenic	Arsenate, As(V), exists under oxidizing conditions and is generally mobile, forming anionic $H_2AsO_4^-$ or $HAsO_4^{2-}$. Reducing conditions yield arsenite, As(III), which sorbs strongly onto iron oxyhydroxide minerals.
Cadmium	Mobility is limited at neutral to alkaline pH values by formation of cadmium carbonate and sorption to soil minerals; coprecipitation with manganese oxide.
Manganese	Very low solubility under oxidizing conditions where MnO_2 stable.
Copper	Cupric ion, Cu^{2+}, exists under oxidizing conditions; solubility is controlled by carbonate and hydroxide mineral phases and sorption to soil mineral phases above neutral pH. Reducing conditions yield cuprous ion, Cu^+, which forms low-solubility sulfide mineral phases.
Barium	Solubility controlled by the formation of $BaSO_4$; sorbs to metal oxides or hydroxides.
Nickel	Sorbs to soil mineral phases; may form nickel oxide or hydroxide mineral phases.
Uranium	U(IV) exists under oxidizing conditions and is generally mobile, forming species such as uranyl, UO_2^{2+} or carbonate or sulfate complexes. Reducing conditions yield U(IV), which typically forms the low-solubility mineral phase uranite, UO_2.
Plutonium	Generally sorbs strongly to soils, depending on pH, clay content, and presence of soil organic matter.[b]
Cesium	Sorbs to soil mineral phases.
Technetium	Pertechnate, TcO4−, is the dominant form under oxidizing conditions; sorbs weakly to mineral surfaces depending on pH and other anions. Reduced conditions produce sparingly soluble Tc(IV) which is readily sorbed by soil constituents and forms complexes with organic matter.[b]

Transformations

In contrast to mass exchange processes, which affect the distribution of contaminant mass between phases, transformation reactions affect the total mass of a particular species in the subsurface environment. Transformation processes include those mechanisms that act to destroy a contaminant altogether, converting it into another material. Examples include radioactive decay and the biotransformation of organic compounds by microorganisms.

Microbially Mediated Transformations of Organic Contaminants

Dissolved organic compounds in groundwater under ambient environmental conditions are inherently thermodynamically unstable and are energetically favored to degrade into stable species such as CO_2 and H_2O via oxidation, or, in certain instances, CH_4 via reduction. Oxidation and reduction reactions generally entail the breaking of covalent bonds, an energy-intensive process. The energy associated with the random, thermal agitation of molecules is often insufficient to allow such reactions to progress at measurable rates even when the reaction is thermodynamically favorable. However, numerous species of microorganisms, particularly bacteria (e.g. Bacillus, Pseudomonas), and yeasts possess enzymes that are capable of facilitating the chemical breakdown of organic contaminants through various reaction pathways. These microorganisms manufacture enzymes such as monooxygenase, dioxygenase, and dehydrogenase to assist, for example, in transferring oxygen atoms to a molecule or for removing hydrogen atoms, and, as such mediate both oxidative and reductive processes. Nevertheless, not all organic contaminants are easily oxidized or reduced via microbial activity; many artificially synthesized organic compounds are deliberately designed to be recalcitrant to transformations.

Oxidation reactions necessarily require a suitable electron acceptor to accommodate the electrons released:

$$C_6H_6 + 12H_2O \longrightarrow 6CO_2 + 30H^+ + 30e^- \qquad (3)$$

The primary electron acceptor in natural waters is dissolved oxygen. Reactions between O_2 and organic compounds are usually highly favorable thermodynamically. Under anoxic conditions (i.e. in the absence of dissolved O_2), other electron acceptors in the aqueous phase (e.g. NO_3^-, SO_4^{2-}) or the solid phase (e.g. $Fe(OH)_3$, MnO_2) may be utilized instead by microorganisms. Under extremely reducing conditions where all other electron acceptors have been depleted, CO_2 itself may act as the electron acceptor in reactions that yield methane as a

reaction product. Evidence of the associated changes in groundwater chemistry in response to the oxidation of organic contaminants has been most frequently encountered in instances of fuel hydrocarbon groundwater plumes. Fuel hydrocarbon compounds are common contaminants that are often released in high concentrations and are relatively susceptible to oxidation by populations of microorganisms utilizing a variety of electron acceptors. Laboratory and field studies have demonstrated the sequential microbial utilization of the common electron acceptors, beginning with dissolved O_2, followed, roughly in order of thermodynamic favorability, by MnO_2, NO_3^-, Fe(III)-oxyhydroxides, SO_4^{2-}, and occasionally CO_2, resulting in zonation of oxidation–reduction processes, frequently noted at field sites (Vroblesky and Chapelle, 1994).

Although many microbially mediated transformation processes involving organic contaminants are oxidative in nature, important reduction reactions also occur in certain circumstances. Reductive dehalogenation, which involves the replacement of halogen atoms (Cl, Br, I) in a halogenated hydrocarbon compound with protons, is the most familiar reductive transformation process. Because halogen atoms are generally characterized by negative electrical charges, carbon atoms associated with halocarbon compounds are relatively oxidized (i.e. less negatively charged) in comparison to their counterparts in nonhalogenated hydrocarbons. As a result, halogenated hydrocarbons are susceptible to reduction reactions, with the most heavily halogenated, and hence the most oxidized, the most susceptible to this process.

Many common halogenated hydrocarbons will undergo reductive dehalogenation under chemically reducing conditions (McCarty, 1996), including halogenated methanes, ethenes, ethanes, and aromatics. The reductive half-reaction of the dehalogenation reaction may be expressed generically as,

$$RX + H^+ + 2e^- \longrightarrow RH + X^- \qquad (4)$$

where R refers to the organic molecule and X the halogen atom. Reaction (4) implies that a suitable electron donor, typically organic carbon, must be readily available. As in the case of oxidative transformations, microbial mediation is usually necessary for reductive dehalogenation to proceed at significant rates (i.e. half-lives on the order of days to months). A well-known exception is in the presence of metallic iron, where the metal acts as both reducing agent and catalyst for the relatively rapid reductive dehalogenation of a number of common halogenated hydrocarbons, notably TCE.

Abiotic Transformations of Organic Contaminants: Some Examples

Oxidative and reductive pathways constitute an important means for transformations of organic contaminants in groundwater. However, other somewhat specialized mechanisms do exist in some instances; often they do not entail microbial mediation. For example, substitution reactions involve the replacement of an atom or functional group on a molecule by another. Hydrolysis reactions, a familiar class of substitution reactions, occur when an organic compound reacts directly with the water to produce an alcohol or a diol and a proton, such as the conversion of methyl chloride to methanol:

$$CH_3Cl + H_2O \longrightarrow CH_3OH + H^+ + Cl^- \qquad (5)$$

Beyond substitution reactions, dehydrohalogenation refers to a transformation mechanism specific to certain halogenated alkanes, entailing the simultaneous removal of a halogen atom and a proton from the molecule, along with the conversion of a single carbon–carbon bond to a double bond, forming an alkene. The one common example of this process is the dehydrohalogenation of 1,1,1-trichloroethane (TCA) to form 1,1-dichloroethene (DCE),

$$CCl_3–CH_3 \longrightarrow CCl_2{=}CH_2 + H^+ + Cl^- \qquad (6)$$

This reaction has been documented in laboratory experiments and observed at contaminated groundwater sites and may be responsible for much of the 1,1-DCE found in aquifers (McCarty, 1996). The half-life of this reaction is on the order of one to two years, depending in large part on temperature.

Many organic contaminants may also undergo reversible reactions that entail simple protonation or deprotonation, so that the compounds act as weak acids or bases in solution. These reactions typically involve functional groups (e.g. carboxyl, carbonyl, and phenyl groups) that exist as portions of a larger organic molecule. Protonation or deprotonation reactions are important in terms of the behavior of particular organic compounds in the environment. For example, charged species may interact with solid-phase mineral and organic surfaces through adsorption mechanisms that differ from uncharged equivalents and may also be characterized by different toxicities or biodegradability.

GROUNDWATER CONTAMINATION: A RISK-BASED PERSPECTIVE

An early introduction for the public to the looming danger that groundwater contamination poses to water quality was provided by the Love Canal hazardous waste site in Niagara Falls, New York, USA., which came to public attention in 1979. In that event, contaminated land had been turned over to the local school board with full deed restrictions but was subsequently used to build not only a school but a housing community and the associated sewage systems,

resulting in the piercing of the landfill's clay liner (Zuesse, 1981). By June 1994, Occidental Petroleum, the custodian of the site, had paid $98 million to cover the state of New York's cleanup costs and by December 1995 they had paid $129 million to cover the federal government's share (MacDonald, 2000). In 1996, a subsidiary of Occidental Chemical assumed full operation and maintenance of the chemical waste treatment plant at the Love Canal site, implying that the site was still not completely remediated at that time.

It was contamination at Love Canal, the associated human health consequences, and the cleanup costs that energized the creation of the Resource Conservation and Recovery Act (RCRA) and the Comprehensive Emergency Response, Compensation, and Liability Act (CERCLA) legislation in the United States to assure that such sites were properly addressed. Implicit in this legislation, which has driven a large portion of groundwater cleanup efforts in the United Sates, is the concept of the risks posed by groundwater contamination. Ultimately, the danger posed by contamination of groundwater resources to human health and the environment can ideally be quantified through an assessment of risk. Risk may be defined in terms of the potential for loss, harm, or damage, and the degree of probability of such harm (Kaplan and Garrick, 1981). Hazard represents the source of danger. In the context of environmental systems, hazards that may create risks are toxins, nuclear materials, and so on. Safeguards may include physical, chemical, or biological barriers to passage, regulatory action, or avoidance of the hazard. Quantitatively, risk is further defined succinctly as a series of three steps: (i) scenario identification or description (i.e. what can go wrong?), (ii) the probability of the scenario (i.e. how likely is it to happen?), and (iii) the consequence or measure of damage (i.e. what are the consequences if it does happen?). Defining the probabilities involved with the hazard, the transport of the hazard (or pathway), and the exposure parameters creates a broader understanding of the risk. For contaminants, risk may be described as the probability that a certain concentration of toxic material will reach a receptor and cause adverse health effects. In 1983, the United States National Academy of Sciences developed a risk assessment paradigm (National Research Council, 1983) that consists of four components:

- *Hazard identification:* The analysis of the physical and chemical properties of the contaminant, the metabolic properties and toxicological effects of the contaminant, including data from both long and short-term animal studies, and the routes of exposure.
- *Dose-response assessment:* The quantification of risk versus dose, confirmation of the effects of the toxin on humans, and extrapolation from the high dosages given to animal test subjects to the low dosages expected to be seen in humans.
- *Exposure assessment:* The analysis of the information for each chemical or mixture, possible sources, the exposure pathways and environmental fate, the measured or estimated concentrations, the exposed populations, and finally an integrated exposure analysis.
- *Risk characterization:* The numerical estimation of risk using the concept of unit risk, the dose corresponding to a given risk, the individual probability of the risk, and the framework to judge the significance of the risk.

Given this paradigm, the simplest approach to risk assessment entails establishing a proscribed concentration threshold for contaminant concentrations in groundwater that is protective of human health, by some definition, regardless of potential exposure pathways. For example, the United States EPA has proscribed Maximum Contaminant Levels (MCLs) for various chemical contaminants (Table 2) that are founded on a generalized risk assessment methodology, taking into account epidemiology studies performed on animals. Although there are advantages for using approaches such as MCLs to establish groundwater contaminant cleanup goals as opposed to site-specific risk assessments, such as consistency and simplicity, these advantages are fast disappearing as risk modeling methodologies improve, particularly through use of databases and geographic information system (GIS) approaches.

In contrast to the general applicability offered by the MCL approach or similar proscribed concentration thresholds, a major advantage for site-specific risk assessments is flexibility in considering the site conditions and the likelihood that receptors such as water resources or humans will be exposed to risk. For example, risk-based goals at groundwater contamination sites in the United States typically range from levels of 10^{-4} to 10^{-6} excess cancer risk over a lifetime from a continuous exposure to a suspected carcinogen contaminant. For noncarcinogens, a hazard index is often developed to quantify the potential for causing harm; cleanup goals are implemented to maintain a low hazard index. Other pseudo risk-based approaches include remediation to background levels or analytical detection limits of the contaminants of concern.

Although risk-based cleanup goals provide a structured framework for implementing remedial action plans, a number of factors may complicate application at any given groundwater contamination site. These may include taste and odor threshold concentrations, which may or may not correspond to toxicity effects, as well as economic and cost-benefit considerations for various remedial options. In cases where institutional controls such as land use restrictions are implemented as part of a remedial solution, the potential may exist for contaminant plumes to migrate under an adjoining property, resulting in property owners potentially

assuming an added liability, with a corresponding detrimental effect on property values, or the institutional controls my be simply ignored, as in the Love Canal example. At sites where analytical detection limits are established as the cleanup threshold, reductions in detection limits at some later date because of technological advances can potentially result in sites that have been declared "clean" being reopened. Finally, conventional risk-based cleanup strategies often fail to assess the costs and benefits of aquifer remediation in comparison with simple wellhead treatment options.

REMEDIATION TECHNOLOGIES

Ideally, strategies to remediate groundwater take into consideration an understanding of the physical and chemical processes that affect contaminant behavior as well as an assessment of the risks posed by contamination in terms of sources, exposure pathways, and receptors. Thus, in principle, many remediation approaches incorporate both technical and administrative components.

Remediation approaches may be grouped broadly into two general categories: active methods and passive methods. Active methods entail the application of engineered technology to physically remove contaminated groundwater for treatment or, alternatively, to actively destroy contaminants *in situ* (refer to Kobus *et al.*, 1996). Passive methods rely upon natural processes in groundwater to mitigate contamination without direct human intervention, other than monitoring. Some of the more widely used active and passive remediation approaches are discussed below.

ACTIVE METHODS

Pump and Treat

"Pump and treat" is the term used to describe the most common technology in use today to remediate contaminated groundwater (National Research Council, 1994). In the simplest case, extraction wells are installed with well screens at the depth of the groundwater contamination. The wellfield is designed such that the placement of the wells and the groundwater pumping rates provide a zone or zones of capture that will remediate the plume. The contaminated groundwater is pumped to a surface-based treatment facility designed to remove the particular contaminant or contaminants from the water. The treated effluent is then discharged in such a manner that it does not interfere with the pumping wellfield, or enhances the capture of the contaminated plume.

In designing an optimal remediation wellfield, it is critical to maintain and sample sufficient monitor wells to understand the effect of the pumping wellfield. Identification of capture zones and how they change with stress on the wellfield, identification of stagnation zones and how they change with individual well pumping rates, and monitoring of contaminant concentrations throughout the plume provide the necessary data to manage the efficient operation of the cleanup. In response to monitoring data, an efficient remediation scheme, designed to cleanup the groundwater as quickly as possible, will alter pumping rates, turn extraction wells on or off, and install new extraction wells at locations that are not being remediated (Hoffman, 1993). Methods for evaluating pump and treat system performance, and tools for creating optimal efficient pumping schemes are discussed in Gorelick *et al.* (1993) and Fetter (1993).

Because of the different physical and chemical characteristics of the individual areas of contaminant plumes and because of the varying public health and environmental risks posed by individual plumes, different pump and treat strategies may be applied (Hoffman *et al.*, 2003). Source areas often contain contaminants as separate-phase or high-concentration dissolved chemicals in both coarse and fine-grained sediments (high- and low permeability materials, respectively) or other aquifer materials. Since it is difficult to hydraulically stress low permeability geologic materials, a pump and treat strategy of hydraulic containment of the source area is often appropriate. Extraction wells are placed downgradient of the source area in such a fashion that the entire source area falls within the capture area of the extraction wellfield. Such a strategy prevents any more contaminant mass from migrating into the distal plume, away from the source area, remediates the contaminated permeable materials within the source area, and begins the remediation of the contaminants in the less permeable zones at a slower rate based on their diffusion rates from the low permeability zones into the permeable zones. For those plumes where it is necessary to prevent any further down-gradient movement, such as those in the vicinity of groundwater supply wells, an extraction wellfield at the leading edge of the plume is appropriate. Such a wellfield is designed to create a capture zone large enough to protect the groundwater resource from the encroaching contamination.

With the source area and leading edge hydraulically controlled, an extraction wellfield can be designed to cleanup the remainder of the distal plume expeditiously. Since this part of the plume is essentially limited to the permeable aquifer materials, a well-designed and monitored wellfield can be operated to remediate the distal plume to specified cleanup levels in much less time than it took the groundwater to be contaminated in the first place. Under this scenario, the source area will take much longer to remediate, but the hydraulic control will hold the contaminants in place pending the deployment, development, or improvement of a technology that will accelerate the extraction of the contaminants from the finer-grained materials. At the time of this writing, source

area remediation remains one of the leading challenges for groundwater cleanup.

Soil Vapor Extraction

Soil Vapor Extraction (SVE) is a cleanup technology that may be useful as part of the cleanup of source areas that are contaminated with volatile components. SVE entails the installation of wells, screened partially or fully within the vadose zone, designed to pump soil vapors, including the contaminants, out of the subsurface. Investigations of the probable source areas are conducted using soil vapor surveys (SVS). An SVS can include active pumping and analysis of vapors from vadose zone wells or passive surveys using devices that are placed in the subsurface to collect contaminants that are being transported by vapors through the vadose zone. These devices are collected and analyzed following a specified deployment period.

If soil vapor transport modeling, using the results of the SVS, indicates that the concentrations of contaminants in the soil vapor could cause an inhalation risk or could eventually result in the contamination of groundwater at concentrations that exceed specified action levels, then SVE may be appropriate for the site provided that the soil air permeability is sufficiently high to allow for efficient operation of the SVE system (Johnson *et al.*, 1990). Soil vapors are extracted from the subsurface, and contaminants are removed or destroyed by various treatment technologies such as activated carbon absorption or combustion.

Permeable Reactive Barriers

Permeable reactive barriers (PRB) involve the emplacement of a physical, biological, or chemical reagent in the pathway of a contaminant plume such that the contaminants are treated as they pass through the barrier. The transport of the contaminants to and through the PRB can be dependent on the natural gradient of the groundwater or enhanced by stressing the aquifer containing the plume through down gradient pumping. A physical reactive agent is designed to sorb the contaminant to prevent its continued movement, while the chemical and/or biological reactants may transform the particular contaminant into nontoxic, nonhazardous, or nonmobile components. A familiar example of the PRB application is the placement of walls of elemental iron filings in the subsurface to chemically reduce contaminants such as chlorinated hydrocarbons (reductive dehalogenation) or uranium (reduction and immobilization). Specific technical issues and deployment experiences with elemental iron-based PRBs are discussed by Gavaskar *et al.* (1998).

PRBs can be emplaced in trenches for shallow systems or injected into place for deeper systems. Injection systems vary from injections at moderate pressures to displace pore water with the reactant, to high-pressure injection systems that inject a combination of reactant and permeable materials. Some PRB designs use the "funnel and gate" technology. "Funnels" consisting of impermeable barriers, such as sheet pilings or slurry walls are installed to direct the contaminant plume to the "gate" where the PRB is emplaced. For shallow systems, the PRB can be installed in a removable cartridge or cartridges whose reactants can be replenished. Multiple cartridges containing different reactants can be installed to accommodate multicomponent plumes. Establishing a biological reactive barrier may include emplacement of nutrients to promote the growth of indigenous microbes or emplacement of colonies of nonnative microbes tailored to the particular contaminant.

The advantages of PRBs are that once they are emplaced, the surface can be restored to its previous beneficial use, and the system itself requires little if any maintenance, and does not consume any resources such as electric power. The disadvantages include the dependence on the slow movement of groundwater to deliver the contaminants to the reactant, and the finite life of the reactant (National Research Council, 1994).

Other Remediation Technologies

Other remediation technologies include chemical injection flooding, augmented bioremediation, thermal techniques, and surfactant flooding. Chemical injection and bioremediation techniques include flooding the area of contaminated plumes with reagents, nutrients, or microbes designed to degrade, destroy, or immobilize contaminants. Surfactants are chemical agents designed to increase the mobility of low-solubility contaminants so that other technologies like pump and treat can be made more effective. The success of this approach is dependent on achieving contact between the surfactant and the contaminant. Details of these and other technologies are provided in Pankow and Cherry (1996) and National Research Council (1999). Thermal techniques such as steam flooding to flush contaminants from one area to an area of extraction, and joule heating to volatilize and increase the mobility of some contaminants, have also been demonstrated (Newmark, 1994).

The uncertainties accompanying these various techniques include the physical mechanisms of ensuring that the emplaced materials will come into contact with the contaminants to allow them to do their work, and, in the case of thermal technologies, uncertainties related to controlling the system once it is implemented.

Passive Methods

Monitored Natural Attenuation

Monitored natural attenuation (MNA) is a broad remedy that may be useful (or acceptable) in those circumstances where natural existing processes in the subsurface are causing the contaminants to degrade, become immobilized, or in other ways not causing an unacceptable risk to human

health or the environment (National Research Council, 2000). The MNA remedy must include an understanding of the physical, chemical, and/or biological processes that reduce the risk of the contaminant and a monitoring network that will continue to ensure that the risk does not increase. MNA approaches are perhaps most familiar in the case of fuel hydrocarbon compounds, such as at leaking underground fuel tank sites, where numerous studies have demonstrated that natural biodegradation processes act to limit the downgradient movement of contaminant plumes (Rice *et al.*, 1995).

In considering instances when MNA may provide a viable remedial option, a number of factors must be taken into consideration. The technical issues that must be resolved include whether a contaminant is destroyed (e.g. fuel hydrocarbons) or merely immobilized by natural processes (e.g. metals), whether the rate of attenuation is sufficiently rapid, whether chemical or biological attenuation mechanisms could produce toxic by-products (e.g. vinyl chloride from the reductive dehalogenation of TCE or PCE), and whether a mixture of compounds may exist of varying susceptibility to attenuation mechanisms (e.g. fuel hydrocarbons and MTBE). Moreover, some decision-assisting protocol must be in place to provide standards for evaluating the validity of proposed attenuation processes at a given site and to determine when MNA provides a suitable reduction of risk. Finally, public concerns in regard to an MNA solution, such as perceptions of continued health risk or threat to property values, must also be addressed.

Institutional Controls

Institutional controls represent not a technology *per se* but rather an administrative approach to reducing risk. Instead of relying upon engineered or natural processes to mitigate contaminant sources or to interfere with contaminant travel pathways, institutional controls seek to remove the receptor from the risk equation. In practice, this is attempted through the use of devices such as deed restrictions, where a landowner is bound not to use a property in a manner that would expose humans to contaminants, or groundwater resource management plans that might control the beneficial use of the pumped water, control the location of extraction wells, or control pumping rates. Institutional controls are often used in tandem with MNA approaches as a means of insuring protection from contaminated groundwater in the event that the MNA solution, which could require years to achieve results, does not perform in an anticipated manner. However, it is important to recognize that institutional controls are only effective when properly recognized and enforced; the case of Love Canal exemplifies the danger of assuming that institutional controls intended to be protective of public health are easily enforced.

CONCLUSION

As a field of study, contaminant hydrogeology has come into its own over the last 50 years as groundwater investigations and new, more sensitive, chemical analytical procedures have been developed, and groundwater problems have been discovered. In this article, the extent of the problems of groundwater contamination around the globe has been discussed and some of the physical and chemical processes that govern transport of contaminants in the subsurface have been described. Many of the common technologies for investigating and cleaning up contaminated groundwater have been introduced and the strengths and limitations of each approach described. While great strides have been made in controlling groundwater contaminant plumes, the challenges of understanding the subsurface environment in chronically undersampled situations continue to provide room for considerable improvement in the field. In the last decade, much of the research in the field has focused on the *in situ* treatment of groundwater contaminants, and the next decade should provide full-scale field demonstrations of their efficacy. Another area of needed study is the behavior of contaminants in fine-grained geologic materials in contaminant source areas and the development of source area cleanup technologies. With the continued improvement of the efficiency of existing groundwater cleanup technologies and the development of new source area and *in situ* technologies, it is hoped that groundwater resources will be restored to a quality that allows it to take its place in responding to future crises in the growing global problems of water shortages.

154: Stochastic Modeling of Flow and Transport in Porous and Fractured Media

SOUHEIL M EZZEDINE

University of California, Lawrence Livermore National Laboratory, Livermore, CA, US

Estimation of various flow and mass transport parameters can be seen as a problem of spatial statistics. The definition of the properties of porous and fractured media in space and time using the concept of random functions provides means for (i) studying the inherent heterogeneity, (ii) evaluating the spatiotemporal variability of the properties, and (iii) assessing the uncertainty associated with their estimated values. In this chapter, the fundamentals of stochastic subsurface hydrology are presented. Applications include mapping hydrogeological properties, flow and transport in porous and fractured media, and inverse problems.

INTRODUCTION

Stochastic analysis has two main historic roots: One is in the analysis of the so-called *random errors* in measurements of physical entities, which has gradually embraced the study of irregularities and *uncertainties* observed in what were believed to be deterministic phenomena and has led to the discipline of *mathematical statistics*; the other root is in the study of *games of chance*, which has led to the *theory of probability*. Originally, both these branches of science were confined to the realm of mathematics and did not interfere much with the deterministic concept of the physical world governed by the laws of Newton's mechanics and uniquely describable by the differential calculus. At that instance, the only problems seemed to be (i) to develop the theory in sufficient detail, (ii) to ascertain the initial conditions, and (iii) to avoid measurement errors. All discrepancies between theory and observation and uncertainties in the prediction of physical phenomena were attributed to human limitations. All this changed with the establishment of the quantum theory, which introduces the revolutionary concept that uncertainty, apart from being the result of human limitations, is also an intrinsic feature of matter itself. This concept has transformed statistics and probability from a tool dealing with a *noise* in the laws of nature into a tool for the formulation of these laws themselves.

Undeniably, natural porous and fractured formations are heterogeneous, and display spatial variability of their petrophysical properties. This variability is of irregular and complex nature. It generally defies a precise quantitative description because of insufficient information at all relevant scales. In practice, however, only sparse scale-dependent measurements are available mainly due to limited costs. Owing to lack of detailed and exhaustive information, the higher the variability the higher is the uncertainty. For this very reason, stochastic approaches have been developed in subsurface hydrology to "fill in" or bridge the gap between the overall knowledge about the "physical law" and the strong spatial variation of the petrophysical properties, which are known through sparse tainted measurements. The theory of random, or stochastic, processes provides a natural framework for evaluating aquifer uncertainties. In the stochastic formalism, uncertainty is represented by probability or by related quantities like statistical moments. Boundary conditions, initial conditions, and parameters can be treated as random functions or fields whose values are determined by probability distributions conditional to sparse measurements or information.

The definition of the properties of porous media in space and time using the concept of random functions has two major advantages: (i) It conceptually defines the properties in space at a given point, without having to define a volume over which these properties must be integrated. (ii) It provides means for studying the inherent heterogeneity and variability of these properties in space, and for evaluating the uncertainty of any method

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

of estimation of their values. The pioneering works of Schvidler (1962) and Matheron (1965) were the backbone of the work of Gedeon Dagan and Lynn Gelhar who have shaped and popularized what stochastic subsurface hydrology is today. A few monographs have since been published to cover the richness, strengths, and weakness of the stochastic methods. These monographs include a wealth of references, and we urge readers to consult them and the references therein. In this article, we will cover the *fundamentals* or in other words what became the *need-to-know* in stochastic subsurface flow and transport. For more advanced topics, we urge interested readers to consult most recent publications.

DETERMINISTIC, RANDOM, AND STOCHASTIC CONCEPTS

Of these three, the term deterministic is probably least ambiguous and involves a one-to-one relationship among events. The term random is often used as a synonym for stochastic, however, statistically speaking, there is a difference. The term *random* will be used for a completely irregular order or arrangement of elements from a given set. Thus, for instance, a random sequence or series will mean one whose terms are mutually independent and therefore uncorrelated. In the literature, this notion is often termed *pure random*. The term *stochastic* will be used for a relationship, a variable, or a process, incorporating both an element of randomness and an element of determinism. Thus a stochastic entity Y, that is, the logarithm of the hydraulic conductivity K, will be viewed as a sum $Y = \langle Y \rangle + Y'$ where $\langle Y \rangle$ and Y' are the deterministic and random components, respectively. The deterministic component is often interpreted as an *overall trend* or *signal* and the random component as *error* or *noise*. In agreement with the original meaning of the Greek word $\sigma\tau\acute{o}o\zeta$ ([stokhos] target or aim), a stochastic relationship can be viewed as one *aiming at* the relationship indicated by the deterministic component. It follows that the two concepts, deterministic and random, are only special cases of stochastic and represent its two end limits approached as one or the other of the two components tends to zero. According to this interpretation, strictly deterministic relationships cannot be proved to exist in the real world since any verification involves measurement on the one hand and exact reproducibility on the other. Whether, due to the *limited accuracy of measurement* or due to the *intrinsic impossibility of exact* or *exhaustive* depiction of any specific petrophysical parameter, there is always a noise and purely deterministic relationship.

It may be noted that our intuitive perception of deterministic laws is in fact stochastic; we expect that actual measurements will agree only approximately with a given deterministic law. As a typical example from hydrogeology, one may take the concept of the pumping test. Though classified as a deterministic model, pumping tests in heterogeneous aquifer are expected to yield integrated and approximated value of the transmissivity (or hydraulic conductivity) and the storativity coefficient of the aquifer. Those values *minimize the square of the errors* between the theoretical model (the physical law) and the measurements (drawdown vs. time) and represent the deterministic component of the intuitively implied stochastic relationship between pumping rate and drawdown.

Similarly, any other deterministic law or model can be interpreted as a stochastic model in which the random component is not explicitly taken into account. It may be too small to be detected by the measuring apparatus or, though detectable, small enough in comparison with the deterministic component to be neglected; or, for the sake of simplicity, it may be *filtered* out. An important aspect of the above definition of *stochasticity* is that it does not imply any specific origin of the random element. It does not differentiate between a case where the latter accounts merely for the analyst's *limited knowledge* of some deterministic components and one where it might be an inherent feature of the analyzed phenomenon.

Limited knowledge of information in both observed data (i.e. hydraulic head, concentration), and measured petrophysical properties (i.e. hydraulic conductivity, porosity) and their spatial distribution causes uncertain predictions. *Spatial variability* and uncertainty have led engineers and geologists to use probabilistic theories that translate the uncertainty to a *random space function* (RSF) or a *random field*, consisting of an *ensemble* of "*infinite*" number of *equally probable realizations* of parameter values, all having the same spatial statistics, particularly correlation structure. Imbedded in this approach is a *geostatistical* model.

Geostatistics is commonly used to analyze and interpolate between measurements using methods such as *kriging* (pronounced as in brid*ging*), where the uncertainties in kriged (pronounced as in brid*ged*) values are also quantified. Usually, these data are collected on different scales that may differ from the required scale of predictions. The task of quantitatively relating measurements and properties on different scales is difficult and intriguing. We briefly present in the following section the essence of geostatistics.

GEOSTATISTICS

Geostatistics has its basis in Matheron's (1965) *Theory of Regionalized Variables*. A random variable is one that has a variety of values in accordance with a particular probability distribution (Journel and Huijbregts, 1978). If the random variable is distributed in space and/or time, we say that it is a regionalized variable. These variables, because of their spatial-temporal character, have a random as well as a

structural component. At first sight, a regionalized variable seems to be a contradiction. In one sense, it is a random variable that locally does not have any relation to the nearby variables. On the other hand, there is a structural aspect in the regionalized variable that depends on the distance of separation of the variables. Both characteristics can be described, however, using a random function for which each regionalized variable is a particular realization. By incorporating the random as well as the structural aspects of a variable in a simple function, the spatial variability can be addressed on the basis of the spatial structure shown by these variables. In this sense, a regionalized variable is a variable that qualifies a phenomenon that is distributed through space and/or in time and that presents a certain correlation structure. Following are useful applications of geostatistics:

- *Characterization of large data sets*: For spatially distributed data, the resolution of measurement points is mostly rather low. By contrast, time series often consist of thousands of measurements. Therefore, condensing the information may be necessary. In this context, the *probability density function* (pdf) of the measured quantity (which is characterized by its mean and variance if the pdf is Gaussian) and some information about the average persistence (like the auto-covariance function, variograms) may be adequate.
- *Interpolation*: Given point-measurements in space, one is asked to create maps of the measured quantity. This requires interpolation. In the geostatistical framework, spatial interpolation is identical to conditioning, that is, in the vicinity of a measurement point, the expected value of the unknown is, due to the spatial correlation, weighted toward the measured value, and the variance is decreased. Taking the mean of the conditional pdf as interpolated value is referred to as kriging. In contrast to other interpolation techniques, kriging allows to evaluate and assess the uncertainty of the interpolated value indicating also where an additional measurement would be most valuable.
- *Inverse modeling*: The geostatistical approach of inversing is essentially identical to that of interpolation. The difference is that cross-covariances describing the spatial correlation between different variables (such as hydraulic head and log-conductivity) are used rather than auto-covariance functions. This is referred to as cokriging. As will be shown later, cross-covariance functions can be calculated from the auto-covariance functions and the governing partial differential equation. Like kriging, cokriging yields not only the best estimate but also the spatial distribution of the uncertainty related to that estimate.
- *Monte Carlo simulations:* (*MCSs*): MCS is somewhat the experimental numerical apparatus of statisticians. By creating equally probable conditional realizations, preferably conditional to measured data, of the hydraulic conductivity field for example, one can simulate the flow and transport for each realization. All the results are then averaged to predict the probabilistic behavior of the flow and transport in the aquifer. In this context, using multiple realizations is justified by the uncertainty in the interpolation between measurements.

Basic Statistical Treatment

As a first step, the quality of the data is proved, and the basic statistical calculations from which the statistics or measurements are obtained are performed. These are the numerical values that enable us to characterize and compare the statistical distributions. These statistics can be made on the variable itself, or some transformation of the variable (e.g. logarithmic, log). They can be of several types, as follows:

1. *Measurements of centralization*: These measurements indicate a value around which the distribution values are distributed. They are generically known as *means*, and have the following forms. The arithmetic mean or mean, m. The median, M, is the value that divides the population into two equal parts. It is the quartile of 50% (Q_2). The lower quartile, Q_1, is the value with 25% of the population below it and the remaining 75% above it. The upper quartile, Q_3, is the value with 75% of the population below it and the remaining 25% above it. The mode, Mo, is the value of the greatest absolute frequency of a distribution. Other means such as harmonic and geometric means are of great interest. The geometric mean is defined as the mean of the log-transformed measurements, and the harmonic mean as the mean of the inverse of the measurements.
2. *Measurements of dispersion*: These measurements indicate the variability of dispersion of the values of a distribution. The variance, σ^2, is the average of the squares of the deviations with respect to the mean. The standard deviation, σ, is the square root of the variance and represents the margin of the variation or the error of estimation in which the data analyzed are included. It has the same units as the variable under consideration. The range, $\Re$, of a distribution is the difference between the extremes, maximum and minimum values. The coefficient of variation, CV, is the quotient of the standard deviation and the mean. It enables us to compare distributions that have different units. There is a direct relation between the value of this parameter and the dispersion of the distribution. The interquartile range, IR, is the difference between the upper quartile and the lower quartile and it indicates the range between which 50% of the central values of the population are distributed.
3. *Distribution moments*: These can be central or with respect to the origin. The central moment of order r,

Table 1 Basic Univariate statistics

$\{x_i \mid i = 1, \ldots, N\}$ being a set of data	
Observations #	N
Histogram and cumulative histogram	$F(x_i)$, $CF(x_i)$
Minimum	$\min/\forall x_i$, $\min \leq x_i$, $i = 1, \ldots, N$
25th% Percentile	Q_i
Mode	Mo
Median or 50th % Percentile	M
Mean	$m = \frac{1}{N}\sum_{i=1}^{N} x_i$
75th % Percentile	Q_3
Maximum	$\max/\forall x_i$, $\max \geq x_i$, $i = 1, \ldots, N$
Variance	$\sigma^2 = \frac{1}{N}\sum_{i=1}^{N}(x_i - m)^2$
Standard deviation	$\sigma = \sqrt{\frac{1}{N}\sum_{i=1}^{N}(x_i - m)^2}$
Coefficient of variation (%)	$CV = \frac{\sigma}{m}$
Range	$R = \max - \min$
Interquartilic range	$IR = Q_3 - Q_4$
3rd Order central moment M_3	$M_3 = \frac{1}{N}\sum_{i=1}^{N}(x_i - m)^3$
Coefficient of skewness	$CS = \frac{M_3}{\sigma^3}$
4th Order central moment M_4	$M_4 = \frac{1}{N}\sum_{i=1}^{N}(x_i - m)^4$
Coefficient of Kurtosis	$CK = \frac{M_4}{\sigma^4}$

M_r, is the average of the deviation with respect to the mean taken to order r.

4. *Asymmetry or skewness measurements*: These provide an idea of the asymmetry of the distribution. A distribution is *symmetric* when the frequencies corresponding to equidistant values with respect to a central value are equal. In the ideal symmetry condition, the values of the mean, median, and mode coincide. A distribution has a *bias to the right* or is *positive* if the frequencies descend more slowly on the right of the histogram. In this case, the mean is greater than the mode. A distribution has its *bias to the left* or is *negative* if the frequencies descend more slowly on the left of the histogram. In this case, the mean is less than the mode. The *coefficient of skewness*, CS, calculated in terms of the moments, is the ratio between the moment of order 3 and the standard deviation cubed.
5. *Measurements of kurtosis*: These indicate the degree of kurtosis with respect to a normal or Gaussian distribution. The *coefficient of kurtosis*, CK, calculated in terms of the moments, is the ratio between the moment of order 4 and the standard deviation taken to the fourth power. In a Gaussian or normal distribution, this coefficient CK is 3 and its curve is normal or *mesokurtic*. If CK is greater than 3, the distribution has a *leptokurtic* curve, which is sharper than the Gaussian one. If CK is less than 3 the distribution has a *platikurtic* curve, which is flatter than the Gaussian one. The analytic expressions of the above concepts are given in Table 1.

Geostatistical Description of Spatially Variable Parameters

Depicting heterogeneity of aquifers is a daunting task and could be achieved through two approaches. On the one hand, solely on the basis of the geological deposition processes, one can create images (realizations) of the subsurface heterogeneity (Gelhar, 1992; Rubin, 2003). Unfortunately, the geology-based models are limited because it is difficult to integrate the geological observations. However, statistical and geostatistical methods honor the measured data regardless of their origin: *hard data* (direct measurements of the variable to be mapped, *primary variable*) or *soft data* (indirect measurements of the variable in consideration, *secondary variable*). Honoring data is usually

referred to as *conditioning*. Conditioning on soft data usually necessitates a physical law and/or a linear or nonlinear relationship or correlation that bind the secondary variable to the primary one (i.e. Ezzedine *et al.*, 1999).

A statistical description of hydraulic properties is equivalent to interpreting the distribution as an outcome of a random process. As a consequence, an infinite number of different distributions sharing the same statistical description are possible. Introducing conditioning decreases the variability but does not change the fact that an infinite number of realizations are equally probable. Our limited knowledge of the "true" setting through only contaminated sparse measurements of hydraulic properties made the stochastic techniques a *must* for interpolation and uncertainty assessment.

For example, one will take a certain number of core samples and analyze them to get point information about the hydraulic conductivity. On the basis of these data one may estimate the hydraulic conductivity distribution. At *every* location within the aquifer, the conductivity value is estimated by *interpolation* and so its level of *confidence* or *uncertainty*. It is rather unlikely that the interpolated value is the true one. Therefore, using the interpolated conductivity field as *unique* (single) realization in a flow and transport simulator may lead to biased outcome.

Statistics of Spatial Variables

In order to describe a spatial field, such as the hydraulic conductivity within an aquifer, by geostatistics, we must conduct as many point-measurements of the quantity of interest as possible. Without loss of generality, we focus on the log-hydraulic conductivity $Y = \ln(K)$. The simplest single-variate statistical description of the data set is the *mean* (1st moment) and the *variance* (2nd moment):

$$\mathbf{E}[Y] \cong \overline{Y} = \frac{1}{n}\sum_i Y_i = \int y f_Y(y)\ \mathrm{d}y \tag{1}$$

$$\mathbf{Var}[Y] = \mathbf{E}[(Y - \mathbf{E}[Y])^2] \cong \sigma_Y^2 = \frac{1}{n-1}\sum_i (Y_i - \overline{Y})^2 \tag{2}$$

where $Y_i(x)$ is the value of Y at a location x_i, and $\mathbf{E}[]$ and $\mathbf{Var}[]$ are the expected, and the variance *operator*, respectively. If Y is *normal* (*Gaussian*), then the first and second moment are sufficient to describe Y, otherwise higher statistical moments are needed. They further enhance the statistical characterization of Y, the hydraulic conductivity is considered as a *spatial random function* (SRF). Its value may differ from one location, $\mathbf{x}_1 = (x_1, x_2, x_3)_1$, to another, $\mathbf{x}_2 = (x_1, x_2, x_3)_2$. Consequently the *similarity* between the values of Y at different locations is expressed by the *covariance* function, which is defined by

$$\mathbf{Cov}[Y(\mathbf{x}_1)Y(\mathbf{x}_2)] = \mathbf{E}[(Y(\mathbf{x}_1) - \mathbf{E}[Y(\mathbf{x}_1)])(Y(\mathbf{x}_2) - \mathbf{E}[Y(\mathbf{x}_2)])] \tag{3}$$

Cov[] is the covariance operator. It is worth mentioning that the covariance does not always exist, given the type of variability of the variable. When dealing with a single data set, **Cov** is called *auto-covariance*. Otherwise, when dealing with multiple data sets, that is, the hydraulic conductivity and head, the similarity is termed as *cross-covariance*. Furthermore, when a SRF is said to be *stationary*, the **Cov** operator depends solely on the separation distance $\mathbf{h} = \mathbf{x}_1 - \mathbf{x}_2$, $\mathbf{Cov}[Y(\mathbf{x}_1)Y(\mathbf{x}_2)] = \mathbf{Cov}[Y(\mathbf{h})]$, regardless their locations, otherwise the SRF is location-dependent and called *nonstationary*. Stationarity has different levels, that is, *weak* and *strong* and we will discuss them later. It is worth noting that when h vanishes, the covariance reduces to σ_Y^2. Similarly, the *correlation function* or *correlogram* ρ of a SRF is also defined. The correlation function $\rho(\mathbf{h}) = \mathbf{Cov}[Y(\mathbf{h})]/\sigma_Y^2$ takes values in $[-1, +1]$. When $\rho = 0$ there is no correlation, the data sets are independent. Otherwise when $\rho = \pm 1$, there is a total (perfect) positive/negative (direct/indirect) correlation. The definition of the covariance assumes that the mean is known, which in reality may not be the case, and that a covariance exists. To overcome this limitation, Matheron suggested the use of yet another similarity measure, the variogram γ defined by

$$\gamma_{YY}(\mathbf{h}) = \frac{1}{2}\mathbf{E}[(Y(\mathbf{x}_i) - Y(\mathbf{x}_j)]^2 = \frac{1}{2n(\mathbf{h})}\sum_{\substack{i,j \\ h=x_i-x_j}}$$

$$(Y_i - Y_j)^2 = \sigma_Y^2 - \mathbf{Cov}[(Y(\mathbf{x}_i) - Y(\mathbf{x}_j)] \tag{4}$$

The word *semivariogram* stems from $1/2$ term in the above notation. The names variogram and semivariogram are used interchangeably. The variogram has two attractive properties: (i) γ is linked to the **Cov** through the variance σ_Y^2, (ii) it is defined even when the variance itself is not finite, that is, does not exist. A stationary SRF with a, not necessarily known, constant mean and a variogram is referred to as *intrinsic hypothesis*. Note that these statistical properties can also be defined in space and time, called *spatiotemporal* statistical tools and we urge the reader to consult Christakos (1992) for more details. These tools have become the main engine behind geology-related estimation problems since the 1960s. Matheron coined the word *geostatistics* since it relates the field of geology to the field of statistics as is in geophysics for example. In the next section we will tackle the variogram analysis, that is, the main step behind any geostatistical application.

Typical Covariances and Variograms

For the sake of clarity, we introduce only the typical covariances and variograms under stationarity hypothesis. The common models are (i) exponential, Gaussian, spherical,

and power-law models. The *exponential* model is given by

$$C_Y(\mathbf{h}) = \sigma_Y^2\, e^{-h}, \quad \mathbf{h} = \sqrt{\sum_{\mathbf{i}} \left(\frac{\mathbf{h_i}}{\boldsymbol{\lambda_i}}\right)^2},$$

$$\gamma(\mathbf{h}) = \sigma_Y^2(1 - e^{-h}) \tag{5}$$

where λ_i are correlation lengths (range, scaling parameters which can be different in different directions, in case of anisotropy of the variability, Figure 1). Because $\mathbf{h}$ is positive, the variogram slowly reaches a finite limit for large values of $\mathbf{h}$. This limit is called *sill* and, in this particular case, it is equal to the variance. Because the exponential model has very attractive mathematical properties, various analytical solutions for stationary Y random fields with an exponential covariance have been developed. One should notice that the derivative at the origin does not vanish. This causes small-scale variability. Such a behavior does not occur in the *Gaussian* model given by

$$C_Y(\mathbf{h}) = \sigma_Y^2\, e^{-h^2}, \quad \mathbf{h} = \sqrt{\sum_{i} \left(\frac{h_i}{\lambda_i}\right)^2},$$

$$\gamma(\mathbf{h}) = \sigma_Y^2(1 - e^{-h^2}) \tag{6}$$

Contrary to the exponential model, the Gaussian model converges faster to the sill (Figure 2). The Gaussian model is much smoother and gradual interpolator than the exponential model. This is different in the *spherical* model:

$$C_Y(\mathbf{h}) = \begin{cases} \sigma_Y^2\left[1 - \frac{3}{2}h + \frac{1}{2}h^3\right], & h \le 1 \\ 0, \text{otherwise} \end{cases}$$

$$\mathbf{h} = \sqrt{\sum_{i} \left(\frac{h_i}{\lambda_i}\right)^2}$$

$$\gamma(\mathbf{h}) = \begin{cases} \sigma_Y^2\left[\frac{3}{2}h - \frac{1}{2}h^3\right], h \le 1 \\ \sigma_Y^2, \text{otherwise} \end{cases} \tag{7}$$

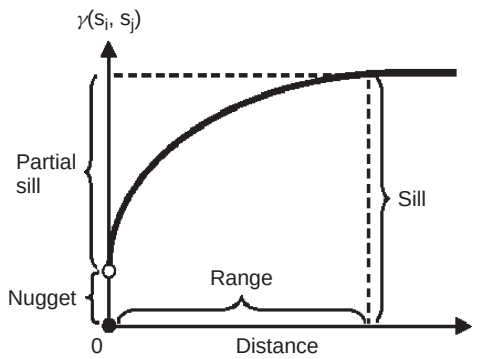

Figure 1 Anatomy of a variogram

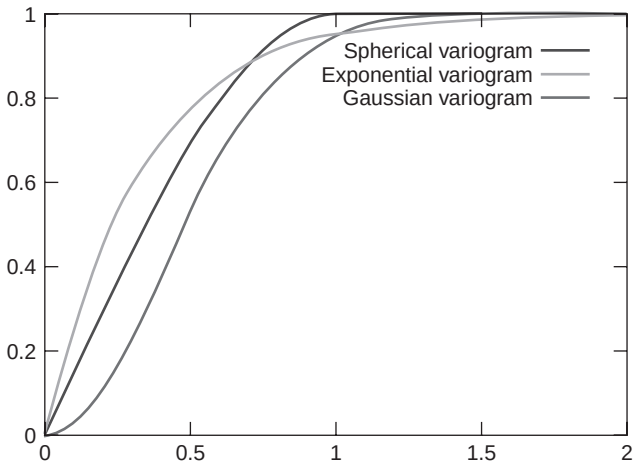

Figure 2 Different variograms. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

The behavior of the spherical model near the origin is nearly linear. Unlike the exponential model, there is no correlation when h is greater than 1. The *power-law*, also called *self-similar* or *fractal*, model in the isotropic case is given by:

$$\gamma_Y(\mathbf{h}) = C\ \mathbf{h}^{2\mathrm{H}}, \quad \text{where} \quad 0 < \mathrm{H} < 1 \tag{8}$$

where C is a constant; H is called the *Hurst* number/exponent. For an exponent $\mathrm{H} = 1/2$, the power variogram reduces to the linear variogram. Y does not have a finite variance because the variability is unbounded, and a covariance function cannot be defined, only a variogram.

Theoretically, variograms vanish at the origin, however, very often, variograms exhibit a finite jump at the origin. This apparent jump at the origin is called *nugget effect* (originated from the mining industry). The nugget effect is taken into account by adding a nugget contribution, γ^0, to γ^t the variogram fitted to the data as if γ^0 were the origin

$$\gamma_Y(h) = \gamma^0(1 - \delta(\mathbf{h})) + \gamma^t(\mathbf{h}) \tag{9}$$

where $\delta(h)$ is the *Kronecker* or *delta function*. A nugget variogram expresses purely random phenomena without any spatial structure. The contribution of the nugget effect may be interpreted as a measurement error or as variability at scales smaller than the measurement scales. Any combination of the mentioned models is possible, and it is called a *nested model* or *nested structure*.

Variograms are direction-dependent; therefore it is useful to evaluate the variogram at different directions (i.e. North, East, West, South and any combinations). Generally, variograms do not show *anisotropy*, different behavior for different direction. If they do, then: (i) it may be a sign that

the assumption of stationarity does not hold, or (ii) the stationarity hypothesis is valid, and thus this anisotropy can be eliminated by a suitable linear transformation of the coordinate system. Otherwise, if the variograms do not show significant directional changes, the variogram is isotropic and *omnidirectional*.

The directional *integral scale* I_i of a covariance function is defined by

$$I_i = \frac{\int_0^\infty \mathbf{Cov}[h_i]\ \mathrm{d}h_i}{\mathbf{Cov}[0]} = \frac{1}{\sigma_Y^2}\int_0^\infty \mathbf{Cov}[h_i]\ \mathrm{d}h_i \qquad (10)$$

where $I = \lambda$ for the exponential model, $\lambda\sqrt{\pi}/2$ for the Gaussian and $3\lambda/8$ for the spherical model. When $I_1 = I_2 = I_3$ the field is isotropic, when $I_1 = I_2 \neq I_3$ the field is axisymmetric, otherwise it is anisotropic.

For sloped strata, a transformation of coordinates into the principal directions of the heterogeneities or a transformation into the stratigraphic coordinates may be necessary to assure that the measurement are correlated with respect to the geological depositions/layering and not to the geographical depth.

Calculation of Experimental Variograms

To estimate a variogram, we use the measurement points Y_i and assume *ergodicity* (i.e. space averages can be used to estimate the averages in the entire set of realizations). First, we define a certain number of distance classes between measurement points. Then, taking into account all possible pairs or points for each class of distances, we calculate: (i) the number of pairs present in that class, (ii) the average distance in the class, and (iii) the average square increments $1/2(Y_i - Y_j)^2$. This is referred to as *experimental variogram*. Generally, the number of pairs is not evenly distributed between the classes of distances due to the scattering of the measurements. There are more pairs at shorter than longer distances. The variogram becomes more uncertain as the separation distance h increases. Once the experimental variogram is calculated, one may fit one of the theoretical models to the experimental variogram. Curve fitting may be biased by the choice of classes and the averaging step. More details on the determination of a fitted variogram are given in Journel and Huijbregts (1978), Isaaks and Srivastava (1989), Kitanidis (1997) to name a few.

Kriging

Consider a set of n measurements of Y with Y_i measured at the location x_i. The variogram $\tilde{\gamma}_{YY}(h)$ is known. We want to estimate the value Y_0 at a location $\mathbf{x}_0$. A linear estimator is a linear combination of the measured data $Y_0^* = \sum_i^n \lambda_{0,i} Y_i$ in which λ_i is the *weighting* factor for measurement Y_i and the * indicates that Y_0 is estimated. If the true unknown value at x_0 is Y_0, the estimation is said to be an *optimal* estimate in the *minimum variance sense* if $\mathbf{E}[(Y_0^* - Y_0)^2]$ is minimal. We also require an *unbiased* estimator; in other words, the expected value of the estimation error is zero: $\mathbf{E}[(Y_0^* - Y_0)] = 0$. The unbiasedness condition yields a constraint on the choice of the weights, that is $1 = \sum_i^n \lambda_{0,i}$, which assumes a constant mean throughout out the domain $\mathbf{E}[Y(\mathbf{x})] = m$. The mean m is not necessarily known. The minimum variance conditions leads to

$$\begin{aligned} &\text{Min } \mathbf{E}[(Y_0^* - Y_0)^2] = \sigma_Y^{2*}(x_0) = -\sum_i \sum_j \lambda_i \lambda_j \\ &\gamma_{YY}(x_i - x_j) + 2\sum_i \lambda_i \gamma_{YY}(x_i - x_0); \\ &\text{subject to} \quad 1 = \sum_i^n \lambda_{0,i} \end{aligned} \qquad (11)$$

To minimization problem, an additional unknown referred to as *Lagrangian multiplier*, μ, (Matheron, 1965) is introduced to enforce the constraint. Taking the derivatives with respect to λ_i and μ, and finding the minimum by equating the derivatives to zero, leads to the following system of n + 1 linear equations:

$$\begin{aligned} &-\sum_j \lambda_j \gamma_{YY}(x_i - x_j) + \mu = \gamma_{YY}(x_i - x_0) \\ &\qquad \forall i = 1, n \quad \text{and} \quad 1 = \sum_i \lambda_i \end{aligned} \qquad (12)$$

This is known as *kriging* system named by Matheron after the South African mining engineer Krige. Because the variogram is a symmetric function, the *matrix* is *symmetric* also, however, it is not *positive definite*. One attractive property of Kriging is that the inverse of the matrix has to be done only once and stored since it does not depend on the location x_0; however, the right-hand vector does dependent on x_0 and has to be updated for each location. The kriging estimator is also referred to as the *Best Linear Unbiased Estimator* (BLUE). Expression for the estimation variance is as follows (Matheron, 1965, see also de Marsily, 1986):

$$\sigma_Y^{2*}(x_0) = \sum_j \lambda_j\ \gamma_{YY}(x_j - x_0) - \mu \qquad (13)$$

The kriging estimator with a constant unknown mean as described here is called *ordinary kriging*. When the mean is known it is called *simple kriging*. One may argue that the contributions of distance measurements are weak and therefore only the immediate measurements within a certain *neighborhood* of x_0, should be considered. In this case, the matrix to be inverted is neighborhood-dependent and has to

be assembled for each point-estimation. Readers are urged to look up Deutsch and Journel (1997), Kitanidis (1997), and Chiles and Delfiner (1999).

Cokriging

Hydraulic conductivity measurements are more intensive to obtain than hydraulic head and, therefore, expensive. Generally, K is estimated using pumping tests; and thus it is not a local measurement but rather an integrated measurement. Head measurements, however, are affordable and sometimes abundant in number. It is imperative then to benefit from the cross-correlation between both SRFs to improve point-estimation of either variable through a more generalized kriging process called *cokriging*. We illustrate it on an exhaustive set of N_Y and N_H measurements of hydraulic conductivity and head, respectively. Assuming that the both $E[Y]$ and $E[H]$ are known the simple Cokriging system for h reads (Rubin, 2003):

$$h(x_0) = E[h(x_0)] + \sum_{i=1}^{N_Y} \lambda_i (Y_i - E[Y]) + \sum_{i=N_Y+1}^{N_Y+N_H} \lambda_i (h_i - E[h]) \quad (14)$$

$$C_{YH}(x_l, x_0) = \sum_{i=1}^{N_Y} \lambda_i C_{YY}(x_l, x_i) + \sum_{i=N_Y+1}^{N_Y+N_H} \lambda_i C_{YH}(x_l, x_i); \quad \forall\, l = 1, N_Y \quad (15)$$

$$C_{HH}(x_0, x_l) = \sum_{i=1}^{N_Y} \lambda_i C_{YH}(x_i, x_l) + \sum_{i=N_Y+1}^{N_Y+N_H} \lambda_i C_{HH}(x_i, x_l); \quad \forall\, l = N_Y + 1, N_Y + N_H \quad (16)$$

and the simple Cokriging system for Y reads

$$Y(x_0) = E[Y] + \sum_{i=1}^{N_Y} \lambda_i (Y_i - E[Y]) + \sum_{i=N_Y+1}^{N_Y+N_H} \lambda_i (h_i - E[h]) \quad (17)$$

$$C_{YH}(x_0, x_l) = \sum_{i=1}^{N_Y} \lambda_i C_{YY}(x_i, x_l) + \sum_{i=N_Y+1}^{N_Y+N_H} \lambda_i C_{YH}(x_i, x_l); \quad \forall\, l = 1, N_Y \quad (18)$$

$$C_{HH}(x_0, x_l) = \sum_{i=1}^{N_Y} \lambda_i C_{YH}(x_i, x_l) + \sum_{i=N_Y+1}^{N_Y+N_H} \lambda_i C_{HH}(x_i, x_l); \quad \forall\, l = N_Y + 1, N_Y + N_H \quad (19)$$

where $E[h(x_0)]$ is the unconditional head mean; $E[Y]$ is the conditional mean of Y; C_{YH} is the $Y-H$ cross-correlation; C_{YY} and C_{HH} are the auto-correlations of Y and H, respectively. When C_{HH} is not defined (unbounded variability) γ_{HH} is used instead and an additional constraint on the unboundedness is added.

Closed form of C_{YH} and γ_{HH} for stationary Y field assuming an exponential covariance function C_{YY}, a uniform steady flow in an infinite domain have been obtained by Dagan (1989) using 2nd order perturbation of the flow field for 2D and 3D cases. The reader is referred to Dagan (1989) and Rubin (2003) for the analytical expressions.

The cokriging process can be generalized to N_Z different Z type of measurements. For illustrative applications of cokriging please (*see* Kitanidis, 1997) and the section on "Inverse Problems as Statistics". It is important to note that the back transform form Y to T is just $T = \exp(Y)$ and that no additional terms are justified, as some authors choose to correct for the biased mean and add a term related to the variance of Y (de Marsily, 1986).

Unconditional and Conditional Simulations

Matheron proposed and implemented the unconditional simulation called *Turning Bands method*. From the 1980s onward, many applications appeared, almost all of which were dedicated to geological mining. In the 1990s, many theoretical aspects have been developed, including new more efficient algorithms such as applications relevant to multiple fields, analysis of basins, treatment of images, simulation of porous and fractured media, simulations of geological lithofacies, and so on. This development has been aided by the widespread use of computers, making it possible to deal with the numerous calculations required. The values of the models obtained using geostatistical simulation agree with the experimental information and reproduce the observed variability. The fact that the variograms of the simulated values and the real values coincide implies that both sets of values have the same spatial and/or temporal variability. We will introduce two different ways on generation random fields. The Turning Bands method, which is an unconditional method, is presented. The Sequential Gauss Simulations (SGS) is then introduced as an example of conditional method. A more sophisticated Bayesian random field will be presented in the Section "Numerical methods – Monte Carlo solution".

Unconditional Simulations: Turning Bands Method

The Turning Bands method involves the simulation of isotropic random fields in two- or higher-dimensional space by using a sequence of one-dimensional processes along lines crossing the space. The algorithm can be described as follows (Figure 3):

1. Choose an arbitrary origin within or near the domain of the field to be generated.

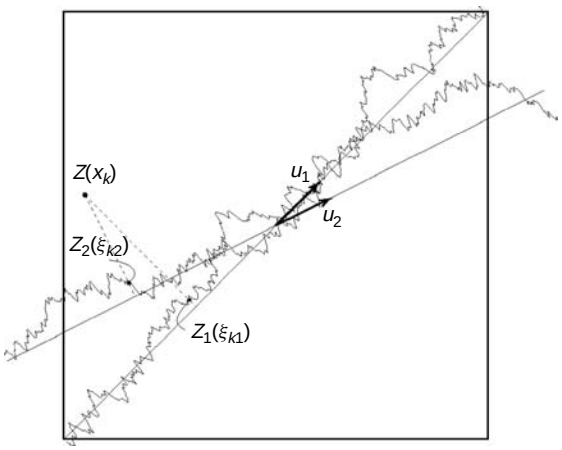

Figure 3 Illustration of the Turning Bands method

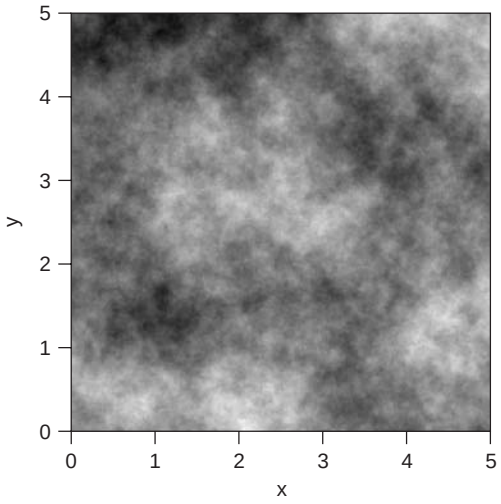

Figure 4 Example of 2D generated random field

2. Select a line i crossing the domain having a direction given by the unit vector $\mathbf{u}_i$, which may be chosen either randomly or from some fixed set.
3. Generate a realization of a one-dimensional process, $Z_i(l_i)$, along the line i having zero mean and covariance function $B_1(d_i)$ where l_i and d_i are measured along line i.
4. Orthogonally project each field point x_k onto the line i to define the coordinate $l_{ki} = x_k u_i$ of the one-dimensional process value $Z_i(l_{ki})$.
5. Add the component $Z_i(l_{ki})$ to the field value $Z(x_k)$, for each x_k.
6. Return to step (2) and generate a new one-dimensional process along a subsequent line until L lines have been produced.
7. Normalize the field $Z(x_k)$ by dividing through by the factor $\sqrt{L}$.

Essentially, the generating equation for the zero-mean discrete process $Z(x)$ is given by

$$Z(x) = \frac{1}{\sqrt{L}} \sum_{i=1}^{L} Z_i(x_i \cdot u_i) \tag{20}$$

which can be an exceptionally fast algorithm, particularly as the number of dimensions of the process increases. It depends on the knowledge of the one-dimensional covariance function, $B_1(d)$. Once this is known, the line processes can be produced using some efficient $1-D$ algorithm such as autoregressive, moving average, or FFT techniques. The covariance function B_1 is chosen such that the multidimensional covariance structure B_n in R^n is reflected in each realization or over the ensemble. For two-dimensional isotropic processes Cressie (1993) gives the following relationship between B_2 and B_1 for $r = |d|$,

$$B_2(p) = \frac{2}{\pi} \int_0^r \frac{B_1(p)}{\sqrt{r^2 - p^2}} \, \mathrm{d}p \tag{21}$$

which is an integral equation to be solved for B_1. In three dimensions, the relationship between the isotropic B_3 and B_1 is particularly simple,

$$B_1(p) = \frac{\mathrm{d}}{\mathrm{d}p}(pB_3(p)) \tag{22}$$

Cressie (1993) supplied explicit solutions for either the equivalent one-dimensional covariance function or the equivalent one-dimensional spectral density function for a variety of common multidimensional covariance structures. In particular, for the exponential type covariance function,

$$B_2(p_1, p_2) = \sigma^2 \exp\left\{-\frac{2}{I}\sqrt{{p_1}^2 + {p_2}^2}\right\} \tag{23}$$

The line processes could be constructed using a $1-D$ FFT algorithm. Line lengths were chosen to be twice that of the field diagonal to avoid the symmetric covariance problem inherent with the FFT method. To reduce errors arising due to overly coarse discretization of the lines, the ratio between the incremental distance along the lines, Δu, and the minimum incremental distance in the field along any coordinate, Δx, is constrained by $\Delta u / \Delta x = 1/2$.

It is worth mentioning here that the unconditional random field can be made conditional with a simple double kriging. Otherwise conditional field can obtained using conditional sequential methods (Cressie, 1993). Figure 4 depicts an example of a 2D random field.

Conditional Simulations: Sequential Gaussian Simulations The procedure required producing a random field where, on one hand, at some specific locations some of the measurements Z are known and must be honored and, on the other hand, at the other locations, where measurements are lacking, must be estimated based on the inferred

correlation structure of the neighboring measurements. This can be accomplished through the kriging estimation. The interpolation by kriging leads to rather smooth distributions of the spatial variable, that is, the interpolated values themselves, although based on a certain variogram, do not satisfy the underlying variogram. This is due to the fact that at each point of interpolation the most likely value is chosen, neglecting the estimation variance. For many applications such as drawing a map of the spatial variable, the smooth estimate by kriging is adequate. However, using the distribution in numerical simulations of flow and transport processes one may undermine the heterogeneities effects. In contrast to the kriging interpolation, there are an unlimited number of possible realizations satisfying the underlying spatial variability variogram. These multiple realizations can then be used for MCSs. Several methods have been developed for the generation of geostatistical realizations (GSLIB library) (Deutsch and Journel, 1997). Here we will restrict our description to the sequential Gaussian simulation (SGSIM, or SISIM its analogue for indicator data). The basic principle of SGSIM is to perform multiple kriging, but rather than choosing the conditional mean at the point of interpolation, a random value is taken from the Gaussian distribution described by the estimation mean and variance. The algorithm consists of the following steps:

1. Choose a random sequence in which all points of interpolation will be considered.
2. For point i, calculate the kriging estimate and its variance using all measured values and the i already generated values for conditioning.
3. Choose a random value from the distribution described by the Gaussian distribution with the conditional mean and estimation variance calculated from kriging.
4. Go to step 2 unless all points have been considered.

The algorithm may be made more efficient if conditioning is restricted to points within a certain neighborhood (otherwise the computational effort for the kriging step increases linearly). An example of Sequential Indicator Simulation (SISIM) is given in Figure 5. As expected both realizations are similar around the boreholes.

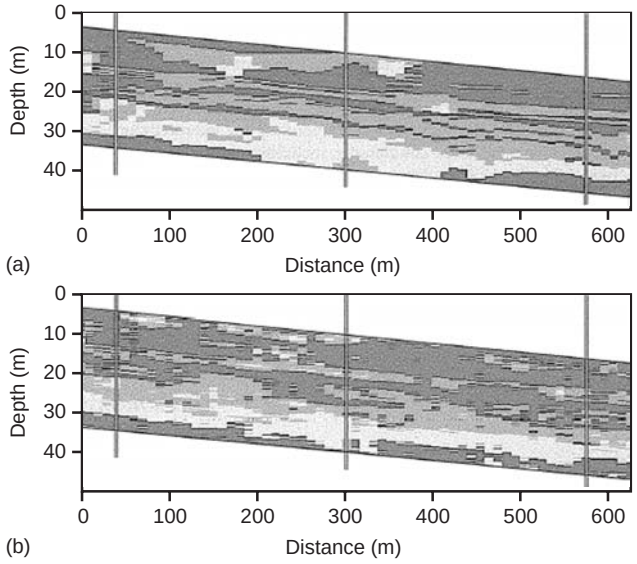

Figure 5 Two random realizations of lithologies using SISIM. The black, gray, and white colors represent shales, shally sandstone, and sandstone, respectively (Reproduced by permission of John Wiley & Sons, Inc. Modified from Chiles and Delfiner (1999))

STOCHASTIC PARTIAL DIFFERENTIAL EQUATIONS AND THEIR SOLUTIONS

Stochastic modeling deals with solving stochastic partial differential equations (SPDEs). To illustrate the concept of SPDE, we limit ourselves to the flow equation. The flow equation in porous media is based on the continuity of the mass balance concept. It is a partial differential equation (PDE) and, under transient conditions, is given by:

$$S_S \frac{\partial h}{\partial t} - \nabla.(K\ \nabla h) = 0 \tag{24}$$

If the hydraulic conductivity of the porous media K and the storativity S_S are assumed random functions, then the flow equation is called a *SPDE*. This means that the solution of the equation itself, the head h, is also a random function. Solving the flow equation implies determining the pdf of h, in particular, its first moments from the prescribed pdf of K and S_S. We introduce in the next section three ways for solving SPDEs, that is, the spectral, perturbation, and the Monte Carlo methods.

Spectral Methods

This method is applicable to the 2nd order stationary stochastic processes for both inputs and outputs. If *Y(x)* is a 2nd order stationary process, the spectrum (or spectral density) of Y is the Fourier transform and the inverse Fourier transform of its covariance function are given by:

$$\varphi(\omega) = \frac{1}{2\pi}\int_{-\infty}^{+\infty} \mathrm{e}^{-i\omega s}\mathbf{Cov}[Y(x+s), Y(x)]\,\mathrm{d}s;$$
$$\mathbf{Cov}[Y(x+s), Y(x)] = C(s)$$
$$= \frac{1}{2\pi}\int_{-\infty}^{+\infty} \mathrm{e}^{iks}\varphi(\omega)\,\mathrm{d}\omega \tag{25}$$

The representation theorem (*Wiener-Kintchine*) states that if the 2nd order stochastic process *Y(x)* is of zero mean $\mathrm{E}[Y] = 0$ and of covariance *C(s)*, then there is an associated complex process Z (and Z^* its conjugate) that satisfies the

Fourier–Stieltjes integral:

$$Y(x) = \int_{-\infty}^{+\infty} e^{i\omega s}\, dZ(\omega)$$

$$E[\, dZ(\omega_1)\, dZ^*(\omega_2)] = 0 \quad \text{if} \quad \omega_1 \neq \omega_2 \quad \text{however}$$

$$E[\, dZ(\omega_1)\, dZ^*(\omega_2)] = \varphi(\omega_1) \quad \text{if} \quad \omega_1 = \omega_2 \qquad (26)$$

Gelhar (1992) gives a one-dimensional steady state flow in an infinite domain, as example, and it is reproduced here for completeness. The steady state flow equation reads:

$$\frac{d}{dx}\left[K(x)\ \frac{dh}{dx}\right] = 0 \qquad (27)$$

We assume that *K(x)* is a 2nd order stationary stochastic process, h is the head. Assuming a constant flow rate, q, throughout the domain, the integration of the flow equation once yields to:

$$\frac{dh}{dx} = -\frac{q}{K(x)} = -r(x)\ q \qquad (28)$$

because K is a nonzero finite physical property, one can define the hydraulic resistivity $r(x) = K(x)^{-1}$. The goal is then to determine the first two statistical moments of the SRF *h(x)* and *r(x)*. Each SRF can be decomposed in two terms: an expected value and a fluctuation around the expected value, $E[h]$ and h', and $E[r]$ and r' such that $E[h] = h - h';\ E[h'] = 0$ and $E[r] = r - r';\ E[r'] = 0$. Substituting these quantities in the above equation leads to:

$$\frac{dE[h]}{dx} = -E[r]\ q;\ \text{thus}$$

$$E[h] = -q\,E[r]\ x + \text{constant} \qquad (29)$$

$$\frac{dh'}{dx} = -q\ r' \qquad (30)$$

Assuming that h and r are 2nd order stationary processes and using the Wiener–Kintchine theorem, we introduce the following two complex stochastic processes:

$$h'(x) = \int_{-\infty}^{+\infty} e^{i\omega x}\, dZ_h(\omega);$$

$$r'(x) = \int_{-\infty}^{+\infty} e^{i\omega x}\ dZ_r(\omega) \qquad (31)$$

Substituting them in the perturbed equation, spectral density of h is given by

$$\varphi_h(\omega) = E[\, dZ_h(\omega)\ dZ_h^*(\omega)] = \left(\frac{q}{\omega}\right)^2 E[\, dZ_r(\omega)\, dZ_r^*(\omega)]$$

$$= \left(\frac{q}{\omega}\right)^2 \varphi_r(\omega) \qquad (32)$$

which gives the spectrum of h given a spectrum of r, and hence both moments are determined.

Perturbation Methods

Perturbation methods aim at rewriting a difficult mathematical problem into an infinite series of easy ones (terms). It is most useful when the first few terms of the series are pertinent to the solution of the original problem, the remaining of the series is assumed to be small. To illustrate this technique, let us apply it to the previous one-dimensional problem. First we assume that K is 2nd order stationary SRF with $E[K]$ its expected value and k' its fluctuation around the mean. Similarly, we assume that h is 2nd order stationary SRF, and $E[h]$ and h' are its mean and fluctuation, respectively. We seek a 1st order (ε^1) solution to the flow equation, thus we assume that K and h are expanded in term of small perturbations: $K = E[K] + \varepsilon k'$ and $h = E[h] + \varepsilon h'$. Substituting those into the flow equation and neglecting term of higher order (ε^2) yield to (de Marsily, 1986):

$$E[K]\frac{d^2E[h]}{dx^2} + \varepsilon\left(E[K]\frac{d^2h'}{dx^2} + \frac{dk'}{dx}\frac{dE[h]}{dx} + k'\frac{d^2E[h]}{dx^2}\right) = 0 \qquad (33)$$

If this holds for any small ε, each term of these two must vanish. Therefore,

$$E[K]\frac{d^2E[h]}{dx^2} = 0; \quad \text{thus} \quad E[h] = \frac{q}{E[K]}x + \text{constant} \qquad (34)$$

Substituting E[h] into the second term leads to

$$\frac{dh'}{dx} = \frac{q}{E[K]^2}k' + \text{constant}; \quad \text{and} \quad \mathbf{Cov}\left[\frac{dh'}{dx}\right]$$

$$= -\frac{d^2}{dx^2}(\mathbf{Cov}[h]) = \left(\frac{q}{E[K]^2}\right)^2 \mathbf{Cov}[K] \qquad (35)$$

After integrating twice one can determine the Cov function for a stationary SRF:

$$\mathbf{Cov}[h(x+s), h(x)] = \left(\frac{q}{E[K]^2}\right)^2 \int_{-\infty}^{s}\int_{-\infty}^{y} \times \mathbf{Cov}[K(x+w), K(x)]\, dw\, dy \qquad (36)$$

Thus, the first two moments of h are defined given the moment of K. It has been shown that the error involved in the method of perturbation compared to the spectral method is less than 10% if $\sigma_Y^2 \leq 1$.

All analytical and numerical solutions of the SPDEs involve the use of either technique (Gelhar (1992), Dagan (1989), Rubin (2003)).

Numerical Methods – Monte Carlo Solution

Given the petrophysical properties of an aquifer, one can, using geostatistical methods, create multiple conditional simulations/realizations of the spatial variability of those petrophysical parameters. These simulations are equally probable and the difference between them is a measurement of the estimation uncertainty. Contrary to the perturbation and spectral methods, the MCS necessitates a prior knowledge of the probability distribution and the covariance function of the parameter, that is, K. For each realization/simulation "i" of the field K_i, the flow equation is solved numerically and for instance, the solution h_i is obtained. It is then possible to statistically analyze the ensemble of computed solutions: expected value, variance, pdf, and so on, for each location x. Stationarity assumption is alleviated since statistics can be evaluated at every point of the field. Unfortunately, MCSs are time consuming for two main reasons. On the one hand, to capture heterogeneity, MCSs require solving numerically the flow and/or transport equation(s) in many detailed realizations of $K(x)$. This can be computationally expensive, especially under transient conditions. Each Monte Carlo grid must capture the detailed heterogeneity of parameter fields. On the other hand, to get meaningful statistics, a large number of realizations/simulations is necessary. It is worth mentioning that the experimental variance is proportional to the inverse of the square root of the number of realizations, and therefore the rate of convergence is slow.

An Application of SPDE to Effective Hydraulic Conductivity

Effective properties are of great interest for hydrogeological applications and especially for numerical simulations. For example, regional-scale models of groundwater flow and transport often discretize the domain into grid blocks larger than typical integral scales of field data (see Section "Typical covariances and variograms"). This process is purely numerical and it is intended to alleviate the complexity of problem and thus the number of unknowns. For heterogeneous formations, the difference between the sale (size) of heterogeneity and the discretization block size is often handled using effective (upscaled) hydrogeological parameters. For example, in the case of flow in large 3D heterogeneous media domain, the flux is given by Darcy's law: $-K\nabla H = \mathbf{q}$ and the effective hydraulic conductivity is defined by: $\langle \mathbf{q} \rangle = -K_{\text{eff}} \langle \nabla H \rangle$, where the brackets denote the expected values, boldface denotes vectors. Second-order analytical solutions were developed by Dagan (see Dagan (1989)) using perturbation methods for axisymmetric anisotropy and by Gelhar and Axness (1983) (see Gelhar (1992)) using spectral methods for fully anisotropic media. The effective tensor of hydraulic conductivity is given by

$$K_{\text{eff},\,ij} = K_G \left[\left(1 + \frac{\sigma_Y^2}{2} \right) \delta_{ij} - g_{ij} \right],$$
$$\text{and} \quad g_{ij} = \frac{1}{\sigma_Y^2} \int \frac{\omega_i \omega_j}{\omega^2} \varphi_Y(\omega) \; \mathrm{d}^3\omega \qquad (37)$$

where δ_{ij} is the Kronecker tensor, K_G is the geometric mean of the hydraulic conductivity, ω is the vector wave (Fourier space), and φ_Y is the spectral form of the covariance of the log-hydraulic conductivity, Y. More results are given in Dagan (1989) and Rubin (2003).

SOLUTE TRANSPORT IN STATIONARY HETEROGENEOUS MEDIA

A good understanding of the physical processes governing the transport of contaminants in the subsurface is crucial to decision makers and risk assessors. In the simplest case of nonreactive contaminants, the transport processes encompasses advection by regional flow and mixing or dispersion that is evident as the spreading of contaminant front in the subsurface. Early studies of the dispersion of the contaminants showed dispersion rates in the field that were much larger than the laboratory measured ones. The disparity between the laboratory and the field scale dispersivity is attributed to the velocity variation induced by heterogeneity in the hydraulic properties of the subsurface. This phenomenon is known as *macrodispersion*. The basis for calculating flow velocities for fluids in a heterogeneous porous medium is Darcy's law, which relates the specific discharge q with hydraulic conductivity K and the hydraulic gradient (∇H). Owing to the strong spatial variation of K and ∇H, which cannot be known in detail, stochastic approaches have been developed. Stochastic transport theories attempt to develop relationships between macrodispersivities and statistical parameters characterizing the hydraulic conductivity spatial variability. To develop such relationships, we need to quantify the statistical structure of the velocity variations resulting from spatial variation of the hydraulic conductivity. The resulting statistical structure of the velocity variations is then used for quantifying macrodispersivities.

Macrodispersion Coefficient

Characterization of the macrodispersion coefficient in terms of the specific discharge spectrum can be approached in two different frameworks. On the one hand, the Eulerian

approach: the solute transport equation serves as the basis for a perturbation approximation to the equation for the ensemble-average concentration field, Gelhar (1992). On the other hand, the Lagrangian approach that relies on the relationship between the dispersion of a passive tracer and the mean square displacement of a particle moving in a random velocity field, originally founded by Taylor (1921) and applied to subsurface hydrology by Matheron and de Marsily (1980) and Dagan (1989). Despite the differences, the results obtained by Gelhar (1992) are identical to those obtained by Dagan (1989). For brevity, we only summarize the main results; more details can be found in the monographs of the mentioned authors. Here we limit ourselves to the Lagrangian approach. Following Dagan (1989), let us assume that at $t = 0$ a body of tracer concentration C_0 is introduced in a fluid and spread subsequently due to both molecular diffusion and convection by the fluid. Taylor suggested that the solute body is regarded as a collection of invisible particles; the concentration is regarded as the relative number per unit volume. For a single particle the motion is described by the displacement:

$$X_i(t) = \int_0^t v_i(t')\ \mathrm{d}t' \tag{38}$$

where v is the Lagrangian velocity which is related to the Eulerian one through: $v(t) = u(X(t))$. The velocity is a random variable and is the sum of the two uncorrelated velocities: (i) a velocity due to the molecular diffusion and (ii) a fluid velocity (advective). The velocity vector is assumed to be a 2nd order stationary random process in time with the following statistics: $\mathrm{E}[v_i(t)]$, and $\mathrm{E}[(v_i(t) - \mathrm{E}[v_i(t)])(v_j(\tau) - \mathrm{E}[v_j(\tau)])] = \mathrm{Cov}[v_i, v_j](t - \tau)$. Thus the mean velocity is $\mathrm{E}[\mathrm{d}X_i/\mathrm{d}t] = \mathrm{E}[v_i(t)]$, and the fluctuation of the particle around the mean is $\mathrm{d}X_i'/\mathrm{d}t = v_i'(t)$. Therefore, the covariance of two Cartesian components of X' is given by

$$E[X_i' X_j'] = \int_0^t \int_0^t E[v_i(t')v_j(t'')]\,\mathrm{d}t'\,\mathrm{d}t''; \quad \forall i, j = 1, 2, 3 \tag{39}$$

The relationship between the dispersion coefficient and the Lagrangian velocity covariance is given by (Dagan, 1989):

$$D_{ij}(t) = \frac{1}{2}\frac{\mathrm{d}E[X_i' X_j']}{\mathrm{d}t} = \int_0^t [\mathbf{Cov}[v_i v_j](t - \tau) + \mathbf{Cov}[v_i v_j](\tau - t)]\,\mathrm{d}\tau; \quad \forall i, j = 1, 2, 3 \tag{40}$$

We present here a few solutions of the displacement tensor, X_{ii}.

Case 1 – 2D zero pore-scale dispersion: planar flow in the horizontal plane, thin aquifer with uniform mean head gradient, exponential covariance for Y, the dimensionless time is given by $t' = tU_1/I_Y$. The solution is given by

$$\frac{X_{11}(t')}{\sigma_Y^2 I_Y^2} = 2t' - 3\ln(t') + \frac{3}{2} - 3E + 3\left[Ei(-t') + \frac{e^{-t'}(1 + t') - 1}{t'^2}\right] \tag{41}$$

$$\frac{X_{22}(t')}{\sigma_Y^2 I_Y^2} = \ln(t') - \frac{3}{2} + E - Ei(t') + 3\left[\frac{1 - (1 + t')e^{-t'}}{t'^2}\right] \tag{42}$$

where E is the Euler constant.

Case 2 – 3D isotropic case, zero pore-scale dispersion. The longitudinal and transversal displacement tensor are given by

$$\frac{X_{11}(t')}{\sigma_Y^2 I_Y^2} = 2t' - 2\left[\frac{8}{3} - \frac{4}{t'} + \frac{8}{t'^3} - \frac{8}{t'^2}\left(1 + \frac{1}{t'}\right)e^{-t'}\right] \tag{43}$$

$$\frac{X_{22}(t')}{\sigma_Y^2 I_Y^2} = \frac{X_{33}(t')}{\sigma_Y^2 I_Y^2} = 2\left[\frac{1}{3} - \frac{1}{t'} + \frac{4}{t'^3} - \left(\frac{4}{t'^3} + \frac{4}{t'^2} + \frac{1}{t'}\right)e^{-t'}\right] \tag{44}$$

Case 3 – 3D anisotropic case, zero pore-scale dispersion. A more general flow case with an exponential axisymmetric covariance for Y, where e is the anisotropy ratio defined as the ratio between the vertical and the horizontal length scales, $e = I_v/I_h$. The displacements are given by (Figure 6):

$$\frac{X_{11}(t')}{\sigma_Y^2 I_Y^2} = 2t' + 2(e^{-t'} - 1) + 8e\int_0^\infty \frac{J_0(kt') - 1}{(1 + k^2 - (ek)^2)^2}\left[1 - \frac{ek}{\sqrt{1 + k^2}} - \frac{ek(1 + k^2 - (ek)^2)}{(1 + k^2)^{3/2}}\right]\mathrm{d}k - 2e\int_0^\infty \left\{J_0(kt') - \frac{J_1(kt')}{kt'} - \frac{1}{2}\right\}\left[-\frac{(ek)^3((ek)^2 - 5 - 5k^2)}{(1 + k^2 - (ek)^2)^3(1 + k^2)^{3/2}} + \frac{1 + k^2 - 5(ek)^2)}{(1 + k^2 - (ek)^2)^3}\right]\mathrm{d}k \tag{45}$$

$$\frac{X_{22}(t')}{\sigma_Y^2 I_Y^2} = -2e\int_0^\infty \left[\frac{J_1(kt')}{t'} - \frac{k}{2}\right]\left[-\frac{e(ek)^2((ek)^2 - 5 - 5k^2)}{(1 + k^2 - (ek)^2)^3(1 + k^2)^{3/2}} + \frac{1 + k^2 - 5(ek)^2)}{k(1 + k^2 - (ek)^2)^3}\right]\mathrm{d}k \tag{46}$$

$$\frac{X_{33}(t')}{\sigma_Y^2 I_Y^2} = -4e \int_0^\infty [J_0(kt') - 1] \left[\frac{1}{(-1 - k^2 + (ek)^2)^2} \left[\frac{1}{2} + \frac{2(ek)^2}{1 + k^2 - (ek)^2} - \frac{ek((ek)^2 + 3 + 3k^2)}{(1 + k^2 - (ek)^2)^3 (1 + k^2)^{3/2}} \right] \right] \mathrm{d}k \quad (47)$$

In the next section, we present how to estimate the displacement tensor from concentration measurements using the concept of statistical spatial moments. Reactive contaminant displacements in saturated and unsaturated zones are covered in Zhang (2001)

Statistical Spatial Moments

A contaminant plume is generally described using the statistical spatial moments. The pth ≤ 1 moment of the concentration distribution in space, $M_{p_1 \ldots p_n}(t)$, is defined here following Aris (1956) by

$$M_{p_1 \ldots p_n}(t) = \eta \int_\Omega C(x,t) \prod_i^n x_i^{p_i} \, \mathrm{d}\Omega \quad (48)$$

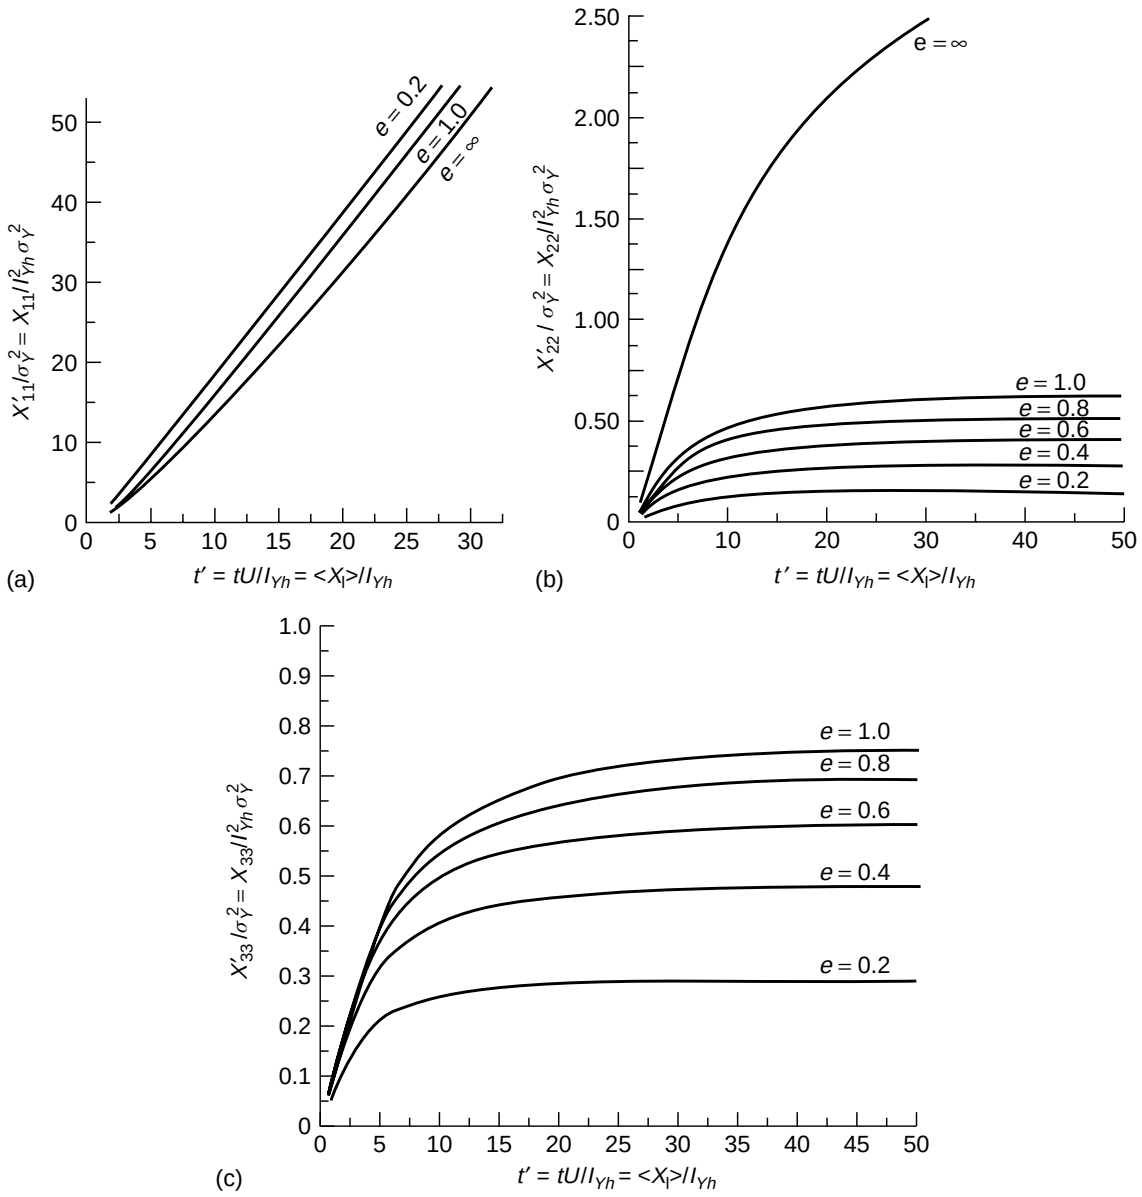

Figure 6 Longitudinal and lateral displacement as function of time (Reproduced from Dagan, 1988 by permission of American Geophysical Union)

where $C(x,t)$ is the concentration at point $x = (x_1, \ldots, x_n)$, and at time t; n denotes the space dimension and can be equal to 2 or 3, depending on the type of analysis being performed; η is the effective porosity; Ω denotes the aquifer domain occupied by the plume, and the order of the moment is given by $p = \Sigma p_i$. Here, we shall deal only with the zeroth, first, and second spatial moments of the plume. The 0th moment measures the mass of the plume, while the 1st moment provides a measure of the displacement of the centroid of the plume $\tilde{X}(t) = (\tilde{x}_{1,c}, \ldots, \tilde{x}_{n,c})$. In three-dimensional space, the centroid of the plume is given by:

$$\tilde{x}_{1,c} = \frac{M_{100}}{M_0}, \quad \tilde{x}_{2,c} = \frac{M_{010}}{M_0}, \quad \tilde{x}_{3,c} = \frac{M_{001}}{M_0} \tag{49}$$

For the case where $p \geq 2$ the central moments of the plume will be used, which are given by

$$M_{p_1 \ldots p_n}(t) = \eta \int_\Omega C(x,t) \prod_i^n (x_i{}^{p_i} - \tilde{x}_{i,c})^{p_i} \, \mathrm{d}\Omega \tag{50}$$

The 2nd moments provide a measure of the spread of the plume around its centroid. The terms of the displacement covariance tensor $\tilde{X}_{ij}(t)$are computed using the following expressions:

$$\tilde{X}_{11} = \frac{M_{200}}{M_0}, \quad \tilde{X}_{22} = \frac{M_{020}}{M_0}, \quad \tilde{X}_{33} = \frac{M_{002}}{M_0},$$
$$\tilde{X}_{12} = \frac{M_{110}}{M_0}, \quad \tilde{X}_{13} = \frac{M_{101}}{M_0}, \quad \tilde{X}_{23} = \frac{M_{011}}{M_0} \tag{51}$$

In applications, Ω is not known exactly, and in many cases it is only partly covered by samplers. Hence, prior to computing the moments, there is a need to estimate Ω. This problem is referred as the "null points" problem, and it has been approached in previous works using methods such as linear extrapolation or surface fitting using spline functions or kriging. A concise presentation of these methods is presented in Chapter **Chapter 147, Characterization of Porous and Fractured Media, Volume 4**.

We illustrate the application of the spatial statistical moments on the large-scale field experiment conducted at Cape Cod (Leblanc *et al.*, 1991) The Cape Cod large-scale natural gradient tracer test began in July 1985 with the injection of 7.6 m^3 of tracer solution in the aquifer through a volume of dimensions of $1.2 \times 3 \times 4\,m^3$. The tracer solution contained a nonreactive tracer, bromide, and reactive tracers, lithium and molybdate. For illustration purposes, we shall concentrate on the displacement of the bromide plume. The plume was sampled over a period of 511 days. In each of the 16 sampling sessions, concentration was measured using a large and dense three-dimensional array of samplers (see Figure 7). Zeroth, first-, and second-order moments were computed and given in Figures 8, 9(a, b), and 10(a–c) (Rubin and Ezzedine, 1997).

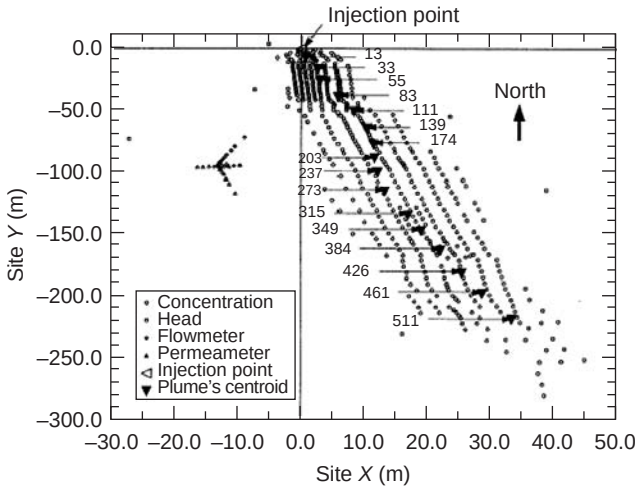

Figure 7 In situ locations of the concentration samplers, circles; the piezometers, squares; the hydraulic conductivity measurements using flowmeter, diamonds; and the permeameter, triangles. The centroids are shown and are referred to by elapsed travel time (in days) (Reproduced from Rubin and Ezzedine (1997) by permission of American Geophysical Union)

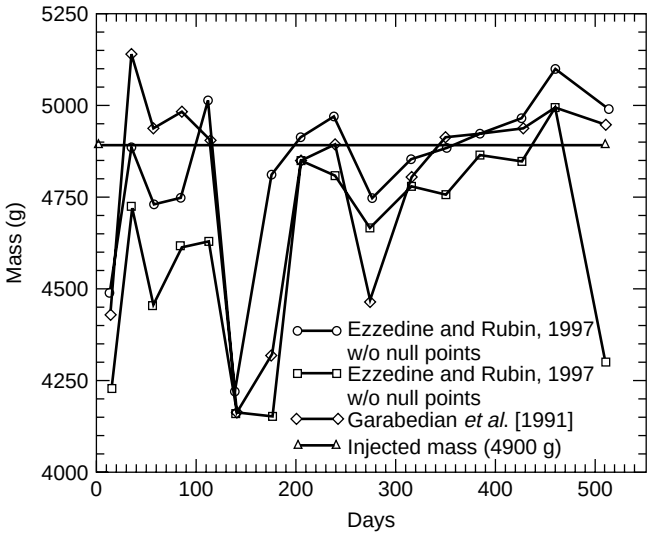

Figure 8 Mass recovery versus time: for (Rubin and Ezzedine, 1997), circles; original data without null points, squares; Garabedian *et al.* (1991) results, diamonds; and the injected mass (4900 g), triangles (Reproduced from Rubin and Ezzedine (1997) by permission of American Geophysical Union)

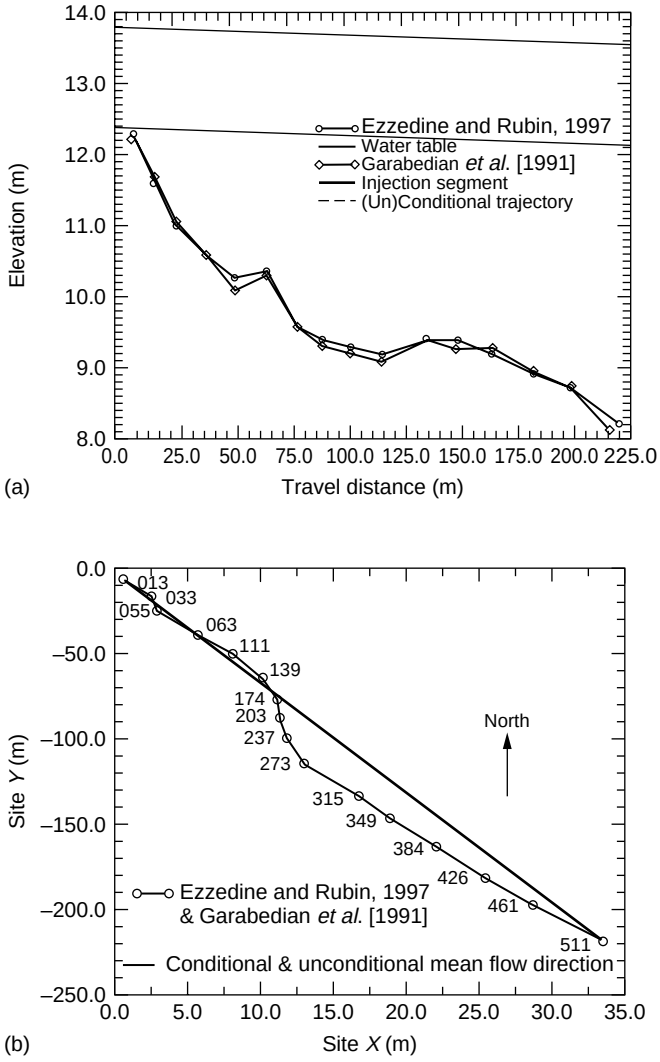

Figure 9 First moments: (a) Horizontal plume's centroid (2) plotted in original coordinates. The injection point is at (site $X = 0$, site $Y = 0$). Centroids are marked with the time elapsed since injection in days. The conditional and the unconditional trajectories are identical. Trajectories computed using the data and the Garabedian *et al.* (1991) results are the same. (b) Vertical plume's centroid versus travel distance (2). Elevation is above mean sea level. The conditional and the unconditional trajectories are identical (Reproduced from Rubin and Ezzedine (1997) by permission of American Geophysical Union)

Ergodicity and Plume Size Effect on Displacement Tensor

A solute plume is ergodic if the mean and covariance of the displacement along the various streamlines are equal to the mean and covariance of the displacement of a single particle. In this case, the ensemble-average concentration plume dispersivity is expected to accurately predict the plume growth using single-particle displacement statistics only when the plume size is much larger than the integral scales of the hydraulic conductivity (Dagan, 1989). It is therefore important to investigate the applicability and limitation of the ergodic hypothesis. On the basis of the concept of relative dispersion, Dagan (1989) reached the following relationship:

$$E[S_{ij}(t)] = S_{ij}(t=0) + X_{ij}(t) - R_{ij}(t) \qquad (52)$$

where $S_{ij}(t)$ is the second spatial moment of the plume of a plume of arbitrary dimension as a random function of trajectories of the particles:

$$S_{ij}(t) = \frac{1}{|\Omega|}\int_{\Omega}[X_i(t|\Omega) - R_i(t)][X_j(t|\Omega) - R_j(t)]\ \mathrm{d}\Omega;$$

$$R_i(t) = \frac{1}{|\Omega|}\int_{\Omega} X_i(t|\Omega)\ \mathrm{d}\Omega \qquad (53)$$

where $R(t)$ is plume centroid. Because X_i is a random function, R is inherently so. $X_i(t|\Omega)$ is the trajectory of a particle emanating from a source of size Ω with and a volume $|\Omega|$. The variance of the centroid of the plume is given by

$$R_{ij}(t) = E[(R_i(t) - E[R_i(t)])(R_j(t) - E[R_j(t)])]$$
$$= \frac{1}{|\Omega|^2}\int_{\Omega}\int_{\Omega} E[X_i'(t|\Omega)X_j'(t|\Omega')]\ \mathrm{d}\Omega\,\mathrm{d}\Omega' \qquad (54)$$

If the plume spreads are much larger than the integral scale of Y, the statistical variability of R becomes narrow and R approaches the ensemble mean displacement. An elaborate discussion of ergodicity and operational ergodicity is given in Rubin (2003, Chapter 10). Ergodicity analysis was performed on the Cape Cod data and results are given in Figures 11(a–c).

Spatial moment concepts could be extended to temporal statistical moments. They are introduced in the following section.

Statistical Temporal Moments

The Lagrangian framework is most suitable for modeling and analyzing travel times. One compelling reason is the lack of discrepancy between the measurement scale in the field and the scale of numerical element used for modeling. Samplers in the field measure the concentration at a streamline, and the streamline is also the fundamental unit in the Lagrangian approach. However, the elegance of the Lagrangian-based solutions can sometimes be lost when confronted by the reality of field data analysis. To illustrate this matter, we proceed by presenting temporal moments statistics. Similar to spatial moments, the temporal moments are commonly defined by the following integrals:

$$\mu_i(x) = \int_{-\infty}^{+\infty} t^i C(x,t)\ \mathrm{d}t \qquad (55)$$

where $\mu_i(x)$ are the ith temporal noncentral moments. To demonstrate these concepts, let us consider the moments of

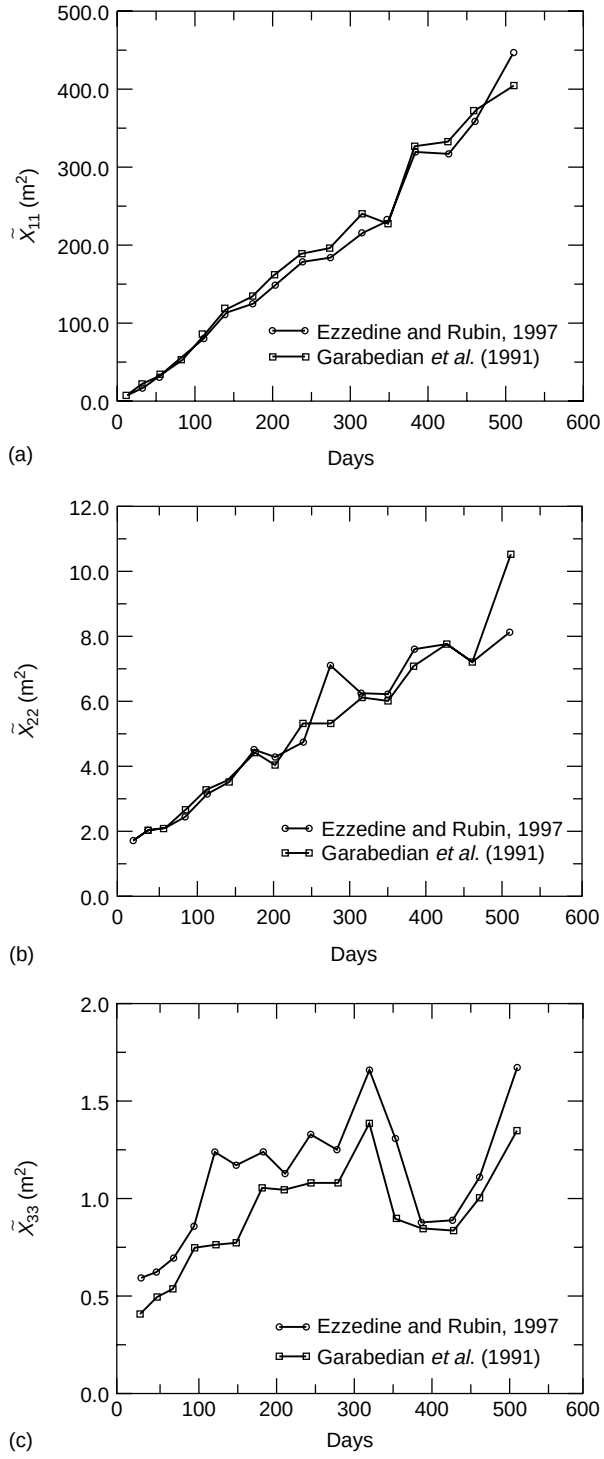

Figure 10 (a) The longitudinal central second moment $\tilde{X}_{11}$ as computed in the present study and by Garabedian *et al.* (1991), (b) The lateral second central moment $\tilde{X}_{22}$ as computed in the present study and by Garabedian *et al.* (1991), (c) The vertical second moment $\tilde{X}_{33}$ as computed in the present study and by Garabedian *et al.* (1991) (Reproduced from Rubin and Ezzedine (1997) by permission of American Geophysical Union)

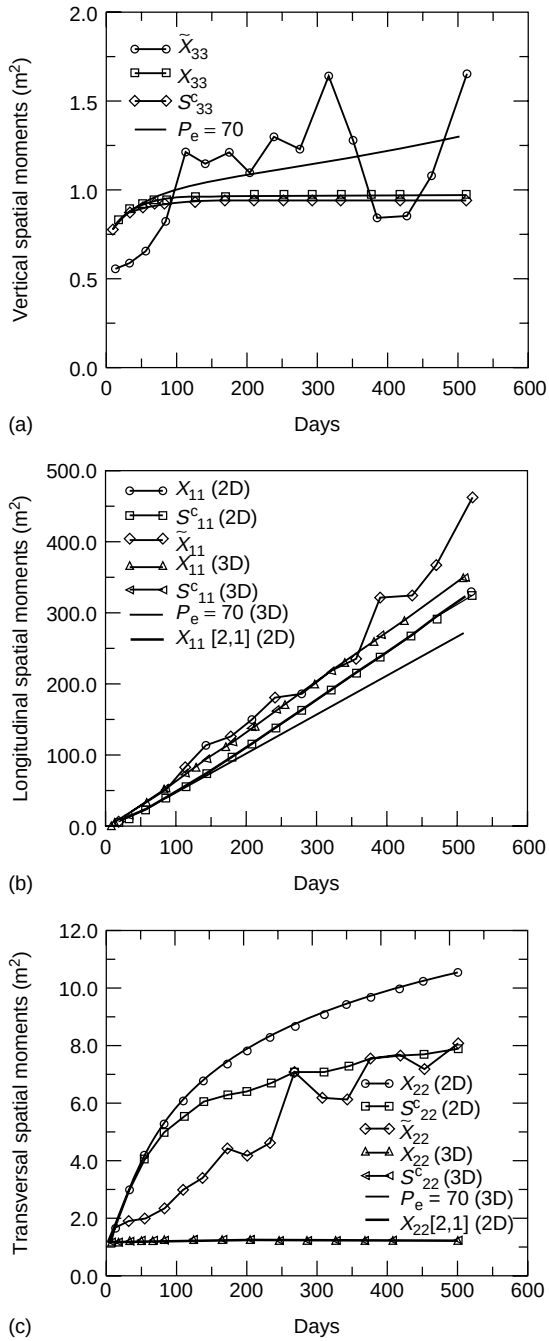

Figure 11 The 3D conditional S^c_{33} computed using (52), the conditional X_{33}, experimental results of vertical spread, and 3D pore scale dispersion (($P_e = 70$), Fiori, 1996). b) the 2D and 3D S^c_{11} computed using (52), unconditional X_{11}, 2D unconditional higher-order approximation X_{11}[1,2] (Hsu *et al.*, 1996) and 3D X_{11} with pore scale dispersion (($P_e = 70$), Fiori, 1996). c) the 2D and 3D S^c_{22} computed using (52), unconditional X_{22}, 2D unconditional higher-order approximation X_{22}[1,2] (Hsu *et al.*, 1996) and 3D X_{22} with pore scale dispersion (($P_e = 70$), Fiori, 1996) (Reproduced from Rubin and Ezzedine (1997) by permission of American Geophysical Union)

the travel time at *s(L)* where L is a distance downstream from the injection source located at x_0, and s is a streamline coordinate system. Moreover, we assume that the tracer is injected at x_0 over a short period of time T_0, such that the following boundary condition for the advection dispersion equation holds: $C(x_0, t) = C_0$ for $t \in [-T_0/2, T_0/2]$ and $C(x_0, t) = 0$ otherwise. Neglecting pore-scale dispersion, the concentration distribution along a streamline is given by the square wave

$$C(t, \tau) = C_0 \left[H\left(t - \tau + \frac{T_0}{2}\right) - H\left(t - \tau - \frac{T_0}{2}\right) \right] \tag{56}$$

where H is the Heaviside step function, and τ, is the time that it takes for a particle emanating from x_0 to reach *s(L)* and is given by

$$\tau(L) = \int_{s(x_0)}^{s(L)} \frac{\mathrm{d}s}{V(s, x_0)} \tag{57}$$

where V denotes velocity. Applying the travel time to the square wave solution leads to the first three travel time moments:

$$\mu_0 = C_0 T_0, \mu_1 = C_0 T_0 \tau,$$
$$\text{and} \quad \mu_2 = C_0 T_0 \left(\tau^2 + \frac{T_0^2}{12}\right)$$
$$\text{and thus} \quad \tau = \frac{\mu_1}{\mu_0} \quad \text{and} \quad \tau^2 = \frac{\mu_2}{\mu_0} - \frac{T_0^2}{12} \tag{58}$$

The spatial average of τ over a control plane of area A perpendicular to the mean flow direction at L distance from the source is given by

$$\overline{\tau}(L) = \frac{1}{A} \int_A \frac{\mu_1(x_0 + L, y, z)}{\mu_0(x_0 + L, y, z)} \mathrm{d}y\, \mathrm{d}z;$$
$$\text{and} \quad \sigma_\tau^2(L) \equiv (\tau^2) - (\overline{\tau})^2 = \frac{1}{A} \int_A \frac{\mu_2(x_0 + L, y, z)}{\mu_0(x_0 + L, y, z)} \mathrm{d}y\, \mathrm{d}z - \frac{T_0^2}{12} - (\overline{\tau})^2 \tag{59}$$

In the Lagrangian approach, mass transfer across streamlines cannot be modeled, yet this aspect of the transport problem must be dealt with in order to make the travel time analysis wieldy. Hereafter, an approach is presented that will allow one to retain the simplicity of the Lagrangian approach yet account realistically for the effects of pore-scale dispersion.

Inspection of the time records of concentration at various samplers reveals that the above theoretical development is somewhat limited (Figure 12). Rather than a single square pulse, or even a diffused, Gaussian-like pulse, we observe trains of signals of different modes, stretching over periods of time much longer than the injection period.

Since the Cape Cod plume was injected over a period of 18 h, and the time-concentration records show pulses that take much longer to travel across individual samplers, it becomes clear that computing the travel time moments based on the entire time-concentration records is the culprit for the mismatch between the theoretical and experimental travel time variances (Figure 13).

To use the time records for inference, the effects of pore-scale dispersion need to be removed nonarbitrarily, and the geometry of the advective pulse reconstructed. To do so, it is suggested that the travel time t to each sampler be taken as the time at which the maximum concentration $C_{\max}$ is detected. We shall refer below to that time as $tc_{\max}$. The parameter $tc_{\max}$ is taken as the most likely estimator of τ, instead of using the Aris estimator. The justification for choosing the peak arrival time as the travel time least affected by pore-scale dispersion is based on the observation that this travel time is associated with the plume centroid, where the concentration is generally the largest and the concentration gradients equal to zero. Additionally, if one considers an ensemble of streamlines with a solute pulse moving in any of them, possibly with different velocities, it can be expected that the concentration that develops in any streamline due to lateral mass transfer will be smaller than that of the pulse that was originally injected, at least over a long time, until the concentration variations smooth out. The first two moments of the travel time are now given by

$$\overline{\tau}(x) = \frac{1}{A} \int_A t_{C_{\max}}(x, y, z)\ \mathrm{d}y\ \mathrm{d}z;$$
$$\sigma_\tau^2(x) = \frac{1}{A} \int_A [t_{C_{\max}}(x, y, z) - \overline{\tau}(x)]^2\ \mathrm{d}y\ \mathrm{d}z \tag{60}$$

The assumption underlying both moments is that $C_{\max}$ is the concentration of the pulse's centroid and that by tracking the displacement of the pulse's centroid, it is possible to capture the effects of advection while removing the effects of pore-scale dispersion. The viability of the suggested approach predicates upon the existence of a distinguishable $C_{\max}$. The time $tc_{\max}$ will become nonidentifiable as the concentration field smoothes out with time due to the effects of pore-scale dispersion.

Figure 14(a) depicts the mean travel time as a function of distance from the source. The results obtained by averaging $tc_{\max}$ over the planes normal to the mean flow direction are very similar to those obtained using Aris moments of order 0, and 1, for both analyses yield results which are close to those obtained using the average velocity. These results suggest that removing the effects of pore-scale dispersion is inconsequential for first moments analysis

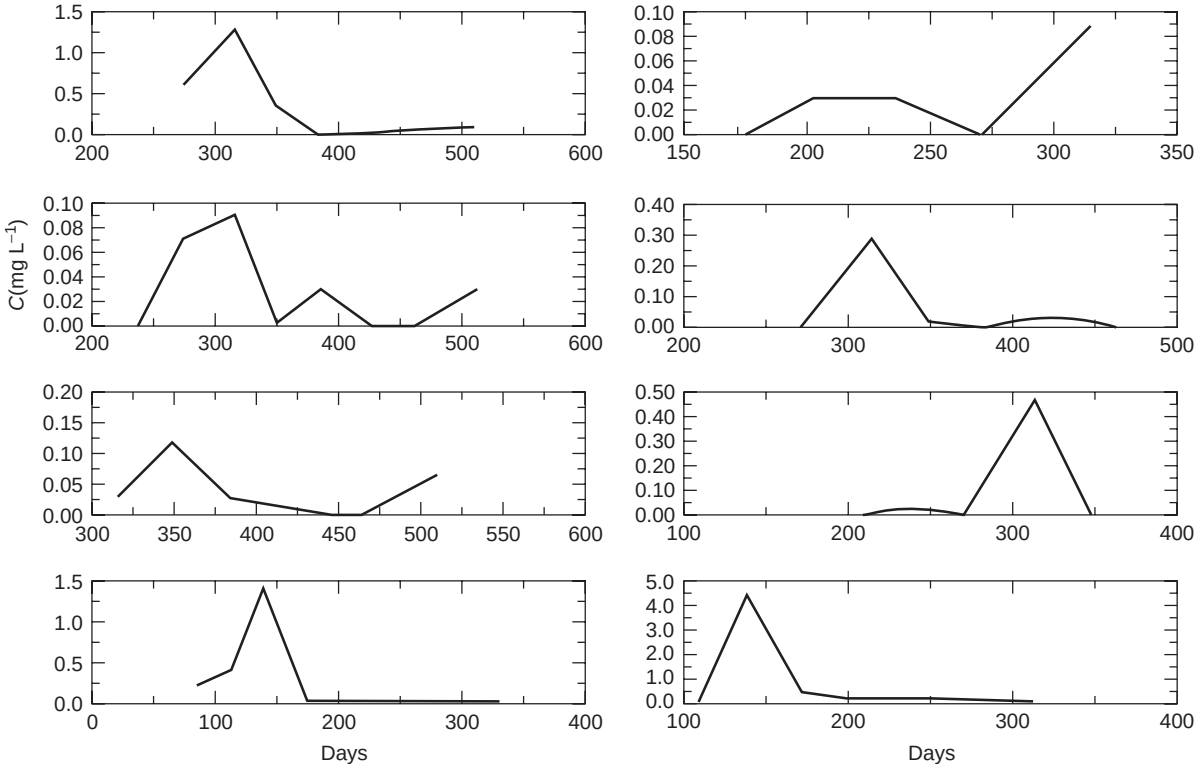

Figure 12 Examples of the concentration versus time records at several samplers. Typically, a high-level detect is followed or preceded by a long train of low-level detects (Reproduced from Rubin and Ezzedine (1997) by permission of American Geophysical Union)

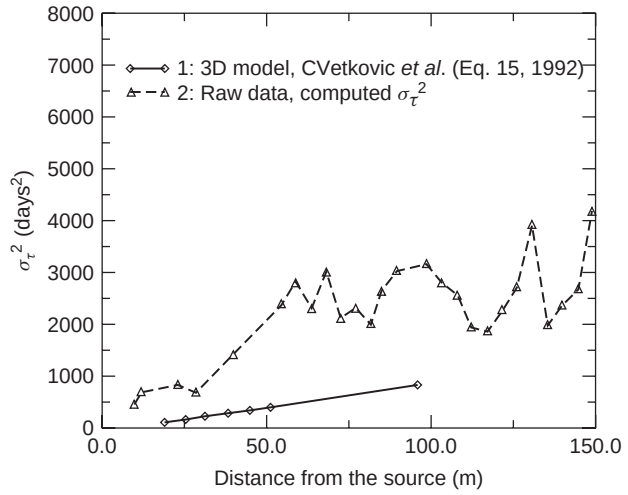

Figure 13 Theoretical and experimental travel time variance (Reproduced from Rubin and Ezzedine (1997) by permission of American Geophysical Union)

and that the large distribution of the pulses over the flow domain cancels out the effects of the low-level concentrations due to averaging. The $\langle\tau\rangle$ model following Rubin and Dagan (1992) is based on a transformation of the single-particle displacement variance, and it shows excellent agreement with the observed data. In analyzing the travel time variances, the situation becomes quite different. Figure 14(b) shows the travel time variance computed using the ensemble of the experimental $tc_{\max}$ over consecutive planes of multilevel samplers. The first and second moments were computed over consecutive planes and compared with the Aris-based experimental results. This comparison shows a dramatic reduction in the magnitude of the experimental variances. A comparison of the experimental results with theoretical results shows a good match.

INVERSE PROBLEMS AS STATISTICS

Much of the problem and initial cost of subsurface remediation concerns field site characterization. A full three-dimensional "picture" of the heterogeneous subsurface is needed in order to identify the key controls on the flow and contaminant transport processes. Natural heterogeneity and the large spatial variability of the permeability predominantly control the flow field and hence the transport. Moreover, natural heterogeneity exhibits variability over a wide range of scales and hence is difficult to characterize due to the scarcity of data and the costliness of

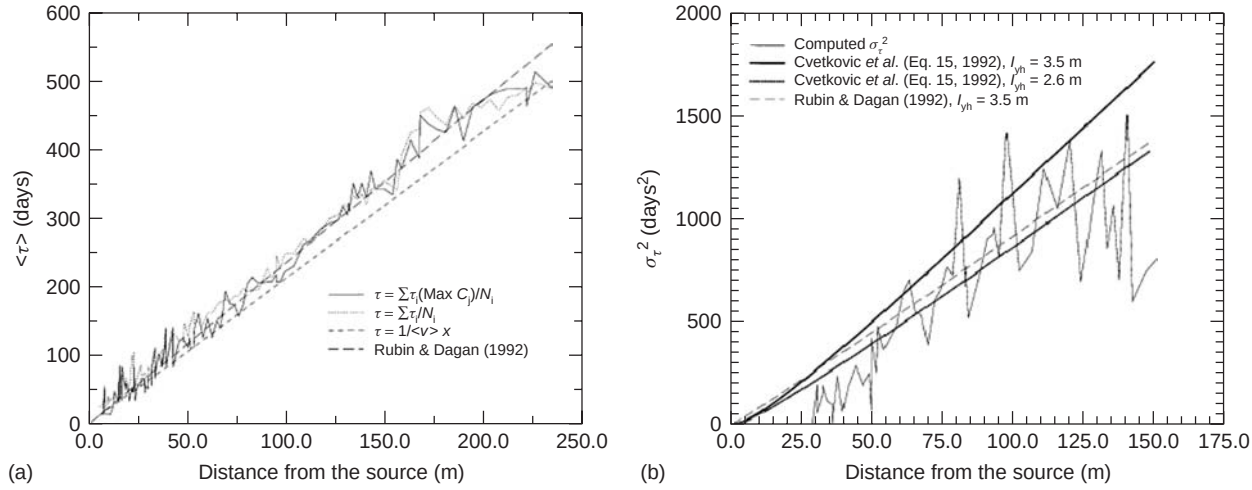

Figure 14 Theoretical and experimental (a) 1st moments (b) 2nd moments

conventional field sampling techniques such as drilling. With poor site characterization, remediation schemes are unnecessarily expensive, because costly overdesign may be required to compensate for uncertainty. Therefore, inverse problems were formulated in order to estimate the hydraulic properties from a spare data of measurements. This section describes how to determine model parameter values. Models are assumed to be valid; the only unknowns are parameter values that define the models. For completeness, we introduce some concepts and terminology commonly used in inverse/forward problem community. An elaborate discussion of the deterministic approach to inverse problems is given in Chapter **Chapter 155, Numerical Models of Groundwater Flow and Transport, Volume 4**.

Well-posed versus Ill-posed Problem

Prediction based on a given set of parameter values is called "forward modeling". Determination of parameter value from observed data is called "inverse modeling". Inversion can be achieved in two ways. On one hand, a modeler iteratively modifies parameter values (such as hydraulic conductivity), run a forward model until attaining best "fit" or "match" between the measurements and the modeled variable, head for instance. This kind of process falls into the trial and error methods. Such forward modeling is sometimes tedious and time consuming. On the other hand, an inverse algorithm is adopted to automatically or semiautomatically obtain the parameter values from the observed data and an initial set of trial parameters values. The procedure also provides an estimate of parameter uncertainty. In both cases, inversion requires minimizing the discrepancy between predictions and observations (Sun, 1994).

A well-posed inverse problem requires "existence" of the problem, the "uniqueness" and the "stability" of the solution or algorithm. Obviously, in view of observed data and our understanding of a real-world physical system, a problem is presumed to exist, for example, detection of contaminant plume in groundwater suggests contamination must have happened in the past. The question then is how to relate the observation to the migration history of the contaminant. A cause generally has an effect. Can an effect result from different causes? Is it unique in theory or model? Even if it is, have we counted and resolved all parameters that define a model? Uniqueness has two levels: the model itself and the model-defining parameters. The latter is related to the stability of a solution algorithm. How sensitive are parameters to uncertainty of observed data? Are the errors amplified during inversion? Is the inversion algorithm efficient in terms of ease of usage and cost of running the inversion program (complexity)? Mathematically speaking, inverse problems are ill-posed problems.

Deterministic versus Stochastic Inversion

To address the inverse problem, two main frameworks have been developed and they are either deterministic or stochastic. In the deterministic framework, the structure of the spatial variability of the parameters is fixed. For example the aquifer is divided into a number of zones, and each zone is supposed to have a constant hydraulic conductivity; then, the algorithm seeks the best hydraulic conductivity values, for which the solution of the flow equation reproduces the observed data. In a stochastic framework, however, the spatial variability of the parameters is statistically mapped. For example, the overall mean and variance, and the variogram of the final realization are specified. This characterization is not enough to fully determine the parameter values at every cell. Thus, a spatial realization is sought, satisfying the statistical constraints and honoring the observed values. As it has been shown in Section "Geostatistics", an infinite

number of realizations can meet the statistical constraints and reproduce the observed data. To make these inferences quantitative in either deterministic or stochastic framework, one must answer three fundamental questions:

- How accurately is the data known, that is, what does it mean to "fit" the data?
- How accurately can we model the response of the aquifer system? In other words, have we included all the physics in the model that contribute significantly to the data?
- Finally, what is known about the system besides the data? This is called *a priori* information and is essential since for any sufficiently fine parameterization of an aquifer system there will be unreasonable models that fit the data too. Prior information is the means by which we reject or down-weight unreasonable estimation models.

There are a variety of "recipes" for constructing estimators; perhaps the most common in statistics are, minimum variance estimation, maximum likelihood estimation (MLE) and Bayesian estimation. The latters have asymptotically optimal properties under certain restrictive assumptions. Hereafter we present three inverse problems; they are introduced in order of complexity.

Illustrations and Examples

A Simple Statistical Inference Problem: Least-square Method

To illustrate the deterministic inversion process, let us consider a classic example of parameters estimation for a pumping test (readers are referred to **Chapter 151, Hydraulics of Wells and Well Testing, Volume 4** for more elaborate details). The solution of a pumping test in a confined aquifer is given by Jacob's semilog approximation for large time:

$$\delta h \approx \frac{Q}{4\pi T}\left(-0.5772 - \ln\left[\frac{r^2 S}{4T}\right] + \ln[t]\right) \tag{61}$$

where T is the transmissivity, S is the storativity, Q is the pumping rate, t is time, h is the hydraulic head and δh is the drawdown. The inverse problem is to determine T and S given a series of error-free observations of δh at different times. The relation (model) between the drawdown and time is not linear but logarithmic. However if $\ln[t]$ is treated as an independent variable the relation between δh and $\ln[t]$ is a linear one and the inversion in the least-square sense is straightforward. The sum of the square of discrepancy ε_i between each predicted δh_i and measured $\delta h_i{}^{\text{obs}}$ is minimized in least-square sense. If the above equation is rewritten as follows:

$$y = ax + b; \quad x \equiv \ln[t]; \quad a = \frac{Q}{4\pi T};$$
$$b = \frac{Q}{4\pi T}\left(-0.5772 - \ln\left[\frac{r^2 S}{4T}\right]\right); \; y \equiv \delta h \tag{62}$$

The goal is then to minimize the sum or the square of errors (minimum variance):

$$\text{Min } \delta^2 = \text{Min}\left[\sum_{i=1}^{n} \delta_i^2\right] = \text{Min}\left[\sum_{i=1}^{n} (y_i - y_i^{\text{obs}})^2\right] \tag{63}$$

The solution of the problem is readily available in textbooks and it is given by:

$$a = \frac{n\sum_{i=1}^{n} x_i y_i^{\text{obs}} - \sum_{i=1}^{n} x_i \sum_{i=1}^{n} y_i^{\text{obs}}}{n\sum_{i=1}^{n} x_i^2 - \left(\sum_{i=1}^{n} x_i\right)^2};$$
$$b = \frac{n\sum_{i=1}^{n} x_i^2 \sum_{i=1}^{n} y_i^{\text{obs}} - \sum_{i=1}^{n} x_i \sum_{i=1}^{n} x_i y_i^{\text{obs}}}{n\sum_{i=1}^{n} x_i^2 - \left(\sum_{i=1}^{n} x_i\right)^2} \tag{64}$$

a and b can be expressed in univariate statistics as shown on Table 1.

The expected transmissivity value is then determined by $E[T \mid \ln(t)] = a \ln[t] + b$.

Cokriging Methods

It has already been pointed out that the final hydraulic property map (realization) cannot disregard the measurement data; they are the only factual knowledge available about the aquifer. However, aquifers are systems, the state of which is described by the spatial distribution of piezometric heads, and by the concentration of the solutes dissolved in water. In general, there is more information about the state of the system than about the parameters that controls it. Therefore, it appears necessary to generate spatial distributions of the parameters that are not only conditional to parameter values, but also consistent with the (partial) knowledge about the state of the system. This matter has already been introduced in the Section "Geostatistics". We present here two examples for completeness.

Cokriging Head and Hydraulic Conductivity

Rubin (2003) used the analytical approach to solve the perturbed flow equation. Rubin calculated $h' = h - E[h]$ and $Y' = Y - E[Y]$ at the points of h, head, and Y, log of

transmissivity; and determined analytically the covariance function of h' and the cross-covariance (h', Y') as a function of the covariance of Y. The covariance of Y is function of a set of parameters θ (i.e. integral scale of Y and its variance). This is actually sufficient to estimate the transmissivity field by cokriging. The cokriging estimator then gives the optimal estimation of Y at any point as follows:

$$Y(x) = \sum_{i=1}^{n_Y} \lambda_i Y_i + \sum_{j=1}^{n_H} \upsilon_j (h_j - E[h_j]) \qquad (65)$$

where the λ_i and the υ_j are optimal weights, that depend on the position x. The cokriging equations that provide the value of the optimal weights simply require that the covariance functions of Y, of h and of h–Y be known. Rubin then calculate by cokriging all the values of Y at the measurement points where Y is known and where it is therefore possible to compare the known value with the one estimated by cokriging – without using the known value of this point in the cokriging equations. As the cokriging estimator is a function of the θ parameters, these parameters can thus be optimized to minimize the errors between the estimated and measured Y values. The Maximum Likelihood method was used for their optimization (*see* Chapter **Chapter 156, Inverse Methods for Parameter Estimations, Volume 4**). Once the θ parameters are known, the cokriging equations give an estimation of Y at all points and a map of Y is obtained (Figure 15).

Cokriging Head and Hydraulic Conductivity for Concentration Estimations The goal is to condition the first two moments of the concentration on measurements of conductivity K and hydraulic head H. In order to model their spatial variability, Y and H will be modeled here as space random functions, so that $Y(x) = m_Y + Y'(x)$, where $m_Y = \langle Y(x) \rangle$, and $H(x) = \langle H(x) \rangle + H'(x)$. Hence Y' and H' represent the fluctuations of Y and H about their respective means. The hydraulic head is assumed to be at steady state. Small variability of the log-conductivity is assumed, and the linearized steady state flow equation is used to relate between Y' and H' and other hydrogelogical variables. Under these conditions, H' becomes a linear function of Y', and their cross-covariance can be derived analytically. Similarly, the concentration C is also viewed as a space random function and we define $C(x) = \langle C(x) \rangle + C'(x)$, where $\langle C(x) \rangle$ is the unconditional mean of $C(x)$.

The goal can now be stated as follows: define $\langle C^c(\mathbf{x}, \tau) \rangle$ and $\sigma^{2,c}_{\langle C \rangle}$, the conditional mean of the concentration and its estimation variance, where conditioning is done over N measurements, M of which are log-conductivities, and the rest are head measurements. These estimates should also reflect the dependence of C on time, τ. A superscript "c" denotes estimators, which are conditional to measurements. This task is accomplished using the following relationships for the conditional mean:

$$\langle C^c(x, \tau) \rangle = \langle C(x, \tau) \rangle + \sum_{i=1}^{M} \lambda_i(x, \tau) Y'(x_i) + \sum_{j=M+1}^{N} \mu_j(x, \tau) H'(x_j) \qquad (66)$$

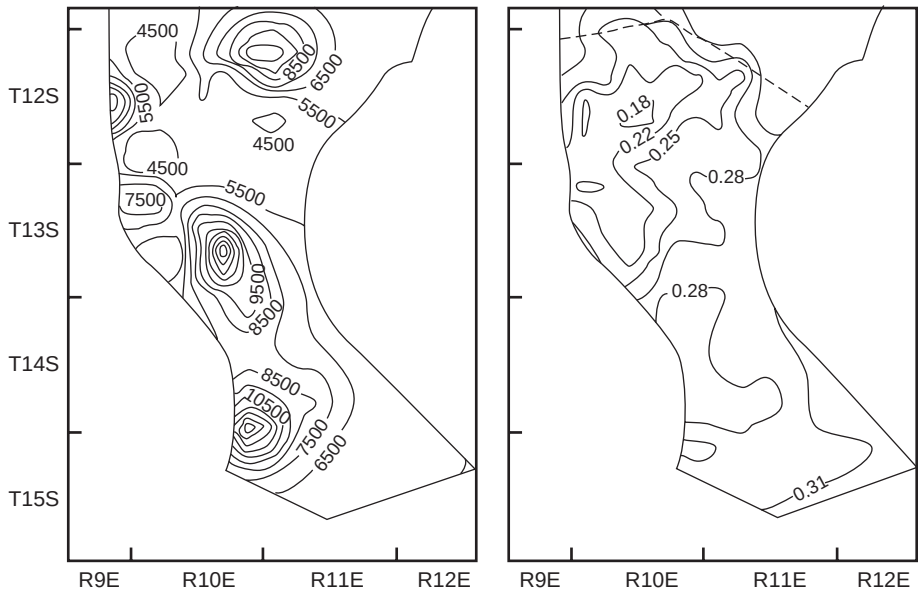

Figure 15 Estimated transmissivity and its variance (Reproduced from Rubin and Dagan, 1987 by permission of American Geophysical Union)

and the conditional estimation variance:

$$\sigma^{2,c}_{\langle C\rangle}(x,\tau) = \sigma^2_{\langle C\rangle}(x,\tau) - \sum_{i=1}^{M} \lambda_i(x,\tau) C_{CY}(x,\tau;x_i) - \sum_{j=M+1}^{N} \mu_j(x,\tau) C_{CH}(x,\tau;x_j) \quad (67)$$

where $\sigma^2_{\langle C\rangle}$ is the unconditional variance of the concentration. The above equations constitute the well-known geostatistical formalism of cokriging. Hence, the estimates of C will be unbiased and of minimum variance. A similar set of equations can be written for the conditional moments of Y and H, using the same cross-covariances, which appear in the above equations. The coefficients $\lambda_i(x,\tau)$ and $\mu_j(x,\tau)$ are the solutions of the following linear system (Journel and Huijbregts, 1978):

$$C_{CY}(x,\tau,x_k) >= \sum_{i=1}^{M} \lambda_i(x,\tau) C_Y(x_i,x_k) + \sum_{j=M+1}^{N} \mu_j(x,\tau) C_{YH}(x_j,x_k), \quad k = 1,\ldots,M \quad (68)$$

$$C_{CH}(x,\tau,x_k) >= \sum_{i=1}^{M} \lambda_i(x,\tau) C_{YH}(x_i,x_k) + \sum_{j=M+1}^{N} \mu_j(x,\tau) C_H(x_j,x_k), \quad k = M+1,\ldots,N \quad (69)$$

In the above equations the following definitions are used to denote spatial moments: $C_Y(x,x') = \langle Y'(x)Y'(x')\rangle$, $C_H(x,x') = \langle H'(x)H'(x')\rangle$, $C_{YH}(x,x') = \langle Y'(x)H'(x')\rangle$, $C_{CH}(x,\tau,x') = \langle C'(x\tau)H'(x')\rangle$ and $C_{CY}(x,\tau;x') = \langle C'(x,\tau)Y'(x')\rangle$. Given a set of N measurements, one can map the conditional expected concentration and its variance. C_{CY} and C_{CH} are depicted on Figure 16(a,b), respectively (Ezzedine and Rubin, 1996). Once these cross-covariances are analytically determined, one can proceed by mapping C conditional to Y and H measurements.

Cokriging Using Displacement and Travel Time for Concentration Estimations As part of the previous developments, the cross-covariances between Y and $X(\tau)$ were obtained. That suggests the possibility of using the time-displacement data to update the estimates of Y. Measured displacement can be coupled or perhaps used as an alternative to concentration measurements.

In fact, the use of displacements and travel times may be a better idea than using concentration data. For once, the concentration of a pulse is affected by pore-scale dispersion, while the travel times and displacements of the centroid of the pulse are affected to a much lesser extent. The concentration cross-covariances C_{CY} and C_{CH} were developed under the limiting assumption of negligible pore-scale dispersion, and by using travel times and displacements, we can avoid this limitation altogether.

In order to demonstrate the benefits of using travel time and displacements versus concentration, consider the following admittedly simplistic case. Solute of concentration C_0 is injected over a very short period. The displacement of the pulse is monitored. Let us assume that at time τ the pulse was located at $\alpha = (\alpha_1, \alpha_2, \alpha_3)$. In the absence of pore-scale dispersion, the concentration is equal to the initial one, that is, C_0. It is clear that

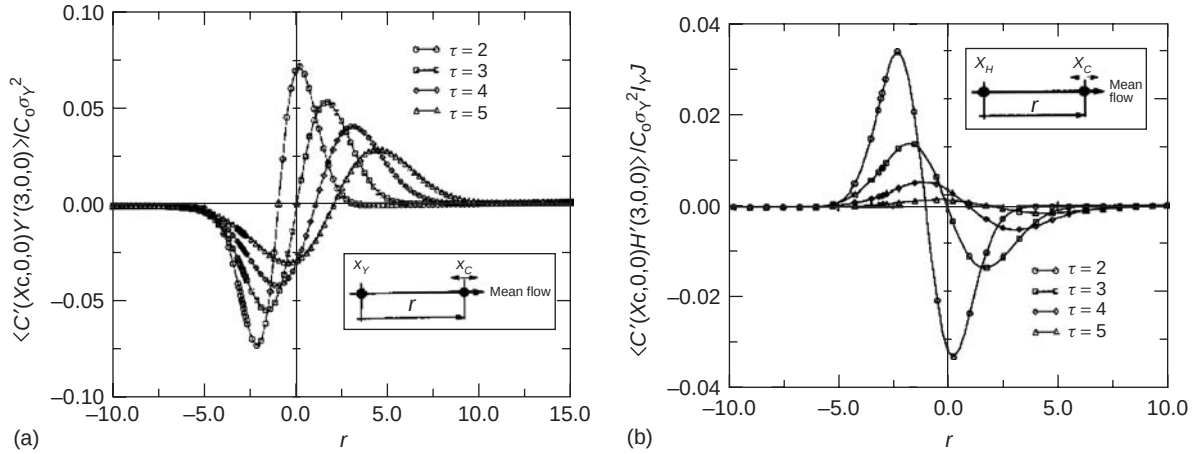

Figure 16 (a) Cross-covariances $\tilde{C}_{CY}(\mathbf{x}_C,\tau;\mathbf{x}_Y)$ for fixed $\mathbf{x}_Y = (3,0,0)$, $\mathbf{x}_C = (x_C,0,0)$ and τ are variables, and $r = x_C - 3$ (b) Cross-covariances $\tilde{C}_{CH}(\mathbf{x}_C,\tau;\mathbf{x}_H)$ for fixed $\mathbf{x}_H = (3,0,0)$, $\mathbf{x}_C = (x_C,0,0)$ and τ are variables, and $r = x_C - 3$ (Reproduced from (Ezzedine and Rubin, 1996) by permission of American Geophysical Union)

the magnitude of the displacement $X(\tau) = \alpha$ as well as the measurement $C(\alpha, \tau) = C_0$ are equivalent in term of the information content. Next we wish to compute the conditional mean and conditional variance of the pulse's longitudinal displacement. These moments can be related to the moments of the concentration (Ezzedine and Rubin, 1996). Conditioning on the concentration through kriging yields to $\langle X_1{}^c(\tau)\rangle = \langle X_1(\tau)\rangle + \lambda\ (C_0 - \langle C(\alpha, \tau)\rangle)$ and the conditional variance $X_{11}{}^c(\tau) = X_{11}(\tau) - \lambda\langle C'(\alpha, \tau)X_1'(\tau)\rangle$ with $\lambda = \langle C'(\alpha, \tau)X_1'(\tau)\rangle/\sigma_C^2(\alpha, \tau)$. The cross-covariance $\langle C'(\alpha, \tau)X_1'(\tau)\rangle$ is given by

$$\langle C'(\alpha, \tau)X_1'(\tau)\rangle = C_0(\alpha_1 - \langle X_1(\tau)\rangle)$$
$$\text{Prob}[\mathbf{X}(\tau) = \boldsymbol{\alpha}] = (\alpha_1 - \langle X_1(\tau)\rangle)\langle C\rangle \qquad (70)$$

we used $\text{Prob}[\mathbf{X}(\tau) = \alpha] = \langle C\rangle/C_0$. Recalling that $\sigma_C^2(\alpha, \tau) = \langle C\rangle(C_0 - \langle C\rangle)$ (Dagan, 1989), the conditional displacement is reduced to $\langle X_1{}^c(\tau)\rangle = \alpha_1$ and $X_{11}{}^c(\tau) = X_{11}(\tau) - (\alpha_1 - \langle X_1(\tau)\rangle)^2/(C_0 - \langle C\rangle)\langle C\rangle$. In the particular case of $\alpha_1 = \langle X_1(\tau)\rangle$ we get $\langle X_1{}^c(\tau)\rangle = \langle X_1(\tau)\rangle$ and $X_{11}{}^c(\tau) = X_{11}(\tau)$ which are the unconditional moments, that is, no reduction at all in the displacement variance is achieved: the result for the first moment is clearly right while the result for the variance is unsatisfactory because it does not show any benefit from the measurement. But this result is not wrong: it is a direct outcome from the $\langle C'(\alpha, \tau)X_1'(\tau)\rangle$ cross-covariance being zero for $\alpha_1 = \langle X_1(\tau)\rangle$: although C and X are not independent, they are not linearly correlated, and $C = 0$ may occur for X_1' either positive or negative (Figure 16a). Repeating this exercise but conditioning on the measured displacement instead will lead to $X_{11}{}^c(\tau) = 0$ due to the exactitude property of the kriging interpolator. The reason the displacement is more effective than the concentration is that unlike concentration, no ambiguity arises from its interpretation: a positive X_1', for example, can only arise from a positive Y'. Hence by a mere change of the interpretation we are able to make a better use of the data.

Bayesian Inversion

For a statistician, an inverse problem is an inference or estimation problem. The data are finite in number and contain errors, as they do in classical estimation or inference problems, and the unknown typically is infinite dimensional, as it is in nonparametric regression. The additional complication in inverse problem is that the data could be directly and indirectly related to the unknown. Bayesian techniques have become more attractive in the hydrogeological communities through the elegant work of Tarantola (1987). One of the fundamental tenets of Bayesian inference is that uncertainty always can be represented as a probability distribution; in particular, the Bayesian approach treats the model as the outcome of a random experiment. The essential defining property of a Bayesian is to talk about the probability $P(H|E)$ of a hypothesis H, given evidence E. Whether one adheres to a Bayesian view, estimators that arise from the Bayesian approach have an attractive property is that the posterior pdf is at least as informative as the prior one. In this case, the likelihood function is called *diffusive* or *totally noninformative*, and the prior estimates are exactly equal to the posterior estimates. It is emphasized that the method does not always guarantee better estimates for a couple of reasons. First, the Bayesian approach provides a pdf, not a single valued estimate. Second, the improvement achieved in the posterior pdf is dictated by the quality of external factors such as the accuracy of the likelihood function. Bayesian inversion is illustrated in the next Section "Joint geophysical-hydrogeological stochastic methods for subsurface characterization" particularly for combining geophysical survey and hydrogeological data for subsurface characterization.

JOINT GEOPHYSICAL-HYDROGEOLOGICAL STOCHASTIC METHODS FOR SUBSURFACE CHARACTERIZATION

Motivation

Combining ground-surface or cross-well geophysical surveys with well logs for enhancing the quality of subsurface characterization has been the goal of recent studies. The primary motivation has been the recognition that geophysical surveys offer unique opportunities for enhancing cross-well interpolation and are particularly promising in situations of data scarcity. Incorporation of two- and three-dimensional densely sampled geophysical data with conventional hydrological data increases the amount of data available for the characterization and thus has the potential to significantly improve the hydraulic parameter estimates over those obtained from borehole data alone.

The key problems are two: the nonuniqueness of the relationships between the hydrogeologic and geophysical rock/soil properties, and the absence of universal rock physics relationships that link the geophysical observable (i.e. electrical conductivity) to the hydrogeologic parameters (e.g. permeability, porosity). While these relations are sometimes difficult to obtain, it is critically important to recognize that even weak correlations can lead to a measurable improvement in estimation of the hydrogeologic variables. Integration of multisources of data is case and site-specific; however, the general framework is similar. The purpose of this section is to address the problem of joint hydrogeologic-geophysical site characterization following the study conducted by the author on Lawrence Livermore National Laboratory (LLNL) site data.

A few observations based on these studies are as follows: (i) No universal methods or petrophysical models are available for converting geophysical attributes to hydrogeological ones. (ii) The most challenging problem is tying well-logging measurements to the geophysical surveys. This issue involves problems of scale disparity and inconsistencies in the methods of data acquisition and interpretation. The last problem was studied extensively by Ezzedine *et al.* (1999) and can be demonstrated by the fact that resistivity at the LLNL site was measured along boreholes using several different tools, each characterized by a different support volume, sometimes leading to dramatically different results. Geophysical characterization is covered in **Chapter 148, Aquifer Characterization by Geophysical Methods, Volume 4**.

The main challenge that Ezzedine *et al.* (1999) had to face was in creating the bridge to link between ambiguously related geophysical surveys and well data. The second challenge was imposed by the disparity between the scale of the geophysical survey and the scale of the well logs. Ezzedine *et al.* (1999) approach is hierarchal and is intended to integrate and transform the well log data to a form where it can be updated by the geophysical survey, and this tends to be a convoluted process. In an ideal situation the geophysically measured attributes correlate well with the hydrogeological ones, for example, permeability, and the conversion of the geophysical survey to a hydrogeological distribution map is straightforward. In more realistic situations, such as the one described here, the conversion of the geophysical attributes to the hydrogeological ones is convoluted and nonunique. The difficulties faced in the implementation of the geophysical survey are several: the survey resistivity is expected to be of a relatively low resolution. At the same time, high-resolution permeability images are needed for flow and transport simulations. Thus the Bayesian framework has been chosen, which allows bridging between measurements of different resolutions.

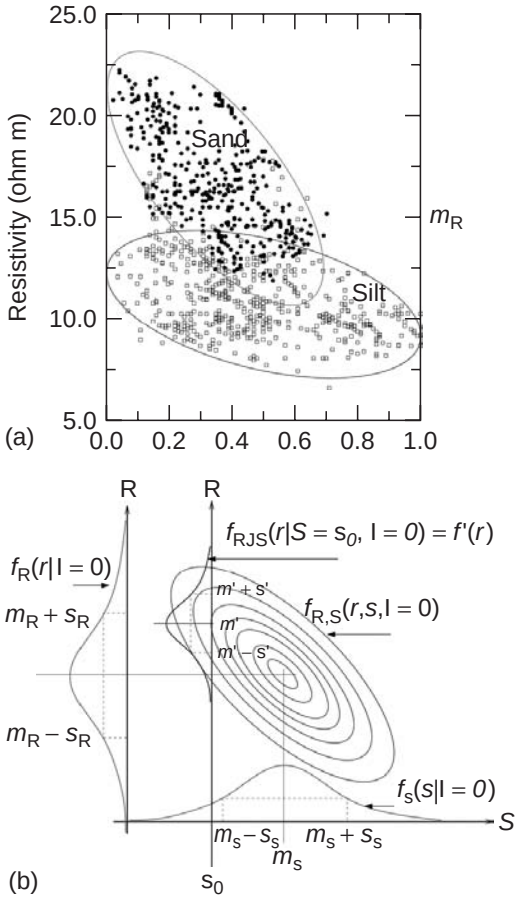

Figure 17 Shaliness versus resistivity cross-plot. (a) Two main clusters are identified: Silt and Sand. Bayesian Data Assimilation

Bayesian data assimilation is developed following a data-driven approach for lithology mapping based on the well log data. The proposed approach is general in its basic principles but at the same time is site specific since the petrophysical models employed are not universal. The general approach is stochastic. The choice is justified given the large uncertainty associated with cross-well interpolation, with the petrophysical models and with the interpretation of the geophysical surveys. The rationale for the approach is based on the following observations:

1. Resistivity and shaliness can be used for lithology identification through the cross-plot (Figure 17). Once a type of lithology is determined, further mapping of hydrogeological properties can be pursued.
2. Facies identification based on the shaliness-resistivity cross-plot is nonunique owing to some overlap between the sand and silt clusters.
3. Borehole resistivity measurements display short correlation range, and it is impractical to develop spatial images of the resistivity using cross-well geostatistical interpolation.
4. Shaliness displays a well-defined spatial correlation structure. It can be used for projecting resistivity measurements indirectly through a combination of geostatistical interpolation-simulation techniques, in conjunction with the nonlinear correlation structure it displays with the resistivity, as expressed through the cross-plot (Figure 17).

On the basis of these observations, the proposed approach consists of sequentially generating a series of collocated

attributes. At the basis of the hierarchy, images of the lithology are generated, conditional to well logs and possibly also to the survey resistivity. Each lithology image then serves as the basis for generating a series of shaliness images, again conditional to well data. The shaliness images are then used to correlate the survey resistivity with the hydrogeological attributes obtained experimentally. The series of generated images all have in common the well data and the same underlying spatial structure, and hence they are all physically plausible. The variations between the images constitute a measure of the spatial variability and estimation uncertainty. The focus is on estimating resistivity, but it can be converted to porosity and conductivity through well-known petrophysical models.

Bayesian Data Integration

The data integration encompasses the following steps:

Step 1: Generation of the lithology images using sequential indicator simulation (SISIM).

The lithology is defined through an indicator variable I according to: $i = 1$ if $\mathbf{x}$ is located in a silt body, 0 otherwise. Note that boldface letters denote vectors, that is, $\mathbf{x}$ is the location coordinates vector. Lowercase i is a realization of the spatial random function (SRF) I. I is characterized through its expected value conditional to the borehole data, $p^c = \mathbf{E}^c\{I\} = \mathbf{E}\{I|\text{measurements}\}$, with a superscript "c" denoting conditional. Since I is binary, p^c is statistically exhaustive. Its spatial variability is defined through the semivariogram and is shown in Figure 18(a,b). These statistics are the cornerstone of the SIS algorithm (Deutsch and Journel, 1997) adopted here.

Step 2: Generation of shaliness images.

This step is similar in principle to the previous one. The differences are in the fact that (i) the shaliness S is not a binary variable and (ii) the pattern of spatial variability of the shaliness may be different between the sand and silt lithologies, that is, $\gamma_S|i$, the semivariogram of the shaliness S, depends on the lithology $i = 0$ or 1. SGS algorithm (Deutsch and Journel, 1997) is adopted here to generate shaliness images. Shaliness S is defined by its mean $m_{S|i}$, its semivariogram $\gamma_{S|i}$ and its covariance, $\mathbf{Cov}_{S|i}$, for a given facies i (Figure 19a,b).

Step 3: Computing the resistivity prior pdf.

Once $\mathbf{x}$ is identified as being either sand or silt and is assigned a shaliness value, a prior pdf for the resistivity $f_{R(x)}(r|I = i, S = s)$ can be defined through Figure 17(a). R and S denote the SRF of the resistivity and the shaliness, respectively, and r and s denote their realizations. Figure 17(b) illustrates the joint pdf of R and S given $I = 0$ (i.e. sand lithology) and the marginals $f_R(r|I = 0)$ and $f_S(s|I = 0)$. Conditioning further on $S = s_0$ leads to $f_{R|S}(r|S = s_0, I = 0)$, which is the Bayesian prior. Scarcity of data leads to condition on ranges of S values rather than on single values. These pdfs are the Bayesian prior pdfs of the resistivity, and hence the stochastic estimation for the resistivity R at $\mathbf{x}$ in case no additional data become available through surveying.

Step 4: Updating $f_{R(x)}(r|I = i, S = s)$ based on cross-well electromagnetic resistivity survey $\rho(\mathbf{x})$.

Defining $f_{R(x)}(r|I = i, S = s) = f'_{R(x)}(r)$ for brevity, and given a collocated survey resistivity $\rho(x)$, the posterior pdf $f''_{R(x)}(r|\rho)$ can be defined through Bayes' rule:

$$f'_{R(x)}(r|\rho) = C_R L(\rho|r) f'_{R(x)}(r), \quad \text{and}$$

$$C_R = \left(\int_{-\infty}^{+\infty} L(\rho|r) f'_{R(x)}(r) dr \right)^{-1} \qquad (71)$$

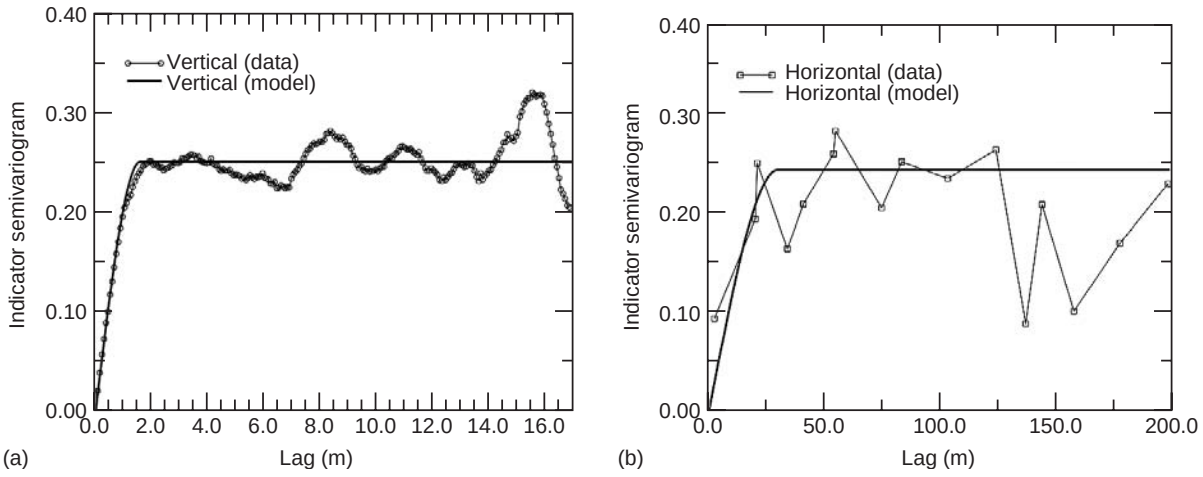

Figure 18 Experimental and theoretical indicator variograms: (a) vertical and (b) horizontal variograms (Reproduced from Ezzedine *et al.*, 1999 by permission of American Geophysical Union). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

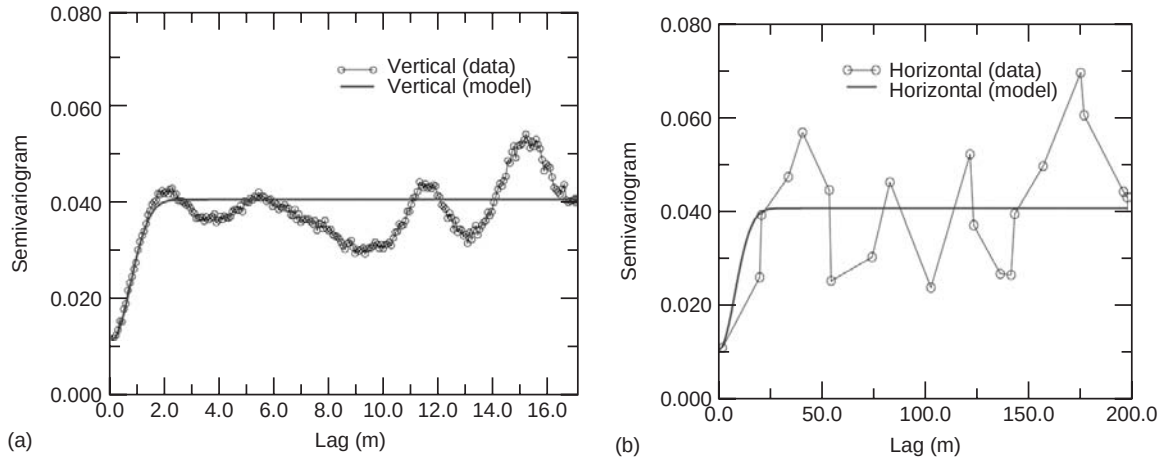

Figure 19 Experimental and theoretical variograms of shaliness: (a) vertical and (b) horizontal variograms (Reproduced from Ezzedine *et al.,* 1999 by permission of American Geophysical Union). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

where $L(\rho|r)$ is the likelihood function, and C_R is a normalized factor. In general, ρ is defined over a support volume larger than the support volume of r. In the case of a high-resolution geophysical survey $\rho(\mathbf{x}) \rightarrow r(\mathbf{x})$ and Bayesian updating is unnecessary. This, however, is not generally the case and the alternative is to update $f'_{R(\mathbf{x})}(r)$ given ρ. Typically we are interested in R representative of a block of scale $\sim$1 m while ρ is defined by blocks of scale $\sim$3 m or greater. The inference of the likelihood function, $L(\rho|r)$, is critical for the successes of the updating process. Once $f''_R(r|\rho)$ is defined, a realization of R at $\mathbf{x}$ can be drawn. The whole process is repeated for all $\mathbf{x}$ until a complete image of the resistivity field is completed. Similarly, the lithology images can be improved through the resistivity survey despite the nonlinear and nonunique relationship displayed in the cross-plot. The approach calls also for Bayesian updating of p^c as well, through the relationship: $p^{c'} = C_I L(\rho|I) p^c$, where $L(\rho|I)$ is the likelihood function, of a similar nature to $L(\rho|r)$, only relating ρ to I rather than R. C_I is a normalized factor similar to C_R.

Step 5. Measure the effectiveness of the Bayesian updating.

To evaluate the effectiveness of the updating procedure, the following statistic were analyzed:

$$\Re_k = \frac{|r_k - m''|}{|r_k - m'|}; \quad \begin{cases} \Re_k \langle 1, & \text{Successful updating} \\ \Re_k = 1, & \text{Unsuccessful} \end{cases} \tag{72}$$

where k is a running index over all the points outside the wells, r is the actual resistivity, m'' is the mean of the posterior pdf $f''_{R(\mathbf{x})}(\mathbf{x})$, and m' the mean of the prior pdf $f'_R(\mathbf{x})(\mathbf{x})$. The ratio $\Re$ compares the performance of the posterior and the prior pdfs. $\Re$ smaller than 1 indicates a successful updating procedure. $\Re = 1$ is a diffuse likelihood and hence a noninformative survey. Figure 20 depicts the variation of $\Re$, as a function of the resolution of the survey. For completeness, statistics were also computed for resistivity surveys of (2×2) and (12×12) block resolution. As expected, Figure 20 shows that $\Re$ decreases with decrease in resolution.

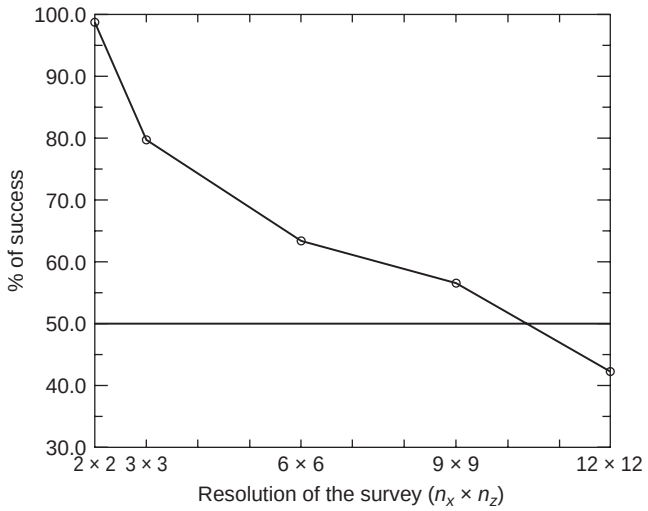

Figure 20 Effectiveness of the Bayesian updating (Reproduced from Ezzedine *et al.,* 1999 by permission of American Geophysical Union). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

THE USE OF STOCHASTIC CONCEPTS IN MODELING FRACTURED MEDIA

Introduction

Most fractured rock systems consist of rock blocks bounded by discrete discontinuities comprised of fractures, joints,

and shear zones, usually occurring in sets with similar geometries. Fractures may be open, mineral-filled, deformed, or any combination thereof. Open fractures may provide conduits for the movement of groundwater and contaminants through an otherwise relatively impermeable rock mass. Major factors affecting groundwater flow through fractured rock include fracture density, orientation, effective aperture width, and the nature of the rock matrix. Fracture density and orientation are important determinants of the degree of interconnection of fracture sets, which is a critical feature contributing to the hydraulic conductivity of a fractured rock system. Only interconnected fractures provide pathways for groundwater flow and contaminant transport. Fractures oriented parallel to the hydraulic gradient are more likely to provide effective pathways than fractures oriented perpendicular to the hydraulic gradient. The cross-sectional area of a fracture will have an important effect on flow through the fracture. Fracture-flux is proportional to the cube of the fracture aperture, this relationship is valid only for fractures with apertures greater than tens of microns (Bear *et al.*, 1993). Fracture apertures, and therefore flow through fractures, are highly stress-dependant, and generally decrease with depth. In recent years, a number of models have been developed to represent fracture flow. We introduce in the next section the most common geometric concepts of the models.

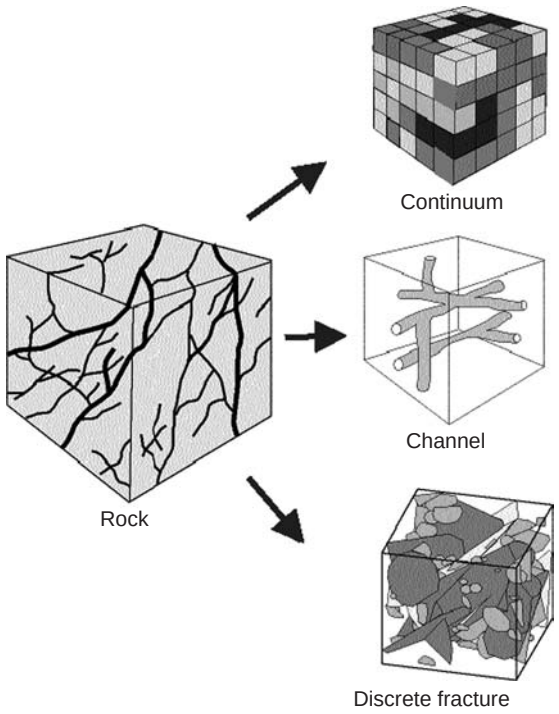

Figure 21 Different conceptual model geometry (Modified from Fractured Reservoir Discrete Feature Network Technologies, by Dershowitz *et al.,* 1998. **www.golder assosiates.com**). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Conceptual Model Geometry

Several different conceptual models have been used to describe flow and transport in fractured media. The most common conceptual picture of flow and contaminant transport in a fractured porous medium is that the advective flow of water and transport of pollutants is largely, or entirely, through the fractures. Water and contaminants may diffuse into and out of the porous rock matrix. This diffusion can act to spread out the contaminant plume in space and time, and to retard it.

In situations where transient water flow is involved, water may also be stored in, and released from, the rock matrix and the dead zones. To the extent that there is sufficient primary porosity in the matrix to allow advective flow and transport, as might be the case for a sandstone, this basic conceptual picture will be in error, as will any model that is based on it. If the rock matrix has very low porosity, such as would be the case for granite, then the role of the rock matrix can often be neglected.

Several different approaches, or concepts, have been used to describe the fractured mass (Figure 21). Models can be roughly classified as equivalent porous media models, multiple interacting continua (MINC) such dual porosity models, and stochastic fracture models. One could also develop models that overlap these categories.

The Equivalent Porous Medium

This approach treats the fractured rock system as if it were an unconsolidated porous medium. This approach is most likely to be successful when the spacing of the fractures is small compared to the scale of the system being studied, and the fractures are interconnected. The validity of using the Equivalent Porous Medium (EPM) approach to model pollutant transport in a fractured system is less well established. EPM could be extended to include models that assume an equivalent unique fracture intersecting the well, such fracture could be horizontal, vertical, and so on. This approach, generally used in the petroleum industry, only gives the local properties of a major fracture and does not necessarily assume that an EPM exists.

For the sake of simplicity, let us assume for a moment that fractures in a three-dimensional space are planes of finite extent, with the shape of irregular polygons or ellipses. If the average size of each fracture is small, and if its density is very low, a situation may arise in which none of the fractures intersects another. In this case, the global permeability of the system would be zero, since water cannot flow from one fracture to another. Whatever the size of the Representative Elementary Volume (REV), there is no EPM. A concept other than just size is thus required for the existence of an EPM; this other topological

characteristic is called the "*connectivity*" of the network and has been thoroughly studied in other areas of physics under the name of "percolation theory". An important concept in percolation theory is that of the "percolation threshold", defining a density of fractures above which the connectivity of the fractures is sufficient for flow to take place through a network, even an infinite one. Below this threshold, a few fractures may be connected, forming a "finite cluster" where flow can take place, but if the size of the domain of interest is increased, the system is globally unconnected, and only local pervious clusters exist.

At present, the best criterion for determining if a fracture network is above or below the percolation threshold is probably the one proposed by Charlaix (1984); the threshold is given by $nr^3 = 0.15$ to 0.30; n is the density of fractures (number of fractures per unit volume of rock); r^3 is the cube of the constant radius of the fractures, assuming that the shape of a fracture is a circular disc. This expression assumes that the orientation of the fractures is random. If fractures are not discs, r^3 should be taken as the average area of the fractures multiplied by their average half-perimeter divided by two.

Multiple Interacting Continua (MINC)

A modification of the EPM is to model the system as if it were composed of two overlapping continua with different porosities and permeabilities (Barenblatt *et al.*, 1960). Low porosity and high permeability are associated with the fractures and high porosity and low permeability are associated with the rock matrix. The model allows for the transfer of contaminants between the fractures and the rock matrix. This MINC approach requires that the fractures be closely spaced relative to the size of the system and that the fractures be frequently interconnected.

A simplified version of MINC is to represent the fractured system by a set of porous matrix blocks of well-defined geometry. The most common examples are parallel prismatic blocks (e.g. cubes, Figure 22) or spheres arranged in a regular array. The spaces between the blocks are the fracture channels. The blocks are assumed to be porous so that solutes can diffuse into and out of the matrix. This approach combines dual porosity with the discrete fracture approach. While no real aquifer has such a well-defined geometry, the model can provide insight into the important factors in solute transport in fractured porous media.

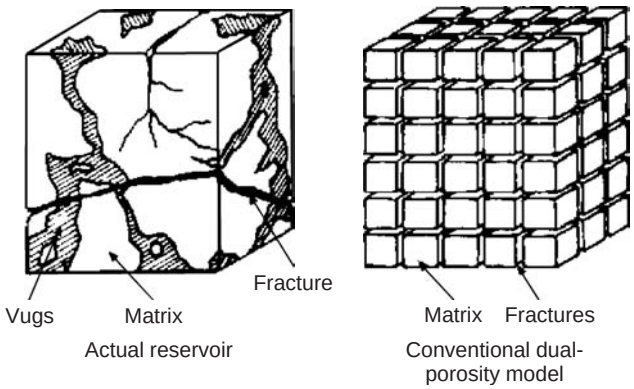

Figure 22 Double porosity model (Modified from Dershowitz *et al.*, 1998. **www.golderassosiates.com**)

Stochastic Discrete Fracture Networks (SDFN)

In the discrete fracture approach, the fracture geometry is explicitly included. Fractures are most often represented as channels with parallel sides, and the individual fractures are combined into fracture networks. The simplest network has a set of parallel fractures in what is basically a one-dimensional problem. A more complex network has two sets of parallel fractures oriented at some angle to each other in a two-dimensional array. A more complex, and one step closer to reality, is to allow the fractures to have varying lengths, locations, and orientations relative to one another (Figure 21).

One obvious problem in the practical application of discrete fracture models is that it is almost impossible to define the fracture system at a site in fine enough detail to apply the model. The best possibility for this approach seems to be through some sort of statistical modeling of the fracture system to duplicate the measured hydrology at the site. Most of the work on complex discrete fracture networks has been done in connection with the disposal of nuclear waste in crystalline rocks and has not included diffusion into the rock matrix. Real rock fractures may have rough surfaces (walls) that are not parallel to each other. The fracture may be partially filled with precipitated minerals or the walls could touch each other under mechanical stresses. In this case, it is better to describe the fracture system with flow through a series of tortuous intersecting channels.

When the SDFN may be simplified to single main channels connecting the center of the intersecting fractures and the center of their respective intersection areas, the SDFN is reduced to 3D network of 1D network of pipes or channels (Figure 21). Integrated hydraulic properties, for example, hydraulic conductivity, are then defined and the problem is solved through classical analogies to electric resistance network. This alternative is very useful when dealing with a large number of fractures and small computational capabilities.

None of the above conceptual pictures is "best" in an absolute sense. Rather, each may be appropriate for a particular situation. Models that are conceptually simpler have the advantage of being easier to implement as a rule, but they may also oversimplify the situation and miss important phenomena that are taking place. More complex models have the potential to provide a more detailed description of what is happening at the site being

modeled, but they are also likely to be more difficult to implement and may require data that cannot be collected with currently available techniques. Concepts introduced in the Section "Geostatistics" can be directly applied to the stochastic continuum approach where fractured mass is reduced to a Rubik's-cube-like equivalent heterogeneous "porous medium" where each block is defined by local EPM properties. Hereafter we focus only on SDFN models and their applications.

Stochastic Discrete Fracture Network Models

In this approach based on the model developed by Cacas (1989) and described in Ezzedine (1994), the fractures are treated as discs. The density and extensions are difficult to determine independently. There are relations between these magnitudes that can be used to test the connectivity of the medium. The hydraulic model is a bond model. The flow is not two-dimensional in the fracture plane but occurs in channels linking the centers of the connected discs. The walls are impervious. An additional parameter called *aperture* or "hydraulic thickness" is attributed to each disc in the model.

Characteristics of the Fracture Families

In natural fractured reservoirs, fractures can usually be grouped into families of directions using Schmidt or Rose diagram (Figure 23). For a single realization, a large number of fractures are drawn sequentially for one family of directions at a time. The families are then combined to

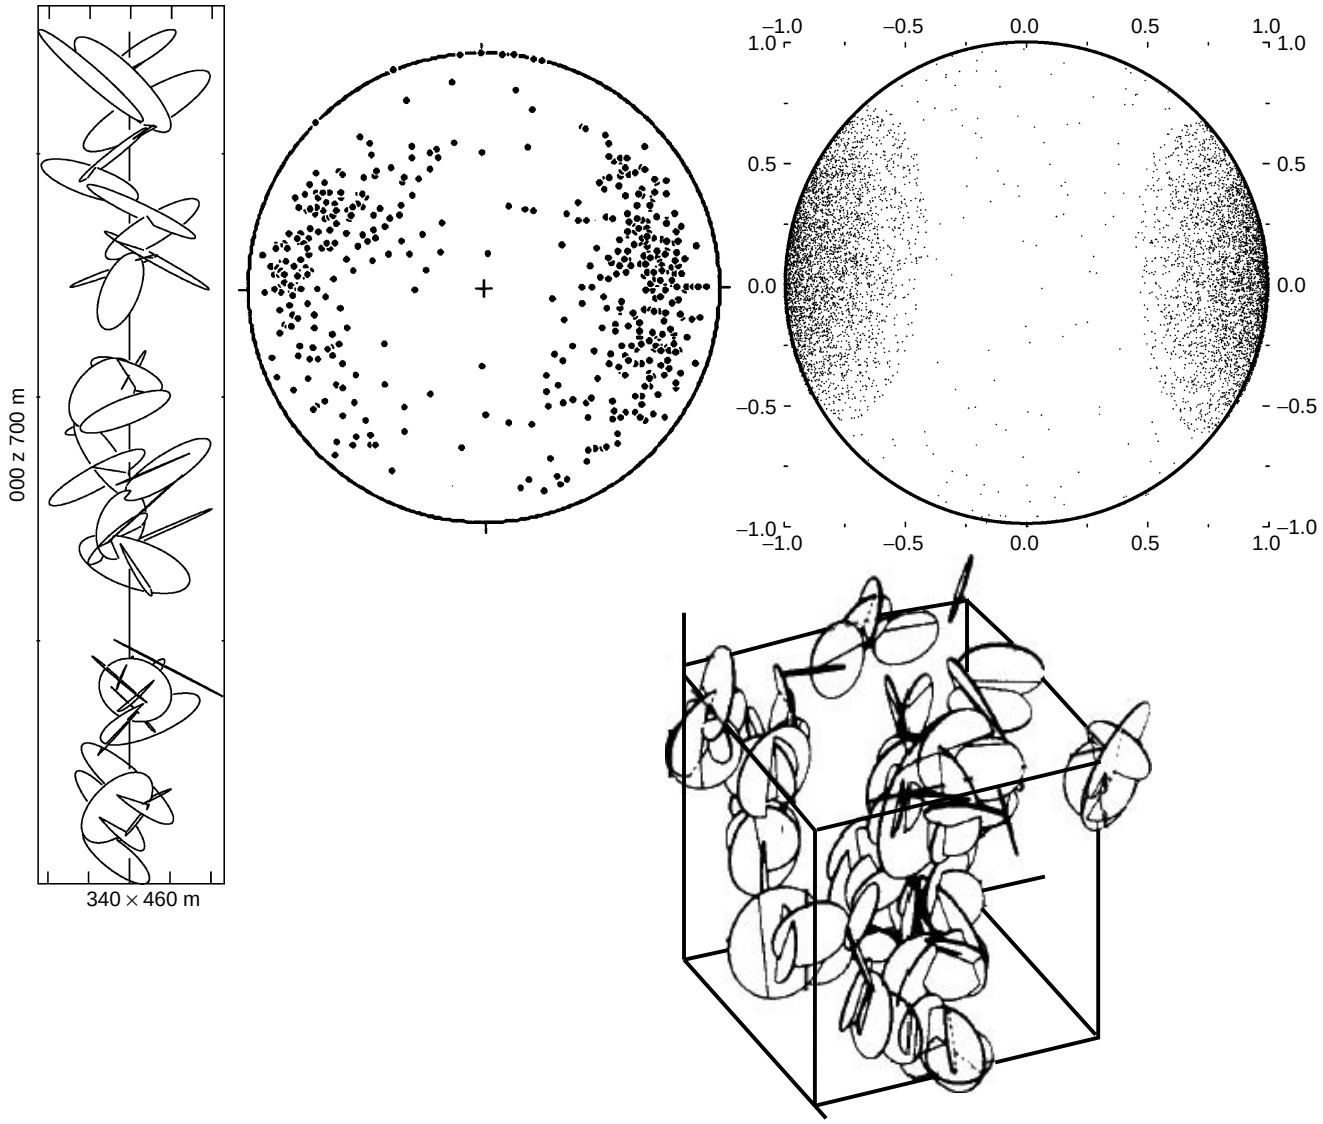

Figure 23 Stochastic discrete fracture network. Observed fracture in a borehole, observed fracture families (Rose diagram), simulated fracture families, and a 3D SDFN model (Reproduced with permission of Ezzedine, 1994)

Table 2 Example of probability density functions and their statistical moments

Law	Density f(x)	Mean E(X)	Variance V(X)
Log-normal	$\frac{1}{\sigma x\sqrt{2\pi}}\exp\left[-\frac{1}{2}\left(\frac{\ln(x)-\mu}{\sigma}\right)^2\right]$	$\exp\left[\mu+\frac{1}{2}\sigma^2\right]$	$\exp[2\mu+\sigma^2]\exp[\sigma^2-1]$
Exponential	$\lambda e^{-\lambda x}$	$\frac{1}{\lambda}$	$\frac{1}{\lambda^2}$
Gamma	$e^{-\lambda x}\frac{(\lambda x)^{k-1}}{(k-1)!}$	$\frac{k}{\lambda}$	$\frac{k}{\lambda^2}$

create the final network. For a given family, the draw is made as follows:

Number of Fractures A Poisson process is used to obtain the number of discs belonging to family i in the simulated volume $V(\mathrm{m}^3)$ as a function of the volumetric density λ_i (number of discs/m^3). The following expression gives the probability of having an N_i number of centers in the volume V.

$$p(N_i = k) = e^{-\lambda_i V}\frac{(\lambda_i V)^k}{k!} \tag{73}$$

Location of the Disc Centers The centers of the discs are independently distributed. The drawing of the Cartesian coordinates of the centers is done in a domain called the "*generation domain*". The (x_i, y_i, z_i) are coordinates of the centers are drawn according to a uniform law in the intervals $[x_{\min}, x_{\max}]$, $[y_{\min}, y_{\max}]$ and $[z_{\min}, z_{\max}]$.

Direction The direction of a fracture is defined by its normal unit vector **N**. The families of directions in a network consist of fractures with similar directions. Their normal vectors form an approximately cone-shaped segment, the axis of which is the "pole" of the family. Fisher's pdf is adopted and expressed as follows:

$$f_\kappa(\alpha) = C(\kappa)e^{\kappa\cos\alpha}\sin\alpha \quad \text{with} \quad C(\kappa) = \frac{\kappa}{4\pi\sinh(\kappa)} \tag{74}$$

where f represents the pdf of the angle α formed with the pole of the family (the pole is here the mean normal vector of the family); α is the angle between the fracture pole and the pole of the family; κ is the parameter of the law. For $\kappa \to +\infty$ the distribution is very concentrated around the mean direction. For $\kappa \to 0$, this distribution is closer to the uniform distribution.

Radius The radius is the parameter describing the extension of the fracture. Several statistical laws are available and given in Table 2 for completeness. Recently, de Dreuzy *et al.* (2001) suggested random fracture networks following a power-law length distribution.

Connectivity

The analysis of the connectivity and the search for continuous paths within such fracture networks use algorithms shared with the theory of graphs. It is, in fact, easy to ascertain whether two fractures are interconnected or not, but in a network of fractures, it becomes very costly to examine all the fracture couples. Therefore, the flow region is cut up into a certain number of blocks. A given disc intersects one or several of these elementary volumes. Two discs will not cut across each other unless both of them together cross at least one of the blocks. It is therefore necessary to test a possible intersection of two discs only if they are geographically fairly close to each other. This method makes it possible to limit the number of tests. Then, in 3D, the number of fracture couples is reduced from $1/2N(N-1)$ to $1/2N^2h^3k^2/R^3$ if the flow region is divided into cubes of volume h^3 and a fracture crosses k-cubes. Thus, the number of tests is reduced by $\sim h^3k^2/R^3$ provided that h is chosen as small as possible and k is of the order of 2 or 3 for one fracture.

Channeling, Integrated Hydraulic Conductivity

The "channeling hypothesis" is taken into account by defining permeability, said to be "integrated", into which the effective flow area is introduced. Once the interconnected geometry of the formation has been constructed, one defines the links connecting the centers of the two fractures that pass through the middle of the intersection segment. Thus, the geometry is reduced to a group of one-dimensional elements placed end to end in a three-dimensional domain

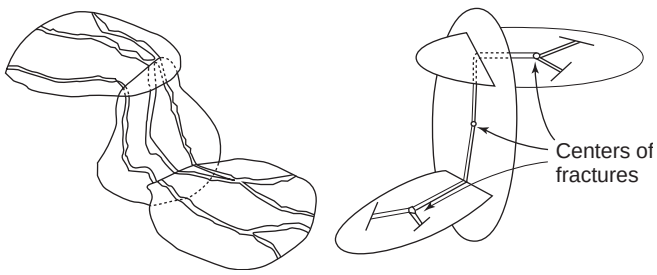

Figure 24 Channeling, ''true'' flow through fractures and simulated flow through pipe network (from Tsang *et al.*, 1991; Cacas *et al.*, 1989)

(Figure 24). Between two intersecting fractures, water circulates in a tube linking their centers and passing through the intersection segment. Assuming a fixed, straight, hollow cylinder of length l, large compared to the diameter $2R$, the volumetric flow in the tube is proportional to the fall of the pressure and to the fourth magnitude of the radius:

$$Q = \frac{\pi}{(8\mu)} R^4 \nabla h \tag{75}$$

μ is the kinematic viscosity and ∇h the hydraulic gradient between the ends of the tube. The "integrated hydraulic conductivity" is then defined as the ratio between the flow rate and the head gradient: $K = \pi/(8\mu)R^4$. The integrated hydraulic conductivity is the product of the "real" hydraulic conductivity (expressed in $\mathrm{m\,s^{-1}}$) multiplied by the cross-section of the flow, which is difficult to measure by hydrogeological tests. In this model, each disc is characterized by an integrated hydraulic conductivity, which is determined by the aperture (radius) according to a lognormal pdf. Effective integrated hydraulic conductivity between two intersecting fractures is estimated using a weighted harmonic average. The weights are the length of the two segments forming the pipe connection between the fractures (Figure 25). This magnitude represents the mean resistance, which prevents the water from circulating between two intersecting fractures. It integrates and lumps the whole flow geometry at the scale of the fracture: wall roughness, tortuosity, flow line lengths and channeling, and so on.

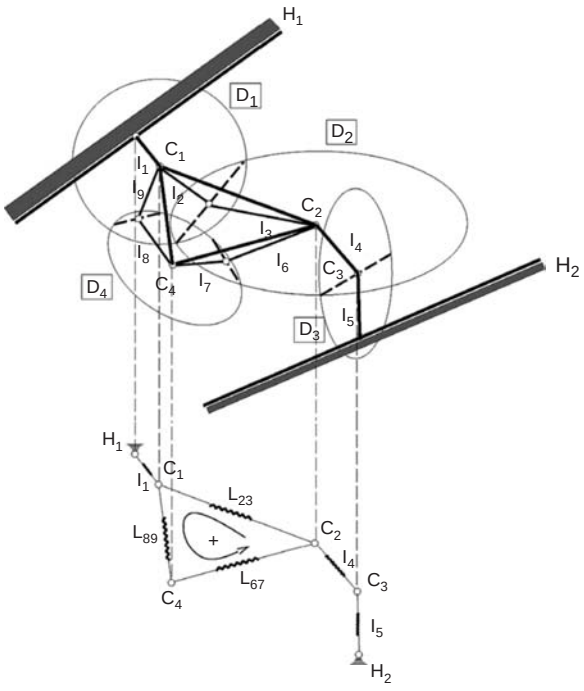

Figure 25 Analogy between flow in fracture network and electrical resistivity network (Reproduced with permission of Ezzedine, 1994). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Flow in Fractured Network

Similar to Kirchoffs law in electricity (Figure 25), when the flow is laminar and steady state in each fracture flowing following Poiseuille's law, at each fracture intersection the continuity of mass balance equation holds.

Consider a branch of a flow network (Figure 26) limited by two nodes i, and j, of length L_{ij} where the flow is governed by Darcy's law. This flow is characterized by a spatial variation of the conductivity k_{ij}. x is the distance between the observed section and the node i, measured along the branch. Because of the Darcy equation, the flow toward node i in branch ij is written:

$$q_{ij} = -k_{ij}(x) \left.\frac{\mathrm{d}h_{ij}}{\mathrm{d}x}\right|_{x=0} \quad \text{and} \quad q_{ji} = -k_{ji}(x) \left.\frac{\mathrm{d}h_{ji}}{\mathrm{d}x}\right|_{x=L_{ij}} \tag{76}$$

Assuming that the nodes have no capacity, the mass balance equation at each node i is $\sum_{j \neq i} q_{ij} = Q_i$, which is a system of linear equations in h_{ij} that can be solved readily using classic numerical techniques.

Modeling the flow through each fracture by a single conduit is restrictive and in some cases does not reflect the more complex reality, especially when the fracture network encompasses only a few fractures. To alleviate these restrictions, Ezzedine (1994) introduced "daughter fractures" that are imbedded into the "mother fractures" in order to create a 2D network of channels of interconnected 1D pipes. The introduction of a random perturbation to the normal vector of "daughter fractures" leads to different intersecting flow channels within the "mother fractures" (Figure 27). This technique allows enhancing the flow within each mother fracture from a 1D flow into 2D flow, which is more representative of the reality.

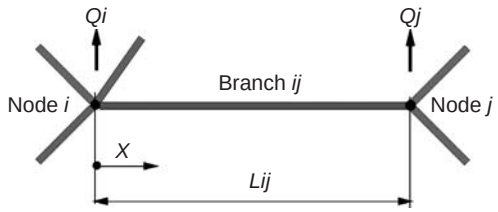

Figure 26 Single branch (pipe) representing a single fracture (Reproduced with permission of Ezzedine, 1994). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

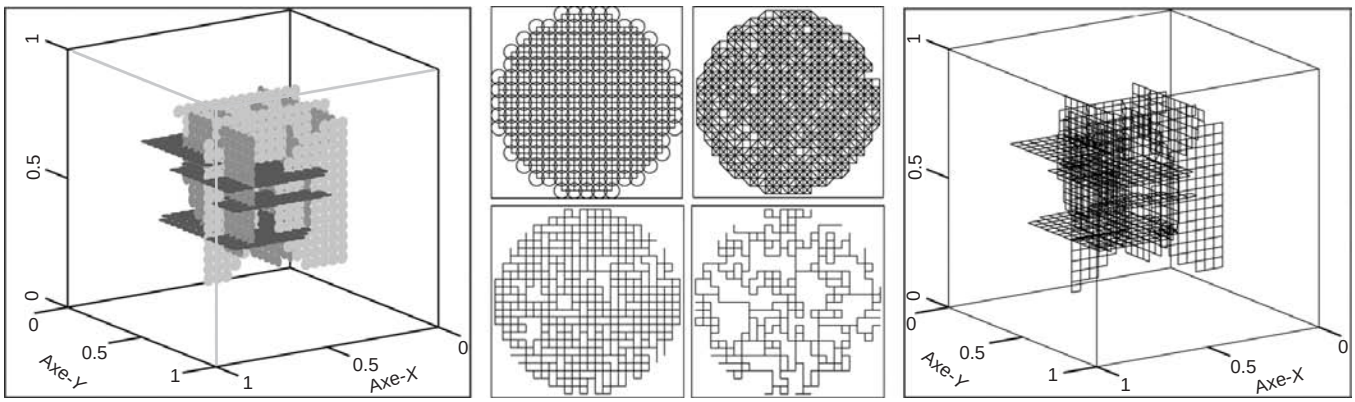

Figure 27 Simple 3D fracture network composed of 4 fractures in each direction (x,y,z). ''Mother'' fractures are mapped using ''Daughter'' fractures, four different cases are shown where the percolation network is depicted. The 3D fracture network is then reduced to a skeleton of 1D connected pipe network system (Reproduced with permission of Ezzedine, 1994)

Unsteady Flow and Transport in Fractured Network

In many applications, however, the assumption of steady flow is restrictive. Therefore, Ezzedine (1994) extended the model to simulate unsteady state flow. The flow at the fracture scale is derived analytically using Laplace transform. Flow at the formation level is then achieved by combining the solution of the generated individual fractures. A real flow injection test, performed at the Hot Dry Rock (HDR) site Soultz-sous-Forêts in Alsace/France, is simulated. Results show that the mechanical properties of the media influenced by the flow injection must be incorporated into the proposed model. In particular, changes in the hydraulic conductivity and the storage coefficient function of the effective stress appear to be quite significant. Consequently, the model is adjusted accordingly to include the mechanical effects that resulted in significant improvements. Heat extraction from Hot Dry Rock (HDR) is not limited to the hydrological phenomena discussed thus far but necessitates that thermal and geochemical processes must be addressed. Similar to fluid flow, a one-dimensional geochemical model was developed that takes into account the equilibrium and/or nonequilibrium transport of the chemical species and the water rock interaction. Thermal processes are modeled using a double porosity approach. The hydrothermal and chemical transport at the formation level is obtained by simultaneously combining the solution of the stochastically generated individual mother and daughter fractures.

The article gives an introduction to numerical modeling of flow and transport problems and to software tools that are currently in use for modeling such phenomena. Details are explained on numerical approximations leading to different numerical models. Extensions for reactive transport are mentioned. Basic guidelines and criteria are given that should be taken into account by the modeler in order to improve the accuracy of results. Inverse modeling is presented as an advanced feature. Some examples of pre- and postprocessing, as implemented in several codes, are given, in addition to fundamental properties of solution methods. Finally, most common codes are listed with basic features and web-sites.

INTRODUCTION

The forecast of state variables that describe flow and solute transport in a given aquifer can be obtained by solving the *mathematical model* that describes these phenomena. Such a model is based on a *conceptual* model that includes a set of verbal statements introducing a simplified version of the various physical, chemical, and biological aspects of the flow domain and the phenomena of transport that take place in it. Because, in most cases of practical interest, analytical solutions of the mathematical models are not possible, the mathematical models are transformed into *numerical models*, which, in turn, are solved by specially designed computer programs (= codes).

The codes account for physical aspects (e.g. multiphase/multicomponent, density-driven, chemical reactions, inertial/drag dominant, energy considerations, small/large matrix deformation, Newtonian/nonNewtonian fluids), modeling aspects (e.g. domain dimensionality, type of boundary conditions, Eulerian/Lagrangian formulation, deterministic/stochastic representations, lumped parameter/continuum/sharp interface approaches, phreatic/confined, unsaturated/saturated), and optimal management (i.e. mathematical procedures deriving the optimal extremum trajectories under different constraints and objectives). These are addressed by sensitivity and inverse methods, analytical and/or numerical (e.g. differences, virtual work/variational approaches) approximations, grid methods (e.g. finite differences, finite elements, volume elements, boundary elements, spectral elements), numerical algorithms (Eulerian/Lagrangian coordinates, particle tracking, explicit/implicit approximations, linear/nonlinear iteration procedures) and their associated reliability/efficiency measures (e.g. stability/monotonicity of the numerical scheme, Peclet/Courant grid based numbers). Such codes, which are the focus of this chapter, are applied by the modeler to set up models (in the literature sometimes the term model is used also for a code, which is not correct). Mostly the codes are executable software files, mostly equipped with user-friendly graphical user interfaces (GUIs). Sometimes source-codes are distributed, which have to be altered, compiled, and linked by the user.

A modeling task can be subdivided into several steps:

- Preprocessing (transformation of data into a format appropriate for the numerical algorithm, including grid generation)
- Numerical calculation (direct modeling)
- Calibration (inverse modeling)
- Postprocessing

Today's software packages or codes assist in all of these modeling steps.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Calibration as a task cannot be separated from the other tasks. Inverse modeling includes direct model runs, performed in order to determine one or more parameter values, which lead to an optimal approximation of measured results. Some pre- and postprocessing may be necessary during the inverse modeling procedure, when its not the standard in- and output variables, on which the calibration is based.

Many different software tools are today available to help users to set up their models. The aim of the models is to assist in the solution of practical problems, simulating processes in subsurface fluids and porous media. In the majority of cases, modeling serves to improve understanding of hydrogeological systems. Forecasting and thus studying the response due to different scenarios is the most ambitious goal of modeling efforts. In scientific literature, this is discussed under the term *validation*

- Validation is a process carried out by comparison of model predictions with independent field/experimental observations. A model cannot be considered validated until sufficient testing has been performed to ensure an acceptable level of predictive accuracy (IAEA International Atomic Energy Agency, 1988)
- Validation: the process of obtaining assurance that a model as embodied in a computer program is a correct representation of the process or system for which it is intended. (United States NRC – Nuclear Regulatory Commission, see Silling, 1983)

The task of code verification is a step towards validation in which numerical results are compared with analytical solutions or with well accepted published results.

Software tools can be subdivided into different classes, for which codes that perform numerical calculations are considered as the core software program. Around these packages have been developed for several pre- and postprocessing tasks. GMS, Visual MODFLOW, and PMWIN are examples, which are build around the MODFLOW code in the core – in most recent versions accompanied by other numerical codes. Other packages, like FEFLOW, embed all tasks in one package.

In judging a numerical code for simulating flow and transport scenarios imposed to a specific aquifer site, one should first verify what aspects are being addressed by the code. This in general accounts for:

- the theoretical and mathematical assumptions and other considerations;
- the numerical method, algorithm, and grid configuration;
- verifications of the code against analytical and numerical solutions as well as laboratory and field observations;
- performance under a variety of time and space increments;
- platforms on which the code can be run.

Input data that is required for code simulations can be classified into:

1. Geometry and topography issues
   (a) Site boundaries and dimensions
   (b) Surface topography (e.g. to detect zones with surface infiltration)
   (c) Location of streams, divides, ponds and so on
   (d) Land use (landfills, dikes, well locations, irrigation systems. . . .)
2. Geology and hydrology issues
   (a) Aquifers (stratification, depth, lithologic parameters, hydraulic conductivities, longitudinal and transversal dispersivities, storativities (i.e. matrix and water compressibilities), porosities)
   (b) Porous medium density
   (c) Water levels at surface reservoirs (rivers, ponds, etc.) compressing shallow aquifers
   (d) Pumping/recharge point sources (well depth, intensity, periodicity, and time of application)
   (e) Distributed sources of inflow, for example, rainfall and irrigation rates
   (f) Distributed sources of outflow, for example, evapotranspiration
   (g) Time dependent data at spatial points
3. Water and porous medium chemical properties
   (a) Sorption (adsorption and desorption) factors.
   (b) Electrical conductivities.
   (c) Temporal and spatial concentration of solutes in the water and the solid phases of the porous medium
   (d) Solutes associated with sources of recharge fluxes (rainfall, irrigation, etc.).
   (e) Concentration of stable isotopes and microelements.
4. Boundary and initial conditions
   (a) Initial field distribution of piezometric head and components concentration.
   (b) Pervious/impervious boundary segments with the ascribed flux conditions.
   (c) Piezometric heads and concentrations along boundaries.

The user has to take into account that codes often differ concerning the input parameters, an aspect that may make some codes more appropriate for a given task than others. As an example many codes allow conductivity anisotropy only in direction the principal axes of the coordinate system. When anisotropies in changing directions have to be taken into account, the modeler has to choose a code that is capable of handling such a situation.

MATHEMATICAL MODELS

Groundwater Flow

Groundwater flow models are based on the differential equations for groundwater flow. Such differential equations, as described in **Chapter 149, Hydrodynamics of Groundwater, Volume 4**, are usually based on Darcy's Law as the linear macroscopic fluid momentum balance equation, considering the drag terms of the Navier Stokes equation as dominant, and on the principle of the fluid mass conservation.

Depending on the special features of the situation to be modeled, different circumstances have to be taken into account. A model for a confined aquifer is different from that for an unconfined (phreatic) aquifer. The spatial dimensionality (1D or 2D or 3D) depends on the physical situation and the aim of modeling. Depending on the very same aspects, a decision about steady state versus unsteady simulations has to be taken, just to name the most basic properties of a model.

There are different formulations of the differential equations. Equation (1) states the mass balance in 3D:

$$\frac{\partial}{\partial t}(\phi\rho_f) = -\nabla\cdot(\rho_f \mathbf{v}) + Q \tag{1}$$

where ϕ denotes porosity, ρ_f fluid density, $\mathbf{v}$ the three-dimensional vector of Darcy velocity, that is specific discharge, and Q represents mass sources or sinks of whatever type. Most models work with a simplified version of equation (1), which is valid for constant density ρ_f. With the help of Darcy's Law, the equation can be reformulated in terms of hydraulic head h. Simplified 2D versions of equation (1) are used quite frequently, which are different for confined or unconfined aquifers. In the confined situation:

$$S\frac{\partial h}{\partial t} = -\nabla\cdot T\nabla h + P - Q \tag{2}$$

in which P and Q represent pumping and recharge rates, respectively, where S denotes the storativity and T the transmissivity. Usually the hydraulic head, h is the dependent prime variable, for which the differential flow equation is formulated and which is calculated by the model. In 2D problems the stream function can be used as an alternative (Holzbecher, 1996). For applications involving variable density, a generalized hydraulic head or pressure p have to be introduced (Holzbecher, 1998) as dependent prime variable.

The codes allow the specification of different boundary conditions, which are relevant for groundwater flow (*see* **Chapter 149, Hydrodynamics of Groundwater, Volume 4**). When the first-type (or Dirichlet) condition is used, h is specified at that location. For the second-type (or Neumann) condition, the normal velocity has to be specified. The often-used no-flow condition is a special case (zero velocity). Third type (or Cauchy) boundary conditions can be used, when a relation between flux and head has to be considered, for example, when an aquifer is connected to a surface water body.

Hydraulic conductivity is an input parameter for most models. In the case of the 2D flow in a confined aquifer, transmissivity (integration of the conductivity over the third spatial direction) is required instead. Unsteady models require specific storativity for unconfined aquifers, and storativity as product of specific storativity and layer thickness for confined aquifers (*see* **Chapter 149, Hydrodynamics of Groundwater, Volume 4**). Porosity is needed when real interstitial velocities have to be determined, for example, when a transport model is to be set up in addition or when travel times along flowpaths are required.

Transport (Mass and Heat)

Transport models are derived from the transport equation, which is the mass balance equation in terms of the concentration of a certain substance in case of solute transport (*see* **Chapter 152, Modeling Solute Transport Phenomena, Volume 4**) through the aquifer system. In case of heat transport, it is a differential equation for temperature as the dependent prime variable (Holzbecher, 1998).

The generic form of the solute transport equation in porous media reads

$$\frac{\partial}{\partial t}(\phi c) = -\nabla(\mathbf{v}c - \phi\mathbf{D}\nabla c) + q \tag{3}$$

with porosity ϕ, combined coefficient of diffusion and dispersion tensor $\mathbf{D}$, specific discharge $\mathbf{v}$ and source/sink-term q. Equation (3) is a balance equation for component mass, which is valid for constant density fluids (*see* **Chapter 152, Modeling Solute Transport Phenomena, Volume 4**). The dependent prime variable is the concentration c. The term on the left side of the equation represents storage in general (gains or losses). The term $\mathbf{v}c$ on the right side represents advection and $\phi\mathbf{D}\nabla c$ is the sum of diffusion and dispersion. The last term is for sources and sinks of all types. Within the heat transport equation, the same terms can be found with different parameters:

$$\frac{\partial}{\partial t}T = \nabla D_{\text{therm}}\nabla T - \kappa\mathbf{v}\nabla T \tag{4}$$

with thermal diffusivity D_{therm} the ratio κ between heat capacity of the fluid and the heat capacity of fluid and porous medium. Internal sources and sinks are neglected in equation (4), which results from the energy balance

equation by dividing through the heat capacity of the porous medium. The dependent prime variable is the temperature T (Holzbecher, 1998).

The types of boundary conditions in general are the same as in flow models. In the first type, a concentration or a temperature needs to be specified. The second type accounts in general for advective and dispersive fluxes. Frequently used is the no dispersive flux condition, where it is required that the derivative of the dependent variable normal to the boundary is zero. The latter condition is not only used at impermeable boundaries. For lack of alternative, it is most often also used at outflow edges. Obviously the condition is not correct for fronts crossing the boundary, or vice versa: it is only applicable when during the simulation period the concentration or temperature gradients are small.

Reactive Transport

Taking into account that only few biogeochemical species in the subsurface are independent from their biogeochemical surrounding, models couple physical transport processes and biogeochemical reactions. The basic features concerning the coupling of transport and reactions are outlined in **Chapter 152, Modeling Solute Transport Phenomena, Volume 4**.

When several species, which are linked to each other by reactions, are modeled, the transport equation has to be solved for each of these species. Two types of reactions have to be distinguished: equilibrium or kinetics. If for an application the timescale of interest exceeds the typical reaction time, the reaction is fast and it can be assumed that the equilibrium is reached, when the reaction is reversible. Equilibria are usually described by the *Law of Mass Action*. For the reaction $A + B \leftrightarrow C$ between species A, B, and C, the equilibrium is given by:

$$\frac{a_C}{a_A a_B} = K \tag{5}$$

where a denotes the activity of the species, and K is the reaction specific equilibrium constant. The activity of a species is the product of the concentration and an activity factor γ, which depends on the charge of the species and the ionic strength of the solution (Krauskopf and Bird, 1995).

When for an application the reaction time is smaller than the time of interest, an explicit formula for the development of the reaction rate in time has to be used. Such a reaction is termed *kinetic*. The difference concerning the coupling with transport.

In general for a set of species, the coupled problem for reactive transport is given by:

$$\phi \frac{\partial}{\partial t}\mathbf{c} = \left(\frac{\partial}{\partial z} D \frac{\partial}{\partial z} - v\frac{\partial}{\partial z}\right)\mathbf{c} + \mathbf{S}_{\text{eq}}{}^{T}\mathbf{r}_{\text{eq}} + \mathbf{S}_{\text{kin}}{}^{T}\mathbf{r}_{\text{kin}} \tag{6}$$

(Saaltink *et al.*, 1998), where the vector $\mathbf{c}$ contains all species concentrations. The vectors $\mathbf{r}_{\text{eq}}$ and $\mathbf{r}_{\text{kin}}$ denote the reaction rates of equilibrium and kinetic reactions, and the matrices $\mathbf{S}_{\text{eq}}$ and $\mathbf{S}_{\text{kin}}$ relate reactions (in rows) and species (in columns) for equilibrium and kinetic reactions.

The problem with (6) is that the rates of the equilibrium reactions are not known beforehand. Thus the entire set of equations is manipulated by linear transformations in order to make the term corresponding with equilibrium reactions vanish. Such a transformation is always possible, but not unique. It can be described by the multiplication of the system (6) with another matrix $\mathbf{U}$ from the left (Saaltink *et al.*, 1998), which is equivalent to the transition from species concentrations to total concentrations, also called *components*.

The system for the total concentrations $\mathbf{u} = \mathbf{U}\cdot\mathbf{c}$ is given by

$$\varphi \frac{\partial}{\partial t}\mathbf{u} = \left(\frac{\partial}{\partial z} D \frac{\partial}{\partial z} - v\frac{\partial}{\partial z}\right)\mathbf{u} + \mathbf{U}\mathbf{S}_{\text{kin}}{}^{T}\mathbf{r}_{\text{kin}} \tag{7}$$

In addition the reaction equilibria have to be taken into account, which can be noted as:

$$\mathbf{S}_{\text{eq}}\cdot\mathbf{log(a)} = \mathbf{log(K)} \tag{8}$$

where the vector $\mathbf{a}$ denotes all activities, and the vector $\mathbf{K}$ all equilibrium constants. Altogether a mathematical system results in which transport differential equations (7) are combined with a set of algebraic equations (8), so-called algebraic differential equations.

Sorption

Sorption denotes a variety of phenomena and processes, which concern the interaction between fluid and solid phase. In the most general approach, sorption reactions can be treated within an extended concept of reactive transport as surface reactions (Parkhurst, 1995). More common are simplified approaches. Kinetic laws can be used to describe slow (nonequilibrium) sorption. The simplest approach is to take first-order kinetics, but this may not suffice for reactive transport, where more complex approaches (for example: Monod) may become necessary. The most common situation of fast (equilibrium) sorption is modeled by combining the transport differential equation with a sorption isotherm (linear sorption, Freundlich-, Langmuir) that describes the equilibrium between solid and fluid phase, leading to the concept of retardation. The details are outlined in **Chapter 152, Modeling Solute Transport Phenomena, Volume 4**.

Different codes handle sorption differently. Some codes allow the direct input of retardation factors (FAST), while others require the specification of the isotherm and the corresponding parameters. Some codes require one isotherm

for the entire domain, others allow the sorption characteristic to change with layers, others by cell (MT3D96).

NUMERICAL MODELS

There are different numerical techniques by which computer algorithms are derived from equations that govern the model. In order to obtain a numerical model, the mathematical (e.g. differential) formulation for continuous variables has to be transformed into discrete form. The discrete variables (e.g. hydraulic head in flow models, concentration, or temperature in transport models) of the model are determined at nodes in the model domain, determined by a *grid*.

Finite Differences

The method of Finite Differences (FD) is derived as approximation of the differential equation. Derivatives (differential quotients) are replaced by difference quotients. For first and second order derivatives, the simplest central stencils (CIS = central in space) are given by:

$$\frac{\partial f}{\partial x} \approx \frac{f_{i+1} - f_{i-1}}{2\Delta x} \qquad \frac{\partial^2 f}{\partial x^2} \approx \frac{f_{i+1} - 2f_i + f_{i-1}}{\Delta x^2} \tag{9}$$

where the f-values denote function values at the grid nodes, that is, f_i is the approximate value of the function at node i, f_{i-1} at the previous node, and f_{i+1} at the following node (see Figure 1). This leads to a system of equations for the unknown values ($f_i, i = 1..N$), where N denotes the total number of nodes. For transport problems, the upwind scheme (BIS = backward in space) is important:

$$\frac{\partial f}{\partial x} \approx \frac{f_i - f_{i-1}}{\Delta x} \tag{10}$$

In two space dimensions (2D), the five-point stencils, describing finite differences, can be visualized as shown in Figure 1. For example, the Laplace-operator $(\partial^2/\partial x^2 + \partial^2/\partial y^2)f$ is represented by a stencil with factor -4 at the center and 1 in the other four nodes.

FD-grids are usually rectangular, and may be irregular, that is, each column, row, or layer may possess individual grid spacing. The values of the dependent variable are calculated at the nodes, while parameters are specified for the spacing between the nodes (node centered grid).

Finite Volumes

The method of Finite Volumes (FV) is derived from a mass or volume balance for all blocks of the model region. As visualized in Figure 2, the load (e.g. volume or mass) balance in block ij is obtained by:

$$\frac{\partial V}{\partial t} = Q_{i-} + Q_{i+} + Q_{j-} + Q_{j+} + Q \tag{11}$$

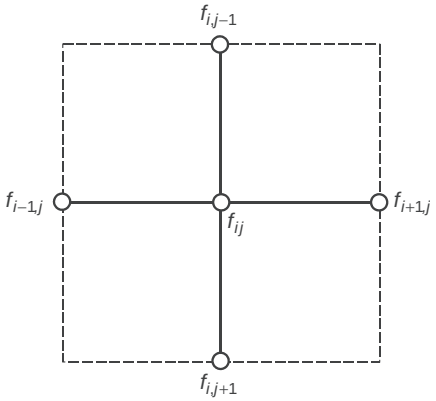

Figure 1 Finite difference stencil for function f in 2D

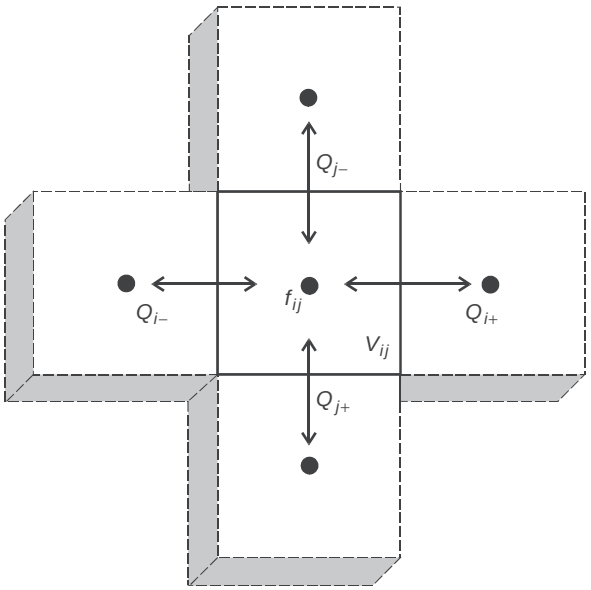

Figure 2 Quadratic finite volume in 2D

where V denotes the volume or mass (see Figure 2) in the block, Q_{i-}, Q_{i+}, Q_{j-}, Q_{j+} the fluxes across the block edges, and Q other sources or sinks for volume or mass.

A set of equations for the values of the unknown variables in the block centers is obtained by expressing the fluxes in terms of that variable. With the help of Darcy's Law, all volume balance equations come into a form that expresses relations between hydraulic heads $f_{ij} = h_{ij}$.

Similarly, Finite Volume grids may be of general form, as they are defined by the budget of fluxes across the boundaries of a block. The dependent variable is calculated at the center of the block (block centered grid). Parameters are specified for blocks, that is, around the block centers. The different form of grids used in FD and FV makes it difficult to compare results obtained by the different methods without interpolation.

Finite Elements

Finite elements grids can be of different shape, but very often they can be recognized by the simple triangular form of the single elements. The triangular shape is convenient to approximate arbitrary shaped regions with small deviations, where rectangular grids often show stairway structures at least at parts of the boundaries.

Using Finite Elements, the solution of the differential equation is found as a combination of shape (or Lagrangian)-functions. These functions are different for different elements. For the most common triangular elements, the prescribed Lagrangian functions are linear within each element (see Figure 3). Thus f is approximated, for example, in Cartesian coordinates, by

$$f(x, y) = a_{\alpha 0} + a_{\alpha 1}x + a_{\alpha 2}y \qquad \text{within element } \alpha \tag{12}$$

All coefficients $a_{\alpha j}$ for all elements are computed as solution of a linear or nonlinear system, which is derived from the so-called weak form of the differential equation (Huyakorn and Pinder, 1983).

Method of Characteristics / Lagrangian Methods

One approach that has been gaining popularity is the mixed Eulerian–Lagrangian method that combines the simplicity of the fixed Eulerian grid with the Lagrangian approach being especially effective in advective dominant regions. Following Neuman and Sorek (1982) for transport problems (e.g. see also Neuman, 1984; Sorek, 1988a,b), for flow problems (Sorek, 1985; Sorek and Braester, 1988) and a modified Eulerian–Lagrangian method for coupled flow and transport model (Bear *et al.*, 1997; Sorek *et al.*, 2000), a technique consisting of the following two steps is used:

1. Formal decomposition of the dependent variable into two parts, one controlled by pure Lagrangian advection and a residual governed by a combination of Euler–Lagrange approaches.

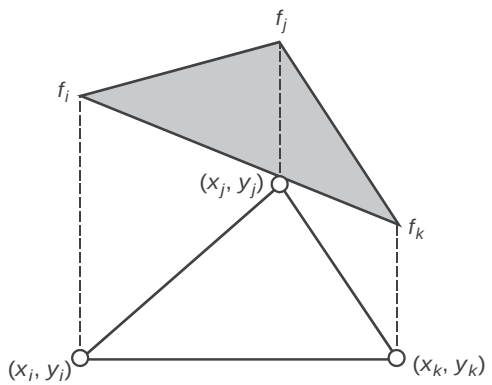

Figure 3 Finite element in 2D

2. Solution of the resulting advection problem by the method of characteristics for forward particle tracking. The residual problem is solved by, for example, an implicit finite element scheme on a fixed grid.

Information is projected back-and-forth between the Eulerian–Lagrangian and the Lagrangian schemes. The major problem of the decomposition strategy is the interpolation (coupling) between the residual and translation solutions as these are obtained at different spatial locations and should be performed in a manner that is mass conservative.

To understand the concept of the decomposition, consider a governing partial differential equation

$$\mathbb{L} f = Q \tag{13}$$

in which $\mathbb{L}$ denotes the differential operator, f denotes the dependent prime variable, and Q denotes the source term. We now decompose (13) into translation, $()_{\mathbb{T}}$, and residual, $()_{\mathbb{R}}$, terms to read

$$(\mathbb{L}_{\mathbb{T}} + \mathbb{L}_{\mathbb{R}})(f_{\mathbb{T}} + f_{\mathbb{R}}) = Q \tag{14}$$

One way to perform the decomposition is to allow

$$\mathbb{L}_{\mathbb{T}} f_{\mathbb{T}} = 0 \tag{15}$$

for which $f_{\mathbb{T}}$ is solved along a characteristic pathline defined by

$$\mathbb{L}_{\mathbb{T}} \mathbf{X} = \mathbf{V} \tag{16}$$

where $\mathbf{X}$ denotes the position spatial vector known only if $\mathbf{V}$ the velocity vector tangent to the characteristic pathline is provided, otherwise iterations are required. By virtue of (14) and (15), the next step is to solve

$$\mathbb{L} f_{\mathbb{R}} = Q - \mathbb{L}_{\mathbb{R}} f_{\mathbb{T}} \tag{17}$$

However, as we may expect the condition

$$\mathbb{L} f_{\mathbb{R}} \gg \mathbb{L}_{\mathbb{R}} f_{\mathbb{T}} \tag{18}$$

and in view of (17) and (18), we obtain

$$\mathbb{L} f_{\mathbb{R}} \cong Q \tag{19}$$

which is similar to a Poisson equation and is not expected to suffer from stability difficulties typical to advection dominant flow regimes. In cases with dominant source terms, we allow $f_{\mathbb{T}}$ to obey

$$\mathbb{L}_{\mathbb{T}} f_{\mathbb{T}} = Q \tag{20}$$

for which by virtue of (17) and (18), we solve $f_{\mathbb{R}}$ by a Laplacian equation in the form

$$\mathbb{L} f_{\mathbb{R}} \cong 0 \tag{21}$$

which is more stable than (19).

Variations of the method of characteristics are implemented in some of the most used transport codes, as MT3D. The user can choose between MOC (method of characteristics), Modified MOC (MMOC), and Hybrid MOC (Zheng and Bennett, 1995). While MOC uses forward tracing along the flowpaths (characteristics), in the MMOC the characteristics are traced backward from the nodes. The hybrid scheme combines both approaches (Neuman, 1984).

Time Stepping

The discretization of time is as a rule implemented as time stepping. The computed values at the previous time level t are used as initial condition for the calculation at the new time level $t + \Delta t$. The time-step Δt may vary. The entire algorithm starts in using the initial condition for the dependent variable of the problem setup, which has to be specified by the user in addition to the differential equation with its boundary conditions.

Simple time-stepping algorithms can be described by the following formula:

$$f(t + \Delta t) = f(t) + \Delta t[\kappa \cdot C(f(t + \Delta t) + (1 - \kappa)C(f(t))] \tag{22}$$

In the notation, the dependency of f on space variables is neglected. The operator C denotes the spatial discretization, which can be achieved using the finite differences (FD), finite volumes (FV), or finite elements (FE) method. κ is a parameter, which either has a fixed value for the implemented method or can be chosen by the modeler. For $\kappa = 1/2$, when both old and new time levels are equally weighted, one obtains the classical *Crank–Nicolson* procedure. For $\kappa = 1$, the totally implicit method results, where the spatial discretization is taken only at the new time level. For $\kappa = 0$, an explicit algorithm results, which is cheaper to solve (as the solution of a linear system is not required). But often the accuracy of the explicit algorithm is poor, or it even does not converge.

Advanced time-stepping algorithms are given by the so-called *Runge-Kutta* methods (Holzbecher, 1996), which can, for example, be found in the FEFLOW code. In mathematical toolboxes, which can also be applied for the solution of differential equations, often an automatic time stepping is implemented, where the accuracy is checked during the simulation and the time step is reduced, if necessary.

Mixing Cells

In contrast to the usual aforementioned procedure, in the mixing cell approach, grid spacing and time stepping are combined. For given velocity v, time-step Δt and grid spacing Δx are related by the formula

$$\Delta t = \frac{\Delta x}{v} \tag{23}$$

The approach is usually applied for constant velocity (1D). The technique can also be used for 1D flow fields with variable velocity, when Δx is varied along the flow paths. But the method is not applicable for general higher dimensional flow fields. Nevertheless, when transverse gradients are small, the mixing cell approach can be used for simulation of 1D transport along a flowpath.

It is obvious from formula (23) that advection with velocity v is modeled without any discretization error. It turns out to be advantageous to combine the mixing cell approach for advection with the conventional FD or FV approach for dispersion. Such operator splitting is implemented in the PHREEQC code (Appelo and Postma, 1993). The PHREEQC code was not originally intended to be combined with a transport model as velocity is not a prescribed input. Instead *lengths* (Δx), *time-step* (Δt), *cells* (number of blocks), and *shifts* (number of time steps) have to be specified as parameters (Parkhurst, 1995).

As for general time stepping, the discretization error, connected with the advection term, turns out to be the most severe in many applications, and the mixing cell approach is very competitive, concerning accuracy with other approaches, when it can be applied.

Reactive Transport

The simultaneous solution of general 3D transport and geochemical speciation is still a challenge for modelers nowadays, as there is a high demand on computer resources' time and space. In the simplest case, the equations for transport can be solved in a first step, delivering total concentrations. The second step is the speciation calculation based on the equilibrium equations (8) depending on the total concentrations available. Speciation calculations require the solution of a highly nonlinear problem, for which the Newton–Raphson algorithm is usually applied (Parkhurst, 1995).

Unfortunately with respect to the outlined solution strategy, the reaction terms for the kinetic reactions mostly depend on species concentrations. Thus the first step cannot be performed without the results of the second step. The problem is handled using three different strategies (Steefel and MacQuarrie, 1996):

- the sequential two step is performed (sequential noniterative approach – SNIA)

- the two-step method is iterated within each time step (sequential iterative approach – SIA)
- discretized differential and algebraic equations are gathered in one system and solved (direct solution approach – DSA)

Surely the SNIA is the cheapest of these methods with respect to the consumption of computer resources, but it delivers incorrect results when there is a strong coupling through the kinetics. Another reason for the popularity of the SNIA is that different available programs for transport and programs for speciation calculations can be loosely coupled, while both other approaches request an internal coupling during each time step.

The coupling of the popular MT3D-MS code for multi-species transport and PHREEQC2 is currently in development (Prommer *et al.*, 2003), for which the SNIA approach is applied.

Accuracy and Stability Criteria

The approximation of a differential equation by a numerical method is not exact, and yields discretization errors. When derivatives are replaced by finite differences, a truncation error results, for which formulae can be derived using the Taylor (or Lagrangian)-series representation. Local errors, due to truncation of derivatives or due to round-off of numbers, may be amplified with the further application of the algorithm. In such a case, the algorithm is called *unstable*.

Concerning accuracy and stability, three dimensionless numbers and three related criteria are relevant:

$$\text{Grid-Péclet number/criterion}: \quad Pe = \frac{v \cdot \Delta x}{D} \leq 2 \qquad (24)$$

$$\text{Courant number/criterion}: \quad Cou = \frac{v \cdot \Delta t}{\Delta x} \leq 1 \qquad (25)$$

$$\text{Neumann number/criterion}: \quad Neu = \frac{D \cdot \Delta t}{\Delta x^2} \leq \frac{1}{2} \qquad (26)$$

The grid-Péclet criterion is relevant for most numerical methods, although an explicit derivation is seldom found, except for finite differences. Figure 4 illustrates typical errors when the criterion is violated. Breakthrough curves from analytical and numerical solutions for 1D front propagation with constant parameters are depicted. The CIS method is burdened by overshooting. In contrast, the BIS method is burdened by enhanced dispersion, the so-called *numerical dispersion*. While the CIS algorithm is stable, when the grid-Péclet criterion is fulfilled the BIS still displays numerical dispersion for $Pe < 2$. An improvement of the BIS method can then be obtained, when the input value for dispersion is reduced by the numerical dispersion value, which according to the truncation error analysis is given by $D_{\text{num}} = v \cdot \Delta x/2$ (Lantz, 1971). The curve,

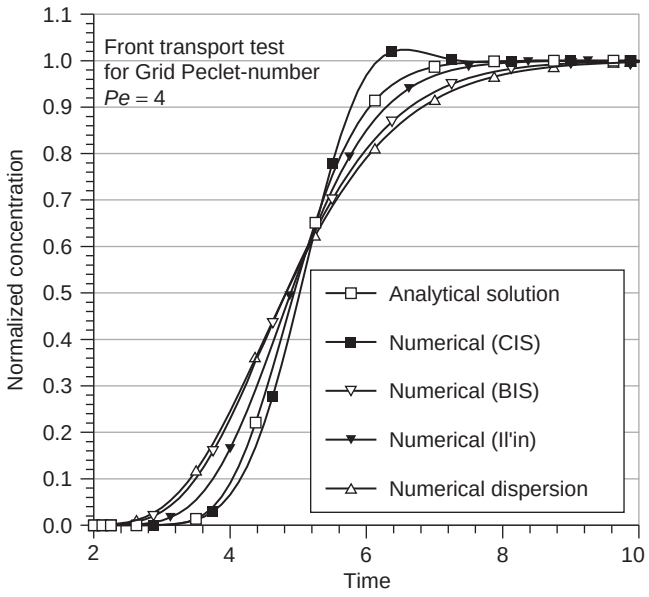

Figure 4 The performance of three numerical schemes for grid-Péclet number $Pe = 4$; all numerical results obtained using automatic time stepping with the Euler method (FIT)

referenced by 'numerical dispersion', depicts the analytical solution for a situation in which D_{num} increases D. The deviation of the BIS-result from that curve shows that the real error of BIS is slightly less than the one predicted by truncation error analysis.

The Il'in method (Il'in, 1969) can be described as a compromise between BIS and CIS. Tests show that it has advantages compared to the other methods only in the vicinity of the critical value for the grid-Péclet numbers, $Pe = 2$. For higher grid-Péclet numbers, the Il'in scheme suffers also from severe numerical dispersion.

The grid-Péclet criterion can be fulfilled when the grid is chosen fine enough, that is, for small Δx. For advection-dominated problems, this may lead to problems when the number of unknown becomes too high.

The Neumann criterion in the given form is valid for explicit algorithms and is less strict or can be completely neglected for implicit algorithms. Both Courant and Neumann criteria can be fulfilled when for a given grid the time step is chosen small enough. This strategy has its limits, as the execution time for a computer run increases with the number of time steps. Especially in 3D modeling, a reduction of the time step may lead to computation periods that are unacceptably high.

The mixing cell method has no discretization error for advection. In order to reduce the discretization error, an operator splitting approach can be applied. It is convenient to use a different time step for diffusion that is a fraction of the advection time step. The PHREEQC code uses a diffusion time-step Δt, which fulfills the condition:

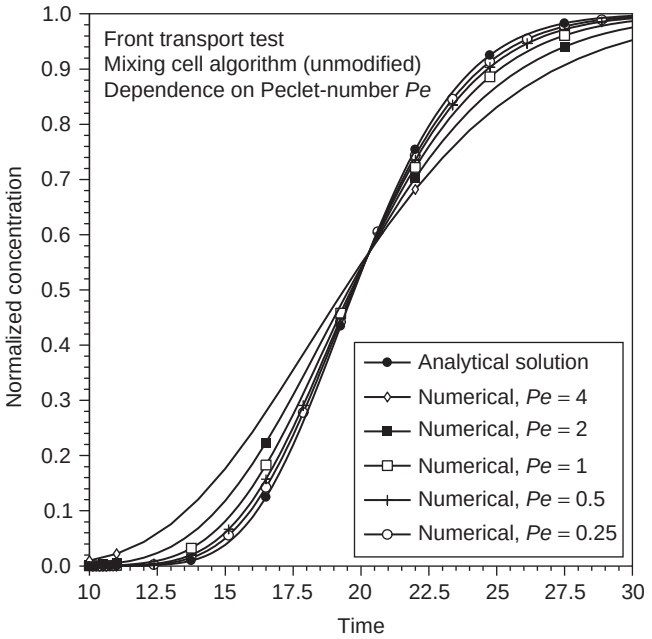

Figure 5 The performance of the mixing cell algorithm for different grid-Péclet numbers; all numerical results obtained using automatic time stepping with the Euler method (FIT)

$Neu \leq \frac{1}{3}$, and which reduces the numerical error very effectively (Appelo and Postma, 1993). Figure 5 shows the performance of a mixing cell method for the 1D front propagation testcase. For given velocity and diffusivity, the grid-spacing and corresponding time step have been reduced, leading to decreasing grid-Péclet numbers *Pe*. The breakthrough curves illustrate how the error is reduced upon reducing of the grid-Péclet number.

INVERSE MODELING

It is the usual task of modeling to determine the dependent variable while the user provides the parameters as input. In groundwater flow models, values for the piezometric head at grid nodes result from using input module for hydraulic conductivities and boundary conditions. But in practical problems, it is often the piezometric heads for which field measurements are available, while hydraulic conductivities are uncertain by at least 1 order of magnitude. In such a situation, the model is used in a different manner. Conductivities as input parameters are varied in order to obtain an optimal match between numerical and measured values of heads.

The illustrated strategy is termed *inverse modeling*, as the role of parameters and variables is exchanged. Inverse modeling is treated in more detail in **Chapter 156, Inverse Methods for Parameter Estimations, Volume 4**. The mathematical procedure is the same for calibration or parameter estimation.

The task of inverse modeling is mostly not implemented in a groundwater modeling code itself. For example, in the ProcessingMODFLOW or FEFLOW, the software package PEST is referred for parameter estimation. PEST or UCODE (alternative in ProcessingMODFLOW) perform all operations concerning the parameter estimation task, that is, new parameter datasets are calculated that are candidates for a model with a better match with the observed data. Then a direct model run is started and finally the results of that run are checked.

Modern GUIs allow the modeler to input measured datasets, to select parameters to be estimated, and to select options for the parameter estimation package. When there are also options for the comparison of measured and modeled data, there is no need to use any other tool for direct and inverse modeling.

PREPROCESSING

Preprocessing is the transformation of data into a form appropriate for the calculating code. Often geologic data are available in a database that cannot be accessed by the modeling program directly. Sometimes special transformation routines are needed to perform this task. Sometimes GIS software for the visualization of geo-data is used.

All operations that are concerned with the selection of the model region, which means especially the location of the boundaries, belong to preprocessing. The modeler can load a background map from some file and construct the model region on the screen using the mouse. Parts of the boundary can be selected for the definition of boundary conditions. Input boxes that require the relevant parameters to be specified open immediately.

Preprocessing includes the choice of model characteristics, such as: confined/unconfined/partially confined, 1D/2D/3D, flow/transport/flow and transport, transient/steady state, solute/heat/solute and heat transport. Nowadays using GUIs most of these options can be selected by mouse-click on a virtual button on the display.

Preprocessing includes the representation of data in a finite grid. Most codes allow external files to be linked with the model. An interpolation routine is then started internally, which delivers parameter values for all elements, blocks, or volumes (see FEFLOW for example). Some codes have options to define parameters as random variable with given statistical properties (see FAST for example).

Finite Element Codes are usually equipped with a *grid generator*. Based on some basic options concerning the approximate number of elements and the type of elements, the GUI usually allows an FE-grid to be created by the push of a button when the model region is defined.

When the modeler is not content with the grid, it can be refined entirely or in parts only. The part to be refined is selected by simple mouse operation. For FD or FV codes that use rectangular grids, such a gridding is usually not necessary.

SOLUTION

The solver is the code that really solves the set of equations for the discrete variable. From GUIs, the solver is started using a submenu entry (ProcessingMODFLOW, Visual MODFLOW, GMS) and for standard situations works with default values for solution parameters. In the case of problems with the solution, that is, no or poor convergence to the numerical solution, or when the results are not accurate enough, the solver or/and parameters should be changed.

Internally mostly a sparse linear or nonlinear system has to be solved. Often there are some options concerning the solution of such a system. Direct solvers can only be recommended for relatively small number of unknowns, that is, for coarse grids. An iterative solver usually is the default. Preconditioned conjugate gradient solvers are mostly used because they are relatively robust, that is, with their standard parameters they work well for a wide range of different problems. For details the reader should consult textbooks like Barrett *et al.* (1994). In some codes, multigrid solvers are included, which are expected to deliver faster convergence.

POSTPROCESSING

After the run of the solver, the discrete representation of the dependent variable is calculated. In order to get specific information from a huge array of numbers, the modeler can perform various postprocessing tasks.

A major postprocessing tool for groundwater flow models is the budget calculator. Fluxes of different type (e.g. inflow, outflow, well recharge, well discharge, groundwater recharge) can be calculated for the entire model region or for user-specified parts of it. For most models such a tool enables quantitative information on the basic fluxes. That is not only a basic information from a completed model, before the completion it is also a basic indicator for errors.

Contour lines (for 2D models) or contour surfaces (for 3D models), which can be plotted for the dependent variable, provide a picture of the variables distribution. Isopleths for hydraulic head, isobars for pressure, isotherms for temperature, isohalines for salt concentration, and streamlines for streamfunction visualize the results of a model run. They not only show where the variable is on an equal level, the minima and maxima also can clearly be identified when the contour levels are chosen appropriate. The different GUIs offer different options for the user to make such a choice.

Contour plots for hydraulic head provide additional information on the flow because flow is normal to the contour lines. When contour levels are equidistant, the density of the isolines gives an impression of the relative amount of the velocity. Regions with dense isolines have higher velocities than regions with less isoline density if the compared regions have the same hydraulic conductivity. Arrow plots give a direct impression of the velocity distribution and flow direction. Long thick arrows represent high velocities in contrast to short thin arrows representing small velocities. In groundwater, the velocities within a model region usually differ by at least 1 order of magnitude, which causes some problem of the arrow plot representation.

Prominent postprocessing tools are codes for particle tracking. For MODFLOW, several of such codes are available (MODPath, PMPath, PATH3D) that visualize streamlines and flowpaths. Some tracking software is designed for steady-state flow fields only, while others can be used for transient flow fields also. For a given flow field, particles can be traced forward or backward in time. There are various different options to set clusters of starting points for the algorithm at inflow or outflow boundaries and/or in the vicinity of wells. Backward particle tracking from positions around a well enables the visualization of the catchments. Similarly the watersheds of groundwater lakes can be determined (Holzbecher, 2001).

Time markers on streamlines or flowpaths indicate isochrones. Most tracking software provides several options to select time markers appropriately, concerning the time levels and the outlook of the marker. In order to calculate traveltimes for a flow field, the porosity has to be specified by the modeler.

Figure 6 depicts a typical output of a groundwater flow model worked out with several postprocessing tools. Added to a background map are well galleries, hydraulic head contour lines, and flowpaths with time markers.

SOFTWARE OVERVIEW

The most prominent code for groundwater modeling is MODFLOW. The most recent version is MODFLOW2000, described by Harbaugh *et al.* (2000). The origins of MODFLOW can be traced back to the beginning of the 1980s. An overview on the history of MODFLOW is given by McDonald and Harbaugh (2003).

Today there are several graphical user interfaces that are 'built around' MODFLOW, like ProcessingMODFLOW, Visual MODFLOW, GMS, and MODFLOW-GUI. These programs assist the user with various pre- and postprocessing tasks; they call MODFLOW for groundwater flow

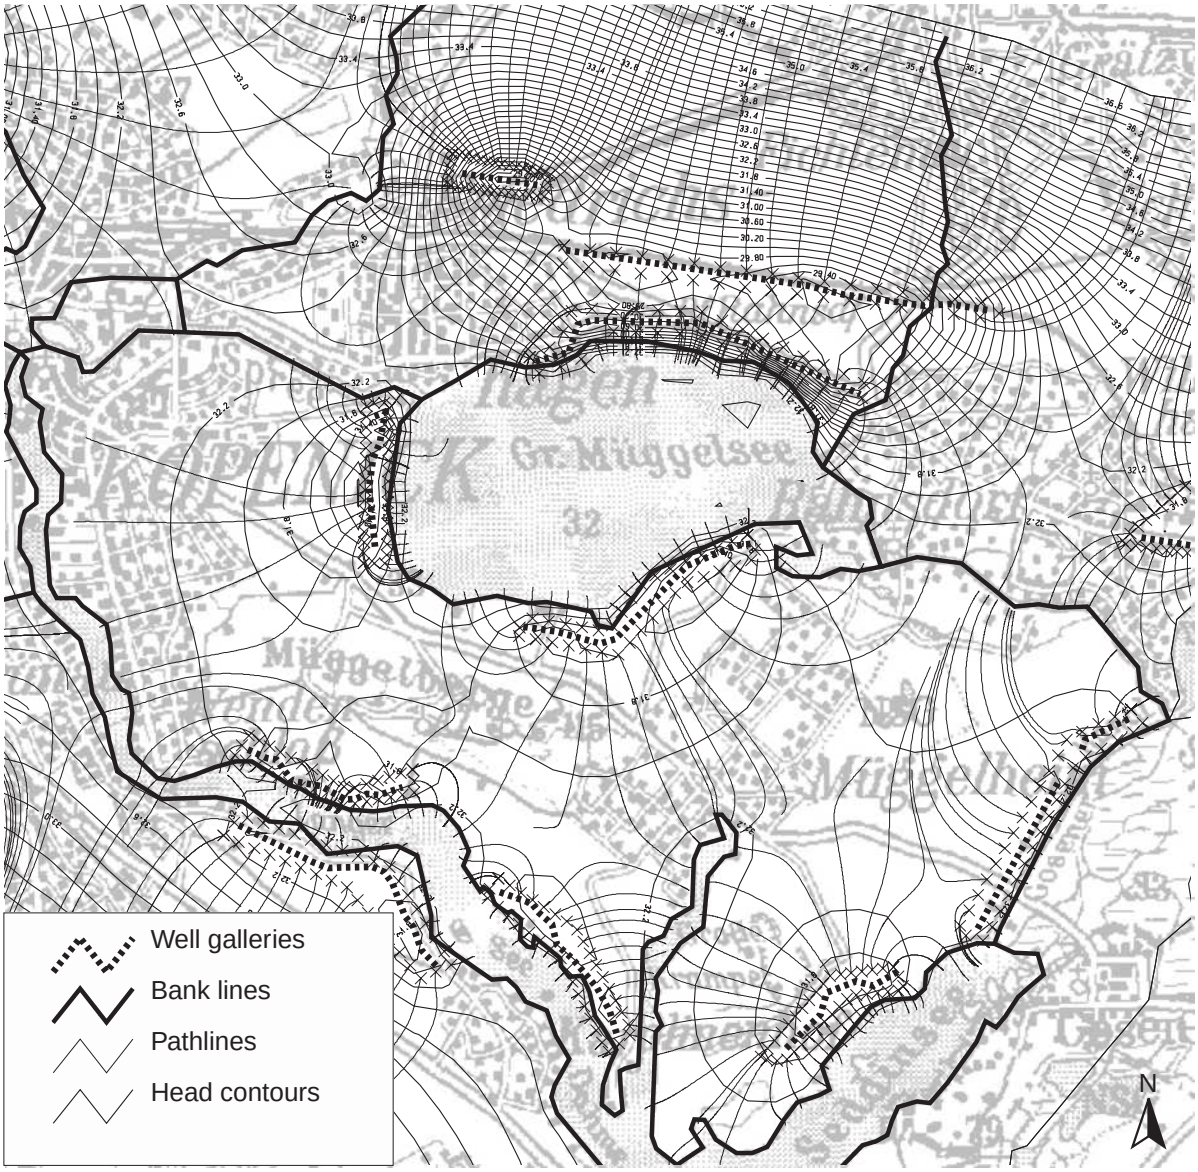

Figure 6 A typical output from a groundwater flow model, depicting background map with well galleries, and the output from several postprocessing tasks: head contours and flowpaths with time markers for illustration of isochrones. The model was setup by M. Zippel using FEFLOW code, postprocessing, and GIS-connection. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

models or other codes for transport simulations or other tasks. Moreover, it is possible to use the GUI for direct and inverse modeling.

A surely incomplete list of groundwater modeling codes is given at the end of this chapter. The second column explains if the code solves the resulting systems of equations itself or if it is build around another solver code as a GUI. Some programs are simply tools for pre- and postprocessing. GUIs include tools. The third column indicates the numerical method used for the discretization (FD = Finite Differences, FE = Finite Elements, FV = Finite Volumes). GUIs, which are connected to different solvers, can have more than one entry. For tools, the discretization method does not have to be given as it depends on the solver.

Acknowledgments

The authors are grateful to Matthias Zippel for the presentation of results of the FEFLOW model of well galleries around Lake Müggelsee, which is to be published as part of his doctorate thesis.

Estimation of various flow and mass transport parameters can be seen as the inverse problem of groundwater modeling. In this article, current methodologies for parameter estimation are classified according to whether they consider the errors in observation data, in parameter structure, and in model applications. The structures of hydraulic parameters are usually very complex and unknown. This article gives an overview on adaptive parameterization methods for simultaneously identifying the parameter values, the complexity level, and the pattern of parameter structure. Methods for model reliability analysis are described. Finally, a generalized inverse problem is introduced that can find a representative parameter for a given model application.

INTRODUCTION

The Forward Problem

Mathematical models of groundwater flow and groundwater quality (**Chapter 149, Hydrodynamics of Groundwater, Volume 4**, **Chapter 152, Modeling Solute Transport Phenomena, Volume 4**, **Chapter 155, Numerical Models of Groundwater Flow and Transport, Volume 4**, **Chapter 150, Unsaturated Zone Flow Processes, Volume 4** and **Chapter 157, Sea Water Intrusion Into Coastal Aquifers, Volume 4**) can be represented in the following general form:

$$L(u; q; p; b; x) = 0 \tag{1}$$

where L is a set of partial differential operators, u a set of state variables, q a set of control variables, p a set of model parameters, b a set of initial and boundary conditions, and x a set of spatial and time variables. When $(q; p; b)$ are given, the problem of solving the state variables u from (1) is called the *forward problem* (FP). The general form of FP solution can be represented by

$$u = M(q; p; b; x) \tag{2}$$

Various analytical methods (**Chapter 151, Hydraulics of Wells and Well Testing, Volume 4**) and numerical methods (**Chapter 155, Numerical Models of Groundwater Flow and Transport, Volume 4**) have been developed for solving FP. Presently, the solution of FP is rather established in geohydrology. In the real world, however, $(q; p; b)$ cannot be determined completely by geological information and direct measurements. When incorrect $(q; p; b)$ are used in a simulation model, the result of model prediction is unreliable and the model may become useless, no matter how accurate the FP solution is. The determination of correct $(q; p; b)$ is, therefore, the key to successful groundwater modeling. Bear (1979) pointed out that there are three basic problems in groundwater modeling: the prediction problem, the calibration problem, and the management problem. A model, including its structure and parameters, must be carefully calibrated by observations of state variables and other correlated information. We must make sure that a model can give reliable prediction results before it is used, for example, in a management problem, for finding the optimal decisions. This article describes how model parameters are calibrated and how the reliability of model prediction can be guaranteed.

The Inverse Problem

For a model given by (2), the observed values of state variables, u^{obs}, at observation locations and times x^{obs} can

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

be expressed by the following *observation equation*:

$$u^{\text{obs}} = M(q; p; b; x^{\text{obs}}) + \varepsilon \tag{3}$$

where ε contains both observation and model errors. It is well known that a useful model must be very carefully calibrated with all available observations, $\{u^{\text{obs}}\}$. The problem of model calibration can be seen, in a certain sense, as the inverse problem (IP) of partial differential equations (Isakov, 1998). IP seeks model parameters (q, p, b) when state variables (u) are measured, while FP predicts state variables (u) when model parameters (q, p, b) are given. In their original meaning, FP finds "results" from "causes", whereas IP finds "causes" on the basis of "results". Because the same "results" may be caused by different "causes", IP is usually ill-posed, that is, its solution (the identified parameters) may be nonunique and discontinuously dependent on data. Examples of ill-posed IPs in groundwater modeling can be found in Sun (1994).

IP can also be considered in statistical frameworks as the parameter estimation problem. With different assumptions on the probability distribution of observation errors, different criteria of parameter estimation can be derived. The statistical method gives not only the estimated parameters, but also the reliability of the estimation.

The Study of IP in Groundwater Modeling

In groundwater modeling, the history of studying IP can be traced all the way back to the beginning. For example, in 1950s and 1960s, analytical solutions were used to identify the hydraulic conductivity and storage coefficient around a well through fitting a curve to aquifer testing data (**Chapter 151, Hydraulics of Wells and Well Testing, Volume 4**). In 1970s, the "history matching" methods developed in petroleum engineering were used to identify hydraulic parameters by numerical optimization (Chavent *et al.*, 1975). Hydrogeologists then developed their own methods for calibrating groundwater models (e.g. Carrera and Neuman, 1986; Yeh, 1986; Sun, 1994; McLaughlin and Townley, 1996; etc.). Currently, many groundwater packages include modules for solving IP. Hydrogeologists solve IP to identify hydraulic parameters, boundary conditions, pollution sources, dispersivities, adsorption kinetics, and reaction coefficients (**Chapter 149, Hydrodynamics of Groundwater, Volume 4**, **Chapter 152, Modeling Solute Transport Phenomena, Volume 4**, **Chapter 155, Numerical Models of Groundwater Flow and Transport, Volume 4**, **Chapter 150, Unsaturated Zone Flow Processes, Volume 4**). The IP-based sensitivity analysis and reliability analysis play very important roles in optimal management of groundwater resources, in optimal design of observation networks, and in feasibility study of remediation plans (**Chapter 153, Groundwater Pollution and Remediation, Volume 4**).

There are two inherent difficulties in solving IP for groundwater modeling: (i) the geological structure of a real aquifer is usually very complex and unknown, and (ii) data that can be used for model calibration are usually very limited, in both quantity and quality. These two difficulties are intertwined in the inverse solution process. A simple model structure (or parameter structure when the model structure is parameterized) may not fit the observed data well. On the other hand, a complicated model structure may cause over-parameterization when data are limited. Attempting to find the real structure of an aquifer and accurate parameter values by solving IP is cost-ineffective and may lead to a useless model. We must systematically consider the relationship between the complexity of model structure, the identifiability of model parameter, the sufficiency of data, and the reliability of model application. A new methodology for parameter structure reduction and robust design (Sun, 2005) may help us to find a way to construct cost-effective and reliable groundwater models.

Parameterization

Hydraulic parameters are usually functions of location and/or time. In this article, we use $\theta(x)$ to represent a distributed parameter (function). Obviously, it is impossible to identify a distributed parameter with infinite degrees of freedom by a finite set of observation data. *Parameterization* refers to approximately representing a distributed parameter by a function with low degrees of freedom. A general representation of parameterization is

$$\theta(x) \approx \sum_{j=1}^{m} \theta_j \phi_j(x, v) \tag{4}$$

where m is called the *dimension of parameterization*, θ_j $(j = 1, 2, \ldots, m)$ are *weighting coefficients*, $\{\phi_j(x, v)\}$ is a set of *basis functions* with a set of shape parameters v. Various parameterization methods, such as the *zonation* method, the finite element method, the spline method, the geostatistical method, the wavelet method, and the natural neighboring method (Sun, 1994; Liu, 1994; Sambridge, 2001), can be seen as special cases of (4). We will use (S, θ) to denote a *parameterization representation* (PR) of a distributed parameter $\theta(x)$, where S represents a parameter structure determined by m basis functions, and the vector

$$\theta = (\theta_1, \theta_2, \ldots, \theta_m)^T \tag{5}$$

consists of parameter values associated with the structure. The same distributed parameter may have different PRs when it is approximated by different structures.

In Sun and Sun (2002), three kinds of inverse problem are identified, namely, the *classical inverse problem* (CIP), the extended inverse problem (EIP), and the *generalized inverse problem* (GIP). In CIP, the structure S is assumed to be known and only the weighting coefficients (5) need to be identified. In EIP, all components in (4) (m, θ_j and $\phi_j(x, v)$, i.e. both S and θ) are identified simultaneously by data. In GIP, these components are identified on the basis of the reliability of model application.

In the next section, CIP is defined in both deterministic and statistical frameworks. Various criteria solution methods for optimal parameter estimation are described. The Section "Parameter structure identification" considers the function identification problem or EIP. All components of PR are optimized by data. Statistical criteria for complexity selection and various algorithms for pattern identification are reviewed. The geostatistical inverse solution is discussed in this section as a special method of function identification. The Section "Structure reduction and experimental design" is dedicated to the solution of the GIP, through which the simplest PR is found and is used to replace the true parameter for model applications. Concepts and algorithms on robust design are discussed. The Section "Software and applications" is a short review on available software packages and application of parameter estimation in groundwater modeling.

THE CLASSICAL PARAMETER ESTIMATION PROBLEM

Inverse Problems as Statistics

In the statistical framework, the estimated parameter, θ, is regarded as a random vector. The problem of parameter estimation can be considered as a procedure that transfers information from observations (u^{obs}) to the unknown parameter (θ) through a model ($u = M(\theta; x)$), and thus reduces the uncertainty of the estimated parameter. The best method of parameter estimation should extract information from data as much as possible, and thus reduce the uncertainty of the estimated parameter as much as possible.

Let $p(\theta)$ be the *joint probability density distribution* (pdf) of a parameter vector θ. The uncertainty associated with $p(\theta)$ is measured by its entropy (Bard, 1974):

$$H(p) = -E(\log p) = -\int_{(\Omega)} p(\theta) \log p(\theta)\, \mathrm{d}\theta \qquad (6)$$

where $E(\log p)$ is the mathematical expectation of $\log p(\theta)$, and (Ω) is the whole distribution space. The negative value of $H(p)$, that is, $-H(p) = E(\log p)$, is defined as the *information content* of the distribution $p(\theta)$. The prior information on parameters θ can be described by a pdf, $p_0(\theta)$, which is called the *prior distribution* of θ. After transferring the information from the observation data to the estimated parameter(s), we obtain a new pdf, $p_*(\theta)$, which is called the *posterior distribution* of θ. The information contents contained in the prior and posterior distributions are $-H(p_0)$ and $-H(p_*)$, respectively. Their difference, $I(p_0, p_*) = H(p_0) - H(p_*)$, measures the information content transferred from the observation data.

The posterior distribution $p_*(\theta)$ is the pdf of θ conditioned by observation data u^{obs}, that is, the conditional pdf, $p(\theta|u^{\text{obs}})$. On the other hand, the conditional pdf, $p(u^{\text{obs}}|\theta)$, is the pdf of u^{obs} conditioned by parameter θ. If there is no model error, $p(u^{\text{obs}}|\theta)$ is equal to $p(\varepsilon|\theta)$ – the pdf of observation errors when θ is given. The conditional pdf, $p(u^{\text{obs}}|\theta)$, is usually called the *likelihood function* of observations and is denoted by $L(\theta)$. According to *Bayes' theorem*, we have

$$p_*(\theta) = cL(\theta)p_0(\theta), \text{ where constant } c = \left(\int_{(\Omega)} p(u^{\text{obs}}|\theta)p_0(\theta)\, \mathrm{d}\theta\right)^{-1} \qquad (7)$$

Equation (7) facilitates the transfer of information from observation data to the estimated parameter. The *maximum a posterior* estimation that maximizes the information transferred from observation data and prior information is given by

$$\hat{\theta} = \arg \min_{\theta}\{-p_*(\theta)\} \qquad (8)$$

Substituting (7) into (8) and using $\ln p_*(\theta)$ to replace $p_*(\theta)$, we have

$$\hat{\theta} = \arg \min_{\theta}\{-\ln L(\theta) - \ln p_0(\theta)\} \qquad (9)$$

The estimated $\hat{\theta}$ thus depends on both the likelihood function and the prior distribution.

Criteria for Optimal Parameter Estimation

Different criteria for optimal parameter estimation can be obtained on the basis of different assumptions on the prior distribution and the distribution of observation error. When $p_0(\theta)$ is a uniform distribution and the admissible region is a multidimensional box $\Theta_{ad} = (\theta_L, \theta_U)$, where θ_U and θ_L are the upper and lower bounds of the estimated parameter vector, we have the following maximum likelihood estimator (MLE):

$$\hat{\theta} = \arg \min_{\theta}\{-\ln L(\theta)\}, \text{ s.t. } \theta \in \Theta_{ad}. \qquad (10)$$

When the observation error vector is normally distributed with zero mean and constant covariance matrix V_ε (an $n \times n$ matrix, where n is the number of observation data), the likelihood function can be specified as

$$L(\theta) = (2\pi)^{-n/2}(\det V_\varepsilon)^{-1/2} \exp\left\{-\tfrac{1}{2}[u^{\text{obs}} - u^{\text{cal}}(\theta)]^T V_\varepsilon^{-1}[u^{\text{obs}} - u^{\text{cal}}(\theta)]\right\} \quad (11)$$

where $u^{\text{cal}}(\theta) = M(\theta, x^{\text{obs}})$, and the MLE (10) reduces to the *generalized least squares estimator* (GLSE):

$$\hat{\theta} = \arg \min_\theta [u^{\text{obs}} - u^{\text{cal}}(\theta)]^T V_\varepsilon^{-1}[u^{\text{obs}} - u^{\text{cal}}(\theta)], \text{ s. t.} \theta \in \Theta_{ad} \quad (12)$$

Furthermore, if all components of ε are independent from each other, V_ε^{-1} reduces to a diagonal matrix, $\mathbf{W}$, and GLSE becomes the *weighted least squares estimator* (WLSE):

$$\hat{\theta} = \arg \min_\theta [u^{\text{obs}} - u^{\text{cal}}(\theta)]^T \mathbf{W}[u^{\text{obs}} - u^{\text{cal}}(\theta)], \text{ s.t. } \theta \in \Theta_{ad} \quad (13)$$

When all observation errors have the same variance, $\mathbf{W}$ reduces to a unit matrix.

When $p_0(\theta)$ is normally distributed with mean θ_0 and covariance matrix V_θ (an $m \times m$ matrix, where m is the dimension of θ), the above estimators must be changed according to (9), that is, adding $-\ln p_0(\theta)$ to the objective function of minimization. For example, the GLSE becomes

$$\hat{\theta} = \arg \min_\theta \{[u^{\text{obs}} - u^{\text{cal}}(\theta)]^T V_\varepsilon^{-1}[u^{\text{obs}} - u^{\text{cal}}(\theta)] + [\theta - \theta_0]^T V_\theta^{-1}[\theta - \theta_0]\} \quad (14)$$

When $V_\varepsilon = \sigma^2\mathbf{I}$ and $V_\theta = \tau^2\mathbf{I}$, where $\mathbf{I}$ denotes the unit matrix, (14) reduces to the following *regularized least squares estimator* (RLSE) with $\lambda = \tau^2/\sigma^2$:

$$\hat{\theta} = \arg \min_\theta \{[u^{\text{obs}} - u^{\text{cal}}(\theta)]^T [u^{\text{obs}} - u^{\text{cal}}(\theta)] + \lambda[\theta - \theta_0]^T[\theta - \theta_0]\} \quad (15)$$

In the *deterministic framework*, when observation error exists, we can only find an approximate inverse solution. IP is thus transformed into an optimization problem. After parameterization, the unknown parameter vector θ can be estimated by minimizing the "distance" (or a misfit function), d_D, between the observed data and the model output measured in the observation space D, that is, let

$$\hat{\theta} = \arg \min_\theta d_D[u^{\text{obs}}, u^{\text{cal}}(\theta)], \text{ s.t.} \theta \in \Theta_{ad} \quad (16)$$

where Θ_{ad} is the admissible region of the unknown parameter that can be estimated by prior information (**Chapter 151, Hydraulics of Wells and Well Testing, Volume 4**, **Chapter 148, Aquifer Characterization by Geophysical Methods, Volume 4**). A norm defined in the observation space can be used to measure the "distance" d_D. When the weighted L-2 norm is used, (16) is the same as the WLSE given in (13) but the weights may have different meanings. For example, we may assign larger weights to those observation wells that are more important for model prediction. Generally, the statistical criteria given above can still be used in the deterministic framework regardless of the statistical assumptions on observation error and prior information. When the observation error is not normally distributed, it is better to use L-1 norm to measure the "distance" in (16):

$$d_D(u^{\text{obs}}, u^{\text{cal}}) = \sum_{i=1}^{n} w_i |u_i^{\text{obs}} - u_i^{\text{cal}}| \quad (17)$$

where $\{w_i\}$ is a set of weighting coefficients. L-1 norm is less sensitive to observation error than L-2 norm and is thus more robust. The following Kullback–Leibler (KL) misfit function provides another robust criterion for parameter identification:

$$d_D(u^{\text{obs}}, u^{\text{cal}}) = \sum_{i=1}^{n} u_i^{\text{obs}}[\ln u_i^{\text{obs}} - \ln u_i^{\text{cal}}] \quad (18)$$

No matter what misfit functions or criteria are used for parameter estimation, the formulated optimization problem might have multiple local minima and its solution might be unstable due to the ill-posed nature of IP and the nonlinearity of the misfit function. The *regularization theory* (Tikhonov and Arsenin, 1977) may significantly improve the stability of the inverse solution with

$$\hat{\theta} = \arg \min_\theta \{d_D[u^{\text{obs}}, u^{\text{cal}}(\theta)] + \lambda R(\theta)\} \quad (19)$$

In (19), $\lambda R(\theta)$ is called a *regularization term*, $R(\theta)$ the *regularization function* and λ the *regularization factor*. For example, we may choose $R(\theta) = d_P(\theta, \theta_0)$, where $d_P\ (\theta, \theta_0)$ is a norm defined in the parameter space that measures the "distance" between the estimated parameter θ and its prior estimation θ_0. When L-2 norm is used, (19) has the same form as the statistical criterion (16). But, regularization is more general and robust. The value of λ represents an appropriate compromise between the misfit of observations and the misfit of prior information. From this point of view, the regularization term can be considered as a penalty function, (19) can be seen as a vector optimization problem, and λ as the weighting coefficient. Finding the optimal regularization factor is still an open problem in

real case studies (Vogel, 2002). Besides the identified parameter, the regularization term may contain also the state variable and its derivatives. In general, we may add more regularization terms to (19) if other kinds of information or measurement are available. When we have the measurements of k state variables $v_1, v_2, \ldots, v_k$, the *coupled inverse problem* (Sun, 1994) can be solved by:

$$\hat{\theta} = \arg \min_{\theta} \left\{ d_D[u^{\text{obs}}, u^{\text{cal}}(\theta)] + \sum_{j=1}^{k} \lambda_j d_{D,j}[v_j^{\text{obs}}, v_j^{cal}(\theta)] + \lambda_{k+1} R(\theta) \right\} \quad (20)$$

In the field of groundwater modeling, (20) has been used to identify the hydraulic conductivity by coupling the measurements of head, concentration, water temperature, water content, water age, flow velocity, as well as geophysical data (e.g. Sun and Yeh, 1990; Portniaguine and Solomon, 1998; Bravo *et al.*, 2002; Lin and Zhang, 2004).

Optimization Algorithms

The criteria for parameter estimation, in both statistical and deterministic frameworks, can be seen as a *constrained optimization problem*

$$\hat{\theta} = \arg \min_{\theta} E(\theta), \theta \in \Theta_{ad} \quad (21)$$

where the objective $E(\theta)$ is a misfit function. Various numerical methods have been developed for solving (21) (Kelley, 1999). An iterative procedure for solving (21) includes: (1) choose a starting point θ_0; (2) designate a way to generate a search sequence: $\theta_0, \theta_1, \theta_2, \ldots, \theta_k, \theta_{k+1}, \ldots$; and (3) specify a termination criterion. The search sequence has the following general form $\theta_{k+1} = \theta_k + \lambda_k \mathbf{d}_k$, where vector $\mathbf{d}_k$ is called a *displacement direction*, and λ_k is a *step size* along the direction. Different optimization methods use different algorithms to generate $\mathbf{d}_k$ and λ_k in each iteration. This iteration process usually leads to or terminates at a local minimum. When L-2 norm is used for parameter estimation, the objective $E(\theta)$ has the form of the sum of squares of functions. In this case, the *Levenberg-Marqardt algorithm,* a modified *Gauss-Newton* method, is often used to generate the search sequence:

$$\theta_{k+1} = \theta_k - (\mathbf{J}_k^T \mathbf{J}_k + \lambda \mathbf{I})^{-1} \mathbf{J}_k^T \mathbf{f}_k \quad (22)$$

where $\mathbf{f}_k = \mathbf{f}(\theta_k)$, $\mathbf{J}_k = \mathbf{J}(\theta_k)$, $\mathbf{f}$ has the components $f_i(\theta) = w_i[u_i{}^{\text{obs}} - u_i{}^{\text{cal}}(\theta)]$, $\mathbf{J}$ is the Jacobian matrix $[\partial f_i / \partial \theta_j]_{n \times m}$, $\mathbf{I}$ is the identity matrix, and λ is a variable coefficient. Starting from $\lambda = 0$, if the condition $E(\theta_{k+1}) < E(\theta_k)$ is satisfied, move to the next iteration, otherwise, increase the value of λ and try again. When the value of λ is large enough, the displacement direction approaches the steepest descent direction (the negative gradient direction) and the step size becomes very small. Therefore, we can expect the condition $E(\theta_{k+1}) < E(\theta_k)$ to be satisfied eventually.

In most real cases of groundwater modeling, a search sequence may be trapped to a *local minimum,* and the value of $E(\theta)$ may stay large, and is insensitive to the change of parameter values. *Genetic algorithm* (GA) is a kind of evolution algorithm that can find the *global optimum* for complex multimodal functions. Useful information on GA and its implementations can be found on the Internet, for example, **www.geneticprogramming.com**. The use of GA for parameter identification consists of the following steps:

1. Define an initial population. According to the prior distribution, we choose a set of possible solutions $\{\theta_1^0, \theta_2^0, \ldots, \theta_s^0\}$ from the admissible set Θ_{ad} as the initial population. For a homogeneous prior distribution, the initial population can be selected randomly.
2. Evaluate the fitness of the initial population. The simulation model is used to calculate the values of $\{E(\theta_1^0), E(\theta_2^0), \ldots, E(\theta_s^0)\}$.
3. Use genetic operators to create newer and "fitter" populations. The most common genetic operators are the selection, crossover, and mutation.
4. Evaluate the fitness of the new generation and test if a near-optimal solution has been found. If not, return to step 3 to create the next generation.

In the above procedure, all units in a generation must be encoded for genetic operations and decoded for fitness evaluation. The fitness of a parameter unit θ is evaluated by the value of $E(\theta)$. When significant computation effort is needed for solving FP, as in the case of groundwater modeling, GA could become very inefficient. An *artificial neural network* (ANN), after being trained, can approximately represent a complicated input-output relationship. Using ANN to replace the solution of the FP for fitness evaluation will significantly increase the effectiveness of GA (Morshed and Kaluarachchi, 1998). Solomatine *et al.* (1999) compared several global optimization algorithms for groundwater model calibration. Giacobbo *et al.* (2002) used GA to estimate the dispersivity parameters in a mass transport model. Shigidi and Garcia (2003) explained how to determine the optimal node number and training patterns of a neural network for transmissivity estimation.

Sensitivity Coefficients

When a gradient-based optimization method is used to solve the inverse problem, the gradient $g = [\partial E / \partial \theta]$ must be calculated in each iteration. When Levenberg–Marqardt method is used, the Jacobian, $\mathbf{J} = [\partial u^{\text{cal}} / \partial \theta]$, must be

calculated. In mathematical modeling, the first-order derivatives of dependent variables with respect to parameters, such as the elements of g and $\mathbf{J}$, are called *sensitivity coefficients*. Sensitivity coefficients are important not only for parameter estimation, but also for model reliability analysis and experimental design. From the analysis of sensitivity coefficients, we can understand the model behavior. There are three calculation methods.

The *perturbation method* uses the finite difference approximation of derivatives. For each component θ_j of θ, we assign an increment (perturbation) $h_j = \lambda\theta_j$, where $\lambda = 1\% \sim 10\%$, and run the simulation model to find the corresponding increment of objective function E (or the increments of the dependent variables u). The sensitivity coefficients are then calculated approximately as the proportion of increments. If the perturbation method is used to obtain the gradient g or the Jacobian $\mathbf{J}$ for an updated θ, we need to run the simulation model $m + 1$ times when the one-side finite difference approximation is used, and $2m + 1$ times when the two-side finite difference approximation is used. The perturbation method is the simplest one for sensitivity analysis and has been extensively used in groundwater modeling software, but its accuracy is low and is dependent on the value of perturbation.

The *sensitivity equation method* differentiates the governing equation as well as its subsidiary conditions with respect to m components of θ to obtain m sensitivity equations and then solves these equations to obtain sensitivity coefficients. For the general model given in (1), that is, $L(u, \theta) = 0$, its sensitivity equations with respect to θ_j are given by

$$\nabla_u L \frac{\partial u}{\partial \theta_j} + \nabla_\theta L \frac{\partial \theta}{\partial \theta_j} = 0, \quad j = 1, 2, \ldots, m \tag{23}$$

The gradient operator $\nabla_u L = [\partial L / \partial u]$ generally has the same structure as the original operator L, and, thus, (23) can be solved the same as the original problem. If the sensitivity equation method is used to obtain the gradient g or the Jacobian $\mathbf{J}$ for an updated θ, we need to solve the m sensitivity equations in (23), in addition to the original equation. The total computation effort is equal to $m + 1$ simulation runs.

The *adjoint state method* uses the variational form of the original model and solves the adjoint state equations to obtain the sensitivity coefficients. By defining the scalar product of two vector functions u and v as $(u, v)_\Omega = \int_\Omega (u \cdot v)\, d\Omega$, where Ω is the time/space definition domain, for a vector operator matrix $\mathbf{A}$, we may find a transposed adjoint operator matrix $\mathbf{A}^+$, such that the following identity stands:

$$(\mathbf{A}u, v)_\Omega = (u, \mathbf{A}^+ v)_\Omega \tag{24}$$

Now consider a general performance criterion $E = \int_\Omega f(u, \theta)\, d\Omega$, where $f(u, \theta)$ is a user-chosen function. The variation of E can be represented by

$$\delta E = \left(\delta u, \frac{\partial f}{\partial u}\right)_\Omega + \left(\delta\theta, \frac{\partial f}{\partial \theta}\right)_\Omega \tag{25}$$

Using (24) and the variational form $\nabla_u L \delta u + \nabla_\theta L \delta\theta = 0$ of the original problem (1), for any vector function ψ, we can rewrite (25) as

$$\delta E = \left(\delta u, \nabla_u^+ L\psi + \frac{\partial f}{\partial u}\right)_\Omega + \left(\delta\theta, \nabla_\theta^+ L\psi + \frac{\partial f}{\partial \theta}\right)_\Omega \tag{26}$$

Let ψ be the adjoint state of the original state variable u, that is, the solution of the following adjoint equation

$$\nabla_u^+ L\psi + \frac{\partial f}{\partial u} = 0 \tag{27}$$

with zero-boundary condition and zero-final condition, the first term on the right-hand side of (26) vanishes. For any component θ_j, we then have:

$$\frac{\partial E}{\partial \theta_j} = \int_\Omega \left[\nabla_\theta^+ L\psi + \frac{\partial f}{\partial \theta}\right]_j d\Omega, \quad j = 1, 2, \ldots, m \tag{28}$$

In the above equation, $[\cdot]_j$ represents the j-th component of vector $[\cdot]$. By selecting different $f(u, \theta)$, E can be a misfit function of parameter estimation or a model output corresponding to an observation. Using the adjoint state method to calculate the gradient $g = [\partial E / \partial \theta]$, we only need to solve the original problem (1) once and the adjoint problem (27) once. To calculate the Jacobian $\mathbf{J} = [\partial u^{\text{cal}} / \partial \theta]$, n adjoint problems need to be solved, where n is the number of observations. In Sun (1994), adjoint problems are derived for various groundwater flow, mass transport, and coupled problems.

When we use the sensitivity equation method (or the adjoint state method), different sensitivity equations (or different adjoint state equations) must be derived for different problems under consideration, the corresponding codes must be developed, and the correctness of each code must be validated. To avoid this manual work, a new approach called automatic differentiation (AD) is being developed that can directly differentiate a Fortran or a C++ code of forward solution to obtain the code for calculating sensitivity coefficients (Elizondo *et al.*, 2002). A complete list on AD software packages can be found from **http://www-unix.mcs.anl.gov/autodiff/AD_Tools**. The AD-based sensitivity analysis has been used in parameter estimation, uncertainty analysis, and experimental design (for example, Barhen and Reister, 2003).

The Reliability of Parameter Estimation

Linearization is the simplest method to estimate the reliability of the estimated parameter. During the estimation procedure, model output $u^{\text{cal}}(\theta)$ can be approximately regarded

as a linear function. In k-th iteration, we have $u^{\text{cal}}(\theta) \approx \mathbf{J}(\theta_k)(\theta - \theta_k) + u^{\text{cal}}(\theta_k)$, where $\mathbf{J} = [\partial u^{\text{cal}}/\partial\theta]$. From the theory of linear regression, when GLSE (12) is used, the covariance matrix of the estimated parameter is given by

$$Cov(\theta, \theta) = (\mathbf{J}^T V_\varepsilon^{-1} \mathbf{J} + V_\theta^{-1})^{-1} \tag{29}$$

Since the diagonal of the matrix gives the variances of estimation, the confidence region can then be calculated. Finding the confidence region for the estimated parameter, however, is not the sole purpose of reliability study. What we need to know is the reliability of model application when the identified parameter is used in the model. Let $g(\theta)$ be a set of given model application. There are several methods that can be used to assess the uncertainty of $g(\theta)$ on the basis of the uncertainty of the identified parameter θ.

When $g(\theta)$ is close to a linear function, we may use the *first-order approximation*:

$$\hat{g} = g(\hat{\theta}), Cov(\hat{g}, \hat{g}) = \mathbf{J}_g Cov(\hat{\theta}, \hat{\theta}) \mathbf{J}_g^T \tag{30}$$

where $Cov(\theta, \theta)$ is given by (29) and $\mathbf{J}_g = [\partial g/\partial\theta]$ can be obtained by the methods of sensitivity analysis. A recent example of using (30) is the work of Kunstmann *et al.* (2002), in which the reliability of groundwater head and concentration predictions is assessed. When $g(\theta)$ is not close to a linear function, we may use the *perturbation method* to find the variation δg from the variation $\delta\theta$ by solving both mean and perturbation equations (**Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**). For example, the uncertainty associated with the model-predicted concentration distribution C is measured by its variance, σ_C^2, which can be directly solved from the perturbation equation (Tang and Pinder, 1979).

In Section "Inverse problems as statistics", we only find the maximum of the posterior $p_*(\theta)$ for parameter estimation. If we can find the whole distribution $p_*(\theta)$, the mean and variance of any model application $g(\theta)$ can be estimated by the following integrals:

$$E(g) = \int g(\theta) p_*(\theta)\, \mathrm{d}\theta$$

$$\text{and} \qquad Var(g) = \int [g(\theta) - E(g)]^2 p_*(\theta)\, \mathrm{d}\theta \tag{31}$$

The above equation is generally applicable for any nonlinear model and the unknown parameter may have any type of distribution. Letting $g(\theta) = \theta$ in (31), we can obtain the mean and variance of the estimated parameter. Moreover, with the whole distribution $p_*(\theta)$, we can search for the global optima for parameter estimation rather then a local one. To obtain $p_*(\theta)$, we can use a *sampling method* to find the values of $p(u|\theta)$ and then use Bayes' theorem to find the values of $p_*(\theta) = p(\theta|u)$. The *Markov Chain Monte Carlo* (MCMC)-based sampling approaches, such as the Metropolis algorithm and Gibbs sampler algorithm, use a constructed random walk procedure to sample the posterior distribution. Readers may refer Gilks *et al.* (1996) for a detailed discussion on MCMC. The sampling method is applicable for solving IP and for uncertainty analysis when the dimension m of θ is not high. Sohn *et al.* (2000) gave an example of using the sampling method in groundwater modeling for uncertainty assessment.

All of the above-mentioned methods of uncertainty analysis are for CIP, and thus they assume there is no parameter structure error. In practice, however, the structure error often dominates the parameter value error and is the cause of model failure. We will discuss this problem in the following sections.

PARAMETER STRUCTURE IDENTIFICATION

Parameter Structure Complexity

The statistical approach can be used not only for parameter estimation and reliability analysis, but also for determining the model complexity level. The classical model selection criteria, such as the Akaike's Information Criterion (AIC) and the Bayesian Information Criterion (BIC), tend to select the simplest model if it can fit the observations in the same extent as complex models do (Akaike, 1974; Schwarz, 1978). For example, the Schwarz criterion is given by

$$d = d_D(u^{\text{obs}}, u^{\text{cal}}) + \frac{m}{n-m}\left(\ln\frac{n}{2}\right) \tag{32}$$

where n is the number of data, m the dimension of the unknown parameter. On the right-hand side of (32), the first term measures the fitting error, the second term is a penalty to the complexity of parameter structure. Another alternative of model complexity selection is resampling (Lahiri, 2003). In this approach, the prediction risk is estimated via cross-validation, and the model providing lowest estimated risk is chosen.

In the statistical learning theory, the following "ε-*insensitive misfit function*" is used:

$$d_{D,\varepsilon}(u^{\text{obs}}, u^{\text{cal}}) = \sum_{i=1}^{n} w_i d_{i,\varepsilon}^2 \tag{33}$$

where $d_{i,\varepsilon} = 0$, when $|u_i^{\text{obs}} - u_i^{\text{cal}}| \le \varepsilon$; otherwise, $d_{i,\varepsilon} = |u_i^{\text{obs}} - u_i^{\text{cal}}| - \varepsilon$. This definition means that the difference between observed and model calculated values is replaced by zero if it is less than ε (the upper bound of observation error, for example). The use of (33) (or its regularization form) in groundwater modeling is strongly suggested because it can avoid fitting noised observations with an overly complex structure. The *structure risk minimization*

(SRM) criterion provides a very general framework for complexity control (Vapnik, 1998). Under SRM, a set of possible models is ordered according to their complexity, the theoretical upper bounds of prediction risk can be found under certain assumptions, and a structure that provides the minimal prediction risk is chosen. Cherkassky and Ma (2003) showed that SRM outperforms AIC and BIC for their testing data sets. In groundwater modeling, we need to identify not only the complexity level but also the pattern (the pattern of hydraulic conductivity, for example). No analytical expression for the upper bound of prediction risk is available in this case.

Identification of the Optimal Parameterization

With different parameter structures for parameter estimation, we will obtain different parameter values and different fitting residuals. When the dimension of parameterization m is too small (under-parameterized), the fitting residual may have a large value. On the other hand, when m is too large (over-parameterized), the model prediction becomes unreliable. Moreover, even if we can find an appropriate m through a model selection criterion, the identified parameter may be still very different from the real one if the structure pattern of the unknown parameter is not correctly assigned. In EIP, structure S and parameter values θ are identified simultaneously by solving the following optimization problem

$$(\hat{S}, \hat{\theta}) = \arg \min_{(S,\theta)} \{d_D[u^{\text{obs}}, u^{\text{cal}}(S, \theta)] + \lambda d_P[(S, \theta) - (S_0, \theta_0)]\} \tag{34}$$

where $u^{\text{cal}}(S, \theta) = M(S, \theta; x^{\text{obs}})$. The second term on the right-hand side of the above equation is a regularization term, in which (S_0, θ_0) is a prior guess of the estimated parameter representation (S, θ). This term may be replaced by a constraint $(S, \theta) \in \Theta_{ad}$. (39) is a combinatorial optimization problem and is very difficult to solve because the dimension of the shape vector may be high. In practice, we can only identify an approximation of the true structure because of data limitation.

Sun and Yeh (1985) was the first to solve problem (34) to identify the hydraulic conductivity of a heterogeneous aquifer without knowing its structure. The shape vector that determines the parameter structure consists of the coordinates of a set of moving basis points and two variable parameters used for determining the type of basis functions, from discrete to continuous. Problem (34) is solved as a min−min optimization problem. The number of basis points is increased one by one. For each increase in basis points, the outer minimization loop finds the optimal structure (shape vector); and for each structure, the inner minimization loop finds the optimal parameter values associated with the structure. The same problem (34) was solved by Zheng and Wang (1996) with simulated annealing to find the global optimization of structure parameters. Heredia *et al.* (2000) presented the following criterion to replace the objective function given in (34):

$$d_D[u^{\text{obs}}, u^{\text{cal}}(S, \theta)] + m \ln\left(\frac{n}{2\pi}\right) + \ln\left|\frac{\det \mathbf{F}}{n}\right| - 2 \ln p_0(S, \theta) \tag{35}$$

where m is the dimension of θ, n the number of data, $\det \mathbf{F}$ is the determinant of the information matrix, $\mathbf{F} = (\mathbf{J}^T \mathbf{J})^{-1}$, $p_0(S, \theta)$ contains the prior information transferred from geology or geophysics on both parameter structure and parameter values. The first term of (35) measures the data fitting error, the second term is the penalty to the structure complexity, the third term is the penalty to the parameter uncertainty, and the final term is the prize to the prior information. In Heredia *et al.* (2000), the identified zonation pattern is obtained by gradually modifying an initially guessed pattern from the available prior information. Recently, Ameur *et al.* (2002) presented an adaptive procedure for pattern identification. In each iteration, a refinement indicator and a coarsening indicator are calculated to determine if a zone should be refined or coarsened. In Tsai *et al.* (2003), a genetic algorithm (GA), a grid search method, and a quasi-Newton algorithm are combined to find the optimal pattern of parameter structure in three dimensions. These optimization processes need huge computational effort.

In order to make the solution of EIP practical, Sun and Sun (2002) presented a simple *tree-regression procedure* that can find a nearly optimal parameter structure with less computational effort. In this procedure, the following nested structure sequence is formed by gradually increasing the complexity:

$$S_1 \subset S_2 \subset S_3 \subset \cdots \subset S_m \subset S_{m+1} \subset \cdots \tag{36}$$

In the above equation, S_1 is a homogeneous structure, S_{m+1} is generated by dividing a selected zone of S_m into two zones with a linear boundary. The parameter value associated with the selected zone is the most sensitive one to the misfit function. The location of the linear boundary and the parameter values associated with all $m + 1$ zones are then determined by the method of Sun and Yeh (1985). This sequence is terminated when one of the following criteria is satisfied: (1) the value of $E(\hat{\theta}_m)$ becomes small compared with the observation error; (2) the difference between $E(\theta_m)$ and $E(\theta_{m-1})$ becomes small; (3) there are no significant changes in parameter values when one zone is divided into two zones; and (4) $E(\theta_m)$ becomes insensitive to all zones. In this case, no more information can be extracted from the observation data. With this tree-regression algorithm, the over-parameterization problem

can be avoided, the dimension of the shape vector is minimized, and all parameters involved in the optimization procedure are sensitive to the observation data.

The Geostatistical Method for Parameter Estimation

We treat the unknown parameter as a random variable because it is identified from the observation equation that contains uncontrollable observation and model errors. From the point of view of geostatistics (Wackernagel, 2003), a distributed physical parameter itself, such as the hydraulic conductivity, may be regarded as a *spatial random field* because of the *variability* of natural formations at different scales (**Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**). Usually, a random field is described approximately by its first two moments. A geostatistical inverse method finds the *mean* and *covariance* functions for the estimated random field $\theta(x)$ using the measurements of the fields (*kriging*) and the measurements of correlated fields (*co-kriging*). In groundwater modeling, for example, the estimated random field is often the log-hydraulic conductivity $\theta(x) = \ln K(x)$, and the correlated fields may be hydraulic head, concentration, water temperature, water content, and so on. The log-hydraulic conductivity is often assumed to be normally distributed with an exponential type of covariance function. For any two points x_i and x_j, we assume

$$Cov_{\theta\theta}(x_i, x_j) = \psi_1 \delta_{ij} + \psi_2 \exp\left(\frac{-d_{ij}}{\psi_3}\right) \qquad (37)$$

where δ_{ij} is the Kronecker delta, d_{ij} is the distance between x_i and x_j, $\psi = (\psi_1, \psi_2, \psi_3)$ are statistical parameters to be identified. The value of the distributed parameter estimated by the geostatistical method at any unmeasured location x is a linear combination of all available measurements:

$$\hat{\theta}(x) = \sum_{i=1}^{m} \lambda_i(x)\theta^*(x_i) + \sum_{k=1}^{K}\sum_{l=1}^{nk} \mu_{kj}(x)u^*_{kj}(x_{kj}) \qquad (38)$$

where $\{\theta^*(x_i)|i = 1, 2, \ldots, m\}$ is a set of parameter measurements, K is the number of correlated fields, $\{u^*_{kj}(x_{kj})|j = 1, 2, \ldots, nk\}(k = 1, 2, \ldots, K)$ are K sets measurements of the correlated fields, $\{\lambda_i(x)\}$ and $\{\mu_{kj}(x)\}$ are kriging and co-kriging coefficients associated with x, respectively. These coefficients can be obtained by solving the kriging and co-kriging equations. The coefficient matrices of these equations depend on the auto-covariance and cross-covariance functions between the parameter field and the correlated fields. The solution of a geostatistical inverse problem consists of two stages. In the first stage, the unknown mean function (characterized by parameters β) and the covariance function (characterized by parameters ψ) are estimated by the MLE on the basis of all sets of measurement data. In the second stage, the same sets of measurement data are used to obtain the co-kriging estimation (38) as the most possible realization. The geostatistical inverse solution can provide distributed values of the unknown parameter for describing the spatial variability. Moreover, it can also give the variance of estimation:

$$Var[\hat{\theta}(x) - \theta(x)] = \sigma^2_\theta - \sum_{i=1}^{m} \lambda_i(x)Cov_{\theta\theta}(x, x_i) - \sum_{k=1}^{K}\sum_{j=1}^{nk} \mu_{kj}(x)Cov_{\theta u_k}(x, x_{kj}) \qquad (39)$$

On the right-hand side of (39), the first term is the unconditional uncertainty, that is, ψ_2 in (37), the second term is the reduction in uncertainty after conditioned by the parameter measurements, and the third term is the reduction in uncertainty after conditioned by the measurements of correlation fields.

There are several problems associated with the geostatistical inverse method described above. First, the estimation variance (39) is not reliable because it does not take account of the structure error. The form of the covariance structure may not be correctly assigned and the statistical parameters in the mean and covariance functions may not be well calibrated by the measured data. Second, although the identified parameter is distributed, its degree of freedom is low. Only a few statistical parameters (β and ψ) are adjusted to fit all measured data. As a result, the fitting residual of the MLE may be significant. To increase the degree of freedom of the parameter structure, a so-called *"pivot point" method* was presented (Ahmed and de Marsily, 1987). In this method, a term $\sum_{p=1}^{np} \lambda_p(x)\hat{\theta}(x_p)$ is added to the right-hand side of (38), where $\{x_p|p = 1, 2, \ldots, np\}$ is a set of pivot points, $\{\lambda_p(x)\}$ the kriging coefficients. Parameter values at these pivot points, $\{\hat{\theta}(x_p)\}$, are identified together with the statistical parameters by the MLE. Lavenue and Pickens (1992) included optimizing the locations of pivot points in the parameter identification procedure. This can be considered as an alternative method of adaptive parameterization.

Gomez–Hernandez *et al.* (1997) presented a similar methodology called "*the self-calibrating approach*". The unconditioned random field is first conditioned by m measurements $\{\theta^*(x_i)|i = 1, 2, \ldots, m\}$ to obtain a seed field. After a set of master locations $\{x_p|p = 1, 2, \ldots, np\}$ is assigned, a method for solving CIP is then used to estimate the unknown statistical parameters as well as the parameter values at the master locations. Assume that the best fitting parameter values at the master locations are $\tilde{\theta}(x_p) = \theta^*(x_p) + \Delta\theta(x_p)$, where $\theta^*(x_p)$ is the value of the original seed field. The seed field is then updated by kriging with all m measurement points $\{x_i\}$ and np master locations

$\{x_p\}$as the basis points, that is, let

$$\theta^*(x) = \sum_{i=1}^{m} \lambda_i(x)\theta^*(x_i) + \sum_{j=1}^{np} \lambda_j(x)\tilde{\theta}(x_p) \qquad (40)$$

There is no essential difference between the revised pivot point approach and the self-calibrating approach. When the unknown parameter is hydraulic conductivity, its measured values (obtained by fitting pumping test data with an analytical solution) may contain significant error. Because the parameter measurement values are regarded as "hard" data, their errors will be finally transferred into the estimated parameter structure. Moreover, when measurement data are limited and the number of pivot points is not appropriately controlled, the over-parameterization problem may occur. Kitanidis (1999) suggested using the generalized covariance functions for structure description that can produce the flattest estimate of a distributed parameter. The geostatistical method was presented in the 1980s for steady-state flow condition. After 20 years of development, it has been extended to transient flow and unsaturated flow conditions. Besides using head measurements, velocity, concentration, arriving time, water age, geophysics, and geology measurements have been also used as correlated data to condition the log-K field (Rubin *et al.*, 1992; Harvey and Gorelick, 1995; Yeh and Zhang, 1996; Hubbard and Rubin, 2000; Medina and Carrera, 2003).

Uncertainty Caused by Structure Error

The error of an identified PR (S, θ) consists of two parts: the structure error in S and the value error in θ. In Section "The reliability of parameter estimation", we only considered the effect of the value error. Now, we understand that the error of parameterization can never be avoided when the true parameter structure is complex and unknown. Without considering the effect of structure error, we may seriously underestimate the uncertainty of model prediction or the risk of model application. In the practice of groundwater modeling, we often see that there are different PRs (or more generally, there are different conceptual models) that can fit the existing data to the same extent (Sambridge, 2001). If there are K parameter structures or models $(S_1, S_2, \ldots, S_K)$ that cannot be rejected by the existing data, we may consider their reliability one by one using the methods mentioned in Section "The reliability of parameter estimation" and find the worst-case estimation. Recently, Neuman (2003) presented a *Maximum Likelihood Bayesian Model Averaging* (MLBMA) method to assess the uncertainty of model prediction in the statistical framework. Assume that the valid structure is one of the K possible structures, the posterior distribution of a prediction Δ for given data D is defined as the weighted average of the posterior distributions with respect to all models (Hoeting *et al.*, 1999):

$$p(\Delta|D) = \sum_{k=1}^{K} p(\Delta|S_k, D)p(S_k|D) \qquad (41)$$

From Bayesian theorem, the weights $p(S_k|D) = p(D|S_k)p(S_k)/\sum_{l=1}^{K} p(D|S_l)p(S_l)$, in which $p(D|S_k)$ is the likelihood of structure S_k. Once the posterior distribution (41) is obtained, the posterior mean $E(\Delta|D)$ and the posterior variance $Var(\Delta|D)$ can be calculated, and the latter gives the reliability estimation of model prediction. Neuman (2003) presented effective methods to calculate $p(\Delta|S_k, D)$ and $p(D|S_k)$ through the maximum likelihood estimation. When the number K is large or infinite as often seen in the parameter structure identification, the calculation of (41) will be infeasible.

STRUCTURE REDUCTION AND EXPERIMENTAL DESIGN

Identification of Representative Parameters

From a practical point of view, making the identified PR (S, θ) of an unknown parameter to be close to its true structure and its true values is generally impossible, cost-ineffective, and unnecessary. Instead of the trueness, we should emphasize on the reliability of model application and the cost-effectiveness of model construction. The GIP defined in Sun and Sun (2002) aims at finding a representative parameter (or a model after it is parameterized) that has the simplest structure, and yet can produce reliable results for given model applications. The basic idea is to offset the error in parameter structure by the error in parameter values. Let $g_E(M)$ be a set of given model applications (predictions, managements, or decisions), where M represents a model or a PR (S, θ). The reliability of model application can be represented by

$$\|g_E(M) - g_E(M_t)\|_E < \varepsilon \qquad (42)$$

where $\|\cdot\|_E$ is a norm defined in the model application space, M_t is the true parameter, ε is an accuracy requirement. The GIP requires finding the *simplest* parameter structure S^* and its associated model parameter θ^* in the admissible region such that (42) is satisfied when PR $M^* = (S^*, \theta^*)$ is used as $M = (S, \theta)$ in that equation. Therefore, the parameter identified by solving GIP is a representative one for the specified model application. The so-defined GIP has the following advantages: first, the reliability of model application is incorporated into the identification procedure; second, the parameter identification problem is replaced by a weak requirement (42). This requirement may be satisfied by parameters that are not close to the true parameter in the

parameter space; third, the data requirement is minimized because GIP attempts to find the simplest representative parameter structure. The complexity of parameter structure is determined by the requirement of model application. Once the complexity is determined, the sufficiency of existing data can be assessed.

The true parameter is data-independent, but the solutions of CIP and EIP discussed before are data-dependent, that is, different parameter structures and values may be obtained for the same parameter when different data sets are used for parameter identification. To make the identified parameter to be independent of data, the cross-validation method is often used: using one set of data for parameter identification and another set of data for validation. This method is often ineffective in groundwater modeling because of data limitation. As a result, most of groundwater models used in real case studies are data-dependent models. Their reliability for different model applications is not guaranteed. The solutions of GIP, on the other hand, are application dependent. The following is a brief description of the stepwise regression method presented by Sun *et al.* (1998) for solving the GIP. Using the nested structure sequence defined in (36), for each complexity level m, we first solve the EIP to find the optimal PR and its fitting residual:

$$RE_m = \min_{S_m,\theta_m} \{\|u_D^{\text{obs}} - u_D^{\text{cal}}(S_m,\theta_m)\|_D + \lambda\|(S_m,\theta_m) - (S_m^0,\theta_m^0)\|_P\} \tag{43}$$

where u_D^{obs} denotes the observed state values based on an experimental design D. We then calculate the maximum model application error introduced by replacing S_m with S_{m-1}, which is defined by

$$AE_m = \max_{\theta_m} \min_{\theta_{m-1}} \|g_E(S_m,\theta_m) - g_E(S_{m-1},\theta_{m-1})\|_E, \quad \text{s.t. } \theta_{m-1} \in \Theta(S_{m-1}), \theta_m \in \Theta(S_m) \tag{44}$$

Let us consider three cases. (a) If both AE_m and RE_m are large, we increase m to $m+1$. S_{m+1} is obtained by dividing a zone of S_m, which is the most sensitive one to the specified model applications, into two zones. The boundary between the two zones is determined by minimizing the fitting residual RE_{m+1}. (b) If AE_m is small, stop and use the EIP solution $(\hat{S}_m, \hat{\theta}_m)$ as the identified parameter. (c) If AE_m is large but RE_m is small, new data need to be collected.

The maximum application error defined in (44) is a special case of the structure error defined in Sun (1994) and Sun *et al.* (1998). Letting (S_A,θ_A) and (S_B,θ_B) be two different PRs of a distributed parameter $\theta(x)$ in its admissible region Θ, the distance between them can be measured in parameter, observation, and model application spaces by d_p, d_D, and d_E, respectively. The overall distance d between the two PRs is defined by $d = d_E + \mu d_D + \lambda d_p$, where μ and λ are weighting coefficients. A PR (S_B,θ_{AB}) is called a *projection* of (S_A,θ_A) onto the structure S_B, when

$$\theta_{AB} = \arg \min_{\theta_B} d(S_A,\theta_A;S_B,\theta_B), \text{ s.t.}\theta_B \in \Theta(S_B) \tag{45}$$

Finding θ_{AB} from (45) is equivalent to solving a classical inverse problem. The *structure error* $SE(S_A,S_B)$ resulted from using parameter structure S_B to replace parameter structure S_A is defined by the following max-min problem:

$$SE(S_A,S_B) = \max_{\theta_A} \min_{\theta_B} d(S_A,\theta_A;S_B,\theta_B), \quad \text{s.t. } \theta_A \in \Theta(S_A), \theta_B \in \Theta(S_B) \tag{46}$$

If we take $\lambda = 0$ and $\mu = 0$ in the definition of distance, $SE(S_m,S_{m-1})$ reduces to the AE_m in (44). Let us introduce the following concept (Sun, 2005): A PR $(S_A,\tilde{\theta}_A)$ is called the *worst-case parameter* (WCP) for simplifying a structure S_A to a structure S_B, if

$$SE(S_A,S_B) = \min_{\theta_B} d(S_A,\tilde{\theta}_A;S_B,\theta_B), \text{ s.t. } \theta_B \in \Theta(S_B) \tag{47}$$

When we know WCP, the structure error can be obtained by solving a min problem (47) rather than a max-min problem (46). WCP is a parameter that is associated with the maximal error when the model structure is reduced. It cannot be located in any inner point of the admissible region $\Theta(S_A)$. *If $\Theta(S_A)$ is a multidimensional box defined by the upper and lower bounds of each parameter component, then WCP must be located at a vertex of the multidimensional box* (Sun, 2005). With this proposition, the genetic algorithm (GA) becomes very suitable for searching the WCP because each vertex can be encoded as a binary string with 0 corresponding to the lower bound and 1 to the upper bound of a parameter component. Note that WCP depends on the flow conditions and may not be unique. Once we have an effective method for calculating the structure error, the stepwise regression procedure for solving the GIP becomes more effective.

Robust Experimental Design

The objective of experimental design is either to provide the maximum information with a certain budget, or to provide certain information with the minimum budget. For groundwater modeling, the decision variables of design include (i) how to excite the system (pumping locations and rates), and (ii) how to observe the responses of the system (observation locations and frequencies). In statistics, the theory of experimental design has been well developed for linear models for which the observation equation can be represented by $u_D^{\text{obs}} = \mathbf{A}_D\theta + \varepsilon_D$, where $\mathbf{A}_D$ is an $n \times m$ matrix. If the observation error ε_D is

normally distributed with zero mean and variance σ^2, the covariance matrix of the estimated parameter $\hat{\theta}$ is given by $Cov(\hat{\theta}) = \sigma^2(\mathbf{A}_D^T\mathbf{A}_D)^{-1}$. The determinant of the covariance matrix is a measurement of the *uncertainty* of the estimated parameter. The matrix $\mathbf{A}_D^T\mathbf{A}_D$ is called the *information matrix*. To maximize a norm of the information matrix means to minimize the uncertainty of the estimated parameter. For example, the *D-optimal design criterion* finds a design D^* from all admissible designs $\{D_{ad}\}$ such that the determinant of $\mathbf{A}_D^T\mathbf{A}_D$ is maximized (or the volume of the corresponding confidence ellipsoid is minimized). Therefore, for a linear model, the optimal design decision variables can be obtained by solving an optimization problem.

A nonlinear model can be linearized by first-order approximation in the neighborhood of the unknown parameter. The sensitivity matrix $\mathbf{J}_D = [\partial u_{\mathbf{D}}^{\text{obs}}/\partial\theta]$ is used to approximate $\mathbf{A}_D$ and the matrix $\mathbf{J}_D^T\mathbf{J}_D$ is used to approximate the information matrix. All the elements of the sensitivity matrix should be evaluated at the true parameter. As a result, for nonlinear problems, the D-optimal design depends on the parameter to be estimated. In this case, a sequential design process is needed. The initial design is based on the initial guess of the unknown parameter, after the design is conducted in the field and the data are collected, a new design is obtained on the basis of the updated parameter. Note that a design obtained by the D-optimal criterion is neither necessary nor sufficient for the purpose of model application.

We have learned that the problem of parameter identification actually is a problem of how to transfer information from observation data to the estimated parameter. No identification method is effective if the quantity and quality of data are not sufficient. But how sufficient is sufficient? For a distributed parameter, the parameter structure error caused by parameterization can never be avoided. A parameter with more complicated structure needs more data to identify and vice versa. Therefore, the identification of parameter structure must be considered in the design stage. The problem of observation design for parameter structure identification is a new and interesting topic. Without knowing the complexity of the estimated parameter, we cannot decide whether the data provided by a design is sufficient. If we do not know how to determine the sufficiency of a design, how can we say a design is the optimal one? The solution of GIP provides important insight into experimental design because it can determine whether the existing data are sufficient for identifying a useful representative model. If the existing data are insufficient, we have to collect more data. A more challenging problem is thus presented: can we determine the sufficiency of an experimental design before it is actually conducted in the field? An experimental design that can provide sufficient information for identifying all parameters in the admissible region is called a *robust design.* We can prove that *if a design is sufficient for a WCP, it must be a robust one*. Once a WCP is found by GA, a robust design can be found through a heuristic procedure, in which the pumping rates, numbers of observation wells, and frequencies are increased gradually until the design becomes sufficient for identifying a representative parameter of the WCP. A numerical example of robust design can be found in Sun (2005).

SOFTWARE AND APPLICATIONS

Available Software Packages

The Levenberg–Marqardt algorithm is used in most parameter identification codes of groundwater modeling, such as PEST developed by Doherty (2000), UCODE developed by USGS (Poeter and Hill, 1999), and the coupled inverse solution code developed by Sun (1994). PEST has been incorporated into several packages of groundwater modeling (GMS, PMWIN, VMF, and others, see `www.scisoftware.com`), in which MODFLOW developed by USGS is used to solve the FP. UCODE has been incorporated into MODFLOW2000 and PMWIN. Parameters used in the flow model, such as hydraulic conductivity, storage coefficient, and recharge rates can be identified separately or simultaneously. In PEST, the sensitivity coefficients are calculated by the finite difference approximation, while in UCODE, the sensitivity equation method is used. In all the above-mentioned software packages, values of objective function, fitting curves, Jacobian, and correlation between parameters can be displayed during the inverse solution procedure. The code developed by Sun (1994) can identify both flow and mass transport parameters simultaneously for groundwater quality modeling. All of these packages can only solve the CIP, that is, the unknown parameter is parameterized by the zonation method with a given pattern. Changing the zonation pattern by hand is a very time-consuming work. Therefore, codes that can identify the parameter pattern automatically are badly needed.

Applications

Most studies of inverse solution in groundwater modeling and all the methods reviewed in this article are aimed at identification of hydraulic conductivity in confined and unconfined aquifers. After 40 years of study, this is still an open problem for highly heterogeneous formations. The methodologies for solving EIP and GIP have not been extensively used in real case studies. During the last decade, using software to solve CIP for model calibration, however, has become more and more popular. Besides hydraulic conductivity, we can identify storage coefficient and specific yield when transient head measurements are

available. Boundary inflow, infiltration, and recharge rates, leaky conductance, and other sink and source terms in the flow equations can also be identified. Generally speaking, any property or any part of a model can be identified provided (i) the property is appropriately parameterized, and (ii) there are data available that are sensitive to the property.

In an unsaturated zone, the hydraulic conductivity is a function of pressure head ψ or a function of water content θ. It is generally expressed by an empirical formula other than parameterized by a set of basis functions. The most often used expression is

$$K(\theta) = K_s S_e^{\lambda}[1 - (1 - S_e^{1/m})^m]^2 \tag{48}$$

where $S_e = (\theta - \theta_r)/(\theta_s - \theta_r)$, $\theta(\psi) = \theta_r + (\theta_s - \theta_r)[1 + |\alpha\psi|^n]^{-m}$, and $m = 1 - 1/n$ (**Chapter 150, Unsaturated Zone Flow Processes, Volume 4**). The function identification problem is then reduced to identifying six constant parameters: $p = (\theta_s, \theta_r, \alpha, n, K_s, \lambda)$. When concentration measurements are available, the dispersion and reaction parameters can be identified simultaneously with the hydraulic parameters. Abbasi *et al.* (2003) shows that n and θ_s in p are the most sensitive parameters to water content, while θ_s and the longitudinal dispersion coefficient D_L are the most sensitive parameters to concentration. Because of the nonlinearity of the unsaturated flow model, the least squares criterion may have many local minima, and it is better to use global optimization algorithms for inverse solution. Altmann–Dieses *et al.* (2002) presented an optimal experimental design method for identifying the parameters in unsaturated zones.

To study groundwater contamination caused by organic compounds, we need to develop models to simulate various reactive transport processes in multiphase flow. The governing equations for this case are a set of partial differential equations that describe the mass balance of each component in each phase. There are a lot of physical, chemical, and biological parameters that must be identified before a model can be used for prediction and design purposes. In recent years, many authors used the least squares criterion to find the best fitting between model outputs and concentration data obtained from experiments (Gramling *et al.*, 2002). The fitting procedure usually contains two steps: first, using tracer test data to identify flow and dispersion parameters, and then fitting the reactive transport data to identify mass exchange, reaction, and decay term. If the model outputs cannot fit the observed data well, more complicated expressions containing more unknown parameters may be used in the reaction model. For a nonlinear kinetic process, mass exchange, reaction, and decay terms are unknown functions of concentrations. The solution of EIP for identifying the functional structure, thus, should be considered. When the number of unknown parameters increases, we must consider the identifiability problem caused by possible correlation between parameters. For example, Sun *et al.* (2001) shows that only two of four parameters characterizing the attachment/detachment process of colloids are identifiable. The study for identifying complex chemical and biological parameters is being developed.

Locating contaminant sources and recovering their release history from the measurements of contaminant plumes are critical for remediation design and environmental litigation support. Three problems were considered in groundwater references: (i) find the release history when a source location is known; (ii) find the location of a source when its release history is known; and (iii) find both source locations and release history. Pollution source identification is a kind of inverse problem. Therefore, all the criteria and methodologies reviewed in the previous sections can be used once the identified source is parameterized. The unknown parameter vector θ associated with a source may consist of its coordinates (x_s, y_s) and the released concentrations $\{C_s(t_j)|j = 1, 2, \ldots, m\}$, where m is the number of times or time periods. When the weighted least squares criterion is used, the objective function of optimization is:

$$E(\theta) = \sum_{k=1}^{K}\sum_{l=1}^{L} w_{kl}[C_{kl}^{\mathrm{cal}}(\theta) - C_{kl}^{\mathrm{obs}}]^2, \theta = (x_s, y_s, C_s) \tag{49}$$

where $\{C_{kl}^{\mathrm{obs}}\}$ are observed values of the plume at K observation times and L locations, $\{C_{kl}^{\mathrm{cal}}(\theta)\}$ are the corresponding model output. The objective function based on WLSE criterion is highly nonlinear and usually nonconvex. Many authors have designed different optimization algorithms, including evolution algorithms, to find the minimum of E(θ) (Mahar and Datta, 2001; Aral *et al.*, 2001). By considering the ill-posed nature of the source identification problem, Skaggs and Kabala (1994) added a regularization term to the objective function to stabilize the inverse solution. Atmadja and Bagtzoglou (2001) used the backward beam equation for source identification, in which the advection transport is reversed in time but the dispersion transport is kept positive because that cannot be reversed. This method can assess the relative importance of each potential source. Neupauer and Wilson (1999) obtained the backward-in-time distribution of a potential source by solving the adjoint state equation that, actually, is equivalent to the solution of the backward beam equation. Snodgrass and Kitanidis (1997) and Michalak and Kitanidis (2003) used the geostatistical method for contaminant history recovery that can give also the variance of estimation error. Up to date, development of accurate and effective methods for source identification is still an open problem.

CONCLUSION

Inverse problems in groundwater modeling can be defined in both deterministic and statistical frameworks. Bayesian inference provides the most general method for parameter estimation. It can incorporate not only prior information but also observation and model errors into the estimation process. Several software packages are available for solving the classical inverse problems in groundwater modeling. Methods that can automatically identify both parameter structure and values from prior information and observed data are badly needed. Because the structure of a real aquifer is usually very complex and unknown, and the available data are always very limited in both quantity and quality, finding a representative model is the only feasible way in groundwater modeling. The generalized inverse problem does not require the uniqueness of inverse solution. Instead, it requires the reliability of model application. Collecting sufficient data is the key of successfully solving the inverse problem. The problem of identifying hydraulic parameters of highly heterogeneous aquifers is still not well resolved. The identification of chemical and biological reaction functions and the identification of pollution sources are being studied.

157: Sea Water Intrusion Into Coastal Aquifers

JACOB BEAR

Department of Civil and Environmental Engineering, Technion – Israel Institute of Technology, Haifa, Israel

The objective of this article is to present the problem of seawater intrusion into a coastal aquifer and the conceptual and complete mathematical models that describe it. Three seawater intrusion models are presented: two- and three-dimensional sharp interface models and a three-dimensional transition zone model.

INTRODUCTION

In many parts of the world, coastal aquifers constitute an important source of water. Often, coastal areas are also heavily populated, a fact that makes the demand for freshwater even more acute. However, the proximity and contact with the sea requires special attention when planning the management of such aquifers, and the use of models to facilitate decision-making. In fact, in many coastal aquifers, intrusion of seawater has become one of the major constraints affecting groundwater management. As seawater intrusion progresses, the part of the aquifer close to the sea becomes saline. As a consequence, pumping wells that exist close to the coast become saline and have to be abandoned. Also, the area above the intruding seawater wedge is lost as a source of freshwater (by natural replenishment).

Since the famous works of Badon-Ghyben (1888) and Herzberg (1901), and the less-known work of Du Commun (Mentioned in Konikow, L. F. and Reilly, T. E. Seawater intrusion in the united states, in Bear *et al.*, 1999) (1828), extensive research has been carried out, leading to the understanding of the mechanisms that govern seawater intrusion. The dominant factors are the flow regime in the aquifer above the intruding seawater wedge, the variable density, and hydrodynamic dispersion. Reviews of the phenomenon of seawater intrusion, and of the research that has been carried out on this subject, both theoretical work, and field and laboratory investigations, may be found in many books and publications, and will not be repeated here (e.g. Bear, 1972, 1979; Bear and Verruijt, 1987; Reilly and Goodman, 1980; and Bear *et al.*, 1999).

Briefly, under normal conditions in a coastal aquifer, the sea is the recipient of freshwater excess, that is, natural and artificial recharge minus pumping. This means that a seaward hydraulic gradient exists in the aquifer. Due to the presence of seawater in the aquifer under the sea, a zone of contact is formed between the lighter freshwater flowing toward the sea and the heavier seawater in the aquifer. Typical cross sections, with interfaces under natural conditions are shown in Figure 1. In this figure, the surface indicated as an "interface" represents an "interface zone" (Figure 2). The detailed shape of the transition zone depends also on whether this zone is advancing inland or retreating. In all cases, the domain in the aquifer that is occupied by seawater has the form of an advancing or receding wedge. One should note that, like all figures that describe aquifers, these are also highly distorted figures, not drawn to scale.

Seawater and freshwater are often referred to as "miscible liquids", although, actually, both constitute a *single* liquid phase – water – with different concentrations of *total dissolved salt* (salt, TDS). For the sake of simplicity, we shall continue to refer to them as two liquids – fresh water, and seawater. Hence, the passage from the portion of the aquifer that is occupied by the former to that occupied by the latter, takes the form of a *transition zone*, rather than a *sharp interface*. Under certain circumstances, depending on the extent of seawater intrusion, and on certain aquifer properties, this transition zone, which is, primarily, a result of *hydrodynamic dispersion* of the dissolved matter, may be rather wide. Under other conditions, it may be rather narrow, relative to the aquifer's thickness, and the passage from the zone occupied by freshwater to that occupied by

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

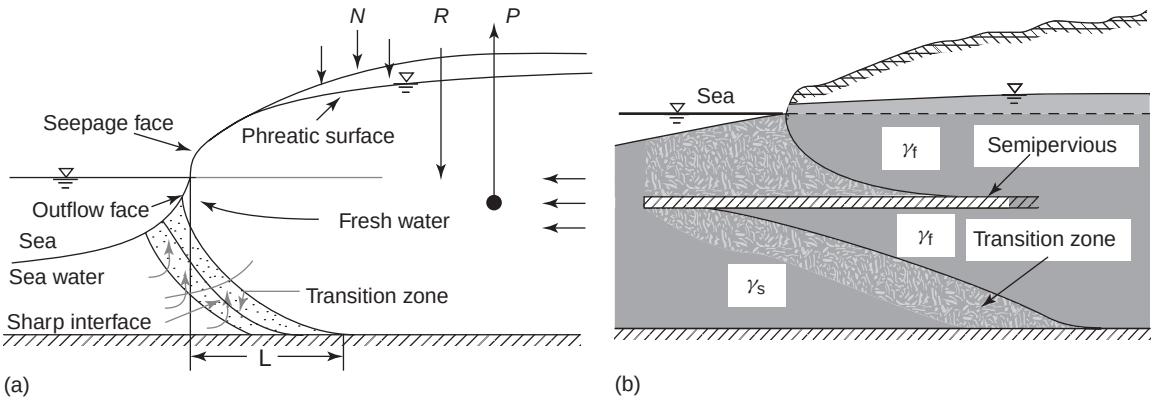

Figure 2 Transition zones in a single layer and in a multilayered coastal aquifer. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

seawater may be *approximated* as a *sharp interface*. Often, the term "interface" is used for the iso-density surface that is midway between fresh and seawater. In this article, the term "interface" will sometimes be used interchangeably with "transition zone".

Under natural undisturbed conditions in a coastal aquifer, a state of equilibrium is maintained, with a stationary interface zone and with a zone of freshwater flow above it. Under these (unrealistic) assumptions of a stationary sharp interface, the seawater is immobile, while the freshwater is flowing seaward above the interface. In reality, the transition zone is fed from below by seawater (Figure 2). When water is pumped from a coastal aquifer, the discharge to the sea is reduced, water levels (or the piezometric head in a confined aquifer) close to the sea are lowered and the transition zone rises. The entire seawater and transition zone wedge advance landward, until a new equilibrium is reached. Wells that operate within the wedge zone pump saline water and have to be abandoned. When pumping takes place in a well located above the transition zone,

the latter *upcones* toward the well. Unless the well is at a sufficient distance above this zone and/or the rate of pumping is sufficiently small, the well will eventually pump sea, or saline water.

As already indicated above, the extent of seawater intrusion, measured, say, by the length of the intruding wedge on the aquifer's bottom, is related to the rate of freshwater drained to the sea. *As this rate is reduced (by pumping), the extent of seawater intrusion increases.* This makes the problem of seawater intrusion into a coastal aquifer a *management problem.* In such a problem, we seek to determine the maximum annual net rate of pumping (i.e. pumping minus artificial recharge) from the aquifer such that a certain goal is achieved (e.g. maximize net benefits), without violating specified (legal, hydrologic, technical, etc.) constraints. Thus, in managing a coastal aquifer, the issue is not *to stem seawater intrusion*, but to determine the *optimal extent of seawater intrusion*. We wish to maximize pumping, in order to achieve certain, say, economic goals, without violating specified constraints. Models of flow, solute transport, and optimization are used in planning aquifer management. An essential constraint to be satisfied, as part of the optimization model, is the mathematical flow and solute transport model, which takes into account the dependence of water density on salt concentration (= variable density flow).

In the past, the *sharp interface approximation* was introduced, primarily, to enable relatively easy solutions, both analytical and numerical, of certain simple seawater intrusion problems of practical interest. However, nowadays, with the availability of new improved numerical techniques, including methods for coping with nonlinearities that are inherent in the transition zone model, and with fast and large memory computers (even PCs), numerical solutions of models that take the transition zone into account should not pose special difficulties. There is also no reason to limit the models to (vertical) two-dimensional flow domains. Indeed, a number of models and computer codes that consider seawater intrusion as a solute transport problem have already been developed (e.g. Konikow *et al.*, 1996). Plenty of information on seawater intrusion into coastal aquifers, the management problem, modeling with the sharp interface approximation, analytical solutions, modeling as a variable density flow and transport problem, numerical solutions, and discussions on specific numerical codes can be found in Bear *et al.* (1999).

THE 3-D SHARP INTERFACE MODEL

As emphasized earlier, except for cases in which the transition zone is relatively narrow, this is an unrealistic model. However, we present it because it gives some insight into certain features of the seawater intrusion problem.

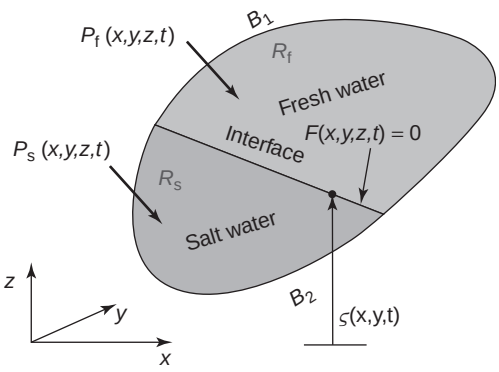

Figure 3 A sharp interface between regions occupied by freshwater and seawater. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

The underlying conceptual model is that the freshwater and the seawater are two liquids of different density and viscosity, each occupying a *distinct* portion of the flow domain. The two portions (R_s and R_f in Figure 3) are separated by a sharp, possibly moving, interface. Sources and sinks of liquid (i.e. artificial recharge and pumping) may exist in both regions. In each of the two regions, we define a *piezometric head*, h (*see* **Chapter 149, Hydrodynamics of Groundwater, Volume 4**) in the form

$$h_\alpha = z + \frac{p}{g\rho_\alpha}, \text{ or, for a compressible fluid:}$$
$$h_\alpha = z + \int_{p_0}^{p} \frac{\mathrm{d}p}{g\rho_\alpha(p)} \tag{1}$$

where α denotes either fresh (f) or seawater (s), p denotes pressure, p_o denotes a reference pressure, ρ denotes the fluid's density, z denotes elevation above some datum level, and g denotes gravity acceleration.

Subject to certain simplifying assumptions, the mathematical model of the two-liquid flow problem can be stated as:

Determine h_f in R_f and h_s in R_s, such that they satisfy the two mass balance equations

$$(a)\quad S_{0f}\frac{\partial h_f}{\partial t} = -\nabla\cdot\mathbf{q}_f - P_f, \quad \mathbf{q}_f = -\mathbf{K}_f\cdot\nabla h_f, \quad \text{in } R_f;$$
$$(b)\quad S_{0s}\frac{\partial h_s}{\partial t} = -\nabla\cdot\mathbf{q}_s - P_s, \quad \mathbf{q}_s = -\mathbf{K}_s\cdot\nabla h_s, \quad \text{in } R_s \tag{2}$$

in which $P_\alpha = P_\alpha(x, y, z, t)$ is a symbol that represents sinks of the α-phase, $\mathbf{K}_\alpha \equiv \mathbf{k}\rho_\alpha g/\mu_\alpha$ is the hydraulic conductivity, $\mathbf{k}$ is the permeability (both tensors), μ is the dynamic viscosity, and $S_{0\alpha}(x, y)$ is the specific storativity, all of the α-phase (*see* **Chapter 149, Hydrodynamics of Groundwater, Volume 4** for the development of (2) and the underlying assumptions). In addition, we have to specify

initial conditions. Boundary conditions for h_f on B_1 and h_s on B_2 are the usual ones encountered in the flow of a single fluid. However, the boundary condition on the interface separating the two fluids requires special attention. Moreover, similar to the case of a phreatic surface (**Chapter 149, Hydrodynamics of Groundwater, Volume 4**), the location and shape of the interface, which is expressed in the form $F = F(x, y, z, t) = 0$, is *a priori* unknown (until the problem is solved).

Denoting the elevation of points on the interface by $\zeta = \zeta(x, y, t)$, the relationship for F becomes

$$z = \zeta(x, y, t), \quad \text{or} \quad F \equiv z - \zeta(x, y, t) = 0 \tag{3}$$

The pressure at a point $P(x, y, \zeta)$ on the interface is the same when the latter is approached from both sides. Hence, from the definitions of h_f and $h_{s'}$, we obtain

$$\gamma_f(h_f - \zeta) = \gamma_s(h_s - \zeta), \quad \gamma_\alpha = \rho_\alpha g,$$
$$\zeta(x, y, t) = h_s(1 + \delta) - h_f\delta; \quad \delta = \frac{\gamma_f}{\gamma_s - \gamma_f} \tag{4}$$

Hence, once we know $h_f = h_f(x, y, z, t)$ and $h_s = h_s(x, y, z, t)$, in their respective domains, (4) becomes the sought equation for the shape of the interface, in the form

$$F(x, y, z, t) = z - h_s(1 + \delta) + h_f\delta = 0 \tag{5}$$

The boundary conditions on the interface defined by (5) – one for each side – are obtained from the fact that the interface is a *material surface* with respect to each of the fluids; no fluid mass crosses it. The two conditions are

$$(\mathbf{q}_{rf} - \phi\mathbf{u}) \cdot \mathbf{n} = 0, \quad (\mathbf{q}_{rs} - \phi\mathbf{u}) \cdot \mathbf{n} = 0, \quad (\mathbf{V}_\alpha - \mathbf{u}) \cdot \mathbf{n} = 0 \tag{6}$$

in which ϕ denotes the porosity, $\mathbf{q}_r$ denotes the specific discharge relative to the solid, $\mathbf{u}$ denotes the speed of displacement of the interface, and $\mathbf{n}$ is the unit vector normal to it, with

$$\frac{dF}{dt} \equiv \frac{\partial F}{\partial t} + \mathbf{u} \cdot \nabla F = 0, \quad \mathbf{n} = \frac{|\nabla F|}{\nabla F}, \quad \mathbf{u} \cdot \nabla F = -\frac{\partial F}{\partial t}$$

In (6), $(\mathbf{V}_\alpha - \mathbf{u}) \cdot \mathbf{n} = 0$, and $\mathbf{q}_{r\alpha} = \phi\,(\mathbf{V}_\alpha - \mathbf{V}_{\text{solid}})$, $\alpha = f, s$, is the specific discharge obtained from Darcy's law (*see* **Chapter 149, Hydrodynamics of Groundwater, Volume 4**). The conditions in (6) can be rewritten in the form

$$\phi\delta\frac{\partial h_f}{\partial t} - \phi(1 + \delta)\frac{\partial h_s}{\partial t} = (\mathbf{K}_f \cdot \nabla h_f) \times [\nabla z - (1 + \delta)\nabla h_s + \delta\nabla h_f] \tag{7}$$

for the R_f-region, and as an analogous equation for the R_s-region. These, *nonlinear* conditions indicate the coupling that exists between the two regions.

In principle, once the problem is solved for h_f in R_f and h_s in R_s, the shape of the interface can be determined by (5).

THE GHYBEN–HERZBERG APPROXIMATION

Consider the interface shown in Figure 4(a). The U-tube superimposed on this figure is intended to demonstrate the conceptual model proposed by Du Commun (1828), Badon-Ghyben (1888), and Herzberg (1901). Essentially, they assumed that a static equilibrium exists under steady-state conditions, with stationary seawater and a hydrostatic pressure distribution in the seaward flowing freshwater zone. This means that the flow is (essentially) horizontal

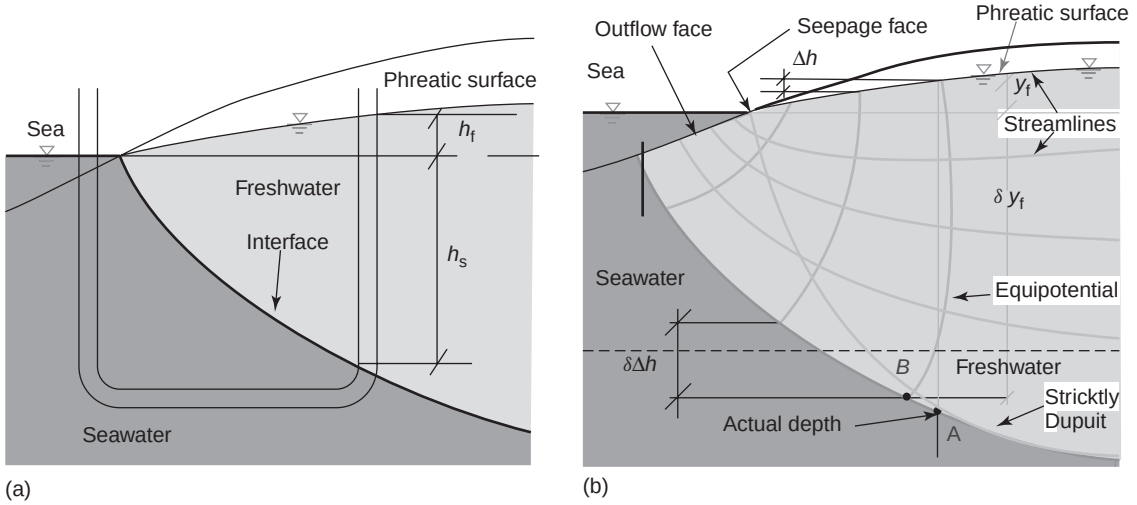

Figure 4 (a) The Ghyben–Herzberg approximation and (b) actual interface. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

and equipotentials (= surfaces of equal piezometric head) are vertical lines or surfaces. This, in fact, is identical to the Dupuit assumption (*see* **Chapter 149, Hydrodynamics of Groundwater, Volume 4**). With the notation of Figure 4(a), we have

$$h_s = \delta h_f, \quad \delta = \frac{\rho_f}{\rho_s - \rho_f} \tag{8}$$

This means that at any distance from the sea, the depth of an *assumed stationary interface* below sea level is δ times the height of the freshwater table above it. Obviously, as the sea is approached, the assumption of essentially horizontal flow is no longer valid. Moreover, this assumption does not provide for an outflow surface through which freshwater can be drained to the sea. Figure 4(b) shows the actual flow conditions near the sea. We note the difference between the actual point (A) and the point (B) determined from the equipotential (= δh_f.), which is the depth predicted by the Ghyben–Herzberg relationship (8). The difference stems from the difference between the actual shape of the equipotentials and the vertical ones assumed by the Dupuit approximation. In a confined aquifer, h_s in (8) is the depth of a point on the interface below sea level, while h_f is the freshwater piezometric head. Bear and Dagan (1964) suggested that for steady flow, (8) gives an error that is less than 5% provided $\pi KB/\delta Q > 8$, where Q is the freshwater discharge to the sea and B is the (constant) thickness of a confined aquifer. In the case of a phreatic aquifer, the Ghyben–Herzberg approximation also overlooks the presence of the *seepage face* shown in Figure 4(b). Note that the interface always intersects the sea bottom as a line that is tangent to the vertical.

ESSENTIALLY HORIZONTAL FLOW MODEL

We continue to assume the existence of a sharp interface, but we introduce the *hydraulic approach*, on the basis of the (Dupuit) assumption of *essentially horizontal flow*. The flow equations are obtained by integrating the 3-D flow model presented earlier in the section 'The 3-D sharp interface model', separately for each region, over the vertical thickness of the respective region (Figure 5a).

For the freshwater region, we integrate 2(a) from the interface at $\zeta_1(x, y, t)$ to the phreatic surface with accretion, at $\zeta_2(x, y, t)$. For the salt water region, we integrate 2(b) from the aquifer's (impervious) bottom at $\zeta_0(x, y)$ to the interface, at $\zeta_1(x, y, t)$. The integration is based on the Leibnitz rule (Bear, 1979; Bear, 1999; Bear and Bachmat, 1990), which takes into account the conditions on the (possibly moving) boundary of integration. By integrating 2(a) and 2(b), we obtain for the freshwater region above the interface and for the seawater region below it, respectively,

$$\begin{aligned}\int_{\zeta_1}^{\zeta_2} \left(\nabla \cdot \mathbf{q}_f + S_{0f}\frac{\partial h_f}{\partial t} + P_f\right) dz = \nabla' \cdot B_f \widetilde{\mathbf{q}}_f' \\ + \mathbf{q}_f|_{F_2} \cdot \nabla F_2 - \mathbf{q}_f|_{F_1} \cdot \nabla F_1 \\ + S_{0f}\left(B_f \frac{\partial \widetilde{h}_f}{\partial t} + \widetilde{h}_f \frac{\partial B_f}{\partial t} + h_f|_{F_2} \cdot \frac{\partial F_2}{\partial t} - h_f|_{F_1} \cdot \frac{\partial F_1}{\partial t}\right) \\ + B_f \widetilde{P}_f = 0\end{aligned} \tag{9}$$

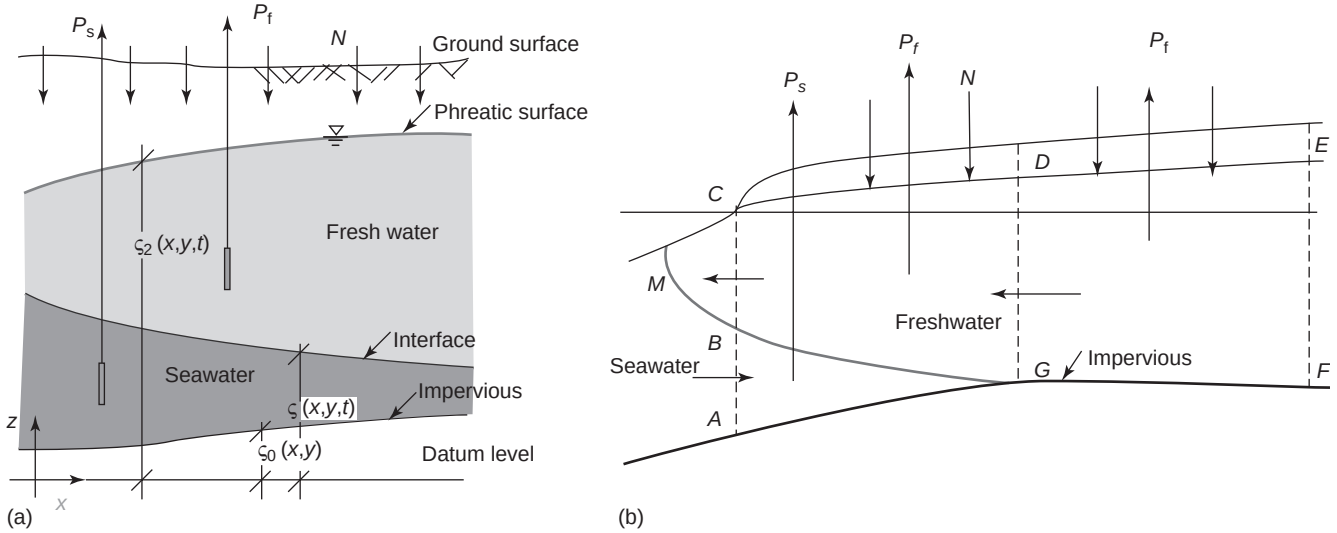

Figure 5 Nomenclature (a) for integrating over the thickness of sub-regions and (b) for boundary conditions. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

$$\int_{\zeta_0}^{\zeta_1}\left(\nabla\cdot\mathbf{q}_s+S_{0s}\frac{\partial h_s}{\partial t}+P_s\right)dz=\nabla'\cdot B_s\widetilde{\mathbf{q}}_s'+\mathbf{q}_s|_{F_1}\cdot\nabla F_1-\mathbf{q}_s|_{F_o}\cdot\nabla F_0+S_{0s}\left(B_s\frac{\partial\widetilde{h}_s}{\partial t}+\widetilde{h}_s\frac{\partial B_s}{\partial t}+h_s|_{F_1}\cdot\frac{\partial F_1}{\partial t}-h_s|_{F_0}\cdot\frac{\partial F_0}{\partial t}\right)+B_s\widetilde{P}_s=0 \tag{10}$$

in which $F_2=z-\zeta_2(x,y,t)$, $F_1=z-\zeta_1(x,y,t)$, $F_0=z-\zeta_0(x,y)$, ∇' denotes the gradient operator in the xy-plane, the prime in $\boldsymbol{q}'$ indicates the specific discharge vector in the xy-plane, $B_f=\zeta_2-\zeta_1$, $B_s=\zeta_1-\zeta_0$, and the tilde ($\widetilde{\ }$) symbol indicates the average over the relevant vertical length.

With $h_f|_{F_2}\simeq h_f|_{F_1}\simeq\widetilde{h}_f$, $h_s|_{F_o}\simeq h_s|_{F_1}\simeq\widetilde{h}_s$, which expresses the assumption of essentially horizontal flow in both domains, we obtain for the freshwater and saltwater domains, respectively,

$$\begin{aligned}\nabla'\cdot B_f\widetilde{\mathbf{q}}_f'+\mathbf{q}_f|_{F_2}\cdot\nabla F_2-\mathbf{q}_f|_{F_1}\cdot\nabla F_1+S_{of}B_f\frac{\partial\widetilde{h}_f}{\partial t}+B_f\widetilde{P}_f=0,\\ \nabla'\cdot B_s\widetilde{\mathbf{q}}_s'+\mathbf{q}_s|_{F_1}\cdot\nabla F_1-\mathbf{q}_s|_{F_o}\cdot\nabla F_0+S_{os}B_s\frac{\partial\widetilde{h}_s}{\partial t}+B_s\widetilde{P}_s=0\end{aligned} \tag{11}$$

We now introduce the conditions on the top and bottom bounding surfaces. On the impervious bottom, $F_0(x,y,z)=0$, the condition is

$$\mathbf{q}_s|_{F_0}\cdot\nabla F_0=0.$$

On the interface, $F_1(x,y,z,t)=0$, the condition is obtained from (5) and (6), that is,

$$\mathbf{q}_f|_{F_1}\cdot\nabla F_1\equiv-\phi\delta\frac{\partial\widetilde{h}_f}{\partial t}+\phi(1+\delta)\frac{\partial\widetilde{h}_s}{\partial t}=\phi\mathbf{u}\cdot\nabla F_1=-\phi\frac{\partial F_1}{\partial t} \tag{12}$$

in which $h_f|_{F_1}\simeq\widetilde{h}_f$, $h_s|_{F_1}\simeq\widetilde{h}_s$. The magnitude of the error introduced by these assumptions depends on the deviation of the actual flow from the assumed horizontal one in the two domains.

On the phreatic surface, $F_2(x,y,z,t)=0$, with accretion at the rate $\mathbf{N}=-N\nabla z$, we obtain

$$F_2(x,y,z,t)\equiv z-\zeta_2(x,y,t)=z-h_f|_{F2}\simeq z-\widetilde{h}_f=0,$$
$$\mathbf{q}_f|_{F_2}\cdot\nabla F_2=\mathbf{N}\cdot\nabla F_2-\phi_{\text{eff}}\frac{\partial F_2}{\partial t}=-N+\phi_{\text{eff}}\frac{\partial\widetilde{h}_f}{\partial t} \tag{13}$$

With these conditions, we obtain the flow equations for the two domains, as

$$\begin{aligned}-\nabla'\cdot B_f\widetilde{\mathbf{q}}_f'+N-B_f\widetilde{P}_f&=(\phi_{\text{eff}}+S_{0f}B_f+\phi\delta)\frac{\partial\widetilde{h}_f}{\partial t}-\phi(1+\delta)\frac{\partial\widetilde{h}_s}{\partial t},\\ -\nabla'\cdot B_s\widetilde{\mathbf{q}}_s'-B_s\widetilde{P}_s&=\{S_{0s}B_s+\phi(1+\delta)\}\frac{\partial\widetilde{h}_s}{\partial t}-\phi\delta\frac{\partial\widetilde{h}_f}{\partial t}\end{aligned} \tag{14}$$

in which we, usually, assume that

$$B_fS_{0f}\ll\phi_{\text{eff}}\approx\phi,\ B_fS_{0f}\ll\phi,$$
$$\text{and}\quad B_f\widetilde{\mathbf{q}}_f'=-B_f\widetilde{\mathbf{K}}_f'\cdot\nabla\widetilde{h}_f,\ B_s\widetilde{\mathbf{q}}_s'=-B_s\widetilde{\mathbf{K}}_s'\cdot\nabla\widetilde{h}_s$$

Then, in terms of interface and phreatic surface elevations, we obtain the set of equations

$$\begin{aligned}-\nabla'\cdot\mathbf{Q}_f'+N-B_f\widetilde{P}_f&=\phi\frac{\partial(\zeta_2-\zeta_1)}{\partial t},\\ -\nabla'\cdot\mathbf{Q}_s'-B_s\widetilde{P}_s&=\phi\frac{\partial\zeta_1}{\partial t},\\ \mathbf{Q}_f'\equiv B_f\widetilde{\mathbf{q}}_f'&=-B_f\mathbf{K}_f\cdot\nabla\widetilde{h}_f,\\ \mathbf{Q}_s'\equiv B_s\widetilde{\mathbf{q}}_s'&=-B_s\mathbf{K}_s\cdot\nabla\widetilde{h}_s,\\ \zeta_2=\widetilde{h}_f,\ \zeta_1&=(1+\delta)\widetilde{h}_s-\delta\widetilde{h}_f\end{aligned} \tag{15}$$

For a confined aquifer, we delete N and ϕ_{eff} in the first equation in (14).

Since we have assumed "essentially horizontal flow", the flow domain, for which we have to solve (15) for $\widetilde{h}_f(x,y,t)$ and $\widetilde{h}_s(x,y,t)$, is bounded by vertical surfaces that pass through the toe of the interface (= point G in Figure 5b) and through the coast (point C). We add a vertical surface (FE) to complete the delineation of the considered aquifer domain (Figure 5b). Appropriate boundary conditions have to be specified on all these boundaries. The conditions on FE are the common ones (of specified flux, or specified head), and need not be considered here. Along the boundary of GD, the considered freshwater domain becomes an aquifer without the seawater wedge, that is, $\zeta_1\equiv\zeta_0$, $F_1\equiv F_0$. In the case of a phreatic aquifer, the flow equation in (15) reduces for the domain without the interface to (Bear, 1979)

$$-\nabla'\cdot B_f\widetilde{\mathbf{q}}_f'+N+B_f\widetilde{P}_f=(\phi_{\text{eff}}+S_{0f}B_f)\frac{\partial\widetilde{h}_f}{\partial t} \tag{16}$$

in which we usually neglect the effect of elastic storativity, as it is much smaller than the specific yield, ϕ_{eff}. As the interface advances or retreats, the boundary between the two aquifer freshwater domains is also moving. On

the common boundary (DG), we have to maintain the same piezometric head and the same normal flux. On the surface that passes through the coastline, we have two parts: the freshwater part, CB, and the seawater one, BA. The boundary between these two parts (B) is not fixed, but varies as the interface advances or retreats. For the freshwater portion, we assume (Bear, 1979) that the aquifer sub-domain BCM acts as a resistance to the flow, so that across it the head on BC is reduced to that dictated by the sea level. This condition is expressed as

$$Q_{fo} = \frac{\widetilde{h}_{\mathrm{f}}|_{\mathrm{BC}}}{\text{Resist.}}, \quad Q_{fo} = -K_{\mathrm{f}}\overline{\mathrm{BC}}\left.\frac{\partial \widetilde{h}_{\mathrm{f}}}{\partial x}\right|_{\mathrm{BC}}$$
$$\Rightarrow \frac{\widetilde{h}_{\mathrm{f}}}{\alpha} + \overline{\mathrm{BC}}\frac{\partial \widetilde{h}_{\mathrm{f}}}{\partial x} = 0 \text{ on } \overline{\mathrm{BC}},$$

which is a third type boundary condition; α is a coefficient. A similar condition, but with a different coefficient, can be written for the seawater portion of this boundary (AB).

To demonstrate the use of the above equations, we consider the simple case of essentially horizontal steady flow normal to the coast in a confined aquifer, with the stationary interface shown in Figure 6(a). For this case, the freshwater flow equation reduces to

$$\frac{\partial Q_{\mathrm{f}}}{\partial x} \equiv \frac{\partial[-K_{\mathrm{f}}h_{\mathrm{s}}\partial h_{\mathrm{f}}(x)/\partial x]}{\partial x} = 0, \Rightarrow -K_{\mathrm{f}}h_{\mathrm{s}}\frac{\partial h_{\mathrm{f}}(x)}{\partial x} = Q_0,$$
$$\delta h_{\mathrm{f}} = h_{\mathrm{s}} + d, \quad \delta h_{f0} = B + d,$$
$$x = 0,\ h_{\mathrm{f}} = h_{f0}, \quad x = L,\ h_{\mathrm{s}} = 0 \tag{17}$$

with the solution

$$Q_0 x = \frac{K_{\mathrm{f}}[B^2 - h_{\mathrm{s}}^2(x)]}{2\delta},$$
$$Q_0 L = \frac{K_{\mathrm{f}}B^2}{2\delta} \tag{18}$$

This equation, which describes a *parabola*, clearly shows the relationship between the length of seawater intrusion, L, the discharge to the sea, Q_0, and the piezometric head, h_{fo}, above the toe (G).

For the phreatic aquifer shown in Figure 6(b), the flow equation, under the same conditions, takes the form

$$-\frac{\partial Q_{\mathrm{f}}}{\partial x} + N = 0,$$
$$Q_0 + Nx = -K_{\mathrm{f}}(h_{\mathrm{s}} + h_{\mathrm{f}})\frac{\partial h_{\mathrm{f}}(x)}{\partial x}$$
$$= -K_{\mathrm{f}}(1+\delta)h_{\mathrm{f}}\frac{\partial h_{\mathrm{f}}(x)}{\partial x},$$
$$\delta h_{\mathrm{f}} = h_{\mathrm{s}}, \delta h_{f0} = B,$$
$$x = 0,\ h_{\mathrm{f}} = h_{f0}, \quad x = L,\ h_{\mathrm{f}} = 0 \tag{19}$$

Its solution is

$$h_{f0}^2 - h_{\mathrm{f}}^2 = \frac{2Q_0x + Nx^2}{K_{\mathrm{f}}(1+\delta)}, \quad h_{f0}^2 = \frac{2Q_0L + NL^2}{K_{\mathrm{f}}(1+\delta)}$$
$$Q_0 = \frac{K_{\mathrm{f}}B^2}{2L}\frac{1+\delta}{\delta} - \frac{NL}{2} \tag{20}$$

Another possible condition at the sea is $x = L$, $h_{\mathrm{f}} = \beta\delta Q_0 K_{\mathrm{f}}$ (Bear and Verruijt, 1987, p. 207).

Again, we see here the relationship between the drainage of freshwater to the sea and the length of seawater intrusion. *Reducing Q_{f0} means an increased L*. By controlling h_{fo}, say by means of artificial recharge, the water table may be lowered landward of the toe, without any additional seawater intrusion.

When water is pumped above the interface, the latter will rise. This phenomenon is referred to as *upconing* (Bear, 1972, 1979). In considering this phenomenon, we should take into account the existence of the transition zone; as it rises, the pumped water gradually become saline.

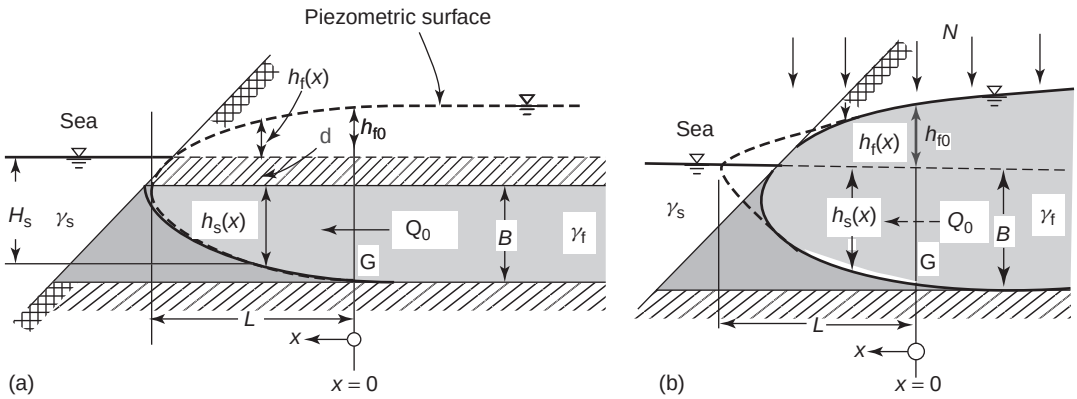

Figure 6 The interface (a) in a confined and (b) in a phreatic coastal aquifer. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

THE TRANSITION ZONE BETWEEN FRESH AND SEAWATER

As already mentioned in the introduction, in reality, the aquifer domain occupied only by seawater, and the aquifer domain occupied only by freshwater are separated by a transition zone. This is a consequence of the fact that the two ("miscible") liquids are actually a single liquid – water – with different concentrations of dissolved salts. The width of the transition zone is dictated by three phenomena: (a) advection of the water – fresh and mixed – toward the sea (or, under certain conditions, landward), (b) dispersion, and (c) molecular diffusion. These phenomena are discussed in (*see* **Chapter 152, Modeling Solute Transport Phenomena, Volume 4**) and need not be discussed here. Suffice it to summarize that a transition zone exists; across it, the salinity of the water varies from that of freshwater to that of seawater. The width of this zone grows as it is being displaced in response to changes in the flow regime and in the discharge of water flow to the sea. The transition zone is also fed by a flux of salt from the seawater zone.

Figure 7 shows a phreatic coastal aquifer with a transition zone between seawater and freshwater. The considered flow domain is ABCDEMFA. The detailed conceptual and mathematical models of flow and solute transport are presented in **Chapter 149, Hydrodynamics of Groundwater, Volume 4** and **Chapter 152, Modeling Solute Transport Phenomena, Volume 4**, respectively, and will not be repeated here. The new feature here is that the flow and the solute transport models are *coupled*, as the density of the liquid continuously varies in response to the changes in dissolved salt concentration. We usually refer to such a model as "density variable flow and transport model". In what follows, we shall present this model, assuming isothermal conditions.

The mathematical model describing seawater intrusion in a coastal aquifer consists of: (a) mass balance equation for the water, (b) flux equation (Darcy's law) for the water, (c) mass balance equation for the dissolved salts, and (d) flux equation for the dissolved salts. The first two equations are often combined as a single *flow equation* for the water. The last two equations may be combined to form a single mass balance equation for the dissolved salts, often referred to as the *advection–dispersion equation*, or *the transport equation*. In addition, the complete model includes: (a) constitutive equations that relate the liquid's density and dynamic viscosity to the total dissolved salt concentration and (b) initial and boundary conditions (Bear, 1999; Zhou, 1999).

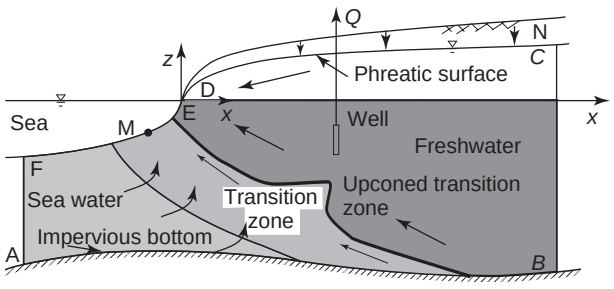

Figure 7 The transition zone with upconing in a simplified vertical cross section of a coastal aquifer, normal to the coastline. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Although, in principle, the flow model can be written in terms of pressure, p, as a state variable, a more (numerically) efficient model is obtained by expressing the flow model in terms of a *reference piezometric head*, h'. Accordingly, we introduce a reference piezometric head, $h'(x, y, z, t)$, associated with a reference water density. We often select ρ_{fw} (= density of freshwater) as a reference density. Thus,

$$h' = \frac{p}{\rho_{fw} g} + z \tag{21}$$

in which z and g denote the vertical coordinate and gravity acceleration, respectively.

To enable the use of the mathematical model to beyond the case of seawater intrusion, discussed here, we consider TDS (= Total Dissolved Solids) in the range where the volume of water may vary with concentration. To facilitate the discussion, we introduce a *normalized salt mass fraction, C(x,y,z,t),* defined by

$$C = \frac{\omega - \omega_{fw}}{\omega_{sw} - \omega_{fw}}, \quad 0 \le C \le 1.0 \tag{22}$$

in which ω and ω_{sw} denote the salt (or TDS) mass fraction in water (= salt solution) and in seawater, respectively, and ω_{fw} is the reference (freshwater) mass fraction. Note that $c = \rho\omega$, in which c denotes the TDS concentration (= mass of TDS per unit volume of fluid).

The constitutive equation that expresses the relationship, $\rho = \rho(p, \omega)$, between the fluid density, the pressure, and the salt mass fraction, ω (mass of dissolved salt per unit mass of fluid), is

$$\rho = \rho_0 \exp[\beta'_p(p - p_0) + \beta'_\omega(\omega - \omega_0)] \tag{23}$$

where p_0 and ω_0 are reference values of pressure and salt mass fraction, respectively, $\beta'_p = (1/\rho)\partial\rho/\partial p$ is the coefficient of water compressibility (at constant salt concentration), and $\beta'_\omega = (1/\rho)\partial\rho/\partial\omega$ is a coefficient that introduces the effect of change in salt mass fraction on the fluid's density (at constant pressure). We usually select $\omega_0 = \omega_{fw}$, that is, equal to the mass fraction of freshwater. The reference pressure is such that for freshwater at $p = p_0$, the density is $\rho = \rho_{fw}$, as the density of freshwater is selected as *a reference density*.

The linearized approximation of (23) is

$$\rho = \rho_0[1 + \beta''_p(p - p_0) + \beta''_\omega(\omega - \omega_0)] \qquad (24)$$

where $\beta''_p = (1/\rho_0)\partial\rho/\partial p$ and $\beta''_\omega = (1/\rho_0)\partial\rho/\partial\omega$. In what follows, we shall assume that for the range of pressures considered here, $\beta''_\omega|\Delta\omega| >> \beta''_p|\Delta p|$, so that we may employ the approximation

$$\rho = \rho_{\mathrm{fw}}(1 + \beta_c C), \quad \beta_c = \beta''_\omega(\omega_{\mathrm{sw}} - \omega_{\mathrm{fw}}) \qquad (25)$$

where β_c may be referred to as a *density difference factor* (dimensionless). In spite of the above assumption, we do take into account the effect of pressure in the expression for the specific storativity appearing in the mass balance equation.

To introduce the effect of concentration on the fluid's dynamic viscosity, we may use the constitutive relationship for dynamic viscosity in the form (Lever and Jackson, 1985)

$$\mu = \mu_{\mathrm{fw}}\mu_r = \mu_{\mathrm{fw}}(1 + 1.85\,\omega - 4.1\,\omega^2 + 44.50\,\omega^3) \qquad (26)$$

in which μ_{fw} is the viscosity that corresponds to $\omega = 0$, and μ_r is defined by (26).

The *specific discharge relative to the solid*, $\mathrm{q}_r \equiv \phi(\mathbf{V} - \mathbf{V}_{\mathrm{s}}) = \mathbf{q} - \phi\mathbf{V}_{\mathrm{s}}$, is expressed by Darcy's law

$$\mathbf{q}_r = \phi(\mathrm{V} - \mathrm{V}_{\mathrm{s}}) = -\frac{\mathbf{k}}{\mu}(\nabla p + \rho g \nabla z),$$

in which $\mathbf{V}$ and $\mathbf{V}_{\mathrm{s}}$ denote the velocity vectors of the water and of the solid matrix, respectively, z denotes the vertical coordinate, positive upward, g denotes gravity acceleration, and the second rank tensor, $\mathbf{k}$, denotes the permeability. We usually, assume, also here, that $\mathbf{V}_{\mathrm{s}} \approx 0$, $\mathbf{q}_r \approx \mathbf{q}$. In terms of h' and C, Darcy's law can be rewritten in the form

$$\mathbf{q}_r = -\frac{\mathbf{k}}{\mu}(\nabla p + \rho g \nabla z) = -\frac{\mathbf{K}^{\mathrm{o}}}{\mu_r}(\nabla h' + \beta_c C \nabla z)$$
$$\mathbf{K}^{\mathrm{o}} = \frac{\rho_{\mathrm{fw}} g \mathbf{k}}{\mu_{\mathrm{fw}}} \qquad (27)$$

with $\mathbf{K}^{\mathrm{o}}$ denoting the reference hydraulic conductivity.

For a single fluid phase, for example, water, of variable density, Bear (1972, 1979) and Bear and Bachmat (1990), as many others, present the general mass balance equations in the form

$$\frac{\partial\phi\rho}{\partial t} = -\nabla\cdot(\rho\mathbf{q}) + (\rho_R Q_R - \rho Q_P) \qquad (28)$$

in which ϕ denotes porosity, Q_R and Q_P, denote, symbolically, the rates of injection of water into and withdrawal of water from the aquifer, respectively (dims. 1/T), ρ_R denotes the density of the injected water, and $\mathbf{q}$ denotes the specific discharge vector. When water is withdrawn and injected through (point) wells, the source terms in (28) may, symbolically, be written as

$$\rho_R Q_R = \Sigma_{(n)}\rho_{Rn} Q_{Rn}(\mathrm{x}_n, t)d(\mathrm{x} - \mathrm{x}_n)$$
$$\rho Q_P = \Sigma_{(m)}\rho_{\mathrm{Pm}} Q_{\mathrm{Pm}}(\mathrm{x}_{\mathrm{m}}, t)d(\mathrm{x} - \mathrm{x}_{\mathrm{m}})$$

in which Q_{Rn} and ρ_R are the injection rate, and fluid's density of water injected through a well at point x_n, respectively, and Q_{Pm} and ρ_{Pm} are the pumping rate and density of water pumped through a well at point x_{m}.

Equation (28) is based on the *assumption that the dispersive flux of the total fluid mass is much smaller than the advective flux*. However, in the case of a fluid of variable density, significant density gradients may develop. For example, it is possible that a rather narrow transition zone will develop, with a relatively large density gradient across it, such that with flow that is more or less normal to such a gradient, significant lateral dispersion may take place. Bear and Bachmat (1990, p. 290) present and discuss a method, using appropriate Peclet numbers (that define the ratio between advective and dispersive fluxes), for examining the conditions under which the dispersive flux of the total mass may be neglected as being much smaller than the advective one. Note that *there is no diffusive flux of the total mass*. In the case of seawater intrusion, we may encounter a rather narrow transition zone, with flow parallel to it. The appropriate Peclet number may be less than or not much larger than one, so that we cannot conclude that advection dominates over dispersion.

Whenever we conclude that the dispersive flux of the total fluid mass cannot be neglected, the mass balance equation (28) should be replaced by

$$\frac{\partial\phi\rho}{\partial t} = -\nabla\cdot(\rho\mathbf{q} - \phi\mathbf{D}\cdot\nabla\rho) + (\rho_R Q_R - \rho Q_P) \qquad (29)$$

in which the dispersive flux of the total fluid (mass per unit area of fluid) is expressed by

$$\mathbf{J}^{*\rho} = -\mathbf{D}\cdot\nabla\rho = -\rho_{\mathrm{fw}}\beta_c\mathbf{D}\cdot\nabla C \qquad (30)$$

In view of the relationship $\rho = \rho(p, C)$, we make use of (27) and (30) to modify (29), rewriting it in terms of the reference piezometric head, h', and C, for example, in the form

$$S_0\frac{\partial h'}{\partial t} + \phi\beta_c\frac{\partial C}{\partial t}$$
$$= \nabla\cdot\left[(1 + \beta_c C)\frac{\mathbf{K}^{\mathrm{o}}}{\mu_r}\cdot(\nabla h' + \beta_c C\nabla z) + \phi\beta_c\mathbf{D}\cdot\nabla C\right]$$
$$+ \frac{\rho_R}{\rho_{\mathrm{fw}}}Q_R - (1 + \beta_c C)Q_P \qquad (31)$$

in which (Bear, 1979) $S_0 = g\rho(\alpha + \phi\beta'_p)$ denotes the *aquifer's elastic storativity*, with α denoting the aquifer's (vertical) compressibility. Other forms are also possible.

For a fluid of constant density, the general mass balance equations for the TDS in the water in the form (*see* **Chapter 152, Modeling Solute Transport Phenomena, Volume 4**):

$$\frac{\partial \phi c}{\partial t} = -\nabla \cdot (c\mathrm{q} - \phi \mathbf{D}_h \cdot \nabla c) + (c_R Q_R - c Q_P) \quad (32)$$

in which $\mathbf{D}_h$ denotes the *coefficient of hydrodynamic* dispersion (a second order symmetric tensor), $\mathbf{D}_h = \mathbf{D} + \mathbf{D}^*_{\mathrm{diff}}$, $\mathbf{D}$ denotes the *coefficient of dispersion* (dims. L^2/T), and $\mathbf{D}^*_{\mathrm{diff}}$ denotes the *coefficient of molecular diffusion in a porous medium*. In an *isotropic* porous medium, the *coefficient of dispersion* is related to the fluid's velocity and to the *longitudinal* and *transversal dispersivities* (dims. L), α_{L} and α_T, respectively, by

$$D_{ij} = \alpha_T V \delta_{ij} + (\alpha_{\mathrm{L}} - \alpha_T)\frac{V_i V_{\mathrm{j}}}{V} \quad (33)$$

in which δ_{ij} denotes the *Kronecker delta*.

For a variable density fluid, with $c = \omega\rho$, the salt balance equation is (e.g. Bear, 1972, 1979)

$$\frac{\partial \phi \rho \omega}{\partial t} = -\nabla \cdot \phi(\rho\omega \mathbf{V} - \mathbf{D}_h \cdot \nabla \rho\omega) + \omega_R \rho_R Q_R - \omega\rho Q_P \quad (34)$$

or, with $\omega_{\mathrm{fw}} = 0$, in terms of C (Zhou, 1999; Bear, 1999)

$$\frac{\partial \phi \rho C}{\partial t} = -\nabla \cdot (\rho C \mathbf{q} - \phi \mathbf{D}_h \cdot \nabla \rho C) + (\rho_R C_R Q_R - \rho C Q_P) \quad (35)$$

When combined with (29), the last equation can be rewritten in the forms

$$\phi\rho \frac{D\omega}{Dt} = \nabla \cdot (\phi\rho \mathbf{D}_h \cdot \nabla\omega) + \phi \nabla \cdot (\omega \mathbf{D} \cdot \nabla\rho) + \rho_R(\omega_R - \omega) Q_R \quad (36)$$

or

$$\phi\rho \frac{DC}{Dt} = \nabla \cdot (\phi\rho \mathbf{D}_h \cdot \nabla C) + \phi \nabla \cdot C(\mathbf{D} \cdot \nabla\rho) + \rho_R(C_R - C) Q_R \quad (37)$$

Altogether, we have to solve the variable density flow equation (31) and the salt transport equation (37) simultaneously, for the two primary variables $h'(x, y, z, t)$ and $C(x, y, z, t)$, making use of (25) to express ρ and (27) to express $\mathbf{V}$ or $\mathbf{q}$.

The initial conditions for the variable density flow and salt transport equations are

$$h'(x, y, z, 0) = h'_0(x, y, z)$$
$$c(x, y, z, 0) = c_0(x, y, z) \quad (38)$$

where $h'_0(x, y, z)$, and $c_0(x, y, z)$ are known distributions.

The conditions on the boundary segments shown in Figure 7, neglecting the dispersive flux of the total fluid mass, are

$$\mathbf{q} \cdot \mathbf{n} = 0, \quad \text{on AB (impervious bottom)}$$
$$h' = h'_p, \text{ or } \mathbf{q} \cdot \mathbf{n} = q_{np}, \quad \text{on BC (land-side lateral boundary)}$$
$$\rho \mathbf{q} \cdot \mathbf{n} = -\left(\rho_N N - (\phi\rho - \theta_{w0}\rho_N)\frac{\partial h'}{\partial t}\right) n_z, \quad \text{on CD (phreatic surface)}$$
$$h' = \varsigma_{\mathrm{DE}}, \quad \text{on DE (seepage face)}$$
$$h' = \beta_c H_{\mathrm{sea}}, \quad \text{on EF (sea bottom)}$$
$$h' = \beta_c H_{\mathrm{FA}}, \quad \text{on FA (sea-side lateral boundary)} \quad (39)$$

where h'_p is the prescribed reference head on a Dirichlet-type boundary, q_{np} is the prescribed fluid flux on a second-type boundary, $\mathbf{n}$ is the unit outward normal vector, with the components n_x, n_y, n_z in three dimensions, N is the replenishment, ρ_N is the fluid's density in the replenishment, θ_{w0} is the irreducible water content assumed to prevail in the unsaturated zone, ς_{DE} is the elevation at a point on the seepage face above a datum, H_{sea} and H_{FA} are the depth of seawater at a point on the sea bottom and the seaside lateral boundaries, respectively. If we wish to take into account the dispersive flux of the fluid's mass, we replace $\rho\mathbf{q}$ by $\rho\mathbf{q} - \phi\rho\mathbf{D} \cdot \nabla\rho$.

The boundary conditions for the salt transport equation are

$$\begin{array}{ll} q^d_n \equiv -\phi D_{ij}\frac{\partial C}{\partial x_{\mathrm{j}}} n_i = 0, & \text{on AB and DE} \\ C = 0, & \text{on BC} \\ q^d_n = \left(\frac{\rho_N C}{\rho} - c_N\right)\left(N + \theta_{w0}\frac{\partial h'}{\partial t}\right) n_z, & \text{on CD} \\ C = 1.0, & \text{on FA} \end{array} \quad (40)$$

where q^d_n is the hydrodynamic dispersive flux normal to a second-, or third-type boundary, and C_N is the salt concentration in the replenishment water.

On the sea bottom boundary, EF, we may have either only landward flow from the sea, in which case the condition there is the same as on FA, or we may have an inflow portion, AM, and outflow portion, MF, separated by a point with zero-normal fluid flux. For the inflow portion, we usually employ either a third-type condition

$$q_n^d \equiv -\mathbf{D}_h \cdot \nabla C = (1.0 - C)q_n \tag{41}$$

or a Dirichlet condition

$$C = 1.0 \tag{42}$$

For the outflow portion, the assumption is often made that the fluid concentrations are identical (i.e. continuous) on both sides of this boundary. Since the fluid fluxes are also identical, the condition becomes a second-type condition:

$$q_n^d \equiv -\mathbf{D}_h \cdot \nabla C = 0 \tag{43}$$

The (moving) point M between the inflow and outflow portions of the boundary is unknown *a priori*. In a numerical solution, during every iteration, we check whether flow along the sea bottom is directed inward or outward, and then assign the appropriate boundary condition accordingly.

We note an *inconsistency* between the head condition on MF, based on the assumption of seawater on the seaside of EM and the assumption of equality of concentration, leading to the flux condition, on this segment. As a consequence, a large error in the salt mass balance may occur in a numerical simulation, when such an inconsistency occurs in the specified flow and transport boundary conditions. To overcome this inconsistency, between the specified flow and transport conditions on the outflow portion of sea bottom, we may assume the presence of a *buffer zone* on the sea bottom, which contains outflowing water. We then take the density of this fluid into account when determining the head condition on this boundary. Iterations may be required in a numerical solution. The thickness of this buffer zone is a calibration parameter (Bear *et al.*, 2001).

A number of computer codes for solving the above set of nonlinear coupled equations are presented in **Chapter 155, Numerical Models of Groundwater Flow and Transport, Volume 4**.

MANAGEMENT OF A COASTAL AQUIFER

The concepts and methodologies for the management of a coastal aquifer are not much different from those of any other aquifer and will not be considered here. The main difference stems from the presence of the sea and the continuous threat of seawater intrusion, with all its negative consequences. In general, as demonstrated by (18) and (20), increasing the net pumping from the aquifer, or reducing freshwater discharge to the sea, will cause an increase in the extent of seawater intrusion. Thus, optimization in this case, or sustainable yield, means finding the right balance between the benefits from increased pumping and the damages or costs incurred by the increased extent of seawater intrusion. These damages will include salinization of wells to the extent that wells have to be abandoned and water has to be supplied from sources that are farther inland. Here, *sustainable yield* of an aquifer is the annual quantity of water that can be withdrawn from the aquifer year after year, as a constant volume, or as one that varies according to some rule, without violating specified constraints, especially **that the source will be preserved (quality and quantity) forever**. The models described above can be used to predict the extent of seawater intrusion in response to proposed management alternatives. Following are a number of additional management considerations.

We have demonstrated that the position of the interface toe (in the sharp interface model) can be controlled by controlling water levels (or piezometric heads) at a desired distance from the sea. In this way, it is possible to create a *barrier* to seawater intrusion. The elevation of the barrier can be achieved either by controlling pumping farther inland and/or by implementing artificial recharge techniques.

In general, pumping above the interface will cause upconing of the interface (or transition zone) toward the pumping well, causing salinization of that well. However, it is possible to avoid salinization, even when wells are operated close to the coast, by controlling their rates and by locating their screens sufficiently high above the transition zone. In Israel, this technique is implemented as a "coastal collector", in the form of an array of shallow wells along a line close to the sea. The objective is to intercept part of the drainage of freshwater to the sea.

Under certain circumstances, it is possible to control seawater intrusion by creating (by pumping) a "trough" parallel to the coast (Huisman and Olsthoorn, 1983), or by constructing a physical barrier in the form of an impervious or semi-pervious barrier wall parallel to the coast (Todd, 1980). The latter will be effective only if it extends over a significant length.

In many parts of the world, the coastal aquifer, which is an important source of freshwater, is plagued by two additional problems. The first is that these aquifers are usually heavily populated. This means that large portions of the ground surface are covered by concrete and asphalt, thus reducing natural replenishment over these areas. The second is that human activity in such heavily populated areas increase the danger of contamination of the aquifer by pollutants originating at ground surface and traveling through the unsaturated zone to the underlying aquifer. Special means and regulations are required, as part of aquifer management, to combat these threats to the sustainable yield of the aquifer.

158: Anthropogenic Land Subsidence

GIUSEPPE GAMBOLATI, PIETRO TEATINI AND MASSIMILIANO FERRONATO

University of Padova, Padova, Italy

Fluid removal from subsurface reservoirs, in the form of gas, oil, groundwater, geothermal water, and brine, produces a compaction of the depleted formations which migrates totally or partially to the ground surface thus inducing anthropogenic land subsidence. The paper presents: (i) a list of the major subsiding areas worldwide, (ii) a review of the mechanism which causes a measurable settlement above aquifer systems and gas/oil fields, (iii) a description of the currently available techniques to measure land subsidence and in situ rock compaction, (iv) a brief description of some mathematical models to predict the magnitude of subsidence, and (v) a description of a few remedial options that are available to control the event and mitigate the related environmental impact.

INTRODUCTION

One major environmental consequence of groundwater pumping and gas/oil/geothermal water production is anthropogenic land subsidence. To be of major concern, subsurface fluid withdrawal must occur in densely populated and highly developed areas located close to the sea or a lagoon or a delta, and take place from unconsolidated geological basins of alluvial, lacustrine or shallow marine origin, formed typically, although not exclusively, in the Quaternary period. Quite often, especially at the onset of the occurrence, land settlement goes unnoticed, to be later discovered when severe damages have already been experienced. At this stage, undertaking effective remedial measures to mitigate the associated environmental and socioeconomical impact may prove tremendously expensive. However, in recent times, the awareness about the damages caused by potential anthropogenic land subsidence has significantly grown at both the political and the general public level, thus contributing to lower the alarm threshold. As a major result, the newest plans for subsurface resource development are usually complemented by a study of the related environmental impact which may include, wherever appropriate, numerical predictions of the expected land settlement above (and close to) the exploited system.

The first observation concerning land subsidence due to fluid removal dates back to the beginning of the twentieth century with the first scientific report on the event written by two geologists (Pratt and Johnson, 1926). Their conclusion was that "*the cause of the subsidence is to be found in the extensive extraction of oil, water, gas, and sand from beneath the affected area*", which was located above the oil field of Goose Creek, S. Jacinto Bay, Texas. The early conjecture of Pratt and Johnson was to be later confirmed and reconfirmed by countless examples of anthropogenic land subsidence (see Table 1), and supported by geomechanical theory as well. The maximum recorded settlement amounts to as much as 14 m, while the depth of pumping wells may range from those tapping very shallow water table aquifers just close to the ground surface to those tapping very deep (4000–5000 m) gas/oil reservoirs.

Over gas/oil fields, the subsidence usually takes on a bowl-shaped appearance with the largest downward displacement occurring near the center of the field. The border of the bowl may roughly resemble the shape of the field although it may extend up to twice or more the area encompassed by the outline of the underlying reservoir. In the case of extensive pumped aquifer-aquitard systems, the overall extent of the sinking area can be much larger, totaling as much as 13 500 km^2 in the case of the S. Joaquin Valley, California (Poland and Lofgren, 1984), and 12 000 km^2 in the Houston–Galveston area, Texas (Gabrysch, 1984). By distinction, subsiding areas over gas/oil fields never reach such a large size.

The analysis and the prediction of the expected anthropogenic land subsidence due to fluid pumping is not

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

[a]groundwater.
[b]thermal water.
[c]oil.
[d]gas.
[e]gas-bearing water.

an easy task. A careful reconnaissance study of the area of interest is required with the detailed recognition of the basin geology and geometry and the reconstruction of its past history. Geomechanical and hydraulic properties are of the utmost importance. Preconsolidation stress, zones of overpressure, and faults must all be reliably identified in formations located at a great burial depth. Advanced technology (2-D and 3-D seismic surveys, *in situ* geophysical measurements, explorative boreholes, field tests, laboratory analyses) can be of great help. Much progress has also been made in accurately recording and monitoring the ground surface movements from the traditional spirit leveling. New techniques include DGPS (Differential Global Positioning System) and InSAR (Interferometric Synthetic Aperture Radar) by which land subsidence is measured from space with a very high precision. Advances have also been accomplished in measuring aquifer system and reservoir compaction by borehole extensometers and radioactive markers, respectively.

We must mention other types of anthropogenic land subsidence that are not addressed by the present contribution, most of which are less important in terms of socioeconomical and environmental impacts. These include underground mining, carbonate rock solution, subsurface erosion, surface loading, land drainage and reclamation, histosoil (peat) oxidation, dissolution of soil carbon and water application (Allen, 1984).

The present paper is organized as follows. The mechanics of rock compaction due to fluid removal and resulting land subsidence is described. The most advanced tools to record and monitor the ground deformations are reviewed. The mathematical models to simulate and predict the occurrence are addressed. Methods to control, mitigate or stop anthropogenic land settlement are finally discussed.

MECHANICS OF LAND SUBSIDENCE DUE TO FLUID WITHDRAWAL

Basic Mechanisms

The mechanism that relates anthropogenic land subsidence to fluid withdrawal is that of subsurface sediment compaction caused by changes of the stress distribution within the solid skeleton. Stresses change because pumping induces a modification of the fluid-dynamic field. The fluid flow system is controlled by a potential field with the fluid head acting as the potential quantity. The introduction of a production well into a natural fluid flow system produces a disturbance that propagates its effect in space and time through the geological medium. Around the well, a cone of depression in the fluid head in the pumped formation develops and expands laterally, and to a minor extent also vertically. The intensity of the head drop at any point of the porous medium and the time lag between the inception of withdrawal and the arrival of the effect at that point depend on the distance of the point from the well field, on the geometric and geologic configuration of the subsurface basin, on its boundary conditions, and on the fluid-dynamic and geomechanical properties of both fluid and formation, specifically fluid density and viscosity, and medium intrinsic permeability, porosity, and compressibility.

The mechanism by which rock deforms and compacts under the influence of a fluid head change is well understood. The total geostatic load σ_t, acting on the aquifer, reservoir, confining beds and caprock, is balanced by the pore pressure p and the effective vertical and horizontal stresses σ_{ev} and σ_{eh} (Figure 1). As the fluid head declines, p declines too and can no longer support as large a percentage of the load of the overlying formations. Therefore, more of this load must now be borne by the grain-to-grain contacts of the geological material itself with a stress transfer from the fluid to the solid phase, and a consequent increase of effective stress in both the pumped units and the adjacent formations (i.e. confining beds, caprock, bottom and lateral aquifer) which are progressively drained, and hence compact, with the amount of compaction primarily related to the compressibility of the compacting layers. The resulting cumulative compaction of subsurface layers extends its effect to the ground surface, which therefore subsides (Figure 1). If the depleted units are seated deeply into the basin, as in the case of a typical gas/oil reservoir (Figure 2), the land surface behaviour resembles that caused by a finite source of stress in a semi-infinite medium. The surrounding rocks absorb part of the loss of support due to the local pressure drawdown, and the actual land settlement depends primarily on depth, volume, and compressibility of the reservoir and adjacent formations.

Typically settlement above gas/oil fields is smaller than the reservoir compaction but it spreads over a larger area than the extent of the field itself. Conversely, aquifer systems are generally shallower and have a much larger areal

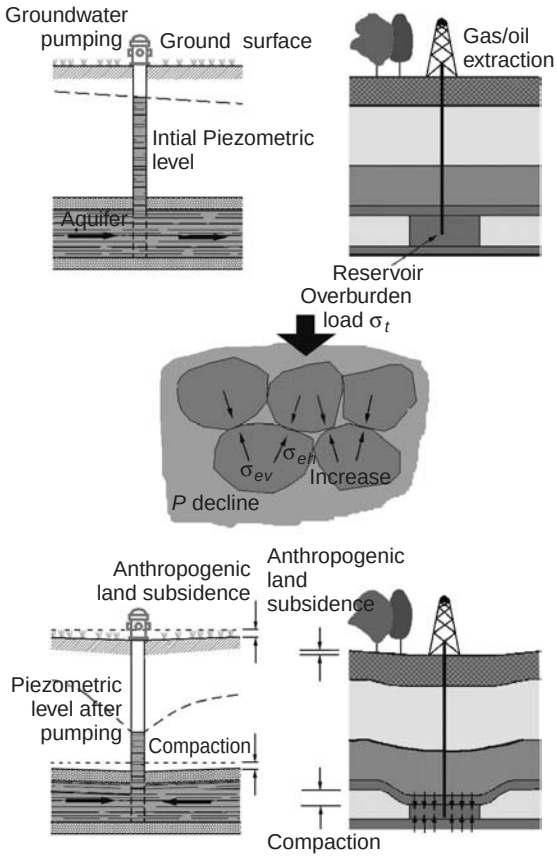

Figure 1 Mechanics of land subsidence due to groundwater and gas/oil withdrawal. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

extent than gas/oil fields. For these systems, the existence of a central zone may be conceived where rock compaction is not contrasted by the overburden and simply migrates to ground surface with a subsidence spreading factor equal to one. Hence, such stratified systems behave mechanically as if they were 1-D structures, and, although fluid flow may be 3-D (e.g. vertical in the confining beds, or aquitards, and horizontal in the aquifers, Figure 3), land displacement occurs mostly in the downward vertical direction.

In addition to dimensionality, other factors differentiate the mechanism of gas/oil field compaction from that of aquifer/aquitard compaction. Usually, both subsurface environments consist of a sequence of sands and clays (aquifers), and sandstones and shales (gas/oil reservoirs). Sandstones are cemented sands, whereas shales are clays that have undergone extensive mineralogical changes in the burial process that associated them with the hydrocarbon bearing strata. These changes may have had a pronounced influence on the shale compaction properties. Freshwater aquifer systems are usually normally-consolidated and normally-pressurized, or only slightly overpressurized, and lack important faults due to the typical

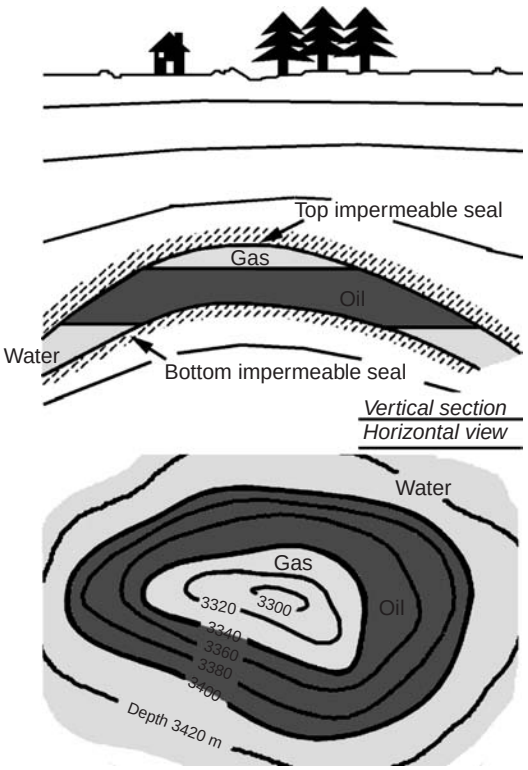

Figure 2 A typical gas/oil reservoir. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

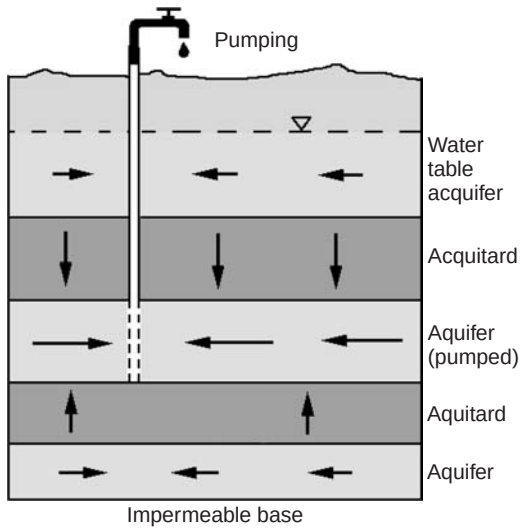

Figure 3 Flow in a typical pumped multiaquifer-aquitard system. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

formation mechanism, that is, a depositional environment without significant interfering tectonic movements. However, the geomechanical simplicity may be partially offset by the litho-stratigraphic complexity related to the distribution of clayey, silty, and sandy soils within the compacting system. It is well known that clay is up to two orders of magnitude more compressible than sand at shallow depth (Chilingarian and Knight, 1960). Hence, land subsidence of a freshwater system is very dependent on the clayey and silty fraction within the system in the form of confining beds, intervening aquitards, and interbedded lenses. Moreover, drainage from these beds can lag behind drainage from the producing sand, thus causing a delayed land subsidence which may manifest itself after wells shut down. By distinction, in deeply seated gas/oil fields, clay (shale) and sand (sandstone) tend to exhibit the same mechanical properties irrespective of lithology (Poland, 1984a; Finol and Sancevic, 1995), and this further differentiates the occurrence above pumped aquifer systems from that above productive gas/oil fields.

When a porous body experiences a change in the internal flow and stress fields, due to, for example, a sedimentation process which yields a σ_t increase, or a fluid pumping which causes a p decrease, the incremental effective stress and the fluid-dynamic gradient that develop are intimately connected. This connection was first recognized by Biot (1941) who developed the coupled theory of consolidation (and hence the coupled theory of land subsidence) where fluid flow influences the porous medium deformation which in turn affects the flow field. Groundwater hydrologists and petroleum engineers, who are mainly concerned with the fluid-dynamic aspects of this coupled interrelation, have advanced the uncoupled flow theory, which is based on the so-called diffusion equation. Theis (1935) solved the single-phase flow of groundwater incorporating the rock structural properties into a lumped geomechanical parameter (i.e. the elastic storage coefficient S_s). Theis' solution to the diffusion equation is calculated separately and independently of the medium structural solution to provide the pore pressure p distribution. Once obtained, p is used as the external driving force to predict the medium deformation, in particular, the vertical displacement at the ground surface, that is, the land subsidence. This is the uncoupled, or two step approach usually implemented for predicting land settlement due to fluid removal (Gambolati and Freeze, 1973; Gambolati *et al.*, 1974, 1991, 1998, 1999; Geertsma, 1973; Helm, 1975, 1976; Brutsaert and Corapcioglu, 1976; Harris Galveston Coastal Subsidence District, 1982; Narasimhan and Goyal, 1984; Martin and Serdengecti, 1984; Rivera *et al.*, 1991; Doornhof, 1992; Gonella *et al.*, 1998; Baú *et al.*, 1999, 2000; Teatini *et al.*, 2000).

Gambolati (1992) and Gambolati *et al.* (1996a,b) have shown that in regional geological settings, the coupled and uncoupled flow solutions are virtually indistinguishable on any timescale of practical interest, with the related land subsidence predictions practically the same. Minor differences have been obtained only in the transient behaviour

of horizontal surface ground displacements (Gambolati *et al.*, 2000).

A few authors (e.g. Cui and Delage, 1996; Delage *et al.*, 1996; Bolzon and Schrefler, 1997; Schrefler *et al.*, 2000) have recently advanced a new mechanism of compaction of gas/oil fields based on capillary suction theory as this relates to porous medium mechanical resistance. However, the capillary theory is not supported by adequate field evidence and the importance of suction on reservoir compaction has not yet been demonstrated using both undisputed physical arguments and *ad hoc* experimental tests.

In summary, a realistic representation of the mechanism of anthropogenic land subsidence due to fluid withdrawal involves a two-step process. The first step addresses the fluid-dynamic part of the occurrence where the substantial impact of the geomechanical porous medium behaviour on flow may be quite effectively accounted for by the elastic storage S_s. The second step solves the structural problem using the fluid pore pressure p distribution calculated in the first step as a driving force within the medium (possibly over or under-consolidated and faulted) to provide the solid skeleton deformation and the subsidence (i.e. the vertical displacement) at the land surface.

Controlling Factors

Four factors may partially combine to produce measurable settlement records: (i) shallow burial depth of the depleted layers; (ii) highly compressible rock laid down in alluvial or shallow marine environments; (iii) large pore pressure decline; and (iv) large thickness of the depressurized fluid bearing sediments. Unless the gas/oil fields are overpressurized, factors (i) and (iii) are mutually exclusive, while they can be both associated with factors (ii) and (iv). For a large subsidence to occur, however, a soft compacting rock is needed and/or a large pressure drawdown. To give a few examples, Mexico City sank by 9 m with a maximum pressure decline of only 0.7 MPa because of the extremely soft high-porosity soils of the compacting shallow formations located within the upper 50 m, while the 9 m and the 6.7 m settlement reported from Wilgminton (Allen, 1969a) and Ekofisk (Zaman *et al.*, 1995; Hermansen *et al.*, 2000) oil fields, respectively, are accounted for by the pronounced pore pressure drop (exceeding 20 MPa in the latter) combined with the large thickness of the compacting units. The Ekofisk case is a very interesting one in that the reservoir rocks have exhibited a sudden increase in compressibility at some stage of the field development with a large irreversible deformation defined as "pore collapse", which is believed to be the main reason for the increased subsidence over the field (Zaman *et al.*, 1995).

Some reservoirs and aquifers may be overconsolidated (e.g. the Venezuela fields, Holzer, 1981; Finol and Sancevic, 1995). Overconsolidation tends to reduce the early subsidence rate with a sudden unexpected growth at some stage of production, when the *in situ* stress exceeds the preconsolidation stress. If the water or gas/oil bearing sediments are preconsolidated, it may be very difficult to predict anthropogenic land subsidence prior to the field/aquifer development. A preconsolidation effect might have been caused in the geological past by uplift followed by erosion of the sediments overlying the fluid bearing layers or by fluid overpressure or both. The aforementioned processes may have led to a reservoir/aquifer system expansion which was much smaller than the original virgin, mostly unrecoverable compaction. When pore pressure lowers due to fluid production, a reloading of the depleted formations takes place. Initially compaction, and hence land settlement, are small. However, as soon as the maximum experienced load is overcome, rock compression occurs on the virgin loading curve with a sudden increase of compressibility, and of the resulting subsidence rate. If there is an important compressibility contrast between the reservoir and the caprock, land may even rise when fluid is removed (Ferronato *et al.*, 2001). This might occur in case the reservoir is overconsolidated and stiffer than the confining bed (and this further adds to the complexity of a reliable land subsidence prediction above overconsolidated reservoirs).

Another factor that may influence the occurrence is the presence of faults within the developed system and the overburden, as in the case, for instance, of Las Vegas (Amelung *et al.*, 1999). Faults may weaken the porous medium structure and make both the analysis and the prediction more difficult.

When a gas/oil field is considered, an additional source of complexity is the lateral/bottom aquifer (called waterdrive). Pore-pressure drawdown may extend to the waterdrive as well, and induce further land subsidence as a consequence of the waterdrive compaction, even after the wells shut down and the field is abandoned. It is not uncommon that land settlement around a field still continue for several years after the cessation of pumping as the result of the residual waterdrive compaction (Baú *et al.*, 2000).

MEASURING AND MONITORING LAND SUBSIDENCE

The occurrence of land subsidence due to subsurface fluid withdrawal quite often goes unnoticed, as it typically progresses at a slow rate and involves large areas. In the absence of observational evidence, such as protrusion of wells or infrastructures (e.g. bridges), submersion of offshore platform facilities, break of pipelines, drainage reversals, or failure of well casings, repeated measurements of ground surface elevation are needed to reveal anthropogenic land subsidence. The problem of monitoring the settlement over large areas is compounded by the requirement for vertically stable reference benchmarks located outside the region affected by subsidence to be used as control points.

Spirit Leveling

Spirit (differential) leveling is the traditional method of determining ground elevation changes, and despite its simplicity, can be very accurate (Table 2). Equipment and procedures are described in detail in several manuals, for example, in Rappleye (1948) and Floyd (1978). The technique, developed in the nineteenth century and much used at present as well, allows the surveyors to carry an elevation from a known reference point to other geodetic marks by the use of a precisely leveled telescope and a pair of graduated vertical rods. For each survey, the elevation difference e_d between two benchmarks is recorded twice by accumulating the elevation differences between a series of temporary turning points. The discrepancy between e_d measured in the forward and backward directions (relative to the direction of the traverse) must not exceed $1.5\sqrt{D}$ mm for a "very high (first order)" precision survey, and $3\sqrt{D}$ mm for a "high (second order)" precision survey, D being the length of the benchmark line in kilometers. Typically, benchmarks are spaced 1 km apart and turning points are 20 to 100 m apart. Once a network of benchmarks has been established and surveyed by precise leveling, a further survey at some later date shows whether vertical movements have occurred and quantifies their magnitude.

Digital levels and invar rods help fulfill the selected accuracy, eliminating the human errors and increasing the measurement speed. To ensure long-term time series, the benchmarks, usually consisting of a brass cup or headed bolt, are grouted into massive artificial structures, such as bridge abutments, or bedrocks, or attached at the top of a bar 5 to 10 m long driven into the ground and protected by an outer sleeve. Examples of leveling networks established to control land subsidence due to fluid withdrawal are published by Poland and Yamamoto (1984) and Tosi *et al.* (2000).

Differential GPS

Large regional benchmark networks warrant the use of the less time-consuming Global Positioning System (GPS) surveying method. USAF NAVSTAR (Navigation Signal Timing and Ranging) GPS uses earth-orbiting satellites to obtain accurate positions based on the time required by radio signals transmitted from the satellites to reach a receiving antenna. Since 1995, NAVSTAR has been operational with a constellation of 24 satellites at an average orbit altitude of 20 200 km, arranged in six orbital planes 55° inclined relative to earth's equator (US Coast Guard Navigation Center, 1996). The satellites, positioned in the orbit planes in such a way as to permit simultaneous vision of at least four of them, continuously transmit ranging signals on two carrier frequencies known as L1 (1574.42 MHz) and L2 (1227.60 MHz) on which a navigation message, including satellite clock data, satellite ephemeris (precise orbit) data, and ionospheric signal-propagation correction data, is superimposed.

Absolute positioning by GPS, that is, the determination of a single point on the earth surface collecting data from multiple satellites, is not sufficiently accurate for precise surveying because of satellite ephemeris, clock errors, and signal path delays through the atmosphere. In land subsidence surveys, Differential GPS (DGPS) technique is used instead to enhance elevation accuracy (Table 2). DGPS determines the relative position of two points on which two GPS receivers are placed to receive signals simultaneously from the same set of satellites. The system takes advantage of the fact that close receivers simultaneously experience common errors, which can be (partially) cancelled by observation data post-processing. When the same points are reoccupied after some time interval, the relative motion that has occurred between the points during the time interval can be measured. Geodetic networks of benchmarks, at least one of them located in a reference stable position, can be surveyed in this way. Since the measurement accuracy primarily depends on the relative benchmark distance (baseline) and baseline occupation time, a proper network design and survey planning are of paramount importance (US Army Corps of Engineers, 1996). DGPS measurement strategy currently

Table 2 Main features of the earth observation techniques presently used to record land subsidence

Method	Spirit leveling	DGPS (Differential Global Positioning System)	DInSAR (Diff. Interferometric Synthetic Aperture Radar)	PS – IPTA (Permanent Scatterers – Interf. Point Target Analysis)
Accuracy[a]	1 mm/year	2–5 mm/year	1–2 mm/year	1–2 mm/year
Spatial scale	line – network	network	map pixel	permanent reflector
Spatial resolution	0.5–1 km	5–10 km	25 m	25–1000 m
Temporal sampling[b]	5–10 years	2–3 years	5 years	2–3 years
Time-cost per survey[c]	2–3 months	1 month	1 week	2–3 weeks

[a]subsidence rate accuracy attainable under optimum conditions.
[b]indicative values for subsidence rate less than 1 cm/year, otherwise frequency must be increased.
[c]indicative values to survey a 50 × 50 km area, including data processing, with state-of-the-art methodologies.

consists of few expensive stations in permanent acquisition characterized by an extensive baseline (e.g. Sato *et al.*, 2003), or closer benchmarks for which the survey is carried on in "static" method, that is, by simultaneously placing on two/three of them time mobile antennas that record the satellite signals for a time ranging from few hours to few days per survey, or a combination of the two (e.g. Bitelli *et al.*, 2000).

InSAR

Interferometric Synthetic Aperture Radar (InSAR) is a powerful new tool that uses radar signals to measure deformation of the earth surface at an unprecedented level of spatial detail (Table 2). Radar transmits an electromagnetic microwave signal that, reflected off the ground surface, is received by the antenna producing a digital image of the scanned ground. Each image pixel carries amplitude and phase information of the microwave field back-scattered by all the scatterers (rocks, vegetation, buildings, etc.) located within the cell. Currently, operational satellite-borne radar systems are carried on the Canadian RADARSAT, the Japanese JERS, and the European ERS-2 and ENVISAT spacecrafts. SAR images are available since 1992. ERS-2 moves along a quasi-polar orbit with a pass every 35 days and an elevation of about 800 km. Its antenna footprint sweeps a 100-km-wide strip on the earth surface with a spatial resolution of about 25×25 m (Table 2).

In the Differential InSAR approach, used in geophysical sciences since the late '80s (Gabriel *et al.*, 1989), two (or more) SAR images taken from very close orbital positions at different times are combined (interferometric processing) to exploit the phase difference of the signals which is related only to the earth surface displacement occurring between the acquisition of the image pair, once the surface topography contribution is removed.

The interferogram phase noise ("decorrelation") restricts the DInSAR use. Major contributions to the phase noise are the temporal and the spatial decorrelation, the former due to the temporal change of the scatterers, as is the case of densely vegetated areas, and the latter to the slightly different viewing positions (interferometric baseline) related to the orbits. The phase noise is estimated by means of the local coherence L, a cross-correlation coefficient of the SAR image pair ranging from 0 to 1, when the interferometric phase is pure noise and phase noise is absent, respectively. The conventional DInSAR approach is performed by analyzing 2 to 10 SAR images characterized by a very small baseline (generally less $\leq$200 m). Requiring $L > 0.3$ on several adjacent pixels, its applicability is restricted to urban, built-up, and not-vegetated areas on which land subsidence is uniformly mapped (Figure 4).

More recently, an alternative approach known as PS (Permanent Scatterers) or IPTA (Interferometric Point Target Analysis) has been developed taking advantage from the

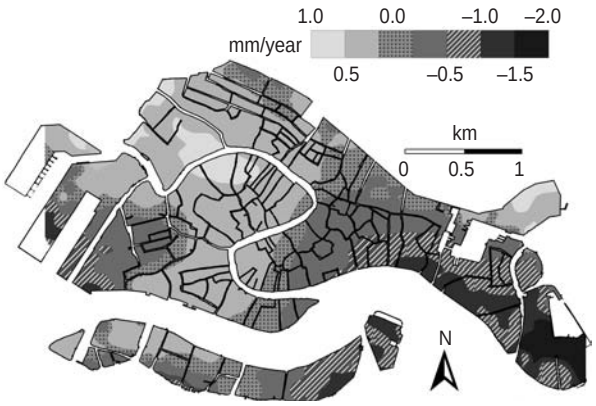

Figure 4 Vertical movement rate (mm/year) at Venice from 1992 to 1996 as detected by DInSAR with a 25-m resolution. Positive values indicate uplift, negative land subsidence [Reproduced by permission of AGU from Tosi L, Carbognin L, Teatini P, Strozzi T and Wegmüller U (2002) *Geophysical Research Letters*, 29, 10.1029/2001GL013211]. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

fact that, when the dimension of a scatterer is smaller than the image resolution cell, the coherence is good irrespective of the image pair baseline. Consequently, more observations are available, thus allowing for a reduction of temporal decorrelation errors. PS/IPTA interferometric phases are thus interpreted only for a number of selected single pixels that are coherent ($L > 0.7$) over long-time intervals and cover the monitored area as a sparse "natural" benchmark net. By the PS/IPTA technique, the interferometric SAR-based subsidence survey can be performed in rural areas as well using existing pointwise reflectors (e.g. buildings, bridges, etc.), which require a permanent scatterer/point target density larger than 1 km^{-2}. The advantages offered by the PS/IPTA technique in comparison with the conventional DInSAR justifies to a large extent the need (hence the cost) for a large number of SAR images (usually more than 30). Examples along with a detailed description of the techniques are given by Ferretti *et al.* (2000) and Strozzi *et al.* (2001).

In order to turn the displacement phase term into an absolute displacement velocity, a reference point is required by both DInSAR and PS/IPTA. Quite often the scene content allows for the specification of stable points. Sometimes, leveling or DGPS surveys may provide the reference point as the present tendency in monitoring land subsidence involves an integrated monitoring approach where all (or more than one) of the surveying techniques described above are simultaneously used to cross-validate the measurements and improve the accuracy of the measurements (e.g. Strozzi *et al.*, 2003).

Finally, it is worth mentioning that natural land subsidence occurring over centuries or millennia can be

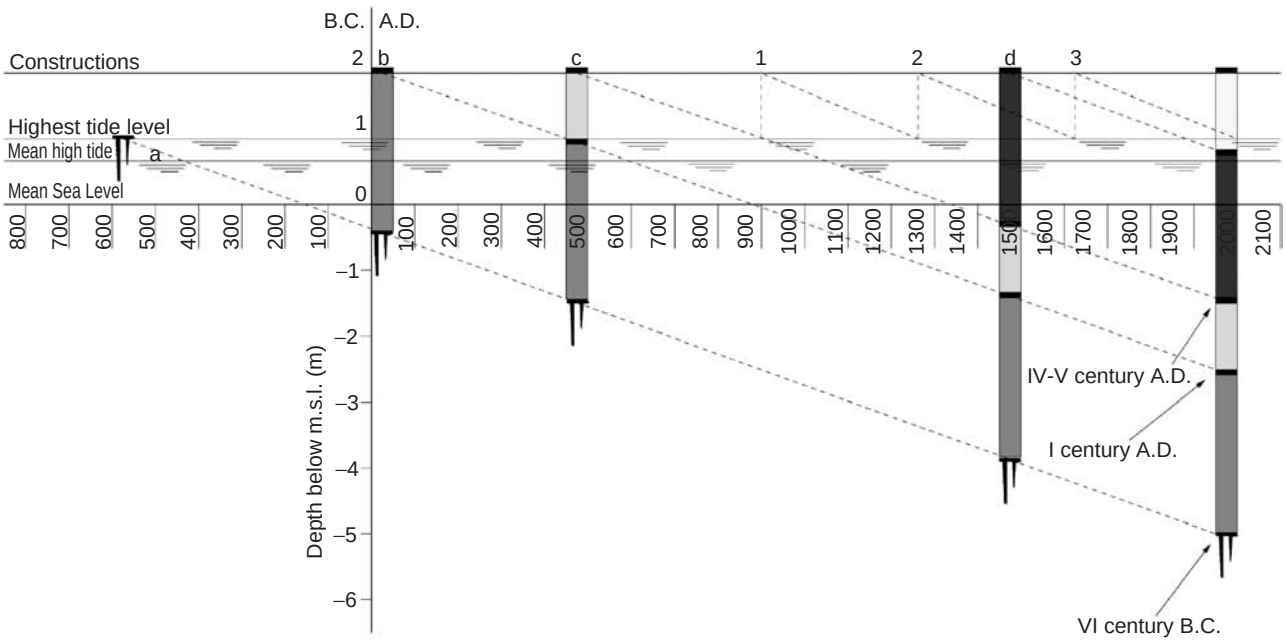

Figure 5 Land settlement at Ravenna in historical times as derived from archeological finds. The main rebuildings of the city are shown: wood on palafittes (a); port development from I century B.C. to II century A.D. (b); empire capital (V century A.D.) and capital of barbarian reigns (VI century A.D.) (c); Venetian domination (XV century A.D.) (d); 1, 2, 3: time of the floor upheaval of the paleochristian basiliques. estimated by relating the age of archeological finds to their depth below the present ground surface. An example of such an approach is offered by the natural settlement of the Ravenna area, Italy, as shown in Figure 5, suggesting an average rate of 2.5 mm/year.

IN SITU COMPACTION/EXPANSION MEASUREMENTS

A major task in managing anthropogenic land subsidence due to groundwater pumping or gas/oil production is the *in situ* measurement of the related medium deformation. First, a continuous monitoring of the ongoing compaction of the depleted formations provides useful information about the environmental consequences of the extraction, and also gives a response to some important technical and operational issues, such as the break or damage of well casings (Friedrich *et al.*, 2000) or the decrease of the formation porosity and permeability with the consequent reduction of the field production life (Ruistuen *et al.*, 1999). Second, the availability of *in situ* compaction data, together with piezometric or reservoir pressure measurements, allows for a realistic evaluation of the geomechanical properties of the producing units, which is essential for a reliable prediction of the expected land subsidence. The main techniques currently available to measure the *in situ* deformation of depleted formations are borehole extensometers for shallow aquifer-aquitard systems and radioactive markers for deep gas/oil reservoirs.

Borehole Extensometry

The first borehole extensometer was installed in 1955 by the US Geological Survey in the San Joaquin Valley, California (Poland and Yamamoto, 1984). Since then, the extensometry technology has experienced a progressive development, playing an important role in relating land subsidence to the compaction of confined aquifer systems. For a review of early and recent developments of this methodology, see Lofgren (1961), Riley (1986), and Heywood (1995). The measuring equipment is schematically shown in Figure 6. A typical extensometer tool consists of a balance beam carrying a cable or a pipe, which is fastened at one end to an anchor weight at the bottom of the compacting system, and at the other end to a counterweight so as to keep the cable at a constant tension. A computer-controlled system records the compaction data versus time. The instrumental precision is very much dependent on the actual extensometer implementation, but a nominal strain resolution of a few parts out of 10^7 can be achieved over a depth from 200 down to 1000 m (Riley, 1986; Heywood, 1995). Recent applications of borehole extensometry for the compaction measurement of shallow sediments have been made in the

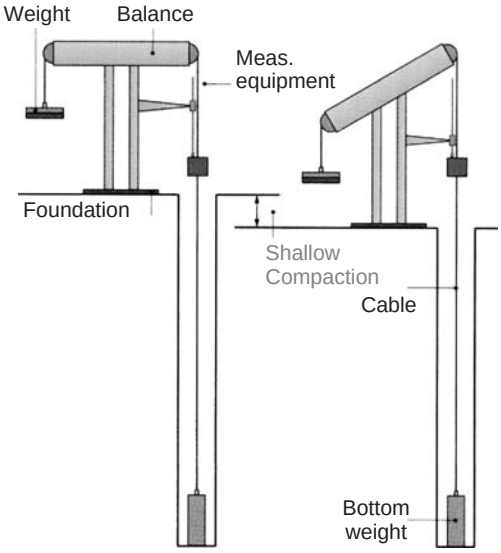

Figure 6 Schematic representation of a borehole extensometer. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Houston area(down to a depth of 936 m) and in the El Hueco basin, Texas, the Albuquerque basin, New Mexico, and above the Groningen gas field, Netherlands.

To be of major interest, borehole extensometers are often coupled to piezometers which record the hydraulic head variations in the depleted units. In the case of multiaquifer systems, several extensometers are usually installed at different depths, so as to monitor the compaction of each single formation. Plotting the vertical strain data versus the pore pressure decrease measured by piezometers during short pumping tests provides a direct *in situ* estimate of the porous medium vertical compressibility, and hence allows for the assessment of the specific storage of the aquifer system. Because of the small impact of water table lowering on the effective stress during a short pumping test, a unit decrease in measured pore pressure corresponds to a unit increase in effective stress, and a stress-strain plot can be drawn giving an estimate of both elastic and inelastic storage coefficients (Riley, 1969). In addition, the time-response characteristics of the system can be used to derive an average vertical permeability for the aquitards. The values of specific storage and hydraulic conductivity thus obtained can be used in numerical simulations to provide a more accurate prediction of land subsidence due to groundwater pumping.

Radioactive Markers

One of the most promising techniques for *in situ* monitoring of deep reservoir compaction relies on the use of weakly radioactive markers. After some pioneering applications performed as early as 1949 in the Wilmington oil field, California (Allen, 1969b), the radioactive marker technique was established 30 years ago in the Groningen gas field (de Loos, 1973) and since then continuously improved (Mobach and Gussinklo, 1994). A schematic representation of the measuring procedure is shown in Figure 7. The marker technique is based on the regular monitoring of the distances between a number of low-emission isotopes (usually ^{137}Cs or ^{60}Co), incorporated into bullet-shaped leak-proof steel containers and shot at fixed intervals along the wall of a generally nonproductive vertical well. The location of each bullet after the porous medium has deformed is obtained by drawing a specific tool bearing γ-ray detectors up through the well from the bottom. As currently implemented by Schlumberger and Western Atlas, the initial spacing between two adjacent radioactive sources is dictated by the logging tool geometry and is approximately 10.5 m, with the vertical strain measurements attaining a nominal accuracy of 10^{-4} (i.e. 1 mm). For a review of the technical and operational details of this technique, see Mobach and Gussinklo (1994), and Macini and Mesini (2000). Radioactive markers have been successfully implemented in a number of gas/oil fields worldwide, including the Ekofisk field, North Sea (Menghini, 1989), the

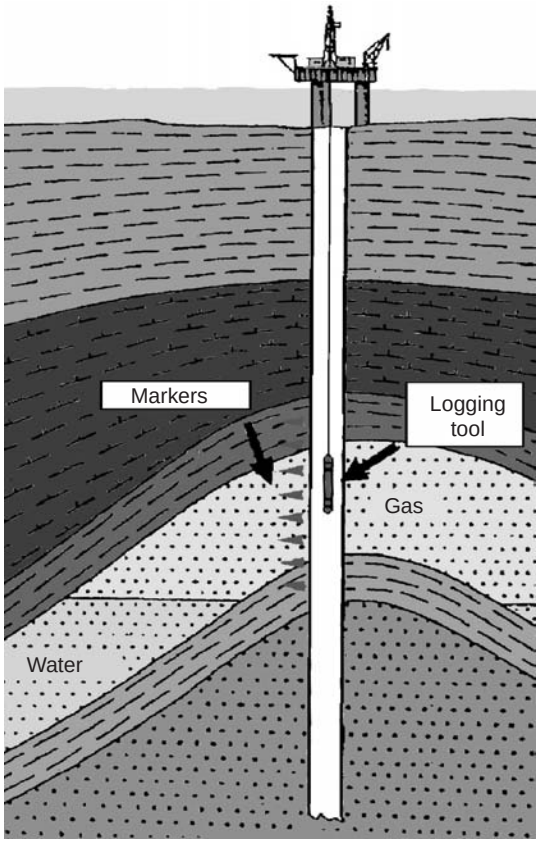

Figure 7 Schematic representation of the radioactive marker technique. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Champion oil field off Brunei (Schmidt, 1996), the Gulf of Mexico area (de Kock *et al.*, 1998), and the Northern Adriatic gas fields, Italy (Cassiani and Zoccatelli, 2000; Baú *et al.*, 2002).

Thin gas/oil reservoirs mainly compact in the vertical direction with a negligible lateral deformation, so that the uniaxial compressibility c_M of the medium encompassed between two consecutive markers can be readily derived as:

$$c_M = \frac{\Delta h}{h_0 \Delta p} \tag{1}$$

where Δh is the measured shortening, h_0 the initial spacing, and Δp the pore pressure variation provided by the available logging tools. The c_M values can be quite scattered, because of the uncertainty affecting each measurement, so that statistical procedures are often required to homogenize the data. Baú *et al.* (2002) suggest using the moving weighted average technique and regressing c_M versus the corresponding vertical effective stress σ_{ev} to obtain an average representative constitutive relationship for the monitored rock formations. It is usually recognized that *in situ* measurements offer more reliable estimates of the actual rock compressibility than laboratory core measurements, mainly because of the preservation of the *in situ* stress field in the tested formation and the elimination of any disturbance and damage during coring and laboratory operations.

Equation (1) provides a straightforward c_M evaluation if Δh indicates compaction and Δp a pore pressure decrease, as expected in producing reservoirs, or if Δh denotes expansion and Δp a pore pressure rise, as is the case in the postproduction recovery phase. In expansion, a smaller c_M is usually found, corresponding to unloading-reloading conditions. However, expansions with a decreased pore pressure, or compactions with zero Δp can be recorded in the field (Ferronato *et al.*, 2004), and of course these measurements should not be processed to get the c_M estimate. Such occurrences can be caused by the lithostratigraphy of the monitored rock units, and, to a lesser extent, by the hydro-mechanical coupling between fluid flow and the porous medium deformation. Ferronato *et al.*'s (2004) study of the Northern Adriatic marker data shows that a geologic configuration with thin producing layers (1–2 m thick or less) incorporated within a low permeable shale matrix can make the marker interpretation quite difficult. This difficulty can be remedied by an *ad hoc* nonstandard analysis using advanced numerical models as is done, for example, by Ferronato *et al.* (2003).

MODELING AND PREDICTING LAND SUBSIDENCE

As mentioned before, it has long been understood that land subsidence is best analyzed with reference to Biot's (1941) theory of consolidation, wherein it is recognized that consolidation itself may represent the response of a compressible porous medium to changes of the fluid flow operating within it. Denote E and ν as the Young and the Poisson moduli of porous medium (the bulk), c_{bm}, c_{br}, and β as the volumetric compressibility of the medium, solid matrix and water, respectively, n as the porosity, k as the tensor of the anisotropic hydraulic conductivity of medium saturated with water, and ε as the medium volumetric dilatation (or volume strain). Note that $c_{bm} = 3(1-\nu)/E$. Biot's (1941) stress and flow coupled equations, as modified by van der Knaap (1959) and Geertsma (1966) for a porous medium saturated with groundwater, read:

$$\begin{aligned}
(\lambda + G)\frac{\partial \varepsilon}{\partial x} + G\nabla^2 u_x &= \alpha \frac{\partial p}{\partial x} + X \\
(\lambda + G)\frac{\partial \varepsilon}{\partial y} + G\nabla^2 u_y &= \alpha \frac{\partial p}{\partial y} + Y \\
(\lambda + G)\frac{\partial \varepsilon}{\partial z} + G\nabla^2 u_z &= \alpha \frac{\partial p}{\partial z} + Z
\end{aligned} \tag{2}$$

$$\frac{1}{\gamma}\nabla(k\nabla p) = [n\beta + c_{br}(\alpha - n)]\frac{\partial p}{\partial t} + \alpha \frac{\partial \varepsilon}{\partial t} \tag{3}$$

where $\alpha = 1 - c_{br}/c_{bm}$ is the Biot coefficient, $G = E/2(1+\nu)$ is the shear modulus of the porous medium, $\lambda = \nu E/(1-2\nu)(1+\nu)$ is the Lamé constant, γ is the specific weight of water, ∇ is the gradient operator, p is the incremental pore pressure induced by pumping, and u_x, u_y, and u_z are the components of the incremental displacement $\boldsymbol{u}$. In (2), X, Y, and Z are the external incremental distributed load per unit volume. Slightly modified versions of (3), developed by Gambolati *et al.* (1996b) and Bai and Abousleiman (1997), but not addressed in the present analysis, are briefly discussed by Gambolati *et al.* (2000).

In the uncoupled formulation, most appropriate for predicting anthropogenic land subsidence due to fluid removal, the term $\partial\varepsilon/\partial t$ is replaced by $\alpha c_M \partial p/\partial t$. Defining with S_s the specific elastic storage coefficient:

$$S_s = n\beta + c_{br}(\alpha - n) + \alpha^2 c_M \tag{4}$$

where

$$c_M = \frac{(1-2\nu)(1+\nu)}{E(1-\nu)} \tag{5}$$

is the vertical medium compressibility, that is, the rate of volume change of a rock sample subject to a unit change of effective stress σ_{ev} along the vertical axis with lateral expansion precluded, equation (3) becomes:

$$\frac{1}{\gamma}\nabla(k\nabla p) = S_s \frac{\partial p}{\partial t}. \tag{6}$$

In the upper freshwater aquifer system, c_{br} is much smaller than c_{bm}. Hence $\alpha = 1$, and equation (6) takes on the form that is most familiar to hydrogeologists:

$$\frac{1}{\gamma}\nabla(k\nabla p) = (n\beta + c_M)\frac{\partial p}{\partial t}. \tag{7}$$

For an elegant discussion of some theoretical assumptions leading to (7), see Verruijt (1969). If flow is multiphase, as is the case with gas/oil fields, equation (7) is replaced by more complex mass conservation equations describing the fluid-dynamics of each single phase (e.g. Aziz and Settari, 1979) and p in equations (2) is a weighted mean of the pressures of each phase. It should be noted that the uncoupled formulation, equations (2) and (6) or (7), does not neglect the influence of deformation on fluid flow but lumps it into a single parameter, namely, the elastic storage coefficient, which accounts for a local pointwise deformation and discards the strength source originating from the remainder of the porous medium and generating the theoretical coupling (Gambolati, 1974, 1977). Gambolati *et al.* (2000) have shown that the separate use of S_s is quite appropriate in problems of land subsidence caused by fluid withdrawal. Also note that uncoupling does not imply a 1-D vertical deformation, as is erroneously assumed by some authors (e.g. Lewis and Schrefler, 1998). Rather, uncoupling simply postulates that fluid-dynamics is well represented by equations of mass conservation where the structural effects on fluid flow are accounted for by S_s. Generally, under the influence of the incremental pore pressure p, the medium undergoes the fully 3-D deformation described by equations (2).

A frequent geological setting of an alluvial aquifer system is that where horizontal or subhorizontal aquifers and aquitards alternate (Figure 3). In this case, flow within the aquifers may be described by a 2-D horizontal equation of the form:

$$\frac{\partial}{\partial x}\left(T_{xi}\frac{\partial p_i}{\partial x}\right) + \frac{\partial}{\partial y}\left(T_{yi}\frac{\partial p_i}{\partial y}\right) = S_i\frac{\partial p_i}{\partial t} + q_j - q_{j+1} \tag{8}$$

where T_{xi} and T_{yi} are the components of the anisotropic hydraulic transmissivity (equal to $b_i k_{xi}$ and $b_i k_{yi}$, respectively, with b_i the ith aquifer thickness and k_{xi} and k_{yi} the anisotropic hydraulic conductivity), $S_i = S_{si} b_i$, and q_j and q_{j+1} are leakage from the overlying j and underlying $j+1$ aquitards. Flow within aquitards j is governed by the 1-D vertical flow equation:

$$\frac{\partial}{\partial z}\left(k_{zj}\frac{\partial p_j}{\partial z}\right) = S_{sj}\frac{\partial p_j}{\partial t} \tag{9}$$

Equations (8) and (9) are hydraulically coupled, as the solution to (9) depends on p_i and p_{i+1}, that is, the pore pressure in the aquifers above and below aquitard j, and in turn q_j and q_{j+1} in equation (8) are calculated from the solutions p_j and p_{j+1} of the aquitards j and $j+1$ overlying and underlying aquifer i. For the implementation of the solution to equations (8) and (9) in a multiaquifer-aquitard system, see Gambolati *et al.* (1986) and Gambolati and Teatini (1996).

Once the pressure variations p_i $(i = 1, \ldots, N)$ and $p_j (j = 1, \ldots, N+1)$, with N the number of individual aquifers within the system, have been predicted by solving equations (8) and (9) for all i and j over the entire multiaquifer, land subsidence $\eta(t)$ at time t since pumping started is obtained simply as the cumulative units compaction:

$$\sum_{j=1}^{N+1}\sum_{k=1}^{M} 0.434\ \gamma(1-n_j)\frac{C_c}{\sigma_{\mathrm{ev}j}} p_{kj}(t)\Delta b_{kj} + \sum_{i=1}^{N} c_{Mi}\, p_i(t) b_i \tag{10}$$

where M is the number of vertical elements into which each aquitard is discretized, C_c is the aquitard compression index, and p_{ki} and Δb_{ki} are the pore pressure decline and the length of the vertical spacing, respectively, in element k of aquitard j. By distinction, c_{Mi}, p_i and b_i are the ith aquifer compressibility, pressure drawdown, and thickness. C_c is calculated from oedometric tests as the slope in a semilogarithmic diagram of the void ratio versus σ_{ev}. Equation (10) is used when aquitard j compacts on the virgin compaction curve with $\sigma_{\mathrm{ev}j} > \sigma_{\mathrm{ev}j,\mathrm{prec}}$, where $\sigma_{\mathrm{ev}j,\mathrm{prec}}$ is the preconsolidation stress. Porosity n_j, jth aquitard permeability k_{zj} and specific elastic storage S_{sj} can be updated by the empirical nonlinear relationships (Rivera *et al.*, 1991):

$$\begin{aligned} n_j &= n_{0j} - 0.434\ C_c(1-n_j)^2\frac{\Delta\sigma_{\mathrm{ev}j}}{\sigma_{\mathrm{ev}j}} \\ &\qquad (\sigma_{\mathrm{ev}j} > \sigma_{\mathrm{ev}j,\ \mathrm{prec}}) \\ k_{zj}(n_j) &= k_{z0j}\left[\frac{n_j(1-n_{0j})}{n_{0j}(1-n_j)}\right]^m \\ S_{sj} &= \gamma\left(0.434\ C_c\frac{1-n_j}{\sigma_{\mathrm{ev}j}} + n_j\beta\right) \\ &\qquad (\sigma_{\mathrm{ev}j} > \sigma_{\mathrm{ev}j,\ \mathrm{prec}}) \end{aligned} \tag{11}$$

with n_{0j} and k_{0j} the initial porosity and hydraulic conductivity, respectively, and m a material-dependent coefficient. C_c must be replaced by the swelling index C_s for $\sigma_{\mathrm{ev}j} < \sigma_{\mathrm{ev}j,\mathrm{prec}}$.

MITIGATION OF LAND SUBSIDENCE BY FLUID INJECTION

Assessing alternative strategies to mitigate anthropogenic land subsidence requires a level of technical support and

a cost-benefit analysis, which are outside the scope of the present paper. Moreover, each individual damage-prevention strategy also comes with an associated set of socioeconomic issues that influence its financial, legal, and political feasibility. The present review is restricted to the most straightforward and apparently simplest action for mitigating land subsidence caused by fluid withdrawal: artificial fluid injection. It goes without saying that other strategies can contribute to the prevention of land subsidence, and these include the policy for groundwater and gas/oil pumping exerted by the central and local authorities such as, withdrawal limits, permits, fees, taxes, metering, and enforcement control activities. Freeze (2000) conveys the general recommendation that land subsidence should be included as a basic driver when defining a fluid exploitation management strategy along with more traditional drivers, namely, water table decline, saltwater intrusion, and avoidance of groundwater contamination.

Generally speaking, when land subsidence has occurred and/or is still occurring, methods to control or mitigate or arrest it include reduction of pumping rates, artificial aquifer recharge from land surface, repressurization of depleted layers through wells, creation of a hydraulic barrier to stop the advancement of the cone of depression, and the generation of an overpressure in geological units that are not affected by pumping in order to build a structural obstacle to the migration of in-depth compaction to ground surface. A combination of any of the above methods can be used as well consistent with the outcome of a cost-benefit analysis. An example of conservative mitigation strategy is one whereby the effective stress within the depleted formation is not further increased beyond the stress level experienced to date. A more aggressive strategy could dictate a decrease of the effective stress and/or the active involvement of overlying formations through the use of fluid injection.

The local geologic conditions suggest whether artificial recharge, which is usually implemented on the basis of a conservative action, may be accomplished by application at the land surface or by repressurizing the aquifers through injection wells. The mitigation program in the Santa Clara Valley (CA) is an example of controlled percolation released from artificial surface reservoirs built close to the larger streams (Poland, 1984c). To reduce the pumping rate, one or more of the following solutions must be implemented (Poland, 1984b): import of substitute surface water, conservation in application and use of water (for instance, by improving the existing irrigation methods and/or changing crops with less-water demanding ones), reuse of treated water by industrial plants, development of well fields in more permeable deposits, as has been done in Shanghai (Liu, 2002), or enforcement of legal control.

Artificial replenishment of a confined aquifer system by application of water at the ground surface directly above the pumped system may not be practicable in many places. However, streams may be used which are connected to the aquifer system by creating surface reservoirs somewhere upstream along the watercourse. In some areas, the aquifer may crop out at or near the margins of the groundwater basin. So, recharging artificially on the outcrop area may be effective in replenishing the depleted formations with a mitigation of the downstream groundwater level decline, and hence of the related land settlement.

Repressurizing confined aquifers through artificial wells may prove a most effective and practical way to cope with anthropogenic land subsidence, especially in coastal areas where recharging reservoirs are difficult to build. The Wilmington oil field in Southern California offers an excellent example of land subsidence mitigation and control through injection wells (Colazas and Strehle, 1995). The water injection started on a major scale in 1958. Eleven years later when $2\,m^3/s$ was being pumped into the oil field, the settling area had been reduced from 58 to $8\,km^2$ with local land surface rebound equal to 0.3 m. However, the maximum subsidence had achieved peak values of 9 m (Table 1). Replenishing groundwater supplies by artificial recharge through wells and pits has been practiced in many sites in California and in Long Island, NY, with generally satisfactory results. In a few cases, problems of wells and aquifer clogging were reported, depending on the actual chemical and physical properties of the injected water. Injection of treated freshwater into a confined aquifer system to create a hydraulic barrier against seawater intrusion has been implemented successfully in Southern California. A paper by Rancilio (1977) describes in detail the typical design of an efficient injection well, cost, rates and head, clogging problems, and operating conditions. The operational injection heads ranged from 9 to 61 m, depending on injection depth, with injection rates from 6 to 28 l/s.

In Italy, ENI-E&P has recently implemented a project of reinjection of formation water below 3500-m depth to generate a barrier against the propagation onshore of the depressurization in the deep Angela–Angelina gas field which partly underlies the coastline. The initial injection rate from the borehole Angelina 1 is planned at $150\,m^3/d$ with the understanding that it can be appreciably increased using seawater, should it prove necessary to obtain a more important mitigation of the coastline subsidence induced by the ongoing gas production.

A numerical simulation of seawater injection beneath the lagoon has recently been performed to raise Venice (Comerlati *et al.*, 2003). As is widely known, Venice has experienced a relative sinking (natural and anthropogenic land subsidence plus average sea level rise) equal to 23 cm over the last century (Carbognin *et al.*, 2005). This has enhanced the Adriatic seawater ingress into the lagoon with a significant increase in the frequency of periodic flooding,

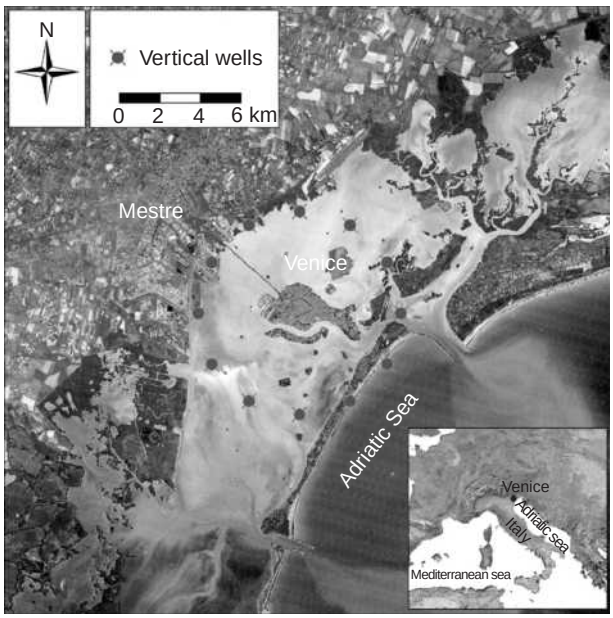

Figure 8 Space view of the Venice Lagoon with the location of the injection wells (Reproduced by permission of AGU from Comerlati *et al.,* 2003). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

the so-called "acqua alta", over the last 50 years. Having identified a suitable geologic formation lying between 600 and 800-m depth beneath the city, saturated with brackish water, an injection rate of 23 Mm^3/y of seawater has been simulated through 12 injection wells properly located around Venice (Figure 8) with the purpose to uplift the lagoon bottom so as to make up for the 23-cm loss experienced by Venice, and thus mitigate the city exposure to the "acqua alta". Based on new information and results from recent studies on the evolution of the Northern Adriatic coastline (Gambolati, 1998), and prediction of land settlement above Adriatic gas fields (Gambolati *et al.*, 1999; Baú *et al.*, 2000; Teatini *et al.*, 2000), which have promoted an in-depth knowledge of the subsurface near the Venice Lagoon, numerical analyses have been carried out with the aid of advanced fluid-dynamic and structural finite element models. The simulations aim at evaluating the amount of rebound Venice might experience because of the pore overpressure induced by seawater injection. Essentially new geomechanical data for a realistic prediction of the surface rebound have become available quite recently (Baú *et al.*, 2002; Ferronato *et al.*, 2003, 2004). Geology and hydrology of the upper freshwater aquifer system are known from previous investigations (Gambolati and Freeze, 1973; Gambolati *et al.*, 1974). Figure 9(a) shows the predicted overpressure distribution at 700-m depth 10 years after the beginning of injection. Figure 9(b) provides the expected rebound of Venice at the same time.

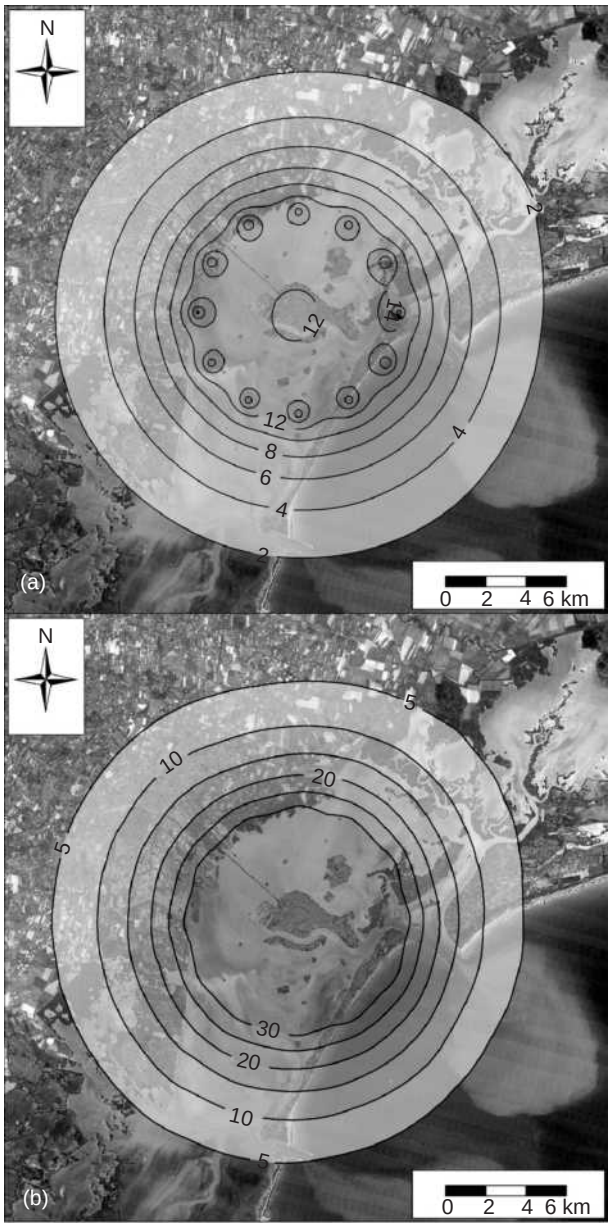

Figure 9 (a) Overpressure (MPa) and (b) expected land uplift (cm) in the Venice Lagoon 10 years after the beginning of injection (Reproduced by permission of AGU from Comerlati *et al.,* 2003). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Note the uniform distribution of the rebound that makes the proposal an extremely appealing solution to the life-long problem of the city protection from flooding. Of course, the practical implementation of such a project requires much more information including an in-depth reconnaissance study of the geology and litho-stratigraphy below the lagoon and a full cost analysis of the engineering project needed for constructing the water pipelines and injection boreholes.

PART 14

Snow and Glacier Hydrology

159: Snow Cover

ROSS D BROWN[1] AND BARRY E GOODISON[2]

[1] *Meteorological Service of Canada, Dorval, QC, Canada*
[2] *Meteorological Service of Canada, Downsview, Canada*

Snow cover is encountered over most of the Northern Hemisphere (NH) mid- and high-latitudes during the winter season and over many mountainous regions of the world for extended periods. Snow cover is an important component of the climate system through its role in modifying energy and moisture fluxes between the surface and the atmosphere, and through its role as a water store in hydrological systems. Snow also plays critical roles in ecological and biological systems, and in nutrient and carbon cycling. This article provides an introductory overview of snow cover including: definition of terms (snowfall, solid precipitation, snow depth, snow density, snow water equivalent); a review of methods for measuring snow cover properties; a discussion of the processes and concepts involved in the spatial and temporal variability of snow cover; a look at avalanches and recent efforts to model these; and finally, a discussion of how snow cover is changing in response to global warming.

INTRODUCTION

Snow cover refers to the blanket of snow covering the ground, and includes the concepts of depth and areal extent (Sturm *et al.*, 1995). Snow cover is encountered over most of the Northern Hemisphere (NH) mid- and high latitudes during the winter season, and over many mountainous regions of the world for extended periods. Figure 1 shows the mean seasonal range in snow cover over the NH from satellite data covering the 1971 to 1995 period (data from NSIDC, 1996). The temporal variability is dominated by the seasonal cycle with average NH snow cover extent ranging from an average minimum extent of 3.6 million km^2 in August to an average maximum extent of 46.8 million km^2 in late-January. Most of the global snow cover extent is located over the NH: with the Antarctic and Greenland landmasses excluded, the Southern Hemisphere (SH) mean maximum terrestrial snow cover extent is less than 2% of the corresponding winter maximum snow cover extent over the NH. In the SH exclusive of Antarctica, most of the seasonal snow cover extent is located over South America.

Snow cover is a key component of the global climate system through its role in modifying energy and moisture fluxes between the surface and the atmosphere, and through its role as a water store in hydrological systems. Snow is a highly reflective material; the reflectivity or albedo of new snow is 0.8 to 0.9, which means that 80–90% of the incident solar energy is reflected away from the snow surface. Densely forested regions, however, will exhibit an albedo as low as 0.2 even with complete ground snow cover. A high albedo, combined with the excellent insulating characteristics of a snow cover dramatically reduces the energy exchange between the surface and the atmosphere. Empirical studies have shown that mean surface air temperatures are typically 5 °C colder when a snow cover is present (Groisman and Davies, 2001). This positive feedback is responsible for the rapid expansion of NH snow cover extent in October–November and is manifest in a typically close negative relationship between snow cover and air temperature (Figure 2).

The larger-scale climatic significance of the snow-albedo feedback is modulated by cloud cover and by the smaller amount of total solar radiation received in high latitudes during winter months. Groisman *et al.* (1994a) observed that snow cover exhibited the greatest influence on the Earth's radiative balance in the NH spring (April to May) period when incoming solar radiation was greatest over snow-covered areas. The impact of snow on surface reflectivity is an example of a direct feedback to the climate system. Snow is also involved in a number of indirect feedbacks through its thermal insulating properties (e.g. influence on sea ice growth and ground temperatures),

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

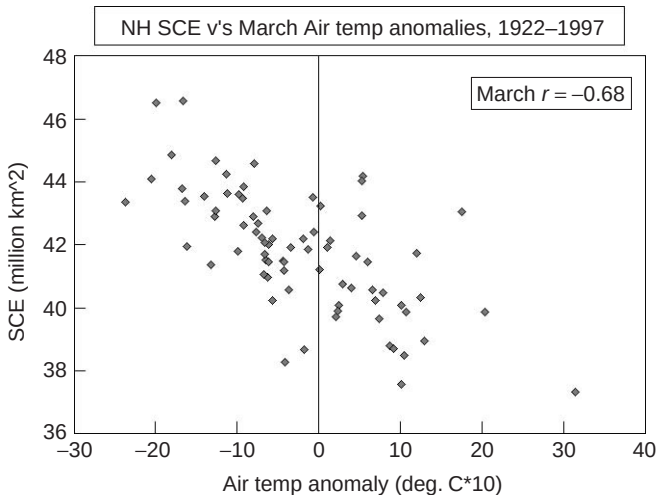

Figure 2 Scatterplot of reconstructed (1922–1971) and satellite-observed (1972–1997) NH snow cover extent from Brown (2000) versus NH midlatitudinal (40–60°N) land surface temperature anomalies for March. Air-temperature anomalies were computed from the Jones (1994) gridded land temperature dataset. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

and snow's role in soil moisture recharge which generates indirect feedbacks to cloud cover and surface temperature (Cess *et al.*, 1991; Randall *et al.*, 1994). The influence of snow on the freeze/thaw status of ground temperatures is particularly important for the hydrology of cold regions. There is an extensive body of literature linking snow cover feedbacks to monsoon circulations (e.g. Vernekar *et al.*, 1995; Gutzler and Preston, 1997). However, recent research suggests snow's role in monsoon circulations may be more limited (Robock *et al.*, 2003). Groisman and Davies (2001) provide detailed reviews of the climatic significance of snow.

MEASUREMENT OF SNOWFALL AND SNOW COVER

Because of the profound influence snow has on natural ecosystems (Jones *et al.*, 2001) and the human environment, snow measurement science has a long and rich history extending from Chinese snow cages in the first millennium (Biswas, 1970) to ultrasonic snow sensors employed on today's automatic weather stations. Reviews of *in situ* snow observing methods are provided by Goodison *et al.* (1981), Pomeroy and Gray (1995), and Doesken and Judson (1997). The main properties of a snow cover that are routinely monitored *in situ* are: snow depth, snow water equivalent, and snowfall (amount and water equivalent). Strictly speaking, snowfall is not a property of a snow cover, but it is included here because of its essential role in the initiation and accumulation of a snowpack. In addition, the solid/liquid fraction of precipitation and the density and crystal structure of new snowfall have important consequences for snowpack evolution and internal structure.

Prior to the late 1800s, there were few systematic measurements of snow depth. However, routine observations were made of snow cover-related variables such as the number of days with snowfall, number of days with snow on the ground, or first/last dates of snow on the ground. The presence of snow on the ground is one of the earliest regularly recorded snow cover observations.

Snowfall and Solid Precipitation

Accurate precipitation data (adjusted for systematic errors) are essential to balance the energy and water cycles in the climate system, for climate monitoring, for determining the global and regional hydrological balance and for understanding key components of the cryosphere, such as, snow-covered area, snow water equivalent and glacier mass balance. Precipitation is expected to increase in response to global warming (IPCC, 1996) and there is evidence (Bradley *et al.*, 1987; Vinnikov *et al.*, 1990; Groisman and Easterling, 1994; Mekis and Hogg, 1999) that precipitation has indeed exhibited a significant upward trend over the last ~100 years. Recent warming has also been associated with a reduction in the solid:liquid ratio of precipitation in shoulder seasons (Karl *et al.*, 1993; Zhang *et al.*, 2000). Accurate information on precipitation intensity, timing, and solid/liquid fractions are essential to correctly simulate snowpack development and snowmelt with detailed energy balance models such as SNTHERM (Jordan, 1991).

It is important to make clear the distinction between snowfall and solid precipitation. Snowfall is the depth of freshly fallen snow that accumulates during the observing period and has been traditionally measured with a ruler. Solid precipitation is the equivalent liquid water of the snowfall intercepted by a precipitation gauge and is influenced by the catch characteristics of the particular gauge. At voluntary observing stations in Canada and the United States, the depth of new snowfall is measured once or twice per day using a ruler and snowboard. In many countries, solid precipitation is estimated from daily total snowfall assuming a fresh snowfall density of $100\,\mathrm{kg\,m^{-3}}$. However, the density of freshly fallen snow varies widely from 10 to $30\,\mathrm{kg\,m^{-3}}$ for dry, cold "wild snow" (Seligman, 1980) to more than $150\,\mathrm{kg\,m^{-3}}$ for warm, wet snow. Most fresh snowfall densities fall within a range of 50 to$120\,\mathrm{kg\,m^{-3}}$ (Pomeroy and Gray, 1995), but commonly exhibit large temporal and spatial variations (Goodison *et al.*, 1981). Manual ruler observations of snowfall are subject to numerous sources of error, the most important being the blowing and drifting of snow, and the melting or rapid settling of snow when it reaches the ground. For example, Goodison *et al.* (1981) monitored average density increases between 8 and $13\,\mathrm{kg\,m^{-3}\,h^{-1}}$ during snow storms with duration less than 12 h. Doesken and Judson (1997) provide a good overview of some of the practical problems associated with observing snowfall.

Solid precipitation is measured with some form of precipitation gauge that can range from a standard rain gauge to a specially shielded snow gauge. A fundamental problem of gauge measurement of snow precipitation is that most precipitation gauges catch less falling snow than the "true" amount because accelerated wind flow over the top of the gauge reduces the number of snowflakes able to enter the orifice. This effect increases with wind speed, and for a relatively modest wind speed of $15\,\mathrm{km\,hr^{-1}}$, an unshielded US standard 8" precipitation gauge has been found to catch only ~50% of the "true" snowfall (Yang *et al.*, 1998). This effect can be reduced by using shielding devices such as the Alter shield, which will increase the catch by 20 to 70% (Goodison *et al.*, 1998; Yang *et al.*, 1999).

Precipitation gauges, shields, and observing practices vary considerably from country to country, and over time (Goodison *et al.*, 1998; Sevruk and Klemm, 1989 and for USSR – Groisman *et al.*, 1991; USA – Groisman and Easterling, 1994; Canada – Metcalfe *et al.*, 1997). Other important systematic sources of error include instrument siting, trace precipitation amounts and wetting loss (the amount of water adhering to the inside of a gauge and not measured each time it is emptied). Metcalfe and Goodison (1993) showed that when trace precipitation amounts were adjusted for wetting loss, they could account for a significant increase in corrected precipitation totals (~30% for a prairie site). This correction is particularly important in the Arctic where some stations report over 80% of precipitation observations as trace amounts (Metcalfe and Goodison, 1993). Guidelines for the correction of commonly used precipitation gauges are provided by Goodison *et al.* (1998).

The recent trend toward increased automation of climate observations has important consequences for the homogeneity of precipitation measurement series. Goodison *et al.* (1998) recommended that heated tipping-bucket rain gauges not be used for measuring snowfall due to excessive evaporation loss. Weighing gauges were found to be the most practical but these can introduce a "timing" error due to snow or freezing precipitation sticking to the inside of the gauge and melting at some later time. Automated gauges, like manual ones, can also catch blowing snow and provide no information on the liquid/solid fractions of precipitation. These problems complicate the real-time interpretation of the data as well as the application of procedures to adjust for systematic errors.

Snow Depth

Snow depth is the most obvious property of a snowpack. It is, however, less useful from a water and energy budget perspective; snow depth can change independently from snow mass due to processes such as metamorphism and melt/refreeze events (Fitzharris *et al.*, 1992). Manual observations of daily snow depth have been carried out in association with regular meteorological observation programs

at principal climate stations in most countries with a seasonal snow cover. Typically, these networks have evolved in response to needs for weather and climate information in support of economic activities, and the spatial distribution of stations tends to follow the population distribution with poor spatial coverage in mountainous and remote areas. In general, there are few stations reporting snow depths before the early 1900s, after which the number of stations increases to a maximum during the 1970s followed by a rapid reduction in the 1990s, often associated with budget reductions and automation. A number of countries have systematic snow depth observations going back to the late 1800s for example, Switzerland (Foehn, 1990), USA (Easterling *et al.*, 1997), the former Soviet Union (Armstrong, 2001) and Finland (Kuusisto, 1984). Canadian snow depth data are available from the mid-1950s (MSC, 2000). When working with these data sets, it is important to remember that snow depth observations are subject to the same sources of inhomogeneity as other climatological elements, for example, changes in station location, changes in observing time, changes in measuring units, changes in observers, and urban effects (warming and dirtying of snow from pollution). Quality control procedures to check the internal consistency of daily snow depth observations were developed for US data by Robinson (1989). It is also important to note that many *in situ* snow depth observing sites are in open locations (e.g. airports) and may not be representative of snow conditions over the surrounding area, especially in surrounding vegetated areas. This is an issue when comparing *in situ* snow depth observations to snow cover information derived from remotely sensed sources.

Automated *in situ* snow depth measurements can be made with ultrasonic snow depth sensors which compute the distance to the snow surface from the time taken for a pulse of sound to reach the snow surface and be reflected back (Goodison *et al.*,1985). Snow depth can be measured with an accuracy of 1 cm, and the sensor can be interrogated at frequent regular time intervals (e.g. hourly) to obtain a detailed history of snow depth changes from settling, wind erosion, and melt that is particularly useful for validation of physical snow process models (Metcalfe *et al.*, 1987). Anomalous measurements may occur during falling or blowing snow, and the ultrasonic sensor may underestimate the depth of very low density freshly fallen snow (Goodison *et al.*, 1985). This requires the application of quality control logic to remove spurious values. An advantage of the automated depth sensor is that the snow layer is undisturbed, and the measurements reflect changes at that measurement point (manual snow depth measurements involve some subjectivity for drifting or patchy snow covers). A limitation of the auto sensor is that it only measures snow depth at a single point (a circular area with diameter 0.2 to 2 m depending on the height of the sensor above the snow surface – Pomeroy and Gray, 1995). This makes careful site selection essential. Another technique for *in situ* measurement of snow depth is the use of vertical thermistor arrays to deduce the location of the snow/air boundary from the observed temperature gradient. Portable Ground Penetrating Radar (GPR) systems linked to GPS systems provide the capability to map snow depth over a range of scales and import the information into GIS systems. These systems are used operationally for snowpack management at some ski centers.

Several attempts have been made to develop global snow depth climatologies from *in situ* observations (US Army Corps of Engineers, 1954; Schutz and Bregman, 1975; Foster and Davy, 1988). The Foster and Davy (1988) snow depth climatology provides global monthly mean snow depth at a ~50 km resolution and has been used extensively in the validation of GCM snow simulations (e.g. Foster *et al.*, 1996). Brown *et al.* (2003) developed a 37 -km gridded snow depth climatology for North America based on a modified version of the operational snow depth analysis scheme used at the Canadian Meteorological Centre (Brasnett, 1999). This climatology was based on extensive *in situ* snow depth observations from the United States and Canada covering snow seasons 1979/80 to 1996/97, and exhibited a number of improvements over the earlier Foster and Davy (1988) product. Figure 3 shows the monthly mean snow depth over NA in February.

A number of remotely sensed methods can be applied to retrieve information on snow depth (for a discussion of the theory of remote sensing of snow see Hall and

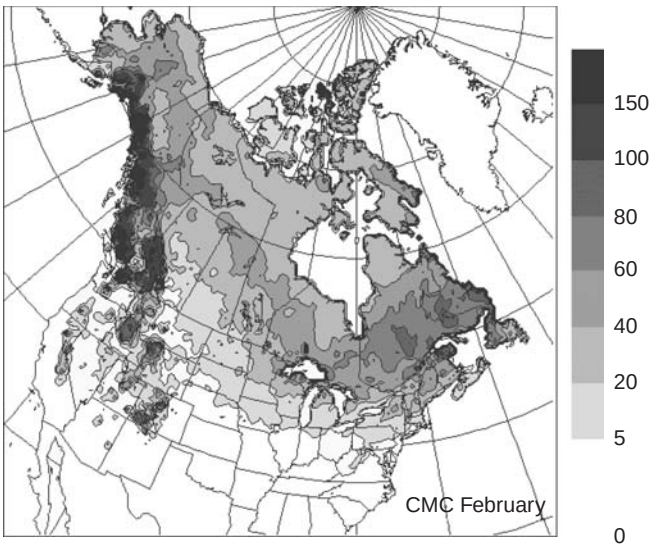

Figure 3 February monthly mean snow depth (cm) over North America from a blend of historical daily snow depth observations and snow model simulations over the period 1979–1997 (Brown *et al.*, 2003). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Martinec, 1985). More recent developments in the remote sensing of snow are covered in detail in Hall *et al.* (2005) (*see* **Chapter 55, Estimation of Snow Extent and Snow Properties, Volume 2**). Snow depth information has been estimated from passive microwave satellite data (e.g. Chang *et al.*, 1987), which has the advantage of all-weather coverage. Passive microwave data are not routinely used for snow depth mapping as they are sensitive to liquid water in the snow, vegetation cover, and seasonal changes in snowpack structure. The derivation of snow depth from passive microwave data also requires that certain assumptions be made about snow density and grain size. For example, the global SMMR-derived monthly snow depth climatology used by Foster *et al.* (1996) assumed a mean snow density of $300\,\mathrm{kg\,m^{-3}}$ and an average snow grain size of 0.3 mm (Chang *et al.*, 1987). High-resolution airborne laser altimetry can provide information on snow depth information in forested terrain through its ability to see between trees (Hopkinson *et al.*, 2001), but this is a relatively expensive mapping tool, and requires one presnow season survey to map the surface elevation without snow. Hopkinson *et al.* (2001) determined that the method was only suitable for deeper snowpack conditions $>\sim$50 cm. Other remotely sensed methods for mapping snow depth include GPR and SAR interferometry, but these are mainly used in research.

Snow Water Equivalent (SWE)

SWE is defined in the International Classification for Seasonal Snow on the Ground (Colbeck *et al.*, 1990) as the depth of water if a snow cover is completely melted, expressed in millimeters, on a corresponding horizontal surface area. SWE is related to snow depth and density by the following relationship

$$\mathrm{SWE(mm)} = 0.01\, h_s * \rho_s \qquad (1)$$

where h_s is the depth of snow (cm) and ρ_s is the density of snow ($\mathrm{kg\,m^{-3}}$). The conversion from a mass of snow ($\mathrm{kg\,m^{-2}}$) to a depth of water (mm) is based on the fact that 1 mm of water spread over an area of $1\,\mathrm{m^2}$ weighs 1 kg.

The most commonly used approach for determining SWE is the gravimetric method which involves taking a vertical core through the snowpack, and weighing or melting the core to obtain the SWE. A variety of coring and weighing systems have been used around the world with varying lengths and diameters depending on measurement units and local snow conditions (see Sevruk, 1992). One of the earliest national SWE observing networks was established in Finland in 1909 (Kuusisto, 1984). However, systematic observation of SWE was not widespread until the middle of the twentieth century. In order to obtain representative values of SWE, measurements are often carried out at regular marked intervals along a permanently marked transect or "snow course". There are many factors involved in the design of a snow course (e.g. purpose, accessibility, terrain, vegetation) and the reader is referred to Goodison *et al.* (1981) for a detailed discussion. The length of a snow course and the number of sampling points depends on the desired level of accuracy and the spatial variability of snow cover. There is extensive literature on this subject for example, Goodison *et al.* (1981), WMO (1981), Sevruk (1992), Pomeroy and Gray (1995).

The accuracy of manual SWE measurements from snow samplers is discussed in detail in Sevruk (1992). The main systematic error (due to instrumentation) is related to a tendency for additional snow to be forced up into a tube as it is pushed through a snowpack. Hence, the design of the cutter and its sharpness is a main contributor to performance and accuracy of a snow sampler (Goodison *et al.*, 1981). Random errors associated with observers and snow conditions include the difficulty in keeping loose granular snow in the sampler, drainage of water from very wet snow, ice crusts, and sampling very shallow, patchy snow cover. Snow course measurements are often carried out on a weekly or biweekly basis, although not all courses have regular measurements throughout the snow cover season. In many cases, measurements made by operational agencies or utilities for runoff management are confined to the late winter and early spring period as the main interest is in determining the peak SWE prior to melt. This can limit the usefulness of some snow course data for climate-related studies. Other limitations for using SWE surface observations in climate-related studies are: uneven spatial distribution of data, relatively short periods of continuous observations, data quality (see Schmidlin, 1990), and a general lack of easily accessible data. Snow survey data sets have been published for Canada (MSC, 2000) and the former Soviet Union (Krenke, 1998).

Automated surface-based observations of SWE are possible from devices such as snow pillows that measure the mass of snow over a small area from displaced fluid or a pressure transducer. Snow pillows are usually octagonal or circular in shape, with an area of $\sim$5–10 $\mathrm{m^2}$, and are most effective for monitoring relatively deep snowpacks in sheltered environments. Interpretation of data can be complicated by "bridging" (from ice or hard snow layers in the snowpack) or by the draining of wet snow (Pomeroy and Gray, 1995). Snow pillows are usually hooked to a land-line or satellite data transmission systems to provide real-time information such as the US Department of Agriculture (USDA) Snow Telemetry (SNOTEL) network over the western United States (Rallison, 1981). An advantage of these automated systems is that they can be interrogated on a daily basis to provide more detailed information during the melt season than regular weekly or biweekly snow course observations. Daily values of SWE from over 600 snow pillow sites in the western United States from 1979

are available from the USDA National Water and Climate Center. A comprehensive analysis of these data for the 1980 to 1998 period was provided by Serreze *et al.* (1999).

Other less commonly employed methods for *in situ* measurement of SWE or snow density include gamma ray attenuation and microwave radar (see Pomeroy and Gray, 1995). The Swiss Federal Institute for Snow and Avalanche Research are developing a system to automatically measure the density, the water equivalent and the liquid water content of a snow cover over a distance of 20 to 30 m using electrical impedance ("SNOWPOWER"). The sensor consists of long flat-band cables along which the dielectric constant is measured (in the time domain) and the impedance is measured at different low frequencies.

Accurate information on the amount and spatial distribution of SWE is essential for water resource management (e.g. agriculture, hydro-electric power generation, flood forecasting). Water authorities and utilities make use of surface-based snow surveys (and snow pillows in mountainous terrain) to monitor peak SWE values prior to snowmelt, as well as satellite imagery to map snow cover extent. In mountainous areas, the elevation of the snowline is particularly important information for water resource planners. SWE information can also be derived from a variety of aircraft or satellite sensors with varying degrees of success (Rango *et al.*, 2000). The most commonly used operational systems are airborne gamma surveys (Foster *et al.*, 1987), passive microwave (Foster *et al.*, 1984) and SAR (Bernier and Fortin, 1998; Baghdadi *et al.*, 2000). Each system has its own particular set of advantages and limitations (see Rango *et al.*, 2000) and in some case these can be exploited by using multiple sensors, for example, wet snow is not seen by passive microwave but is seen by SAR. Reviews of satellite remote sensing of SWE are provided by Rango (1996) and Hall *et al.* (2005) (*see* **Chapter 55, Estimation of Snow Extent and Snow Properties, Volume 2**). The derivation of consistent spatial SWE information over a range of land cover surfaces and terrain types requires the blending of *in situ*, satellite- and model-derived information. Considerable progress has been made in this area in recent years (Hartman *et al.*, 1995; Carroll *et al.*, 2001).

SNOW COVER INTERANNUAL VARIABILITY

Regional and continental snow cover exhibit large interannual variability in response to atmospheric circulation patterns that influence temperature and precipitation. There is an extensive body of literature documenting significant correlations between Eurasian winter snow cover extent and the North Atlantic Oscillation (NAO) and the related Arctic Oscillation (AO) mode of atmospheric variability (e.g. Gutzler and Rosen, 1992; Bamzai, 2003), and recent work (Gong *et al.*, 2003; Bojariu and Gimeno, 2003; Saito and Cohen, 2003) suggests that snow cover variations play a role in exciting and maintaining dominant NH winter patterns such as AO-NAO. Over North America, snow cover interannual variability is most closely related to the Pacific–North America (PNA) pattern (Gutzler and Rosen, 1992; Serreze *et al.*, 1998). The snow cover response to ENSO (El Niño–Southern Oscillation) is less pronounced and exhibits large regional variability (e.g. Cayan, 1996; Clark *et al.*, 2001; Hsieh and Tang, 2001) with a tendency for El Niño events to be associated with greater snow cover over Eurasia and less snow cover over North America (Groisman *et al.*, 1994b). A detailed review of snow cover–atmosphere relationships is provided by Groisman and Davies (2001).

DISTRIBUTION OF SNOW COVER

As outlined in Pomeroy and Gray (1995), the areal distribution of snow cover reflects processes and terrain/vegetation influences that occur over a range of spatial scales. At the regional-continental scale ($\sim$10–1000 km) factors such as proximity to moisture sources, location of winter storm tracks, orography, elevation, and latitude are dominant. At the local scale, ($\sim$100 m–10 km) terrain features (e.g. ridge/valley) and vegetation exert important influences, while at the microscale ($\sim$10–100 m), small-scale variations in topography (slope, aspect, surface roughness) and vegetation (height, density, interception efficiency) affect snow accumulation and ablation patterns through their influence on drifting and blowing snow and sublimation, canopy interception, and the surface energy budget. Extensive reviews of terrain and vegetation influences on snow cover are provided in McKay and Gray (1981), Kind (1981, 1986), Woo (1982), Sevruk (1992), Pomeroy and Gray (1995), and Marsh (1999). The understanding and parameterization of wind redistribution, blowing snow sublimation and canopy interception/sublimation processes is critical for accurate simulation of the energy and water balances in cold regions over a range of scales. For example, Pomeroy and Gray (1995) estimated sublimation loss over prairie environments to be 15 to 41% of annual snowfall precipitation. In forested environments, they observed that approximately one-third of total snowfall falling on spruce and pine was lost due to canopy sublimation.

The physical understanding of blowing snow and blowing snow sublimation has been incorporated into a number of models, notably: PBSM (Pomeroy *et al.*, 1993), PIEKTUK (Déry *et al.*, 1998), and SnowTran-3D (Liston and Sturm, 1998). When coupled with simple models for wind flow over complex terrain, these models are capable of generating realistic patterns of snow accumulation in various environments (e.g. Essery *et al.*, 1999; Greene *et al.*, 1999). One area of uncertainty is the sensitivity of the blowing snow sublimation process to relative humidity.

Time-dependent diffusion models such as PIEKTUK generate an increase in relative humidity and decrease in air temperature in the surface layer during blowing snow events, so that sublimation becomes self-limiting over longer fetches. Humidity observations during blowing snow events (Mann *et al.*, 2000) confirm that humidity does in fact increase, but not to the extent predicted by PIEKTUK. Déry and Yau (2001) concluded that entrainment and advective processes reduce the effect of the self-limiting feedback, and that blowing snow sublimation rates were 1.8 times larger than those predicted by the stand-alone application of PIEKTUK. There are still a number of uncertainties in the theory of turbulent transport of snow particles (e.g. their effective settling velocity, and the appropriate specification of particle concentrations and size distributions at or near the ground surface).

Forest canopy interception and sublimation are important processes for the water and energy budgets of large regions of the northern hemisphere with dense coniferous forests. Reviews of snow interception process and modeling research are provided by Hedstrom and Pomeroy (1998) and Marsh (1999). A coupled forest interception–sublimation model was developed by Pomeroy *et al.* (1998). As noted by Marsh (1999), there are numerous physically based algorithms controlling snow interception, sublimation, melt, and unloading. However, the challenge is to incorporate this knowledge into regional and global climate models, many of which have only rudimentary treatment of snow-canopy processes. Another challenge facing the modeling community is the availability of detailed datasets that can be used to assess the performance of snow-vegetation models.

Statistical Characterization of Snow Cover

The parameterization of the important physical processes, and topographic and land-cover factors affecting the spatial distribution of snow cover and its properties is a major challenge for climate and hydrological models. In the case of climate models, computational overheads are an important concern, and surface processes must be handled on grid dimensions on the order of 100 to 200 km. Realistic representation of snow processes into this framework requires an understanding of the scale that processes operate on, and the development of techniques to parameterize important subgrid scale processes. Knowledge of scale is also important when comparing datasets such as *in situ* observations and remotely sensed data.

A comprehensive review of the theory of scaling issues in snow hydrology was provided by Bloschl (1999). Bloschl (1999) defined three different types of scale: process scale, measurement scale, and model scale, and defined the term "scaling" to denote a change in scale which happens whenever interpolation, extrapolation, aggregation, and disaggregation are carried out. The "variogram" is fundamental to the concept of scale. The characteristic length of a variable can be estimated from the variogram which is essentially the between-data variance computed as a function of data separation (distance). Fitting the experimental variogram with an analytical function (often an exponential function) yields the spatial variance and the correlation length. For linear processes, (i.e. where simple averaging can be applied) such as mapping SWE over a basin, the variogram is used in standard geostatistical approaches such as kriging to interpolate data. For nonlinear variables and processes (e.g. the depletion of a patchy snow cover), alternative approaches are required. For example, Woo and Steer (1986) used Monte Carlo methods to account for vegetation effects on snow depth, while Walland and Simmonds (1996) used the cumulative frequency distribution to incorporate subgrid-scale topographic variability into a GCM. Shook and Gray (1996) discussed the application of fractals to describe the spatial distribution of snow depth and SWE in open terrain, and Pomeroy and Schmidt (1993) discussed their use for modeling intercepted snow on vegetation.

AVALANCHES

Avalanches are a well-documented hazard in most mountainous regions of the world, and a hazard that more people are being exposed to with increasing interest in back-country ski-touring and heli-skiing. An extensive review of avalanche theory and management practice is compiled in *The Avalanche Handbook* (McClung and Schaerer, 1993). Considerable progress has been made in recent years simulating the one-dimensional complex layered structure of a snowpack and the internal metamorphic processes such as depth hoar development that contribute to enhanced avalanche risk, for example, the French model CROCUS (Brun *et al.*, 1992) and the Swiss model SNOWPACK (Bartelt and Lehning, 2002; Lehning *et al.*, 2002). CROCUS has been coupled with a mesoscale model for the Alps and an expert system linking avalanche risk to simulated snowpack stability to form a comprehensive tool for regional avalanche risk assessment (Durand *et al.*, 1999). Extensive historical records of avalanches have been compiled in several countries such as Canada (Fitzharris and Shaerer, 1980), the United States (Mock and Birkeland, 2000) and Switzerland (Laternser and Scheebeli, 2002). There is some evidence that avalanche frequency is linked to atmospheric teleconnection patterns such as the PNA in the Rocky Mountains (Mock and Birkeland, 2000) and the NAO in Iceland (Keylock, 2003). However, many of the factors involved in avalanche formation and release operate at daily to weekly timescales, so the potential for seasonal prediction is limited. As noted by Fitzharris and Schaerer (1980), major avalanche winters are not necessarily related to large snowfall winters; it is the formation of weak layers and the

superposition of heavy snowfall and/or rapid advection of warm air that trigger major avalanche episodes. A number of dynamical models of avalanches have been developed to predict avalanche impact pressures on structures and runout length (Naaim and Gurer, 1998; Bartelt *et al.*, 1999; McClung, 2001). These provide quite realistic results but modeling the initiation of snow failure is still an area of ongoing research (Schweizer, 1999; Louchet, 2000).

SNOW COVER AND CLIMATE CHANGE

Snow cover extent (SCE) exhibits significant negative correlations to air temperature in many regions of the NH (see the "temperature response regions" in Groisman *et al.*, 1994b), and for the hemisphere as a whole (Robinson and Dewey, 1990; Karl *et al.*, 1993; Brown, 2000) (also see Figure 2). This negative relationship reflects the positive snow–albedo feedback. Analysis of NH snow cover changes over the recent period of satellite data (since ~1970) has shown that the most significant decreases have occurred in the second half of the snow year when the snow albedo feedback is strongest (Groisman *et al.*, 1994a; Pielke *et al.*, 2000). Satellite records indicate that the Northern Hemisphere annual SCE has decreased by about 10% since 1966 largely due to decreases in spring and summer since the mid-1980s over both the Eurasian and American continents (Robinson, 1999). Analysis of reconstructed SCE since 1915 (Brown, 2000) showed that most of the observed reduction occurred during the second half of the twentieth century. This period has been characterized by widespread trends toward earlier snowmelt (Brown and Braaten, 1998; Stone *et al.*, 2002; Dye, 2002) and earlier snowmelt runoff, with important implications for water resources. For example, reduced storage of water in the snowpack and earlier melt translate to a lower freshwater pulse for recharge of soil moisture and reservoirs, and increased potential for evaporation loss. Global Climate Model (GCM) simulations suggest widespread reductions in snow cover over the next 50 to 100 years in response to global warming. However, there is considerable uncertainty in model-projected regional patterns of snow cover change (Frei and Robinson, 1998) particularly in mountainous regions. A discussion of the impacts of reductions in snow cover is provided in Fitzharris (1996). A fundamental problem for realistic simulation of snow cover by GCMs is the realistic simulation of precipitation by atmospheric models (amount and phase). Evaluation of GCM simulations of winter regional precipitation (IPCC, 1996) documented errors ranging from −25 to +125% of observed precipitation over central North America, and major discrepancies have also been documented in modeled precipitation over high elevation and high latitude regions (e.g. Walsh *et al.*, 1998).

SUMMARY

Snow cover is a key component of the global climate system through its role in modifying energy and moisture fluxes between the surface and the atmosphere, and through its role as a water store in hydrological systems. Snow also plays critical roles in ecological and biological systems, and in nutrient and carbon cycling. The ability to describe the spatial and temporal variability of a snow cover (and its time- and depth-varying physical properties) is fundamental for many scientific needs and applications. This starts with accurate precipitation information for example, precipitation type, solid–liquid fraction, and water equivalent adjusted for systematic errors. Accurate measurement of solid precipitation is a major challenge, however, both in terms of instrumentation and in sampling. Recent trends toward automation of precipitation measurements have further complicated the situation with loss of information on precipitation type and the introduction of timing errors from snow or freezing precipitation sticking to the side of gauges.

Systematic *in situ* observations of snow depth and snow water equivalent are available from manual observations and snowpillows for various periods and locations. In general, the spatial distribution of *in situ* snow observations over the NH is concentrated to the populated midlatitudes (with major gaps in northern latitudes and mountains) and to the period after WWII. Only a few countries (e.g. Finland, Switzerland, former Soviet Union, and USA) have systematic snow depth observations for more than 100 years. Remotely sensed information on snow cover extent and SWE is available from various sources from the late-1960s onward with each sensor having its own particular set of advantages and disadvantages. Recent advances in physical snowpack modeling and the availability of reanalysis datasets have provided a means for systematically assimilating snow cover information from these various sources.

The ability to specify the areal distribution of snow cover and its physical properties at the local scale (~100 m −10 km) has received increasing attention in recent years. In particular, understanding and parameterizating wind redistribution, blowing snow sublimation, and canopy interception/sublimation processes has been determined to be critical for accurate simulation of the energy and water balances in cold regions. This requires an understanding of the fundamental scales on which these processes operate (e.g. Bloschl, 1999).

Considerable progress has been made in simulating the one-dimensional complex layered structure of a snowpack and the internal metamorphic processes such as depth hoar development. These advances have contributed to enhanced capabilities for forecasting avalanche risk in Switzerland and France. A number of dynamical avalanche

models have also been developed in recent years to predict avalanche impact pressures on structures and runout length. These provide quite realistic results but there are still major uncertainties in modeling the initiation of snow failure.

In situ data and satellite observations confirm significant reductions in NH snow cover extent and a trend toward earlier spring snowmelt in many regions of the NH since the 1970s. These changes are consistent with Global Climate Model (GCM) simulations which suggest widespread reductions in snow cover over the next 50 to 100 years in response to global warming. However, there is still considerable uncertainty in model-projected changes in precipitation and snow cover in mountainous regions.

160: Energy Balance and Thermophysical Processes in Snowpacks

MICHAEL LEHNING

WSL, Swiss Federal Institute for Snow and Avalanche Research SLF, Davos Dorf, Switzerland

This contribution discusses heat and mass fluxes relating to snow. The first process treated is heat flux through snow. Snow can be described as a bulk material or as consisting of different phases. When a separate water vapor phase is considered, vertical mass flux due to vapor pressure differences can be treated. A significant amount of heat is transported along with the vapor fluxes because of the phase changes occurring when water molecules enter the vapor phase at one point and deposit back onto the ice matrix somewhere else. The vapor fluxes in snow also cause snow metamorphism changing the crystals' form and size. Equilibrium metamorphism dominates when weak, large-scale temperature gradients exist, and water molecules are mainly rearranged locally by surface tension differences. Metamorphism is called kinetic when vertical vapor fluxes due to a large-scale temperature gradient lead to a snow crystal re-formation.

Mass- and energy fluxes in the snow cover are driven by surface exchange. The surface turbulent fluxes of sensible heat and moisture are derived from atmospheric surface layer similarity theory. The long-wave radiation balance leads to a strong surface cooling especially during cold nights. Short-wave radiation penetrates the snow cover and deposits energy at greater depths. Finally, the surface mass transport process of snow redistribution is treated with its subprocesses, saltation and suspension.

INTRODUCTION

On a yearly average, approximately 14% of the earth's surface is covered by snow (Brown, 2000 and references therein). The snow cover is thus an important part of the world's climate and weather system. The role of the snow cover is particularly important because of the strong snow – albedo positive feedback mechanism. Additionally, the seasonal snow cover is a major economic factor in tourism, transport, and water management. Therefore, the complex processes in the snow cover and at the snow – atmosphere interface need to be understood with enough detail so that we can assess and predict the role of snow in: (i) weather and climate development, (ii) natural hazard generation such as avalanches, floods, or mud flows, (iii) water resource management, and (iv) transportation maintenance and winter tourism.

Snow differs from other land surfaces in several aspects: First, snow has the highest albedo of all major land surfaces. This means that over snow a large part of the incoming solar radiation is reflected and not converted to heat. A positive feedback mechanism results because part of this reflected energy is subsequently lost to space, which leads to a cooling of the atmosphere and possibly to more snow. Of course, this feedback mechanism also means that if the average global snow coverage decreases, more short-wave radiation is absorbed from space, which is of great concern in recent years of rising temperatures. The high albedo of fresh natural snow makes it important to look at rapid changes of the albedo due to the presence of dust, sand, organic matter (such as lichen or snow algae), and metamorphism. A further particularity of snow is that it can be transported and redistributed by wind. The transport of snow changes the local mass and energy balance and may also alter the overall mass and energy balance over snow because the turbulent fluxes of heat and moisture are influenced. The turbulent fluxes are additionally influenced by the change of surface roughness associated with seasonal snow.

In this contribution, the relevant processes associated with the snow cover are treated. First, an overview on the

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

processes and their interaction is given. Second, snow is introduced as a material and two complementary ways of snow description are treated. As a next step, the energy and mass exchanges at the snow surface are treated with an emphasis on the important role of the radiation balance and the turbulent fluxes. The energy and mass-transfer processes within the snow cover are treated and linked to snow metamorphism in the subsequent section. The final section is devoted to drifting snow.

OVERVIEW OF PROCESSES IN AND OVER SNOW

In the following, we concentrate on those snow processes that are of a thermophysical or mechanical nature. We do not treat snow chemistry or snow biology (*see* **Chapter 163, Hydrochemical Processes in Snow-covered Basins, Volume 4**). We briefly touch upon snow-water transport but redirect the interested reader to (*see* **Chapter 161, Water Flow Through Snow and Firn, Volume 4**). Figure 1 gives a schematic overview of snow processes.

Of particular importance are the mass and energy exchanges with the atmosphere. Snow cover dynamics are almost entirely driven by atmospheric forcing, except for a small heat flux contribution from below. First of all there is snow precipitation, which leads to the buildup of the snow cover. The buildup of the snow cover is very much dependent on ambient meteorological conditions: snow that falls at cold temperatures and low wind speeds differs significantly from snow that is deposited during a snow storm at high temperatures. Furthermore, initial grain shape is dependent on the cloud temperature and moisture conditions (Nakaya, 1954). During high wind conditions, snow is transported, creating – particularly in complex terrain – a very uneven snow distribution. A further important influence of precipitation comes from rain on an existing snow cover, which adds energy to the snow. If the snow is still at subfreezing temperatures, a large amount of energy is released by freezing the rain water. If the rain is warmer than the melting temperature, an additional but much smaller amount of energy is released by cooling the water to freezing temperature.

For snow-covered surfaces, radiation is the most important energy transfer process. Usually, two types of radiation transfer processes are distinguished: short-wave and long-wave radiation energy transfers. During clear nights (or during polar winter) the snow surface loses much energy by long-wave radiation. If the sun is shining, the snow cover gains energy through short-wave radiation that penetrates the snow to some depth. The penetration of short-wave radiation depends on the snow density, its impurity content, and the grain shape. It also depends on wavelength: the shorter the wavelength, the deeper the penetration. The penetration of radiation into the snow cover is important not only for the overall energy balance and thus for subsurface metamorphism but also for growth of organic material such as plants or snow algae and photochemical processes (Albert *et al.*, 2002).

In addition to the radiative fluxes, the turbulent fluxes of heat and moisture play an important role in the snow-surface energy balance. It is important to note that moisture transport is not only an energy-relevant process but also

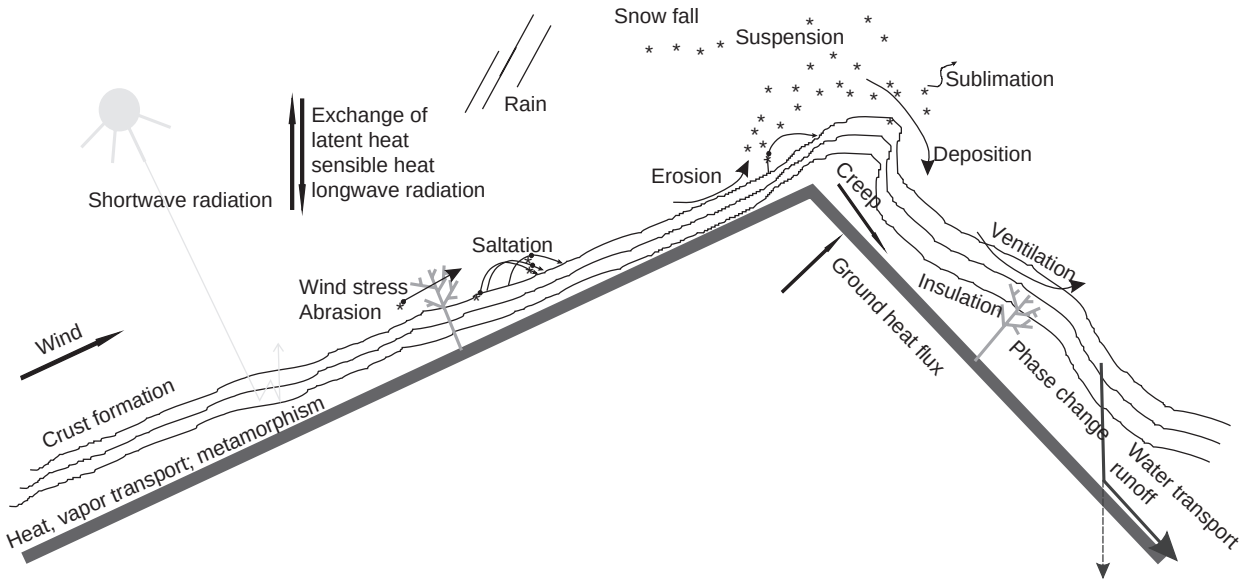

Figure 1 Schema of important physical processes in and over the snow cover. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

brings in or removes mass from the snow cover. In case of surface hoar, this mass frequently develops into a weak layer that may cause release of avalanches. In the case of warm winds such as Föhn, significant mass can be lost from the snow cover by sublimation. The question is still not answered as to what extent the turbulent moisture flux and therefore also the local mass balance is influenced by drifting snow. A further complication is the fact that the airflow (wind) penetrates the uppermost snow layers under certain conditions (ventilation), potentially altering the turbulent heat fluxes. While the process is not completely understood yet, its influence on snow metamorphism and energy exchange is significant.

Once the snow has settled on the ground, the crystals start to change shape and size immediately. A fast and important process is sintering, whereby the individual crystals or flakes form connecting bridges (bonds) to their neighbors. This process goes along with the so-called decomposing metamorphism, which tends to break the crystals down into smaller and rounder grains. The decomposing metamorphism dominates under conditions of weak temperature gradients in the snow cover. If there is no large-scale temperature gradient, water vapor is generated only by local differences in surface energy and as a result, only the edges of dendritic crystals disappear and round grains and bonds develop and grow. It is also interesting to note that the bonds between the grains will also grow in conjunction with snow settling, when the individual grains move closer together as the snow densifies. During the long time in a typical winter, the snow surface is cold but the insulating snow cover causes temperatures close to 0 °C at the snow – soil interface. This creates a strong temperature gradient in the snow, with the result that faceted crystals develop. This type of metamorphism is a real recrystallization and new crystals form. This recrystallization is the result of strong vapor fluxes that take place in the snow matrix (Akitaya, 1974). Because of the temperature gradient, vapor is generated at the upper part of existing snow grains, which have a relatively higher vapor pressure than the pore, diffuses upwards, and again undergoes a phase change to ice when it encounters an ice surface of lower vapor pressure. This recrystallization is only active in temperature gradient condition when vapor flows vertically over some distance larger then the grain size.

The macroscopic vapor fluxes also transport heat, because heat is consumed in the vapor generation process, while it is released when the vapor is deposited to form the new ice crystal. This is among the reasons why the heat conductivity of snow depends on snow microstructure: In snow with small pores and accordingly small grains (e.g. decomposed snow), the vapor flow is inhibited and can contribute less to heat transport. In snow of the same density but with larger pores and grains (e.g. depth hoar) much more heat can be transported by vapor. Therefore the bulk or macroscopic heat conductivity of snow is not a function of density only.

Phase change processes affect the development of the snow cover during its entire life cycle. When there is enough energy available, snow will start to melt and produce liquid water. Additional liquid water may come directly from rain. The water is retained up to a certain amount in the snow matrix and excess water moves downward under the influence of gravity. This behavior is similar to that of soil. However, the exact amount retained and the velocity of water movement in the snow matrix are difficult to predict because the water itself rapidly changes the snow matrix. First, snow grains develop into large round grains and form clusters. Second, preferential flow paths develop, where water moves rapidly downward, independent of a mean matrix potential controlling water movement in the remaining pore space. Water movement in snow governs water release for runoff and soil and is therefore an important subject, for example, for runoff prediction. It is treated in detail in (*see* **Chapter 161, Water Flow Through Snow and Firn, Volume 4**).

SNOW DESCRIPTION

Snow is a mixture of primarily water and air. Because it is – at environmental conditions – at a high homologous temperature, the water phase of snow undergoes rapid phase changes. In snow, at least two phases of water are present at all times: solid water (ice) and water vapor. Very often, water is present also in its liquid form. In addition to water and air, many other substances usually exist in natural snow. Primarily, organic matter and inorganic dust are present. Important from an environmental point of view are chemicals such as nitrate or other nutrients. Because of its high surface area, snow is also a good chemical reactor, in particular, since a strong exchange of trace gases between the snow and the atmosphere exists. The multiphase material snow can be described in a variety of ways. Traditionally, snow is described as a homogeneous material with its bulk properties given as density, effective thermal conductivity, viscosity, or elasticity. The microstructure of snow is neglected, as well as its composition of different phases. A simple bulk approach is, for example, to parameterize the other snow properties as a function of bulk snow density. However, it must be mentioned that, for example, effective thermal conductivity can vary up to an order of magnitude for different snow of identical density (Sturm *et al.*, 1997). Alternatively to this simple bulk approach, snow, or any other porous material (Hassanizadeh and Gray, 1990) can be treated as a mixture. The conservation laws of mass, momentum, and energy are applied to the mixture. This

results in a complex mathematical treatment of snow (e.g. Brown *et al.*, 1999; Morland *et al.*, 1990).

Mixture theory may be formulated to account for snow microstructure. The bulk properties such as thermal conductivity and viscosity can now be parameterized as a function of snow microstructure. As an example, the SNOWPACK model (Bartelt and Lehning, 2002) uses this approach. In SNOWPACK, snow is modeled as a three-component mixture:

$$\theta_i + \theta_a + \theta_w = 1. \tag{1}$$

The volumetric fractions of ice, θ_i, moist air, θ_a, and liquid water, θ_w, are required to always add up to 1 for all settling, phase change, or mass transport processes considered. Other common bulk snow properties can then be defined as a function of the volumetric fractions, for example, snow density, ρ:

$$\rho = \theta_i \rho_i + \theta_a \rho_a + \theta_w \rho_w. \tag{2}$$

Here, the material densities of ice, ρ_i, liquid water, ρ_w, and air, ρ_a, ($\mathrm{kg\,m^{-3}}$) are also used. The use of a bulk approach basically means that the complex geometry of the phase distributions in snow is collapsed to a simple volumetric description such as sketched in Figure 2b.

In order to improve the snow description, it is possible to parameterize the effect of snow microstructure. Snow properties, which depend on snow microstructure, can be treated in the form of microstructure parameters of grain size, bond size, dendricity, and sphericity. These four independent parameters have their own rate equations describing how they develop as a function of environmental conditions. More detail is given in the section on "Snow metamorphism" in the following text.

ENERGY AND MASS TRANSFER IN SNOW

Energy and mass exchanges in snow are governed by heat conduction in the ice and pore matrices, vapor transport, short-wave radiation absorption, water transport, and phase changes. Phase changes can take place between water and ice, water and vapor, and ice and vapor. They are highly relevant in terms of both energy and mass transport.

Heat Conduction

The energy conservation law applied to a snow cover in its bulk form gives the balance between the snow temperature change and the energy fluxes entering or leaving the snow cover. In a very simplified form, where the effect of water vapor transport is lumped into the effective conductivity, k_e, ($\mathrm{J\,m^{-1}\,K^{-1}}$) (Jordan, 1991) or into the phase change source or sink term, Q_{pc}, ($\mathrm{J\,m^{-3}}$) the equation in its one-dimensional form reads:

$$\rho_s c_p \frac{\partial T}{\partial t} + k_e \frac{\partial^2 T}{\partial z^2} = Q_{sw} + Q_{pc} \tag{3}$$

Here, ρ_s is the bulk density of snow and $c_p(\mathrm{J\,kg^{-1}K^{-1}})$ the bulk heat capacity at constant pressure. T is the bulk snow temperature, z stands for the vertical (surface perpendicular) coordinate and lateral heat fluxes are neglected. Q_{sw} is the short-wave radiation balance entering the snow cover and Q_{pc} contains the phase change contributions from both water vapor transport and melt-freeze phase changes. A form of equation (3) is common to the three most detailed snow models currently in use, namely, CROCUS (Brun *et al.*, 1989), SNTHERM (Jordan, 1991) and SNOWPACK (Bartelt and Lehning, 2002).

Transport of Water Vapor

Since water vapor transports significant amounts of heat through phase changes at the ice surface and drives snow metamorphism, it is of advantage to treat it explicitly. Under the assumption of Fickian diffusion of water vapor in the pore space, mass continuity leads to the following partial differential equation:

$$\theta_a \frac{\partial \rho_v}{\partial t} - \frac{\theta_a D_v}{\tau} \frac{\partial^2 \rho_v}{\partial z^2} = \frac{Q_{pc}^{s/v}}{L^{s/v}} \tag{4}$$

Here, $\rho_v(\mathrm{kg\,m^{-3}})$ is water vapor density in the pore space, D_v is the water vapor diffusivity in air ($2.2\ 10^{-5}$ $\mathrm{m^2\ s^{-1}}$), which has a small temperature and pressure dependence (Massman, 1998), and τ is the snow tortuosity, which is of the order of 2. Q_{pc} and L at the right-hand side of equation (4) give the source term through phase change and the latent heat, respectively. The superscript $^{s/v}$stands for sublimation or vaporization, depending on whether the phase change is between vapor and liquid or vapor and solid water. Note that the latent heat values are different ($L^s = 2.83\ 10^6 \mathrm{J\,kg^{-1}}$; $L^v = 2.50\ 10^6 \mathrm{J\,kg^{-1}}$) for both processes and further have a small dependence on temperature and pressure.

Discussion

Equations (3) and (4) are a coupled set of partial differential equations, which can be solved numerically to describe vertical mass and energy transport in a phase changing snow cover. If both equations are solved, the vapor-ice or vapor-water phase change is the coupling term. In SNOWPACK, only equation (3) is solved, and vapor transport is parameterized by using an appropriate formulation for the effective thermal conductivity, k_e

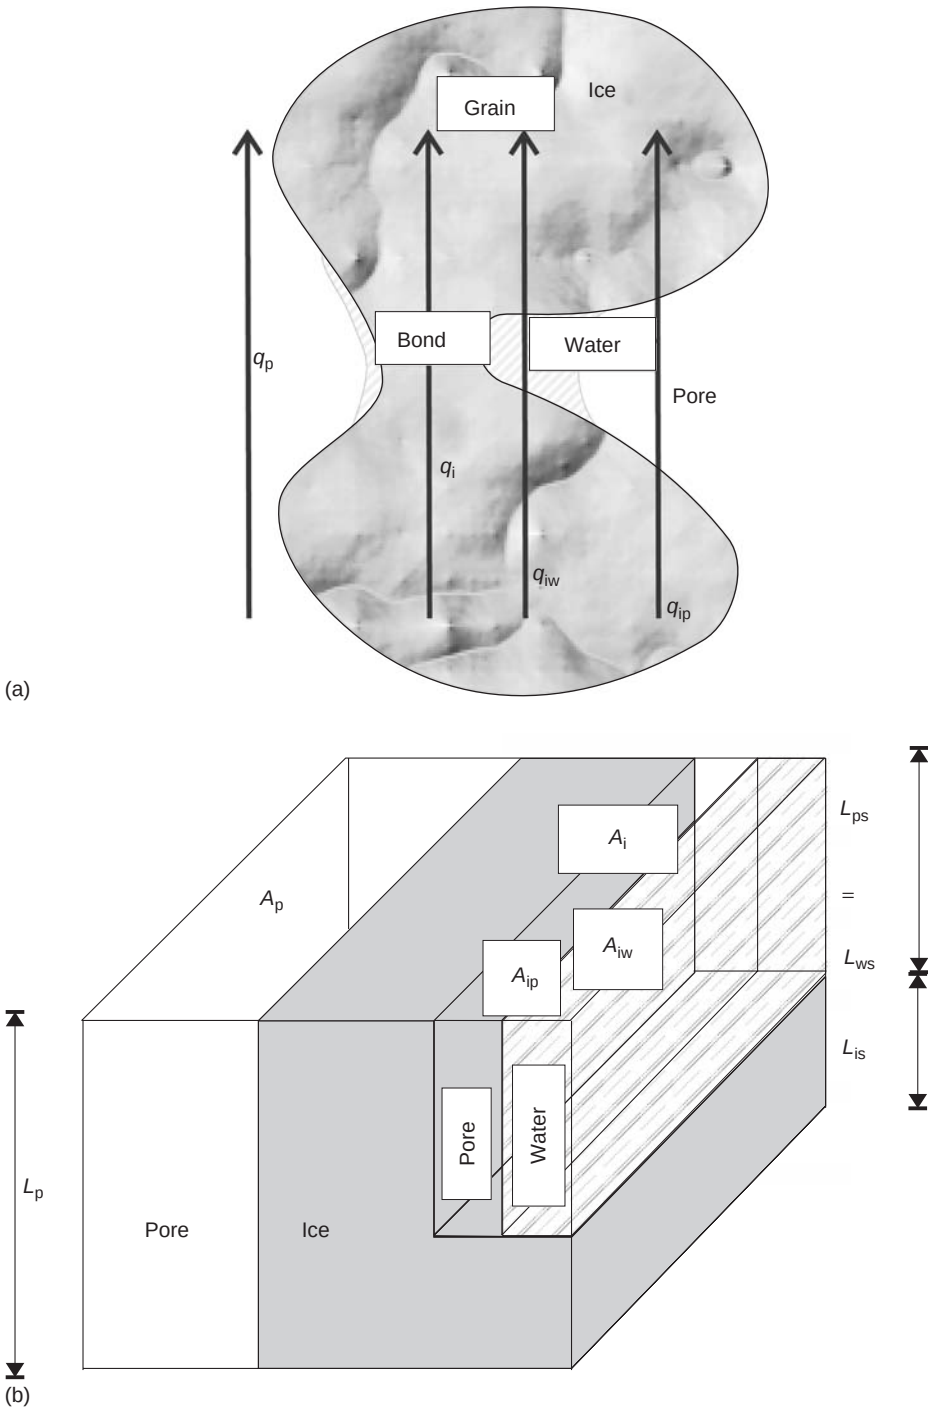

Figure 2 (a)Definition of ice, water, and air phases in snow and possible heat flux situations; (b)schematic representation of the phases in a bulk model

(Lehning *et al.*, 2002a; Fierz and Lehning, 2001). More recently, advanced versions of SNOWPACK (Bartelt *et al.*, 2004) have been developed. They have separate temperature equations for the air and ice phases and solve the vapor transport equation explicitly. However, the separate equations for the air and ice phases now contain heat exchange terms, which are used as fitting parameters in Bartelt *et al.* (2004). In addition, this separate treatment needs separate boundary conditions, which are not available from routine measurements. In fact, they cannot be measured or predicted with current techniques at all.

Not all transport processes in the snow cover are diffusive at all times. In addition to water flow in snow (*see* **Chapter 161, Water Flow Through Snow and Firn, Volume 4**), evidence also exists for convective air movements under certain circumstances. Those air movements, which are driven by atmospheric pressure fluctuations from above, are commonly called *ventilation* (Albert and McGilvary, 1992). If they are driven by buoyancy (which requires lateral differences), they are rather called *convective movements* (Sturm and Johnson, 1991). A correct description of these effects requires, in any case, that snow is treated in at least two dimensions. Therefore, equations (3) and (4) do not contain an airflow velocity. However, it is possible to include the effect of ventilation or convection even in a one-dimensional model description. This can be done by parameterizing the effect on the diffusivities of heat, k_e, or water vapor, D_v. An example of such a parameterization is given by Lehning *et al.* (2002b), while Bartelt *et al.* (2004) allow explicitly for a vertical velocity in their equations, which are driven by arbitrary pressure fluctuations.

Snow Settling

A final advective mass transport occurring in snow is snow settling. Fresh snow settles very fast initially, but settlement slows down very quickly. Snow is sometimes treated as a visco-elastic material that undergoes large irreversible deformations. For one dimension, a simple rheological Maxwell law relates the viscous strain rate, $d\varepsilon_v/dt$, to the mean stress in the snow, σ_s, where η_s is the snow viscosity.

$$\frac{d\varepsilon_v}{dt} = \frac{-\sigma_s}{\eta_s} \tag{5}$$

This law is applicable when elastic deformations are small, as is the case for snow settling under its own weight. As shown by Mellor (1975), the viscosity of snow can vary by several orders of magnitude over the density range of natural snow covers. Since snow viscosity is highly dependent on microstructure, it is very challenging to find good formulations of snow viscosity. An attempt to formulate snow viscosity as a function of snow microstructure by considering processes such as linear and nonlinear flow laws for ice and pressure sintering has been described by Lehning *et al.* (2002a). However, more work is needed to reduce the need for empirical adjustments.

SNOW METAMORPHISM

The primary driving mechanism behind dry snow metamorphism is the phase change associated with water vapor flux. Figure 3 shows a simplified scheme of snow metamorphism. The process starts immediately after snow has been deposited on the ground. The dendritic crystals have a high surface energy and vapor is created at the edges and deposited in the crystal cavities. In this way, a first snow texture consisting of grains and bonds is created. Further development strongly depends on the temperature conditions. Traditionally, kinetic and equilibrium metamorphism

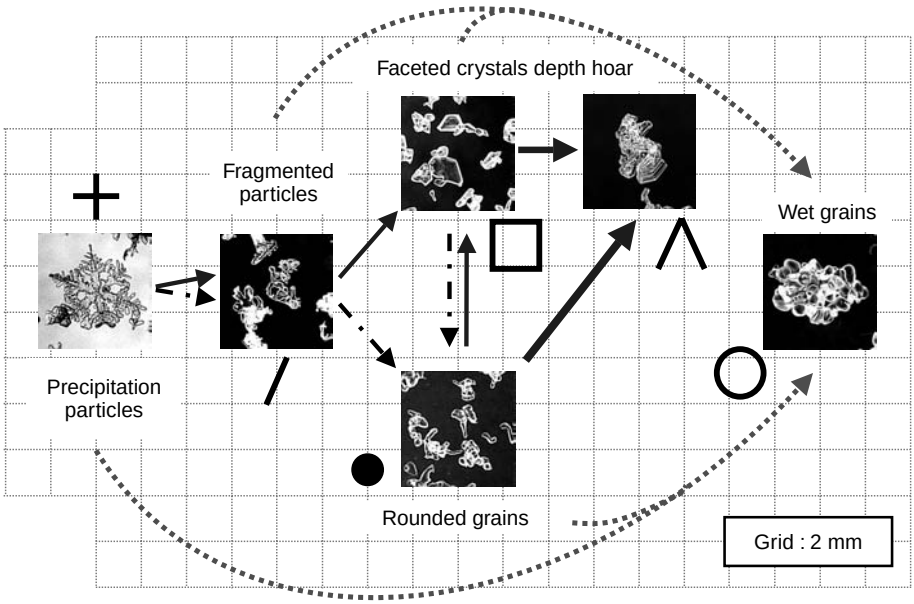

Figure 3 Schema of snow metamorphism; the snow grain types are shown as photographs and as the standard international symbols. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

are distinguished. They are treated in more detail in the following text. Another process is melt metamorphism, when large and round grains develop, which may also form clusters (Colbeck, 1997). They develop under the influence of liquid water.

Equilibrium Metamorphism

Equilibrium metamorphism takes place when no "global" vapor flux exists, that is, vapor molecules are relocated, but the source and sink grain may be the same. The driving force behind equilibrium metamorphism is differences in vapor pressure due to convex and concave surfaces as described by Kelvin's equation (Colbeck, 1980):

$$p_s = p_s^0 e^{\frac{2\sigma}{RT_i\rho_i r_s}} \tag{6}$$

Here, p_s is the saturation vapor pressure (Pa) over the curved ice surface at the temperature T_i (K), $p_s{}^0$ is the saturation pressure (Pa) over a flat ice surface, which can be obtained from an empirical form of the integrated Clausius-Clapeyron equation, R is the water vapor gas constant ($461\,\mathrm{J\,kg^{-1}K^{-1}}$), σ is the surface tension of ice ($\mathrm{N\,m^{-1}}$), and r_s is a mean ice surface radius of curvature (m). In order to apply equation (6) to describe snow metamorphism, the snow pore and ice geometry must be known and described to a high degree of detail. Therefore, it is still common to use semiempirical laws (Brown *et al.*, 2001) to describe equilibrium snow metamorphism. Snow microstructure development is modeled using rate equations for structure parameters. For example, the development of grain and bond size is most important for equilibrium metamorphism in the snow cover model SNOWPACK (Lehning *et al.*, 2002a). The bonds between the snow grains grow by vapor deposition and to a lesser degree by pressure sintering, which is related to snow settling. The end form of equilibrium metamorphism is fine grained snow with rather strong bonds, which is mechanically stable.

Kinetic Metamorphism

Kinetic metamorphism starts when macroscopic temperature gradients (i.e. temperature gradients over distances larger than the grain size) lead to vapor pressure differences that are not only local. If the pore space is sufficient, water vapor will then move. Small grains may disappear completely at certain locations in the ice matrix (source grains), while at other locations, where vapor gets deposited, grains develop into large faceted crystals. Kinetic metamorphism is therefore sometimes called *snow recrystallization*. Because of the high growth rate, these crystals develop as faceted hexagonal crystals (Petrenko and Whitworth, 1999). Depending on temperature conditions, prismlike structures, plates, or cups develop. If enough pore space is available, the end form of kinetic metamorphism, under high temperature gradient conditions, is cup-shaped crystals, also called *depth hoar*.

Model descriptions of kinetic metamorphism are predominantly empirical (Marbouty, 1980) or semiempirical (Lehning *et al.*, 2002a). In SNOWPACK, rate equations are developed for grain growth, bond growth, and change in sphericity. A classification routine is then used to recover conventional grain types. Figure 4 shows an example of grain type development as calculated by SNOWPACK for the infamous avalanche winter of 1999 at the study plot site Weissfluhjoch Versuchsfeld.

Discussion

A correct model of snow metamorphism is crucial for a correct snow description because the snow thermal and mechanical properties strongly depend on the snow microstructure. Therefore, a more physical model description of snow metamorphism is desirable. Miller *et al.* (2003), have presented a quasi two-dimensional model of snow metamorphism, based on the physical principles of vapor and heat transport as discussed previously. Introducing growth laws for faceted crystals, they can successfully describe equilibrium and kinetic metamorphism with their model. They can also predict growth dependency on available pore space, temperatures, and temperature gradients.

SURFACE ENERGY AND MASS EXCHANGE

The energy conservation law (equation 3) must be solved numerically with a correct set of boundary conditions. For all cases, Neumann boundary conditions can be employed for the upper boundary:

$$k_e \frac{\partial T}{\partial z} = q_{sh} + q_{lh} + q_{lw} + q_{rr} \tag{7}$$

Here, the four surface energy flux terms, sensible heat, q_{sh}, latent heat, q_{lh}, net long-wave radiation (incoming minus outgoing), q_{lw}, and energy through liquid precipitation, q_{rr}, ($\mathrm{W\,m^{-2}}$) determine the heat flux through the snow surface. They will be treated in more detail in the following text. While the surface of the snow cover is a fractal and therefore physically not precisely defined, latent and sensible heat fluxes as well as the net long-wave radiation balance are usually treated as surface energy sources. Note that implicitly the control surface contains no mass or volume, so equation (7) has no storage term. Short-wave radiation penetrates the snow and is therefore considered to be a volume source (equation 3). Short-wave radiation penetration is also treated in the following text.

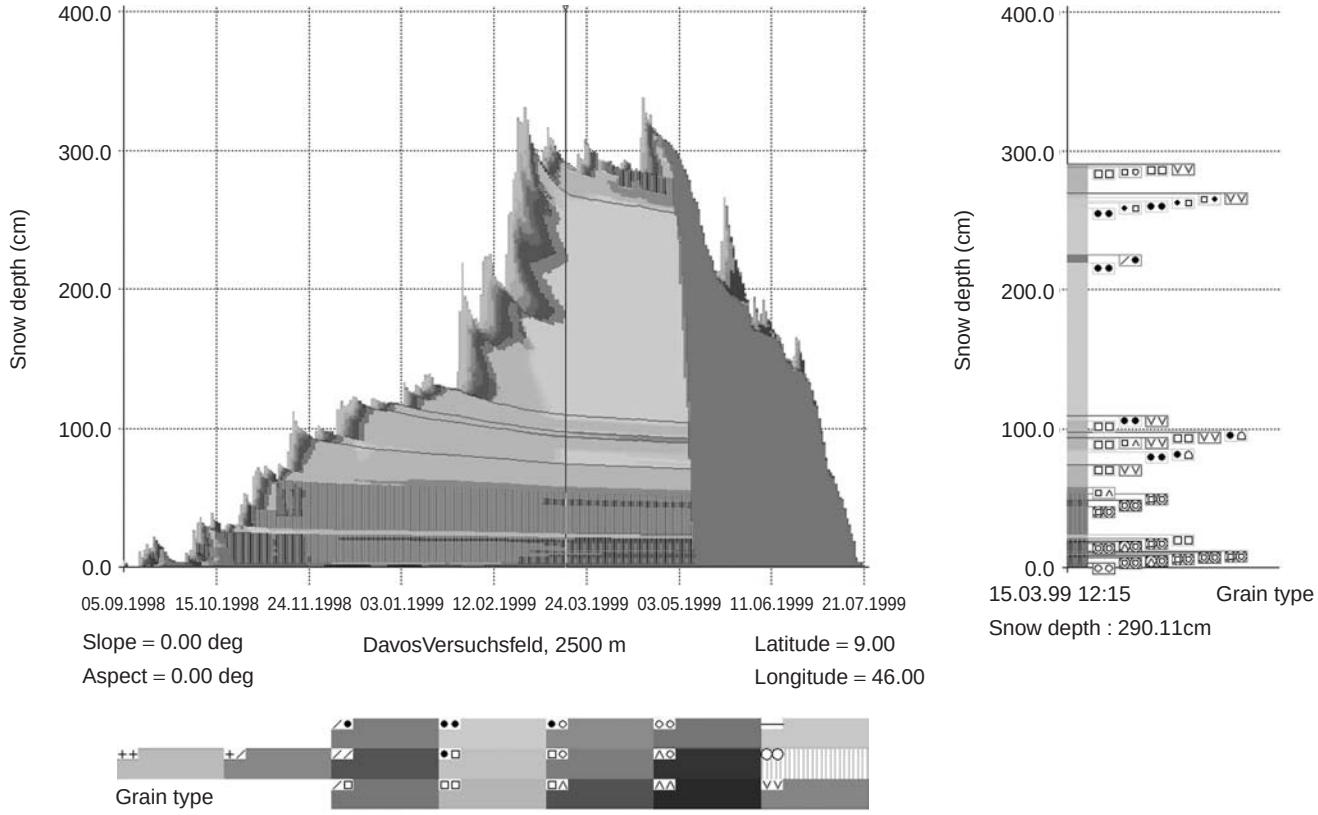

Figure 4 Development of snow grain types at Klosters. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Instead of Neumann boundary conditions, Dirichlet boundary conditions can also be used. This means measuring the temperature at the snow surface. This is a very good way to solve equation (3), as long as no phase change processes are taking place, and the sum of the surface energy fluxes is uniquely determined by the surface temperature. For all practical applications, one is allowed to neglect sublimation phase changes and work with a Dirichlet boundary condition as long as no melting (or refreezing) occurs. As soon as melt processes are involved, the surface temperature does not determine the surface energy exchange any more. The lower boundary condition can be formulated in the same way as the upper ones. Note that then the soil heat flux replaces the sum of the surface heat fluxes.

For a numerical solution of equation (4), boundary conditions must be formulated as well. The latent heat flux treated in the following discussion serves as an upper boundary condition. For all practical applications, a zero-flux condition can be used at the bottom.

Sensible Heat Exchange

From similarity theory for the atmospheric surface layer (e.g. Stull, 1988), the gradient of the scalar quantity air temperature, T_a, takes the form (Note here that since we are only concerned with minor changes in altitude within the surface layer, we do not have to use potential temperature instead of temperature.)

$$\frac{\partial T_a}{\partial z} = \frac{-0.74}{k\ z\ u_f} \frac{q_{sh}(z)}{\rho_a\ c_p} \tag{8}$$

Here k is the Karman constant (0.4) and u_f the friction velocity. In the surface layer (constant flux layer), the fluxes at any height are approximately equal to the surface flux, $q_{sh}(z) = q_{sh}(0)$.

The empirical constant 0.74 comes from data in the neutral atmospheric boundary layer and is related to the fact that the turbulent exchange coefficients for heat and momentum differ (e.g. Stull, 1988). The surface is not entirely smooth, and the roughness length, z_0, is a parameter describing the aerodynamic surface roughness. It is also known that the roughness length is always smaller than the height of the individual roughness elements. Thus, the measured surface temperature (of snow) is postulated to be equal to the air temperature at $z_0 : T_a(z_0) = T(0)$. We can now integrate equation (8) from z_0 to the height of the

measured air temperature to receive:

$$T_a(z) - T(0) = \frac{-0.74}{k\ u_f} \frac{q_{sh}(z)}{\rho_a\ c_p} \ln \frac{z}{z_0} \tag{9}$$

and the surface sensible heat flux, $q_{sh}(0)$ can be obtained from the measurement of wind speed and temperature at any height, z, and the surface temperature, $T(0)$:

$$q_{sh}(0) = \frac{-k\ u_f}{0.74 \ln \frac{z}{z_0}} \rho_a\ c_p (T_a(z) - T(0)) \tag{10}$$

It is easily seen that equation (10) is analogous to the form of the usual bulk transfer equation for surface fluxes and suggests an expected value for the kinematic transfer coefficient, C ($m\,s^{-1}$):

$$C = \frac{k\ u_f}{0.74 \ln \frac{z}{z_0}} \tag{11}$$

Latent Heat Exchange

The development for the latent heat flux, q_{lh}, is identical to the one for sensible heat and we derive using equation (11):

$$q_{lh} = -C \frac{0.622 L^{s/v}}{R_a T(z)} \left[e_s^w (T_a(z))\, rH - e_s^i (T(0)) \right] \tag{12}$$

R_a ($287\,J\,kg^{-1}\,K^{-1}$) is the gas constant for air, $e_s^{w/i}$ is the saturation vapor pressure (Pa) over water or ice respectively, and rH (1) is the relative humidity. The constant 0.622 is the ratio of the gas constant for dry air over that for water vapor. At the snow surface we use the saturated vapor pressure over ice. The saturation vapor pressure is approximated by common semiempirical integrations of the Clausius-Clapeyron equation (e.g. Magnus formula).

Discussion

The above formulations are very robust descriptions of surface turbulent flux exchange over snow. They should be used if measured meteorological variables are available at one height only and the snow surface temperature is known or can be estimated. When meteorological variables are only available at one height above the surface, the roughness length of the site must be estimated *a priori*. Note that usually the roughness length is not determined by the snow grain size but is a function of surface structures such as sastrugi, topography, or buildings. For a small flat field surrounded by mountainous terrain, a typical value for the roughness length is 7 mm. With the known roughness length, the friction velocity can be calculated from the logarithmic wind profile, u:

$$u(z) = \frac{u_f}{k} \ln \frac{z}{z_0} \tag{13}$$

The development above is stable and simple. However, especially over flat terrain, atmospheric stability effects may become important. The above development can be done in an identical way when stability correction functions are required (Essery, 1997). Another simplification is the assumption implicitly invoked that roughness lengths are equal for momentum, heat, and moisture fluxes. Measurements show that this is not the case, in particular, for snow surfaces (Calanca, 2001). Andreas (1987) describes a theory to include different roughness lengths for heat and moisture into the flux formulations.

Long-wave Radiation Balance:

The term, q_{lw}, in equation (7) is the net surface long-wave radiation balance source term, that is, long-wave radiation received from above at the snow surface minus the long-wave radiation emitted by the snow surface. Long-wave radiation is emitted from each body as described by the Stefan-Boltzmann law. The law can be applied directly to the snow surface, to determine the energy emitted from the snow surface. Snow has an emissivity (and absorptivity) very close to one. The long-wave radiation received from the sky is more difficult to determine, because dry air has a low emissivity/absorptivity and the snow surface sees a mix of radiation emitted from the air close to the surface, from clouds above (when there are any) and from space. Therefore, for a correct description of the surface energy balance, an accurate measurement of incoming long-wave radiation is advantageous. Alternatively, if the cloud cover, the air temperature, and the relative humidity are known, it is also possible to parameterize the incoming long-wave radiation quite accurately (Konzelmann *et al.*, 1994).

Rain Energy

The energy added to the snow cover by (warm) rain, q_{rr}, is treated as a flux boundary condition. Assuming that rain has the same temperature as the air, the flux of energy due to rain is given by:

$$q_{rr} = r_{rr} c_p^w (T_a(z) - T(0)). \tag{14}$$

Here r_{rr}($kg\,s^{-1}$) is the rain rate and $c_p{}^w$ the specific heat of water ($4190\,J\,kg^{-1}K^{-1}$). The rain mass is added to the uppermost element of the snow cover and the water will then undergo phase changes or will be transported downwards. Note that in the case of snow temperatures below 0 °C most of the effect of rain on snow will be due to the phase change energy when the water freezes.

Short-wave Radiation Balance

A photon that hits a snow crystal has a very low probability to be absorbed. A high fraction of the incoming direct and indirect short-wave radiation hitting the snow surface will be scattered back from crystals near the snow surface and become a part of the upwelling diffuse short-wave radiation. This is the reason for the high albedo of snow. This also means that a good radiative transfer description in snow will allow prediction of the snow surface albedo. On the basis of measurements made in Greenland, (Meirold and Lehning, 2004) such a transfer model has been developed, which takes into account snow density, snow grain size and snow grain form. Figure 5 shows spectrally resolved measurements of radiation penetration in snow. With a model based on ray tracing (Macke, 1993) and the delta Eddington approximation a good description of this transfer is possible (Figure 6). It is important to take the impurity content of snow and the influence of different grain shapes into account. Because snow crystals have a high refractive index, small amounts of impurities can lead to a significantly enhanced absorption.

For determining the volume source term, Q_{sw}, in equation (3), a simple extinction formulation with a density-dependent extinction coefficient has proven to satisfactorily calculate the energy penetration, provided that the albedo is known (Lehning *et al.*, 2002b). However, future snow models will certainly make use of the more complex techniques described above for two main reasons. First, the complex technique will provide an estimate for snow albedo and second, more and more applications such as snow chemistry will require that a spectrally resolved radiation flux in snow is known.

SNOW TRANSPORT AND THREE-DIMENSIONAL EFFECTS

Snow transport by wind is a spectacular and important phenomenon (Figure 7). It crucially influences the seasonal buildup of the snow cover and avalanche activity in Alpine terrain. It also influences the growth of vegetation and the storage of water and pollutants. Snow transport has been studied extensively over the last few decades, and much progress has been made in modeling and understanding of

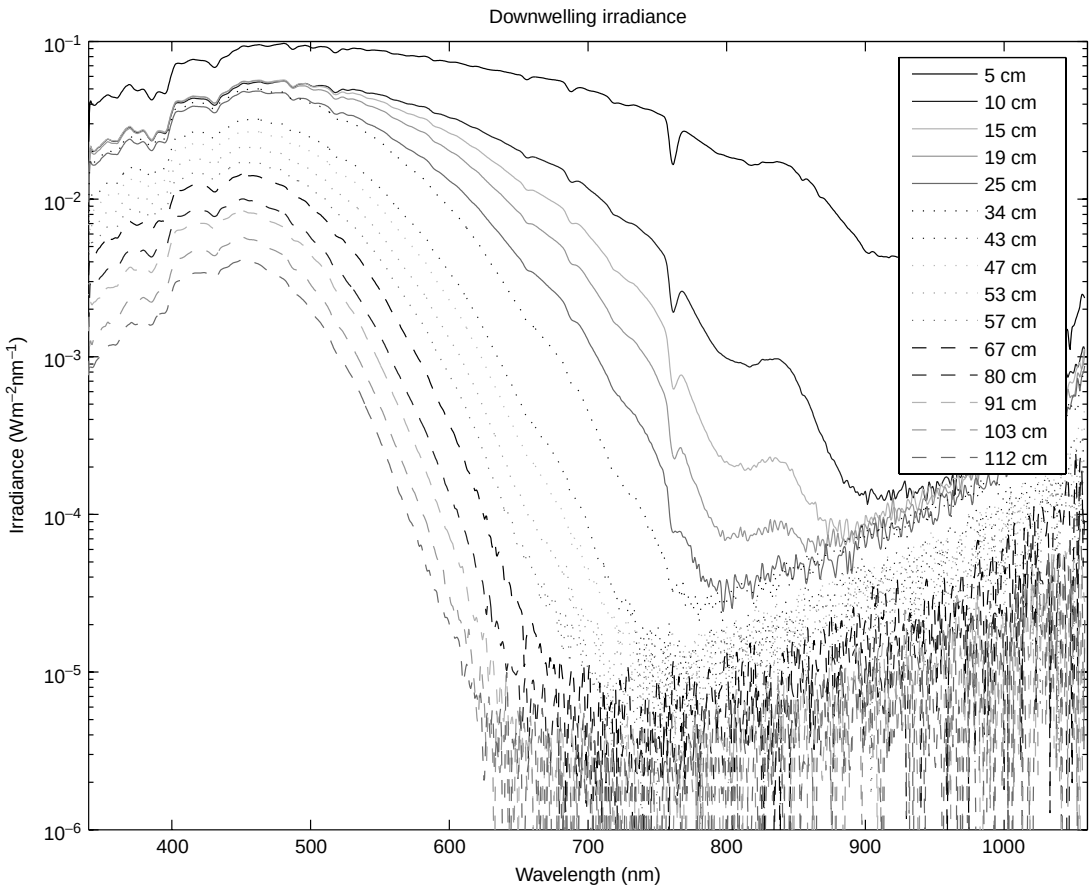

Figure 5 Spectrally resolved measurements of radiation transfer as a function of depth in snow at Summit, Greenland. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

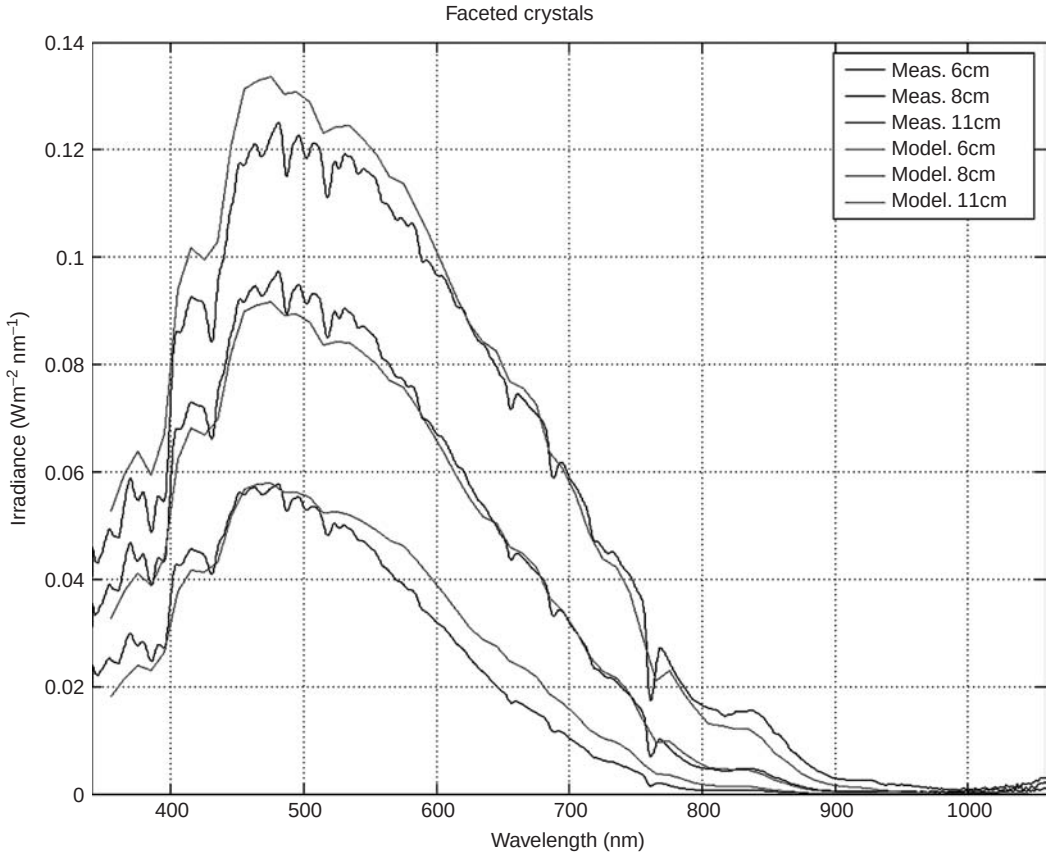

Figure 6 Comparison of measured and modeled radiation fluxes in snow. A good agreement is reached by accounting for snow impurities, snow-grain size, density, and snow-grain shape using a ray tracing technique. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

snow drift. Despite these efforts, due to the complexity of the physical processes involved, complete descriptions of snow redistribution by the wind hardly exist.

Traditionally, snow drift research has been motivated by engineering efforts to mitigate the adverse effects of blowing and drifting snow or to assess the mass and energy balance of snow and ice surfaces in high latitudes (Andreas, 1995; Mann *et al.*, 2000; Gallée *et al.*, 2001). Recently, modeling efforts have been intensified, in an attempt to describe the effects of drifting snow on the atmospheric boundary layer (Bintanja, 2000; Déry *et al.*, 2001). Snowdrift is also a notorious problem for avalanche warning (e.g. Gauer, 2001), because certain slopes may be loaded by huge amounts of additional snow and therefore, redistribution changes snow characteristics in a way that leads to a higher probability of avalanche release.

Snow Saltation

We usually distinguish between two major transport modes. The first is snow saltation (drifting snow), where grains hop over the snow surface following ballistic trajectories. The second transport mode is snow suspension (blowing snow), when grains become suspended by the airflow and follow the streamlines of the flow. In principle, an additional transport process, namely creep or reptation exists, where grains roll along the snow surface. This process only transports minor amounts of snow, however.

Snow saltation is believed to be the dominant transport mode in flat terrain. By definition, saltation can only take place over an existing snow cover, when wind speeds are high enough to lift grains from the ground. The exact mechanism of saltation initiation is not completely clarified. However, newer results suggest that a certain ratio of aerodynamic entrainment to rebound or splash dominates the saltation cloud (Doorschot and Lehning, 2002). Aerodynamic entrainment is the process by which grains are lifted because of the shear stress of the airflow, while rebound or splash is the process whereby an already saltating grain interacts with the surface and rebounds or ejects other snow grains. In any case, the initial velocity of the grain and the "ejection" angle determine to a significant degree the track of the snow grain. The flow conditions determine whether the energy gain of the particle during its jump is sufficient to counterbalance the energy loss at

Figure 7 Suspension cloud over a mountain ridge. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

the next impact with the surface and therefore whether saltation will continue. Obviously, the energy lost with each impact is also a strong function of the material properties of the grain and the surface. This is the reason why snow saltation is more complicated than sand saltation, in which the elasticity of the grains is much higher and no strong adhesive forces act between the grains on the ground. The state-of-the-art model of snow saltation has been presented by Nemoto *et al.* (2004), where individual trajectories are calculated to predict an overall snow mass flux. The model includes also the transition from saltation to suspension. However for an application-oriented use, those models are computationally too expensive. Therefore, various empirical formulations for saltation transport rates remain important (e.g. Pomeroy and Gray, 1990). Most of them have in common the fact that the snow transport rate, Q ($\mathrm{kg\,m^{-1}\ s^{-1}}$) is assumed to be proportional to the flow mean shear stress, u_f, or the flow velocity, u raised to some power, x, which is often exactly or approximately 3. A good model of this type is that of Sorensen (1991), which also takes into account the dependence on the threshold for snow saltation initiation. It must be emphasized, however, that none of these simple formulations is valid over sloping terrain, where the effects of drifting snow are most important. In fact, to our knowledge no data set exists which describes snow saltation on slopes. In the following, we present results from a 3-D snowdrift model (Drift@ALPINE3D), which uses an equilibrium saltation model in the form described by Doorschot *et al.* (2004). It should, in principle, also work for steep slopes although it has not yet been validated for that case. The equilibrium model is simpler than the fully dynamic model of Nemoto *et al.* (2004) but is still based on physical principles and is computationally much less expensive.

Snow Suspension

Snow in suspension can originate from the snow cover or directly from precipitation. When wind speeds increase, saltating particles will be picked up at some point by turbulent eddies and transported away over longer distances. Frequently, suspension clouds can be observed over steep mountain ridges (Figure 7). Over flat terrain, on the other hand, suspension is less important and is most commonly described assuming an equilibrium concentration profile coupled to some concentration derived from the saltation model (e.g. Liston and Sturm, 1998):

$$c(z) = c(z_{\mathrm{ref}})\frac{z}{z_{\mathrm{ref}}}^{\frac{-s}{ku_{\mathrm{f}}}} \tag{15}$$

Here, c is the concentration (volume fraction), z_{ref} is a reference height, s is the settling velocity of snow flakes in still air ($\mathrm{m\,s^{-1}}$), k is the Karman constant (0.4), and u_{f} is the friction velocity ($\mathrm{m\,s^{-1}}$). This concentration profile is based on the assumption that the snow settling velocity

is counterbalanced by turbulent diffusion. The suspension mass balance can then be obtained by integrating the concentration profile multiplied by the mean wind-speed profile with height. More interesting is the case for complex terrain, where suspension is often described with a common advection–diffusion equation:

$$\frac{\partial c}{\partial t} + u\frac{\partial c}{\partial x} + v\frac{\partial c}{\partial y} + (w - w_s)\frac{\partial c}{\partial z} - K\frac{\partial^2 c}{\partial z^2} = 0 \qquad (16)$$

Here w_s is the settling velocity in still air and K is a diffusion coefficient ($m^2 s^{-1}$). While the applicability of equation (16) is given, the numerical implementation is very difficult because the transition to the saltation layer below cannot be resolved with current numerical meshes with a reasonable computational effort. For the results of Figure 8, we use a numerical solution of equation (16) but parameterize the effect of atmospheric turbulence into a modified settling velocity and set K to zero. Furthermore, we use equation 15 as a wall function to bridge the distance between the reference height determined from the saltation and the lowest grid level of the atmospheric model, which is also the lowest grid level for the solution of the suspension equation. The mass balance for the saltation layer includes then the contribution from suspension and gives as a result the local erosion or deposition values.

Figure 8 shows the final snow distribution for the Gaudergrat ridge after the major drift period of the avalanche winter 1999. Simulated is a drift period of 5 days. The wind fields have been calculated with the ARPS mesoscale

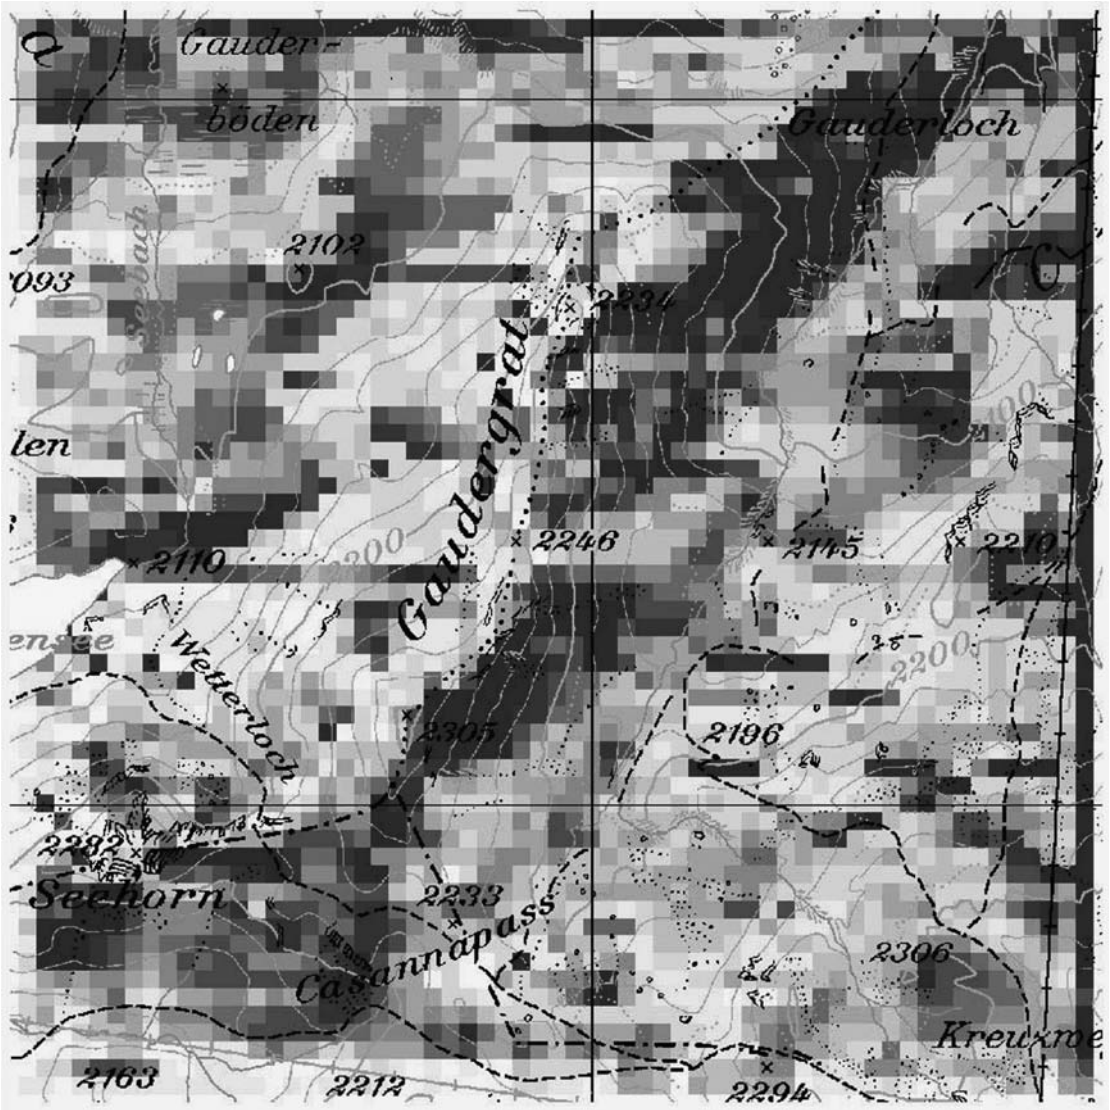

Figure 8 Snow distribution over the Gaudergrat ridge after the five-day storm period of the avalanche in the winter of 1999. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

atmospheric model. One example of such a wind field is Figure 9. It is clear that zones of very low wind speed but high turbulence are present in the lee of the ridge. These are the zones of maximum snow deposition. The grid size for wind and transport simulations was 25 m.

Radiation Balance in Steep Terrain

Traditionally, snow cover models have been one-dimensional and this contribution largely describes processes occurring vertically in and over the snow cover. This chapter has been an exception in that three-dimensional snow distribution is treated. With increasing computer power, future generations of hydrological and meteorological models will have a resolution that is high enough that three-dimensional effects in steep terrain (such as snow transport) become important. For a correct description of the energy balance and therefore mass balance in snow-covered steep terrain, additional processes need to be considered. These processes include shadowing from mountains, multiple reflections of short-wave radiation at slopes, and long-wave radiation emitted by neighboring slopes or other objects. Recently, first treatments of such three-dimensional surface processes have become available (Fierz *et al.*, 2003).

The SNOWPACK software package

The processes discussed above are available from SLF as an integrated software package programmed in the C/C++ programming language and with a JAVA user interface. More information and downloads are possible from the SNOWPACK home page at **`www.slf.ch/snowpack`**.

161: Water Flow Through Snow and Firn

PHILIP MARSH

NWRI Saskatoon, Saskatchewan, SK, Canada

Water flux through snow and firn has important implications for the timing and magnitude of runoff from seasonal snowpacks, glaciers, and ice caps. Studies conducted over the last few decades have greatly improved our understanding of water flux through snow and firn, including knowledge of the development of wetting fronts as meltwater enters dry snow, preferential flow paths, grain growth of wet snow, and the growth of ice layers and ice columns within the snowpack. Such studies have resulted in the development of a variety of analytical and numerical models for calculating runoff from melting snow and firn. Although our understanding of key processes continues to increase, there are major gaps in our knowledge that limit our ability to formulate comprehensive physically based models of snow metamorphism and water flux through snow and firn. Part of the problem is a lack of data, which is due to the great difficulty of conducting experiments on snow near 0°C and our inability to measure the properties of snow required for estimating the value of parameters needed for numerical simulations. In order to overcome these problems, there is a need for the development of new measurement techniques and carefully designed field and laboratory experiments. Comprehensive models are required for predicting not only melt runoff, but also the release of pollutants from the snowcover, the large-scale properties of the snowcover necessary for understanding large-scale energy-balance and global-change problems, and the release of meltwater from cold glaciers and icecaps under future climate scenarios.

INTRODUCTION

Water flux through snow and firn has important implications for the timing and magnitude of runoff from seasonal snowpacks, glaciers, and ice caps. In addition, it has implications for ecology (Jones *et al.*, 2001), solute release from snowpacks (Tranter and Jones, 2001), and snow avalanches (McClung and Schaerer, 1993). Previous reviews of water flow through snow have been provided by Colbeck (1978), Wankiewicz (1979), Marsh (1991), and Marsh (1999).

Although our understanding of snowmelt runoff processes continues to increase, there are major gaps in our knowledge that limit our ability to model all aspects of water flux through snow and firn. These have been noted by Marsh (1991), Waldner *et al.* (2004), and Gustafsson *et al.* (2004). The most important of these include (i) the relationship between water saturation and grain growth rates; (ii) the effect of grain properties on the water saturation, pressure, and permeability relationships; (iii) the physical properties of ice layers/columns and the mechanisms controlling their formation and persistence; (iv) the mechanisms controlling preferential flow or flow fingers; and (v) the relationship between flow fingers, grain growth, and internal flow systems as revealed by surface rill patterns, for example. Although some aspects of these have been considered over the last decade, our lack of understanding still limits the application of numerical models derived from basic physics (i.e. Tseng *et al.*, 1994; Sellers, 2000; Gray, 1996). A better understanding of the physical processes controlling water flux through snow and firn is required before a complete physically based model of heat and mass fluxes through melting snow covers can be developed.

This article will outline our knowledge of vertical, unsaturated water flux into both dry and wet snow. In addition, the advantages and limitations of the physically based models that are currently available will be discussed. Although important, solute release from snowpacks and the occurrence of snow avalanches are beyond the scope of this article. In addition, as few studies have considered water flux through firn, this article will concentrate on snow, but will discuss firn when possible.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

PROPERTIES OF SNOW AND FIRN

The physical properties of snow and firn influence water movement through these porous media. As detailed information is readily available in other articles of this Encyclopedia (*see* **Chapter 160, Energy Balance and Thermophysical Processes in Snowpacks, Volume 4**; **Chapter 159, Snow Cover, Volume 4**; **Chapter 165, Mass and Energy Balances of Glaciers and Ice Sheets, Volume 4**) and elsewhere (Gray and Male, 1981; Singh and Singh, 2001; Fountain and Walder, 1998), we will only provide a brief overview of these properties.

Snow covers, either seasonal snow over terrestrial surfaces, glaciers, or multiyear snow found on perennial snow patches or glaciers, are layered. Each layer is formed by snowfall, wind drift, or a combination of these two processes (Figure 1), and modified by compaction, surface melting, and the refreezing of water within the snowcover (Figure 2) (Gustafsson *et al.*, 2004). Each layer varies in terms of grain size, shape, and density (less than $550\,\mathrm{kg\,m^{-3}}$), and resulting liquid permeability, depending on metamorphic changes once the snow is deposited on the ground (Colbeck, 1983, 1986a). Atmospheric processes control the nature of the falling snow (Magono and Lee, 1966; Nakaya, 1954), and therefore the properties of the upper layer of the snowcover. However, metamorphism is sufficiently rapid that snow deposited for more than a day, bears little resemblance to the initial form. When added to the snowcover, liquid water results in large changes in snow properties, including an increase in mean grain size, with the larger grains growing at the expense of the smaller grains (Colbeck, 1974b, 1986b).

Firn occurs in the accumulation zones of glaciers, and is found below the seasonal snowcover and above the glacial ice. It is defined as rounded, well-bonded snow that is older than one year, has partially closed air-pores, and has a density greater than $550\,\mathrm{kg\,m^{-3}}$. It is sometimes also referred to as *névé*. Snow with similar properties is also found in perennial snow patches. In temperate regions, firn develops because of the melting and pronounced settling. In polar regions, settling dominates. Firn formation is the intermediate step in the transformation of snow into glacial ice.

Figure 1 Multiple layers in a premelt snowcover. Each layer has a different hardness and can easily be highlighted by smoothing each layer with a brush. Thermistors are located at each layer. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

WET SNOW/FIRN

Definitions

The liquid-water content of snow/firn has important implications for the metamorphism of the snowpack and runoff from it. The liquid water content (Θ_w) expressed as a fraction of the total volume, is related to liquid saturation (S_w) expressed as a fraction of the pore volume, by

$$S_w = \frac{\Theta_w}{\phi} \tag{1}$$

where ϕ is the snow porosity. For calculations of water flux in snow, two other liquid-water measurements are commonly used. These include the irreducible water saturation (S_i) or irreducible water content (Θ_i), which are defined as the maximum liquid water which is held by capillary forces and is not available for flow, and the effective saturation (S^*), which is defined as the fraction of the pore volume occupied by mobile liquid. S^* is calculated as

$$S^* = \frac{(S_w - S_i)}{(1 - S_i)} \tag{2}$$

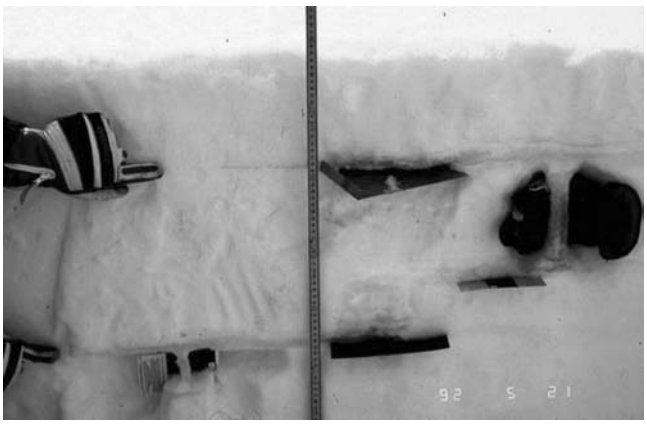

Figure 2 Horizontal ice layers and vertical ice columns are shown in this vertical profile through a melting snowcover. These ice bodies are formed by the freezing of meltwater at premelt horizons (as shown in Figure 1) and by freezing of water in vertical flow fingers. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

S^* is commonly used when considering water flow through snow because snow permeability, which is a function of water saturation, is equal to zero when S^* is equal to zero.

The liquid water content of snow can be measured by a number of techniques, including calorimetry and capacitance probes (Denoth *et al.*, 1984). The measurement of liquid water content in snow is most precise using a capacitance probe and concurrent density measurement. Combined determinations of water content and density using the imaginary part of the dielectric number of ice are less reliable. *In-situ* Time Domain Reflectometry (Schneebeli, 1998) was successfully used to determine the relative changes in water content, but absolute values must be corrected using density from other measurements (Stähli *et al.*, 2004). Brzoska *et al.* (1998) developed a flash-freezing/thick sectioning method to visualize the location of water within the ice matrix. This method is not suitable for field use.

Liquid Water Regimes

Wet snow/firn consists of a sintered ice matrix, enclosed by liquid water of variable thickness, and air. Only at water contents exceeding approximately 30% does the ice matrix dissolve into separated ice grains. The distribution of liquid water in snow is highly variable, with three distinct regimes (Colbeck, 1973). These include (i) the pendular regime, which occurs at low water saturations, where water rings the contact points of the snow grains, with air occurring in a continuous path through the snow. Only a thin liquid layer covers the surfaces of the grains. At very low water saturations the capillary forces are sufficiently large that water flow does not occur; (ii) the funicular regime, which occurs at higher water saturations, where the air becomes isolated as individual bubbles; and (iii) the saturated regime, which occurs when the pore volume is completely filled with water.

Freely draining snowpacks are in the pendular regime. Water saturations are less than 7% for old, coarse-grained snow, but typically range from 7% to 15% depending on the snow type (Colbeck, 1973; Denoth, 1980; Ambach and Denoth, 1980; Denoth, 1999). Typical values for the irreducible saturation (S_i) range from 2% to 7%, depending on snow properties (Lemmela, 1973; Ebaugh and DeWalle, 1977; Colbeck, 1974a; Gerdel, 1948). Field and laboratory measurements show that, as with other porous media, the irreducible saturation (S_i) decreases with increasing grain size. Since snow grains grow in size with the introduction of liquid water, S_i decreases with time after snow is first wetted. As a result, water is initially stored in the pack and is then gradually released as the snow grains grow in diameter.

Relationships Between Water Saturation and Permeability

Marsh (1991) reviewed a number of relationships between water saturation, water pressure, and water permeability of snow. However, the most commonly used relationship relating saturated permeability (κ_s) to grain size and porosity (represented by density) was provided by Shimizu (1970) using both air and kerosene permeameters:

$$\kappa_s = 0.077 d^2 \exp\left[-7.8\frac{\rho_d}{\rho_w}\right] \tag{3}$$

where d is the grain size, ρ_d and ρ_w are the dry snow density and liquid density respectively. Shimizu (1970) found that this equation was applicable to new snow, fine-grained compact snow, and coarse-grained snow. For snow density between 300 and 500 kg m^{-3} and grain size between 0.4 and 2.0 mm, κ_s ranges from 1 to 20×10^{-9} m^2. Equation (3) has often been used for both snow (Marsh, 1991) and firn (Ambach *et al.*, 1981).

Sommerfeld and Rocchio (1993) provided measurements of the relationships between snow density, grain size, and permeability, and suggested the following:

$$\kappa_s = 1.096x10^{-8} \exp[-9.57\rho_d] \tag{4}$$

Major differences noted by Sommerfeld and Rocchio (1993) between equations (3) and (4) include (i) the inclusion of the grain-size term did not improve the relationship; and (ii) permeability at any density averages about half of that suggested by equation (3). Sommerfeld and Rocchio (1993) suggested a number of reasons for these differences, including differences in snow type. They felt that, because

of the small sample size, their results were not definitive and that further studies are required.

Jordan *et al.* (1999), considered the relationship between permeability, capillary rise, and pore structure. Their results show a linear relationship between permeability and the ratio of porosity and the square of capillary rise, and suggest that this is in agreement with Shimizu's equation above.

Saturated (κ_s) and unsaturated permeability (κ) for varying water saturation are related by:

$$\kappa = \kappa_s (S^*)^{\varepsilon} \tag{5}$$

where $\varepsilon = \eta/\lambda$, and η and λ are exponents in relationships between either S^* or κ, and water pressure (Marsh, 1991). Unfortunately there are few estimates of the values of these parameters. However, Wankiewicz (1979) suggested the values for both η and λ from a limited number of samples. Substituting his values for η ($= 13$) and λ ($= 4$) gives $\varepsilon = 3.3$. This value was suggested by Colbeck (1978) for natural snow covers and is similar to the reported values of approximately 2.5 to 5.5, with a median value of 3.5, for sand (Mualem, 1978).

Grain Growth in Wet Snow/Firn

One of the major differences between water movement through typical porous media such as sand and through snow is that snow particles grow rapidly in size with the introduction of liquid water, with the resulting increasing liquid permeability (see Section "Relationships between water saturation and permeability").

The processes responsible for grain growth in wet snow, which at the larger scale is isothermal at 0 °C, have been described in a series of articles by Colbeck (1973, 1974b, 1979a, 1980). Grain growth occurs because of the effect of grain size on the equilibrium temperature among the solid, liquid, and vapor phases of water at the scale of individual grains, with the melting temperature increasing with increasing grain size. The resulting temperature gradient between particles of different radii, produces a heat flux from the larger to the smaller particles, with the larger grains growing at the expense of smaller grains, smaller grains disappearing and the mean grain size increasing with time. Since the heat flux is predominantly through the liquid/solid interface, the heat flux and therefore growth rate is greater with larger water saturations.

Observations of grain growth under saturated conditions in the laboratory (Wakahama, 1968, 1974; Colbeck, 1986b) and in the field (Marsh, 1987) have agreed with theoretical predictions showing (i) the rate of grain growth declines with time; (ii) grain size slowly approaches infinity; and (iii) growth rate increases with increasing water saturation. Colbeck (1986b) suggested that the rate of grain growth could be estimated from:

$$d = d_o + A\ t^{B} \tag{6}$$

where d is the grain diameter (mm), d_o is the initial grain diameter (mm), t is the time in days since the snow was first wetted, and A and B are coefficients. For saturated snow, Colbeck (1986b) suggested that $A = 0.42$ and $B = 0.36$, while Colbeck (1976) estimated $A = 0.1$ and $B = 0.5$ for pendular saturations, from the laboratory data of Wakahama (1968). Marsh (1987) used field observations to suggest $A = 0.44$ and $B = 0.89$.

Brun (1989) provided the first laboratory measurements of grain growth at low water contents typical of natural snowcovers. These results agreed with earlier studies, and confirmed that the mean volume of snow crystals increases at a constant rate, that the rate of increase increases with water content, and that the rate of increase can be expressed as a power function of the water content.

Pressure Gradients in the Snowcover

Assuming that the lower ($S_w = 0.07$) and upper ($S_w = 0.14$) boundaries of the pendular regime are representative of the water-saturation regime of natural snowpacks, then the resulting water pressures vary from approximately -500 to near $-4000\,\mathrm{N\,m^{-2}}$ (Marsh, 1991; Wankiewicz, 1979; Jordan, 1983a). As a result, the pressure gradients in freely draining snowpacks are relatively small (Colbeck, 1978; Wankiewicz, 1979; Pfeffer and Humphrey, 1996) and can often be ignored. However, there are a number of situations where the pressure gradient may be large. These include water flux at very low-flow rates, in the zone immediately above wetting fronts (Pfeffer and Humphrey, 1996), in snowpacks with closely spaced laminations, and above interfaces either within the snow or at the snow pack base. For example, Marsh (1991) showed a hypothetical case where the pressure gradient was $-180\,\mathrm{N\,m^{-2}\,m^{-1}}$ for the gravity-flow zone, and $-8500\,\mathrm{N\,m^{-2}\,m^{-1}}$ in a 0.07 m zone above an impermeable layer.

WATER FLUX INTO DRY SNOW/FIRN

Melting at the snow surface results in the percolation of liquid water into the underlying snow/firn. This movement of water into dry snow/firn is dominated by: (i) the development of a wetting front that separates wet snow/dry snow; and (ii) if the lower layer is below 0 °C, the refreezing of water within the snow. The resulting time lag between the melt and runoff is dependent on whether the snow was dry or already wetted, the snow temperature and snow depth. For seasonal arctic snowpacks, runoff to the stream channel can be delayed by up to 10 days (Marsh and Woo, 1984b), while for deep temperate snowpacks and cold glaciers and ice caps, the delay between melt and runoff may be longer. For glaciers and icecaps, these processes have significant implications for increased runoff and sea level rise under potential climate warming (Pfeffer *et al.*, 1990). Pfeffer

et al. (1991), for example, suggested that refreezing may reduce the runoff contribution from Greenland under a warmer climate by up to 0.4 mm year^{-1} sea level equivalent. Pfeffer *et al.* (1991) reviewed the literature on the influence of freezing on numerous aspects of cold glaciers, including glacier mass balance, changes in snow/firn density and structure, and the interpretation of ice cores.

Field observations of wetting fronts and freezing are difficult to obtain as even slight disturbance of the snow can change the thermal regime of the snow substantially because of the large variability in stratigraphy over small spatial scales and the lack of appropriate measurement techniques. Numerous studies have mapped the location of ice layers and pipes in snow pits (Marsh, 1991; Bøggild, 2000), while Marsh and Woo (1984a) used covered snowpits and excavated the snowpit wall daily to map sequential changes in wetting front locations, ice layers, and columns. Other studies have used tracers (Schneebeli, 1995), snow thick sections (McGurk and Marsh, 1995), buried temperature sensors (Conway and Benedict, 1994; Pfeffer and Humphrey, 1996), heat-flux transducers (Sturm and Holmgren, 1993), and Frequency Modulated Continuous Wave (FMCW) radar (Albert *et al.*, 1999) to infer water movement through the snowpack, and subsequent changes to the snowpack.

Wetting Fronts

The movement of liquid water into dry snow is controlled by capillary forces, which raise the liquid water content from zero to the irreducible water saturation (S_i) (Pfeffer and Humphrey, 1996). The resulting wetting front splits the snow into distinct zones (Yosida, 1973): (i) an upper layer of wet snow that is isothermal at 0 °C (noting that snow is not truly isothermal because of grain-scale temperature gradients that result in grain growth in wet snow) and (ii) a lower dry zone where the liquid water content is zero and the temperature is less than or equal to 0 °C. Pfeffer *et al.* (1990) describe a third zone between these two zones. This dynamic zone is composed of subfreezing snow grains surrounded by water at 0 °C. Unlike pores in soils, snow pores are too large to allow supercooling of water, and as a result, this dynamic zone in snow/firn is in thermodynamic disequilibrium (Pfeffer *et al.*, 1990). This dynamic wetting zone is typically small (less than one cm) and can often be ignored.

The heat and mass transfer in these zones can be described as follows. In the wet isothermal zone, mass and latent heat are transferred by water flow. No sensible heat or conducted heat is transferred as the zone is isothermal at 0 °C. In the dry zone, energy transfer is only by conduction along temperature gradients. In the dynamic zone, energy is transferred by mass transfer and by the release of latent heat of freezing. This energy is transferred from the 0 °C water to the subfreezing snow grains by conduction.

In temperate snowpacks, the snow often reaches an isothermal state before meltwater moves through the snowpack, while in cold snowcovers, the lower portions of the snowpack have a temperature below 0 °C at the start of melt. In this situation, the snowpack is warmed to 0 °C by the refreezing of water within the snowpack, and the subsequent conduction of heat through the dry snow.

Calculating Uniform Wetting Fronts without a Dynamic Zone

Colbeck (1974a) suggested that capillarity diffuses the leading edge of wetting fronts, but that the effect is small compared to the diffusive effect of flow fingering. As a result, and in order to simplify wetting front calculations for estimating the delay between melt and runoff, it is possible to ignore the dynamic zone and to assume that the wetting front is a discontinuous front where the water content jumps from zero to irreducible.

Given these assumptions, the downward rate of wetting front movement is controlled by (i) filling the irreducible water saturation (S_i) and raising the water saturation (S_w) to a level greater than S_i that is sufficiently large to transport the water flux (U) immediately above the wetting front; (ii) if the snow has a temperature below 0 °C, the refreezing of meltwater onto the snow grains at the leading edge of the wetting front. This results in the release of latent heat of fusion, and the raising of the snow temperature immediately below the wetting front to 0 °C. It is assumed that the rate of heat conduction away from the wetting front is sufficiently rapid that it can transfer all of the heat released by the freezing process. In most cases of low water flux and uniform wetting fronts, this assumption is reasonable. When these liquid and thermal storages are filled, additional water is available to move the wetting front downward, but the rate of movement of the wetting front is always slower than that of the meltwater above the wetting front (Yosida, 1973). The downward rate of movement of a horizontal, one-dimensional wetting front ($d\xi/dt$) is then given by (Colbeck, 1976):

$$\frac{d\xi}{dt} = \frac{U}{\phi S_w + (\phi - 1)\dfrac{T_s \rho_i}{(L_f/C_i)\rho_w}} \tag{7}$$

where U and S_w are the melt-water flux and water saturation immediately above the wetting front, ϕ is the snow porosity, T_s is the snow temperature immediately below the wetting front, ρ_i and ρ_w are the ice and water densities respectively, L_f is the latent heat of fusion, and C_i is the specific heat of ice.

For temperate snow with a temperature above approximately −4 °C, the liquid requirements dominate the wetting front advance, while for regions with lower snow temperatures the thermal requirements dominate (i.e. Marsh and Woo, 1984a).

Preferential Flow Paths

Preferential flow paths occur during fluid flow in many types of porous media (Glass *et al.*, 1989) due both to inhomogeneities in the porous media and to flow instabilities (e.g. Beven and Germann, 1982) that are triggered in both uniform and nonuniform media (Hill and Parlange, 1972; Raats, 1973; Glass *et al.*, 1989). In snow, these features are referred to as *flow fingers* (Colbeck *et al.*, 1990). One of the effects of flow fingers is to concentrate water into a smaller cross-sectional area than would occur with a uniform wetting front. For example, Marsh and Woo (1984a) and Kattelmann (1995) showed that flow fingers carry upwards of 70% of the total flow through only 20% of the horizontal cross-sectional area. In a laboratory experiment, Waldner *et al.* (2004) found that preferential flow paths occupied 10% of the horizontal cross-sectional area. Owing to their effect on flow, flow fingers have implications for solute release from snow (Marsh and Pomeroy, 1999), and they reduce the lag between melt and runoff (Marsh and Woo, 1984b; Bøggild, 2000). Examples of flow fingers in snow have been provided by Seligman (1936), U.S. Army (1956), Marsh and Woo (1984a), Kattelmann (1995), Albert *et al.* (1999), Schneebeli (1995), and Waldner *et al.* (2004). Waldner *et al.* (2004) found that flow fingers may have nearly or fully saturated conditions and are sharply delineated from the surrounding dry snow. This results in increased grain growth and therefore higher permeability and water flux.

Glass *et al.* (1989) noted that finger width increased with flow in porous media, and Kattelmann (1995) suggested that with low melt rates, flow fingers are small in size (up to 10 cm across) and occur at densities of up to $100\,m^{-2}$. These sizes are comparable to the mean finger diameter of 4 cm reported by Hill and Parlange (1972) for laboratory soils. Examples have been provided by Wankiewicz (1979), Colbeck (1979b), Marsh and Woo (1984a), Marsh (1988), Kattelmann (1995), McGurk and Marsh (1995), Albert *et al.* (1999), and Williams *et al.* (2000). With high flow rates, and especially with fresh snow, Kattelmann (1995) suggested that larger drains (approximately 30 cm in diameter) commonly occur. Examples have been provided by (Wakahama, 1968; Woo *et al.*, 1982; Kattelmann, 1995). Marsh (1991) suggested that these larger flow paths may also be related to dendritic rill patterns and the related internal flow channels described in a number of environments (e.g. Higuchi and Tanaka, 1982).

Although considerable research has been conducted on flow fingers in porous media (e.g. Glass and Yarrington, 2003), the processes controlling the development of preferential flow paths in snow are not well known. An early attempt to explain these processes was provided in Wankiewicz's (1979) "Flow Impeding, Neutral, or Accelerating"(FINA) conceptual model. FINA describes the interaction of water flux and snow layers as: (i) Impeding: flow is impeded if the snow water pressure required for gravity flow to occur is greater in the upper layer than the lower layer. In this situation, water accumulates above the snow layer boundary until the water pressure in the adjacent part of the upper snow layer increases to a value needed to force penetration of the lower layer. If the boundary is sloping, the stored water will move laterally downslope. (ii) Accelerating: flow is accelerated if the snow water pressure in the lower layer is less than that in the upper layer. In this situation the snow layer boundary will accelerate the flow as the wetting front becomes unstable at this boundary and fingering occurs in the lower layer. (iii) Neutral: layers have no effect on the flow if water pressures are similar on either side of the snow layer boundary. Wankiewicz (1979) hypothesized that the permeability – water-pressure relation for snow exhibits a crossover at some pressure, and as a result any given layer may be impeding, accelerating, or neutral depending entirely on the value of the flux.

On the basis of field observations, Pfeffer and Humphrey (1996) noted that impeding flow occurs most frequently in fine-to-coarse transitions in the snowpack. Waldner *et al.* (2004) described capillary barrier effects or impeding effects in a laboratory experiment with fine/coarse horizons. They also noted that coarse/fine horizons had little effect on water flow.

Waldner *et al.* (2004) carried out one of the few laboratory experiments that considered flow fingers in snow. From this work they suggested that the persistence of flow fingers is affected by two offsetting conditions. First, increasing grain size and permeability and the blocking of pores at the edge of flow fingers result in the persistence of flow fingers. In contrast to this, increasing pore size and high water contents result in gradual lateral movement of the flow fingers. Waldner *et al.* (2004) also noted that preferential flow is extremely nonlinear, and that the use of continuum concepts to model flow through snow using the Darcy–Buckingham law is inadequate for modeling preferential flow.

In addition, the flux value in flow fingers may be sufficiently large that the assumption for equation 7 may not be valid, and a dynamic zone of sufficient thickness forms. The implications of this are discussed in the following section.

Implications of a Dynamic Zone

As described in the previous section, a dynamic zone can develop between the upper wet layer, and the lower dry zone. With larger flux values, especially in flow fingers, this dynamic zone can be sufficiently large to affect the wetting-front advance.

The dynamic zone has two distinct temperatures: water at 0 °C and snow grains with a temperature below 0 °C. Heat fluxes include both intergrain conduction and latent heat from freezing of water onto the grains. Pfeffer *et al.* (1990) suggested that the latent heat fluxes are much larger than the intergrain fluxes, which could therefore be ignored.

Although the dynamic zone is small and can be ignored in simple models of wetting fronts, it is necessary to consider this process in numerical models for use in cold snow (Pfeffer *et al.*, 1990).

Including the dynamic zone in numerical models requires detailed knowledge of the temperature profile, the 3-D snow grain geometry, and the pore scale flow paths. Since such information is not easily obtained, Pfeffer *et al.* (1990) described two possible approaches using simple snow pack geometries. One of these represented snow grains as isolated spheres, and the other considered the flow paths as capillary tubes in ice. Model results suggest that the time required for snow grains to be warmed to 0 °C is of the order of 0.5 s and, as a result, can be ignored in simulations considering the time delay between melt and runoff. However, for detailed models of the physics of water flow, the dynamic zone must be considered.

Refreezing Within Snow/Firn

As noted previously, freezing of meltwater occurs at wetting fronts in order to raise the snow temperature to the freezing point. Depending on a number of factors, the freezing may be sufficient to block the pore spaces, resulting in ice bodies. For uniform wetting fronts, freezing does not fill all pore spaces. However, where the snow is sufficiently cold, freezing may fill all the pore spaces, resulting in an ice body (Colbeck, 1978).

Marsh and Woo (1984a) noted that all refreezing occurs within a zone of mixed wet and dry snow (this is not equivalent to the dynamic zone). This mixed wet and dry snow zone, with wet areas at 0 °C and dry areas with a temperature below 0 °C, occurs between the uniform wetting front and above the deepest flow finger. Within this zone, refreezing of meltwater occurs in various locations. First, as given in equation 7, freezing occurs at the leading edge of the wetting front. This adds mass to the ice grains, but typically is not sufficient to block the snow pores. Second, under certain conditions, the heat flux from the wet snow to the dry, cold snow is large enough to freeze sufficient water to fill the snow pores, resulting in ice bodies. This commonly happens (i) within flow fingers to form vertical ice columns, (ii) at premelt stratigraphic layers to form horizontal ice layers, and (iii) at the base of the snowcover to form an ice layer overlying the underlying impermeable surface. For terrestrial snowcover, this ice layer is referred to as *basal ice* (Woo *et al.*, 1982; Gardner, 1983), while on glaciers it is called *superimposed ice* (Wakahama *et al.*, 1976; Wadham and Nuttall, 2002). Depending on the amount of freezing, ice bodies may be composed of large polycrystalline melt-freeze particles (3 – 5 mm in diameter), which are frozen together into a permeable, honeycomb structure, or if freezing continues, low-permeability ice with a density of over 800 kg m^{-3} forms (Marsh and Woo, 1984a). Albert and Perron (2000) used a permeameter to measure permeabilities for ice layers between 1 and 3 mm in thickness. Typical values were between 1×10^{-10} and 19×10^{-10} m^2, a value considerably higher than for typical snow (equation 3). As noted by Langham (1974b) and Albert and Perron (2000), the permeability of ice layers often doubled within 24 h early in the melt period.

Ice columns form because of the heat flux from the flow finger to the surrounding dry, subzero snow. Growth ceases either when the snow surrounding the ice columns is warmed to 0 °C by conduction of the latent heat released by the freezing of water in the ice column, or when the ice column is overtaken by the background wetting front. Ice columns are similar in size and distribution to flow fingers (Marsh and Woo, 1984a; Kattelmann, 1995), with both small, evenly spaced columns and irregularly spaced, large columns found in both seasonal and perennial snow (Sharp, 1951).

When flow fingers reach a premelt impeding horizon, water spreads laterally along the horizon, with dry, subzero snow both above and below the horizon. This wet layer freezes to form a horizontal ice layer. The rate of ice-layer growth and the total thickness of the layer are related to the heat flux into the dry snow above and below it. Ice layers cease growing for the same reasons as noted for ice columns. Ice layers are commonly of 1 mm to 200 mm in thickness, and vary in horizontal extent from less than 0.2 m to more than 3 m (Langham, 1974a; Marsh and Woo, 1984a).

Basal/superimposed ice forms when the substrate is impermeable and has a temperature below 0 °C and therefore a negative heat flux from the snow to the substrate during snowmelt. Freezing continues until the substrate heat flux is reduced to zero, or the snowcover is removed by melting. Basal ice layers may grow for longer periods of time, and therefore develop greater thicknesses (up to 0.71 m reported by Woo *et al.*, 1982 for a seasonal snowcover) than ice layers within the snowcover. Longer periods of basal ice formation may occur at the base of thick perennial snowpacks. The development of superimposed ice on glaciers may also continue for many weeks, and results in the development of very thick superimposed ice layers. For example, Wadham and Nuttall (2002) describe superimposed ice formation on a high Arctic glacier in both early winter and summer, with the summer formation occurring for over five weeks. The formation of such ice layers plays an important role in the mass balance of such glaciers.

The relative importance of freezing at the wetting front as ice columns or ice layers is not well known. For a cold arctic snowcover, Marsh and Woo (1984a) reported that ice columns were a minor component, with the majority of freezing split between the wetting fronts and ice layers. In this case, the wetting fronts accounted for approximately

12% and ice layers 88% of the total refreezing within the snowpack.

The total volume of water that refreezes is determined by the initial snow temperature and the soil heat flux. In temperate areas, the soil heat flux is negligible, so that refreezing in the snow is controlled entirely by the cold content of the snow. When the snow is underlain by frozen soil, however, the soil heat flux can be large. For example, Marsh and Woo (1987) reported a soil heat flux of $-80\,\mathrm{W\,m^{-2}}$ (i.e. from the snow to the soil). This increased the refreezing within the snow by up to four times compared to that due to the snow cold content alone.

Modeling Wetting Fronts and Refreezing

Analytical, Quasi-two-dimensional Models

Marsh and Woo (1984b) described a quasi-two-dimensional model (MW model) that included the effect of flow fingers, the growth of ice layers, heat flux within the combined snow/soil system, and soil infiltration. The MW model considered the fingering phenomenon by incorporating a two-component wetting front, with one section representing the background front and the other depicting the finger front. It did not, however, consider the development of ice columns. The relative width and the volume of water reaching each front was determined from field observations. The water fluxes at the finger front (U_f) and background front (U_b) were then calculated as:

$$U_\mathrm{f} = U\left(\frac{F_\mathrm{f}}{A_\mathrm{f}}\right) \tag{8}$$

$$U_\mathrm{b} = U\left[\frac{(1-F_\mathrm{f})}{(1-A_\mathrm{f})}\right] \tag{9}$$

where U is the mean surface flux due to either snowmelt or rainfall. U_f and U_b can then be substituted into equation 7 to calculate the velocity of each front.

Freezing of water in the snow was calculated both directly at the wetting fronts from equation (7) and at ice strata within the snowpack. This occurred when the ice stratum was located between the two wetting fronts, with the rate of ice-layer growth controlled by the temperature gradient above and below the ice layer. As long as the water supply from the flow fingers was greater than the rate of freezing, the rate of heat released by freezing equaled the rate of heat conduction away from the ice layer. The water flux reaching the finger front was reduced by the rate of growth of the ice layers, and as a result, the finger front only advanced when the water flux in the fingers was greater than the rate of ice-layer growth. If there was no excess water, then the finger front did not move downward until either the rate of ice-layer growth declined, or the water flux increased.

The MW model also included the heat flux between the snow and soil, the infiltration of meltwater into the soil, and the freezing of this infiltrated water. In addition, if the soil infiltration capacity was exceeded and the soil heat flux was negative (i.e. from the snow into the soil), then a basal ice layer was allowed to form at the snow/soil interface. If a basal ice layer formed, it continued to grow until the underlying soil was warmed sufficiently to decrease the soil heat flux to zero. The growth of the basal ice layer limited the volume of water immediately available to runoff.

The MW model simulated a number of important features of wetting front and icelayer interaction. First, it showed that for cold arctic snow covers the rate of ice-layer growth could be sufficiently large to stop the finger-front advance for short periods of time. Second, ice layers were primarily responsible for warming the snow to near 0 °C, such that by the time wetting fronts entered dry snow, the snow temperature had been raised to near 0 °C. A third result was that the velocity of the background front was not affected by the initial snow temperature, while the finger-front velocity varied greatly with the initial snow temperature. This was not due to freezing at the wetting front, but due to the abstraction of water from the finger to grow ice layers.

VERTICAL, UNSATURATED WATER FLUX IN WET SNOW

Given typical low melt and rainfall rates, and the coarse-grain size and high permeability of wet snow, the vertical flux of water through freely draining, wet snow that is isothermal at 0 °C, is always nonsaturated. Various studies, including Colbeck (1972) and Jordan (1983a), for example, have considered water flux in such conditions. Owing to the complexities of metamorphic changes to wet snow, however, it is usually assumed that such changes are sufficiently slow that they can be ignored, and that the snowcover can be regarded as a simple, rigid porous medium. The following provides a brief overview of the processes controlling water flux through wet snow and various methods for modeling it.

Darcian Flow

Assuming that the snow is within the pendular regime and blockages do not occur, the downward water fluxes are balanced by an equal upward flux of air. The downward, nonsaturated flux of water (U) may be written as

$$U = -\left[\frac{\kappa_\mathrm{s}}{\mu_\mathrm{w}}\right]\left[\frac{\partial p_\mathrm{w}}{\partial z} + \rho_\mathrm{w} g\right] \tag{10}$$

where z is the elevation above a datum, and the permeability (κ) is related to hydraulic conductivity by

$$\mathrm{K} = \kappa \frac{\rho_\mathrm{w} g}{\mu_\mathrm{w}} \tag{11}$$

where ρ_w and μ_w are the density and dynamic viscosity of the water respectively and g is the acceleration due to gravity.

Modeling Vertical, Unsaturated Water Flux

The use of Darcy's Law for modeling unsaturated flow in snow has generally involved either the gravity-flow solution derived by Colbeck (1972, 1978) (i.e. Dunne *et al.*, 1976; Marsh and Woo, 1985), or the application of numerical techniques (i.e. Jordan, 1983b; Bengtsson, 1982; Illangasekare *et al.*, 1990).

Gravity-flow Model

For vertical percolation, where the water pressure gradients are normally less than 2% of the gravitational gradient, the effects of the pressure gradients are usually ignored, and equation (10) simplifies to

$$U = -\frac{\kappa}{\mu_\mathrm{w}} \rho_\mathrm{w} g \tag{12}$$

Colbeck (1972, 1978) used Darcy's Law and an analytical solution of the continuity equation to calculate water flux through wet, ripe snow. Colbeck assumed that the permeability followed a power relationship between the saturated permeability and the effective water saturation, and that the downward flux of water was balanced by the upward flux of air. Using a continuity equation and solving by the method of characteristics, Colbeck showed that any value of flux U propagates through the snow at the speed ($[\mathrm{d}z/\mathrm{d}t]_U$) given by

$$\left[\frac{\mathrm{d}z}{\mathrm{d}t}\right] U = \frac{\varepsilon \alpha^{1/\varepsilon} \kappa^{1/\varepsilon}}{\phi^*} U^{(\varepsilon-1)/\varepsilon} \tag{13}$$

where ϕ^* is the effective porosity calculated as $\phi^* = \phi(1 - S_\mathrm{i})$, and ϕ is the snow porosity.

Equation (13) shows that for constant snowcover properties, the rate of movement of flux U increases with increasing melt-water flux. As a result, during diurnal snowmelt events slow-moving fluxes in the morning are overtaken by faster-moving afternoon fluxes, and a flow discontinuity or shock front develops which is bounded by large fluxes ($U+$) above the front and smaller fluxes ($U-$) below the front. The rate of propagation of this shock front ($\mathrm{d}\zeta/\mathrm{d}t$) can be calculated as (Colbeck, 1978):

$$\frac{\mathrm{d}\zeta}{\mathrm{d}t} = \alpha^{1/\varepsilon} \frac{{\kappa_s}^{1/\varepsilon}}{\phi} [U+^{(\varepsilon-1)/\varepsilon} + U+^{1/\varepsilon} + U-^{1/\varepsilon} + U-^{(\varepsilon-1)/\varepsilon}] \tag{14}$$

Equations (13) and (14) may be used to predict the water flux through unsaturated, wet, ripe snow. The snowpack parameters required to use these equations include κ_s, ε, ϕ, and S_i.

The surface melt data used as the input are normally obtained from calculation of surface melt, which may be determined from either temperature-index or energy-balance methods (Male and Gray, 1981). The output is the water flux at any depth within the cover. This technique has been successfully applied to seasonal snow (Marsh and Woo, 1985) and firn (Ambach *et al.*, 1981).

Albert and Krajeski (1998) provided an analytical solution to water flow through snow – a method that is more easily implemented in a computer model than Colbeck's equations (13) and (14), but which provides very similar results.

Gravity-flow Methods for Uniform Snow/Firn

The gravity-flow equations may be used to reconstruct the melt-flux hydrograph at any depth in the snowpack. Dunne *et al.* (1976) described a graphical method for applying equations (13) and (14). Tucker and Colbeck (1977) developed a Fortran program that utilizes these two equations, and Albert and Krajeski (1998) used another analytical approach. Either approach provides satisfactory results, reproducing the major components of melt-water flux waves that have been observed in snow covers. For example, with increasing snow depth the rise to the peak steepens, the peak flow decreases in volume and arrives later, and the recession limb of the hydrograph lengthens and the minimum flow increases.

The gravity-flow model predicts the general timing of the rise to the peak and the recession from the peak in both homogeneous and heterogeneous snow. A common problem, however, is modeling the rising limb of the flux wave and the magnitude of the peak flux. In homogeneous snow, this problem is related entirely to the effect of pressure gradients that diffuse the wetting front. As a result, a shock front does not form. In heterogeneous snow, the problem with the rising limb is even more pronounced because of the additional effect of flow fingers, ice layers, and pressure gradients at interface boundaries. The effects of flow fingers and ice layers are believed to dominate, increasing the flow in some sections of the pack and decreasing it in others. This highly variable flow over short horizontal distances results in flow velocity being increased in some sections and decreased in others. The overall effect is that, on a sufficiently large scale, the rising limb is diffused. The relative importance of the pressure gradients versus flow fingers and ice layers in diffusing the rising limb is not well known.

Two methods have been used to overcome these problems. The first considers the snowpack as an equivalent uniform medium which accurately represents a natural, heterogeneous porous medium (Freeze, 1975; Colbeck, 1975,

1979b). This approach uses a snowpack equivalent permeability that is obtained from lysimeter measurements of water flux through snow (McGurk and Kattelmann, 1986; Marsh, 1991). The second approach, which is described in the following section, uses a multiple flow path model to estimate the effects of such variable flow in heterogeneous snow/firn.

Heterogeneous Flow in Snow/Firn

Water flux through wet snow is usually highly variable over short horizontal distances. Marsh and Woo (1985) used lysimeters to demonstrate flow variability at the sub-1 m^2 scale. They measured flow variability with standard 0.25 and 1.0 m^2 lysimeters and a 0.25 m^2 multicompartment lysimeter with 16 separate compartments. They found that between lysimeters, the flow was relatively uniform, always being within approximately 10% of the mean flow. Within a lysimeter, however, the flow varied from 0 to 240% of the mean flow. Although the multicompartment lysimeter was composed of discrete compartments, Marsh and Woo (1985) suggested that in reality the flow varied continuously from areas of high flow to areas of low flow, so that the flow could be characterized by a smooth curve. The degree of variability was dependent on flow volume, being more variable on low-flow days and less variable on high-flow days. In addition, they noted that the variability did not seem to be related to the number of ice layers in the snowcover or the snowcover depth. These characteristics of the variation in flow were caused by several factors: (i) the ice layers did not have distinct drains, but instead had continually varying permeability, such that the flow was concentrated beneath some areas and depleted between others with a smooth variation between the extremes; (ii) the principal effect of multiple ice layers is not to increase the flow variability, but instead to redistribute the location of high- and low-flow zones; and (iii) with increasing flow, lateral redistribution both at ice layers and within the flow helps to even out the flow. Kattelmann (2000) used lysimeters up to 10 m^2 in area to consider the spatial variability of flow in deeper, mountain snowpacks. He suggested that the rule of thumb that the flow of water is uniform over areas greater than the square of the snowpack depth is reasonable (Male and Gray, (1981)).

McGurk and Kattelmann (1988) and McGurk and Marsh (1995) used thick-section photography to demonstrate the existence of areas of larger grain size, which they interpreted as flow fingers with higher flow rates. These studies showed flow finger spacing at a scale similar to that of Marsh and Woo (1985).

Sommerfeld *et al.* (1994) and Williams *et al.* (1999) reported integrated studies from lysimeters, aerial photographs, and surface wetness measurements to demonstrate that flow variability also occurred at a larger scale than showed by Marsh and Woo (1985). They demonstrated that a correlation length of 5 to 7 m was typical. Other studies by Schneebeli (1998) also showed preferential flowpaths at a scale of 5 m.

Multiple Flow-path Models

Colbeck (1979b) suggested that variations in flow could be modeled by extending the "gravity-flow theory ... to describe simultaneous flow along different paths", including flow along fingers and flow that passes directly through ice layers. Colbeck described a technique that accomplished this by including the generation of fingers at each ice layer, with the flow in each finger being larger than the background flow. The application of this model was limited by the need to know (i) the number of ice layers; (ii) the number of fingers generated per unit area at each ice layer; and (iii) the flow in each finger. Marsh and Woo (1985) took a different approach in developing a multiple flow-path model based on Colbeck's gravity-flow theory. Instead of modeling the interaction with each ice layer, they made direct measurements of the flow variability in natural snow covers and then used this information to scale the flow in each flow path. Using this approach there is no need to know whether flow fingers, ice layers, or grain growth in wetter parts of the pack are responsible for variations in flow. Instead, all that is required is knowledge of the distribution of flows. To be applied to different snow covers, therefore, it is necessary to either measure the flow variability or to develop relationships between snow properties and flow variability. A major assumption of this model is that each flow path extends the complete depth of the snowcover and that the lag time due to lateral flow along ice layers or the residence time at each ice layer can be ignored.

In the examples given by Marsh and Woo (1985), 10 flow paths were used as a compromise between accuracy in representing the continuum of flow conditions and increased computation time. The flux in each path is then calculated as:

$$U_{\mathrm{F}}(j) = U(j)\left(\frac{V}{S}\right) \tag{15}$$

where $U_{\mathrm{F}}(j)$ is the flow in each path for hour j, $U(j)$ is the mean surface flux, S is the fraction of unit area covered by each path ($S = 0.1$ for 10 flow paths) and V is the percent of flow occurring within each flow path. This was determined from the multicompartment lysimeter measurements. For example, using measured flow data, the path (10% of the total area) with the least water would carry approximately 6% of the total flow, while the path (10% of the total area) with the most water would carry 22% of the total flow.

Since the arctic snowpacks studied by Marsh and Woo (1985) did not exhibit large lateral variations in snow properties, each flow path was assumed to have the same snow properties. The snow permeability was calculated

from equation (3), the water flux in each path was then calculated from equations (13) and (14) using the program of Tucker and Colbeck (1977) and the total flow from all flow paths was calculated by summing all the individual paths. The results of this model predicted the time of the hydrograph rise to within 1 h without any systematic error in flow magnitude. The rate of rise to the peak, the peak flux and the recession were also in good agreement with the observed.

In order to apply the Marsh and Woo (1985) multi flow-path model to different environments it is necessary to know the relationship between flow variability and snowpack properties in different environments. Do different snow covers respond differently in terms of flow variability, or are the flow variability data presented by Marsh and Woo (1985) representative of snow in other environments? Unfortunately the answer to this question is not well known. Examples of other environments are shown by Kattelmann (1995), Sommerfeld *et al.* (1994), and Williams *et al.* (1999).

NUMERICAL MODELS

Various methods have been used to develop numerical models of water movement through snow (Illangasekare *et al.*, 1990; Tseng *et al.*, 1994; Gray, 1996; Sellers, 2000). Each has various advantages and disadvantages, but all are currently limited by basic unknowns of the physical properties of snow. Given these limitations and the extensive nature of the equations, details of various numerical models will not be given in this article. Instead, readers are directed to the original articles.

Illangasekare *et al.* (1990) and Tseng *et al.* (1994) presented a numerical model of melt-water infiltration into subfreezing snow. This model was developed to consider the physics that govern wetting front advance into snow, and to allow a variety of numerical experiments to consider the importance of various processes described earlier in this article. It was hoped that such an approach would overcome limitations caused by the assumptions required in the above-mentioned models, including the consideration of the dynamic zone, capillary pressure gradients, and 1-D flow, for example.

The model of Illangasekare *et al.* (1990) and Tseng *et al.* (1994) is a two-dimensional, finite element, numerical model that includes an explicit coupling between water flow through partially saturated snow, phase change through the refreezing of meltwater in subfreezing snow, and heat conduction. As noted by Tseng *et al.* (1994) water flow in subfreezing snowpacks is highly complex, and as a result, there was a need to make a number of assumptions for want of experimental data. Some of these include (i) no fingering at the wetting front; (ii) no snowpack settling; (iii) condensation, sublimation, and evaporation within the snowpack are ignored; (iv) heat flux due to convection of air or water is ignored; (v) the dynamic, or nonequilibrium zone is neglected; (vi) hysteresis is ignored; (vii) freezing point depression is ignored; and (viii) there is no transfer of momentum due to viscous or frictional forces. Although these assumptions affect the generality of the model, they still allow the model to be used for investigating various aspects of melt-water infiltration into subfreezing snow. The authors also note that there are severe limitations on the use of this type of model due to uncertainties in the snow-water characteristic curves, which describe the pressure-water saturation relationship and the uncertainties in the water saturation-permeability relationships.

Gray (1996), who also considered various numerical approaches to numerical modeling of water flux in wet snow, noted that these models encounter severe difficulties at low saturation and fail completely when saturation approaches zero. Solution of these problems requires studies into alternate capillary pressure relations. Sellers (2000), presented a numerical model solution based on Colbeck's theory of water transport through snow, which is extended to account for the movement of the snow surface due to surface melting.

SATURATED FLOW

Saturated conditions only occur at impeding layers within the snowcover and at the base of the snowpack if the snow is overlying an impermeable surface. If this saturated layer is sloping, then horizontal, saturated flow occurs along the slope. Flow within this layer can be calculated following the methods of (Colbeck, 1974c). Wankiewicz (1979) suggested that laminar flow occurs only if slopes are less than 10°, and grain size and density are less than 0.5 mm and 300 kg m^{-3} respectively. The existence of nonlaminar, or turbulent flow in snow is suggested by the occurrence of open conduits or macropores. They are common in both ice and firn in glaciers and they have also been reported in ice layers at the base of arctic snow cover (Woo *et al.*, 1982). Kattelmann (1985) reported circular openings of between 5 mm and 3 cm in diameter as well as larger features (from 3 cm in diameter up to 1000 cm^2 in cross section), which were oval in cross section with the width exceeding the height. These macropores were located in the bottom one-half meter depth of the snowpack, with grain diameters of about 2 mm and on slopes of temperature less than 10°.

CONCLUSION

A number of studies conducted over the last few decades have greatly improved our understanding of water flux through snow and firn. As a result, there is considerable

knowledge of the development of wetting fronts in dry snow, the growth of ice layers and columns within the snowpack, and a variety of models for calculating runoff from melting snow covers. Even though there have been a number of attempts to develop numerical models of water flux through cold snow, these have had limited success. The primary deficiency with these models is the lack of understanding of critical processes. Part of the problem is a lack of data, which is due to the great difficulty of conducting experiments on snow near 0 °C. There are deficiencies in our ability to measure the properties of snow required for estimating the value of parameters needed for numerical simulations. The changes in hydraulic properties (porosity and permeability) are not currently measurable, and the ever-changing properties of snow make comparable experiments difficult. In order to overcome these problems, there is a need for the development of new measurement techniques and carefully designed field and laboratory experiments to provide the necessary information required to formulate comprehensive physically based models of snow metamorphism and water flux. These models are required for predicting not only melt runoff, but also the release of pollutants from the snowcover, the large-scale properties of the snowcover necessary for understanding large-scale energy-balance and global-change problems, and the release of meltwater from cold glaciers and icecaps under future climate scenarios.

162: Hydrology of Snowcovered Basins

BRUCE DAVISON AND ALAIN PIETRONIRO

Environment Canada, National Hydrology Research Centre, National Water Research Institute, Saskatoon, SK, Canada

Snowcovered catchments are an integral part of the earth's physical, chemical, and biological regulatory processes. Catchment-based assessments of snow are typically derived from snow surveys and snow courses. Remote sensing is also a valuable tool for use in understanding the nature and distribution of snowcover in a catchment. Snowcovered basin classifications are founded on the source and timing of runoff and the characteristics of the snow. In order to understand the hydrology of snowcovered catchments, it is important to understand the physics of snowmelt and other related phenomena, such as canopy effects that influence the temporal and spatial distribution of snow within a catchment, including both the energy and mass balance components. Operational temperature index models for basin snowmelt and statistical models for horizontal snowcover distribution help approximate some of the physical processes that are not (or cannot be) directly measured. Hydrological models are an attempt to articulate an understanding of the complex and nonlinear interactions within the hydrological cycle using a rational mathematical approach such as an index method or the energy balance approach. A number of projects have been completed or are underway to compare these models. Hydrological applications, avalanche forecasting, weather forecasting, and climate modeling have all driven snow research, with much cross fertilization between these fields.

INTRODUCTION

Large areas of the earth are covered by seasonal or permanent snow. Catchments located at higher altitudes and/or latitudes tend to experience the most snow. In the Southern Hemisphere, less land at lower latitudes limits the amount of snow on the surface of the earth, but results in larger areas covered by sea ice. Figure 1 illustrates the spatial and temporal distributions of snowcover in the Northern Hemisphere for four time periods (Groisman *et al.*, 1994).

In many countries, snow accounts for the largest portion of the water budget. The spring runoff event (freshet) generally produces the annual maximum flow in all but the smallest of rivers. The hydrology of snowcovered basins has long been a focus of study by the hydrological sciences community. As noted in Gray and Male (1981), snow can be a pervasive element that temporarily paralyzes a community. It may have adverse economic impacts when it manifests itself in an extreme form and it has been responsible for many military and socioeconomic failures. Nonetheless, snowcovered basins provide the world with much of its hydroelectric capacity, irrigation and drinking water, and countless recreational opportunities.

Historically, operational hydrologists studied snowcovered basins to determine the snowmelt runoff in these basins. Runoff estimates were used in reservoir management and planning for consumptive use, power generation, public works, and land development. As a result, a number of snowmelt hydrological models were developed to predict snowmelt runoff with a focus on capturing or predicting peak flows and volumes for engineering design and reservoir management purposes. There is also a great need to understand the hydrology of snowcovered catchments for protection against snowmelt-induced floods.

The influence of snow in flooding depends on a number of factors, including basin size, the amount of snow in the basin prior to spring breakup, ice jamming, and the ability of the basin to store melt and rainfall. The importance of these factors is different in different regions. At one extreme, small urbanized catchments with little basin storage experience their annual maximum flood

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

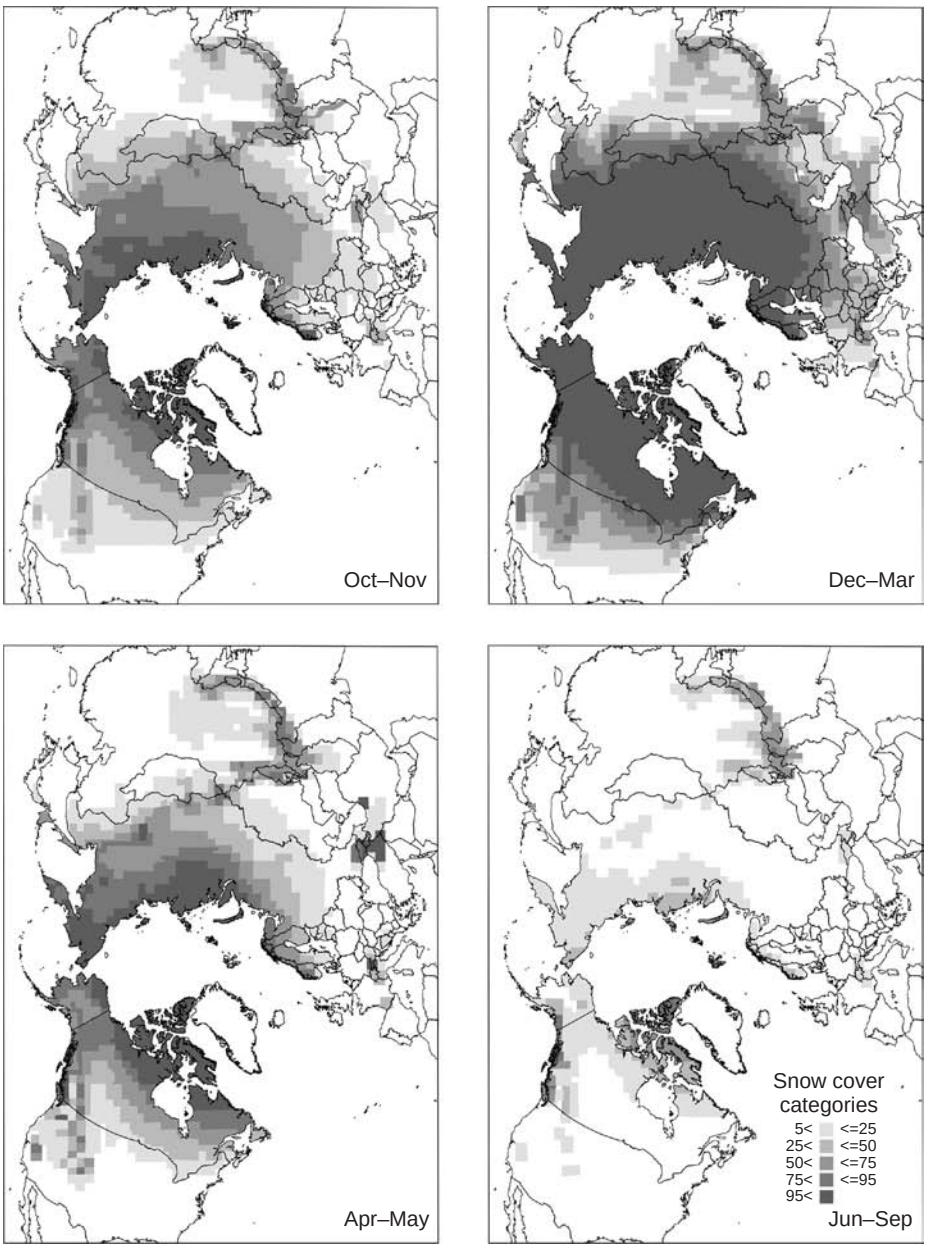

Figure 1 Spatial and temporal distributions of snowcover extent in the Northern Hemisphere for four seasons. Percentage time with snowcover in each season for the period 1973–1992

because of rainfall, regardless of the return period. At the other extreme, large northern watersheds, such as the Mackenzie river basin in Canada or the Lena river basin in Russia, experience their annual maximum flood because of snowmelt. In between these extremes, floods are caused by both snowmelt and rainfall, which is of particular interest to operational hydrologists concerned with the immediate needs of society.

Within this context, four possible cases of frequency relations with respect to snow on the ground and rain can be considered. This assumes two separate and independent probability distributions for the snowmelt and rainfall return periods. The four cases are described by Stoddart and Watt (1970). These four cases depend on the relative sizes of the means and standard deviations of the snowmelt (plus any rainfall) floods and rainfall (without any snowmelt) floods (Stoddart and Watt, 1970; NRC, 1989a). A special case of flooding in snowcovered basins results from ice jamming (NRC, 1989b). Ice jams occur on small and large rivers and have been a concern in many populated areas. The two general kinds of ice jams are freeze-up jams and breakup jams and these events can occur at any time of the year but

are typically coincident with the spring freshet. Attempting to predict ice-jam-induced floods is very difficult. The interested reader is referred to **Chapter 171, River-Ice Hydrology, Volume 4** for a detailed description of ice-covered rivers and ice jams.

While the primary impetus for much of the research on snowcovered catchments has been the importance of snow as a resource, snow also has an important role to play in the energy balance of the Earth's surface as a major influence on climate and weather. Snowcover delays air temperature warming in the spring, intensifies seasonal cooling in the fall (Cohen, 1994), and has considerable local, regional, and global influence on energy exchange through its high surface albedo and low thermal conductivity (Walsh, 1987). Snow also affects the energy balance because of its high latent heat. During melt or freezing, the exchange of latent heat within the snow pack is considerable. During sublimation or condensation, the exchange of latent heat with the atmosphere can also be important. The spatial distribution of snow determines the extent of its impact on the energy balance. Figure 2 illustrates one estimate of the distribution of snow depth over the Northern Hemisphere for December–January–February and March–April–May (from Marshall *et al.*, 1994, based on Foster and Davy, 1988).

The ecology of areas where snow occurs is intimately associated with the nature of the snow pack, and snow plays an important role in the ecological balance of many high latitude and high altitude catchments. As an example, snowmelt is the most significant hydrological event in the boreal forest biome, as its duration and timing exert strong controls over net primary production and the exchange of energy and carbon (Metcalfe and Buttle, 1998). Of all biomes, however, snow has the strongest influence in tundra regions, strongly affecting the vegetation patterns in these regions (Walker *et al.*, 2001). A sufficient pack will provide insulation for plants, protecting their root systems, and will also provide cover for mammals that do not migrate (Groisman and Davies, 2001). Many microorganisms such as bacteria, algae, and fungi have adapted to the extreme fluctuations of energy, water, and nutrients often found in snow environments, setting the stage for nivian (snow) food webs and other biogeochemical processes (Hoham and Duval, 2001). All animals that come into contact with snow are affected by the physical, chemical, and microbiological processes of the snow, possibly influencing the ability of many animals to survive (Aitchison, 2001).

Clearly, snowcovered catchments are an integral part of the earth's physical, chemical, and biological regulatory processes. They play an important role in global water and energy balance. They also effect an important ecological control in cold regions' ecosystems. This article briefly describes the hydrology of snowcovered catchments, with an emphasis on understanding the hydrological response of these cold-region basins. In order to understand the hydrological response of snowcovered catchments, knowledge of the temporal and spatial distribution of snow within the catchment is also very important. Snow pack accumulation and ablation, especially during the spring thaw, are significant inputs into daily hydrological forecasting systems that are in turn extremely useful for flood prevention and hydroelectric generation. Hence, the measurement and characterization of the distribution of snow within a catchment are critical to the prediction of subsequent melt.

MEASUREMENT OF SNOW

In Situ Estimates of Catchment Snowcover

The snowfall within a catchment provides a natural storage element that can release water to a stream at variable rates over time, depending on snow distribution and the physiographic features of the basin in question. Snow water equivalent (SWE) is a fundamental hydrological property that describes the amount of water present in a snow pack and is typically expressed in units of equivalent water depth. The relationship between SWE and snow depth is simply a density conversion. Pomeroy and Gray (1995) noted that, although newly fallen snow is often assumed to have a density of $100\,\mathrm{kg\,m^{-3}}$, densities in the range of $50\,\mathrm{kg\,m^{-3}} - 120\,\mathrm{kg\,m^{-3}}$ are often observed. Temporal increases in density have been measured by Goodison (1981), while Gray *et al.* (1970) noted increases in windpack snow density of up to six times the original density (Pomeroy and Gray, 1995). Seasonal changes in SWE show gradual increases with the density of melting snow, reaching values of $500\,\mathrm{kg\,m^{-3}}$. Clearly, the density of snow is variable in both space and time, making the true estimate of the amount of snow in a catchment difficult to obtain from point measurements. Nonetheless, because of the importance of catchment-wide snow assessments, several methods of measurement of depth, density, and SWE are used routinely in hydrology.

The WMO Guide to Hydrological Practices (1994a) notes that catchment-based assessments of snow are typically derived from snow surveys and snow courses. Snow courses are permanently marked lines where a snow survey, defined as a series of snow depth (and density) measurements, is taken. Surface-based depth and density measurements are obtained from simple ruler measurements of depth and density using a snow core sampler (WMO, 1994b). Density measurements along these transects are usually made with a graduated hollow tube and a cutter, where both the weight and volume of the snow sample are estimated. Snow courses must be carefully selected so that the resulting SWE estimates are representative of the basin. As a general rule, the Guide to Hydrological Practices (WMO, 1994c) recommends that in high-relief regions, snow courses are at

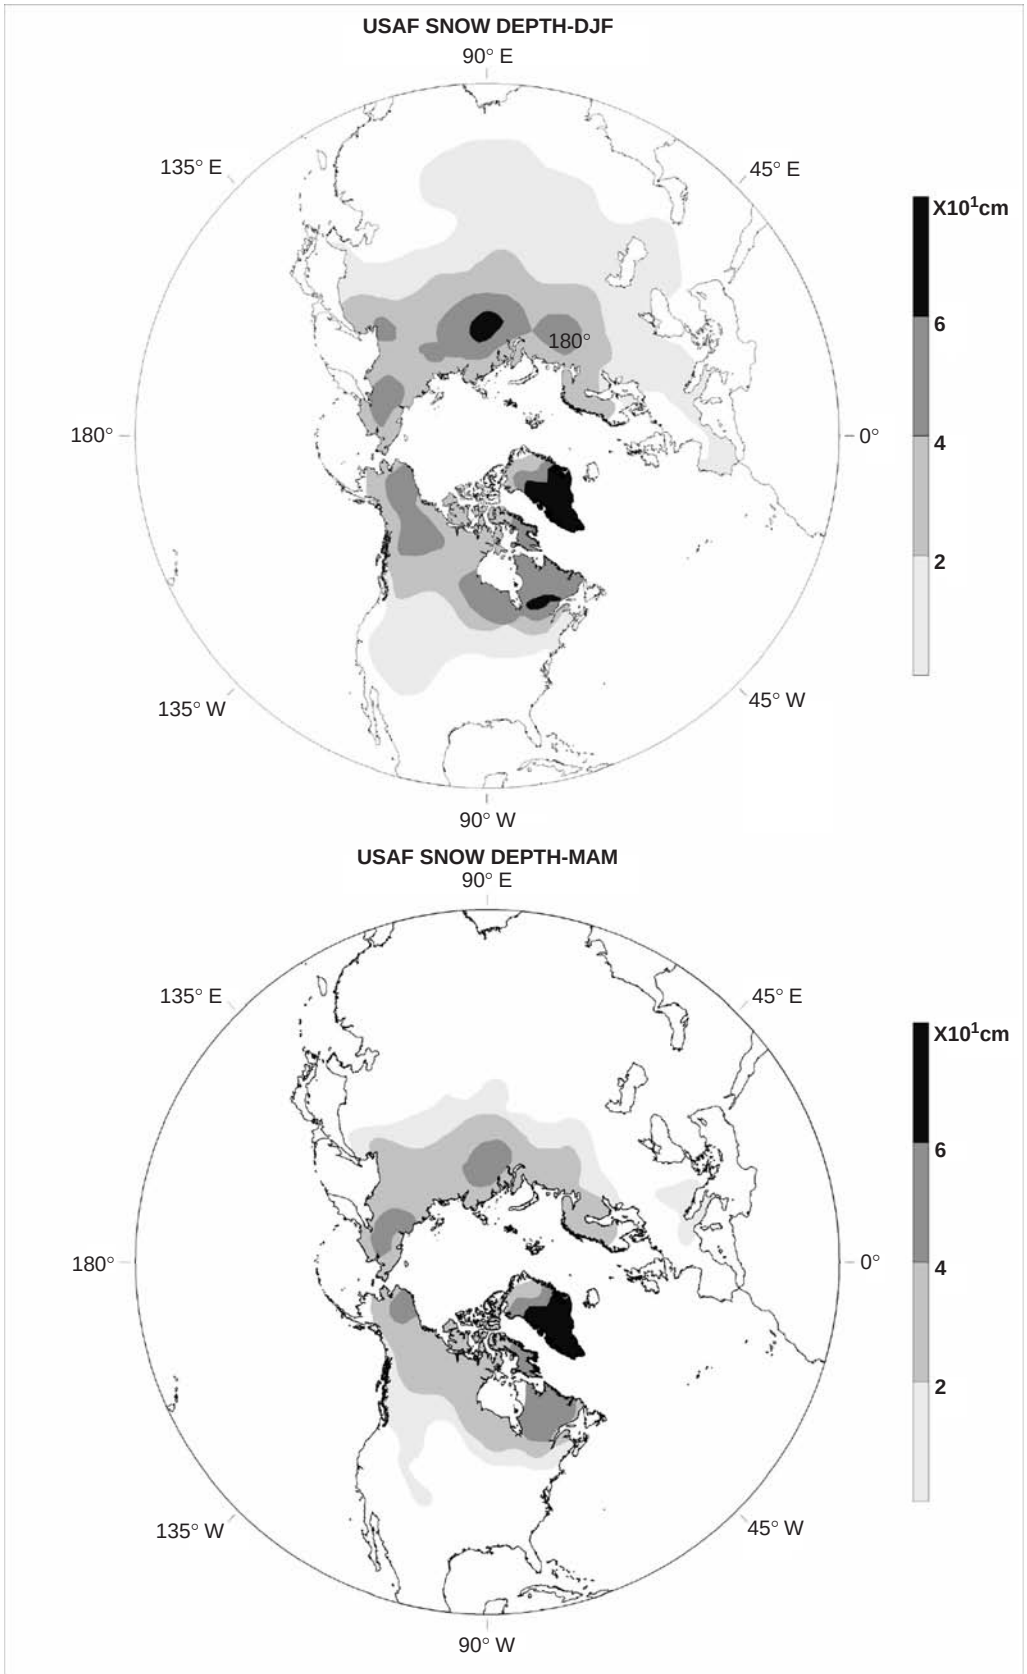

Figure 2 One estimate of the distribution of snow depth for December–January–February and March–April–May

elevations and exposures where there is little or no melting until peak accumulation is achieved. In mild to low-relief regions, these surveys need to represent the average snow conditions within a given catchment, and should be carried out on a variety of landscapes in order to properly depict the natural variability of the landscape.

Point estimates of snow mass can be obtained using a snow pillow apparatus. This method is common in many western states of the United States where traditional snow course methods are too costly or too difficult. Snow depth can also be estimated on tower-mounted instrumentation using ultrasonic depth sounding, where the sensor is placed above the snow pack and the distance to the snow pack is used to calculate snow depth. These point measurements, however, only provide an index of mass or depth at a fixed location in space, and are often supplemented by traditional snow courses.

Remote Sensing of Snowcovered Catchments

Remote sensing is a valuable tool for use in understanding the nature and distribution of snowcover in a catchment. To date, snow can be readily identified and mapped with the visible bands of satellite imagery, and the use of satellite data to map snowcover extent has become operational in several regions of the world. For example, digital snowcover maps of about 4000 basins in North America are produced from NOAA-AVHRR (National Oceanic and Atmospheric Administration – Advanced Very High Resolution Radiometer) images by the US National Weather Service National Operational Hydrologic Remote Sensing Center on a weekly basis and data distribution is possible in real time (Carroll, 1995).

Applications of microwave remote sensing to snow hydrology are also very promising. As an example, since the early 1980s, the Meteorological Service of Canada (MSC) has developed expertise on the use of passive microwaves for estimating SWE for dry snow (Figure 3). Maps of SWE for the Canadian Prairies are produced on a weekly basis using Special Sensor Microwave/Imager (SSM/I) data and are distributed to operational hydrological forecasters (Goodison *et al.*, 1990). Poor spatial resolution (25 km) limits the use of SSM/I to very large areas. Active

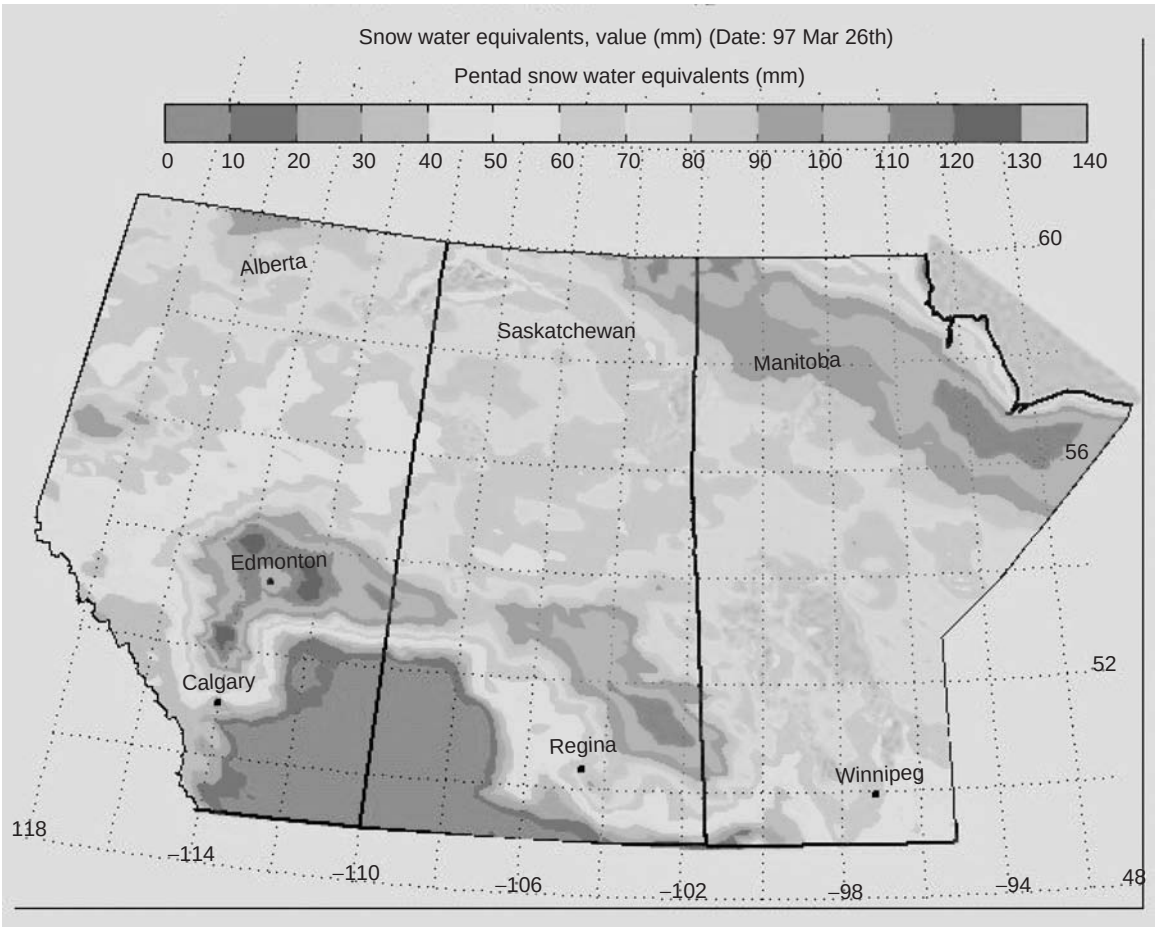

Figure 3 SWE estimates from SSM/I for the Canadian Prairies: March 26th–March 30th, 1997. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

microwave sensors, such as SAR (Synthetic Aperture Radar), can discriminate between wet and dry snow (Shi *et al.*, 1994) and have spatial resolutions (10–100 m) that make hydrological studies at the watershed scale possible.

Visible/near-infrared applications for mapping snowcover are widely accepted (Rango, 1996). For example, Lemieux *et al.*, (1995) have shown that daily remote sensing of snowcover NOAA-AVHRR images is efficient and could become operational in the context of hydropower production. Other promising applications include Landsat Thematic Mapper (TM) derived reflectance and albedo values of snowcovered surfaces (Crevier and Duguay, 1995), and mapping surface snow grain size from Landsat TM data (Brugman *et al.*, 1996). Landsat TM imagery has also been used to derive a canopy closure index, which, combined with ground-based canopy density measurements, allowed the study of spatially distributed snowmelt rates in a boreal forest basin (Metcalfe and Buttle, 1998).

A number of operational remote sensing products for snowcover are available from the United States. The National Weather Service's National Operational Hydrologic Remote Sensing Center maintains time series and spatial products of modeled and observed snow data, including national and regional snow analyses and airborne gamma snow surveys (NOHRSC, 2004). The National Aeronautics and Space Administration's (NASA's) Moderate Resolution Imaging Spectroradiometer (MODIS) satellite produces 500 m and 1 km resolution global snow and ice products within the United States, including daily and 8-day composite snowcover maps (NASA, 2004). In addition, NASA's Advanced Microwave Scanning Radiometer – Earth Observing System (AMSR-E) instrument on the NASA EOS Aqua satellite provides global passive microwave estimates of daily SWE at a 25 km resolution (NSIDC, 2004).

The interested reader is referred to **Chapter 159, Snow Cover, Volume 4** for a more detailed description of the measurement of snow.

CLASSIFICATION OF SNOWCOVERED AREAS

Two kinds of snowcovered basin classifications can be found in the literature. One is a classification founded on the source and timing of runoff and the other is a classification founded on the characteristics of the snow. In the first case, the classification is watershed-based because it is determined from runoff. In the second case, the classification is not watershed-based because it is determined from meteorological and snow conditions.

Basin Classification

Church (1974) has classified northern hydrological regimes on the basis of the source and timing of runoff. The four categories are: subarctic nival, arctic nival, proglacial, and muskeg. The subarctic nival regime exhibits a snowmelt flood in the spring, usually followed by low flows throughout the summer. The low summer flows can be augmented by rainstorm floods that are occasionally higher than the spring flood, especially if mountain snowmelt and rainfall contributions are high. Winter dry subarctic nival regimes, usually larger rivers in the north, freeze entirely and maintain no flow at all in the winter. Perennial flow subarctic nival regimes maintain low flow levels throughout the winter because of groundwater seepage from unfrozen gravels along the rivers.

Arctic nival regimes occur in continuous permafrost zones, usually eliminating the possibility of groundwater flow. The spring melt produces the most streamflow, except for intense rainfall events in very small watersheds. Proglacial regimes are influenced by glaciers that contribute to runoff throughout the summer as higher parts of the glacier experience melt. As a result, the spring melt does not represent as significant a portion of annual streamflow. Arctic and subarctic nival regimes can also mimic proglacial regimes if late-lying snowbanks contribute to streamflow into the summer (Marsh and Woo, 1981). Muskeg regimes are characterized by poor drainage because of shallow slopes, irregular landscapes, and an ability to retain large amounts of water. In tundra zones, the vegetation and hummocky surface restricts flow while the numerous small bodies of water in lowland tundra zones attenuate flow (Prowse, 1990). Hydrologically speaking, the end result is an attenuation of flood flows similar to the effect of lakes.

Figure 4 illustrates Trail Valley Creek (TVC; 68° 45′N, 133° 30′W), a typical arctic nival streamflow regime. The first peak in each year is the result of snowmelt runoff. The summer peaks in each year are the result of convective rainstorms. This 63 km^2 basin is located 40 km northeast of Inuvik, Northwest Territories, Canada (Marsh and Pomeroy, 1996).

Snow Classification

The natural variability of snow has given rise to a number of efforts to classify the physical nature of seasonal snowcover (Formosov, 1946; Richter, 1954; Benson, 1969; McKay and Gray, 1981; Pruitt, 1984; Sturm *et al.*, 1995). The classification by Sturm *et al.* (1995) as described by Groisman and Davies (2001) consists of seven classes of snowcover, namely: tundra, taiga, alpine, maritime, ephemeral, prairie, and mountain.

Tundra snow is a thin, cold, windblown snow usually found above the tree line. Taiga snow is a thin to moderately deep, low-density, cold snowcover found in cold forest climates with low winds, low initial snow densities, and low average winter temperatures. Alpine snow is deep, with intermediate to cold temperatures and often contains

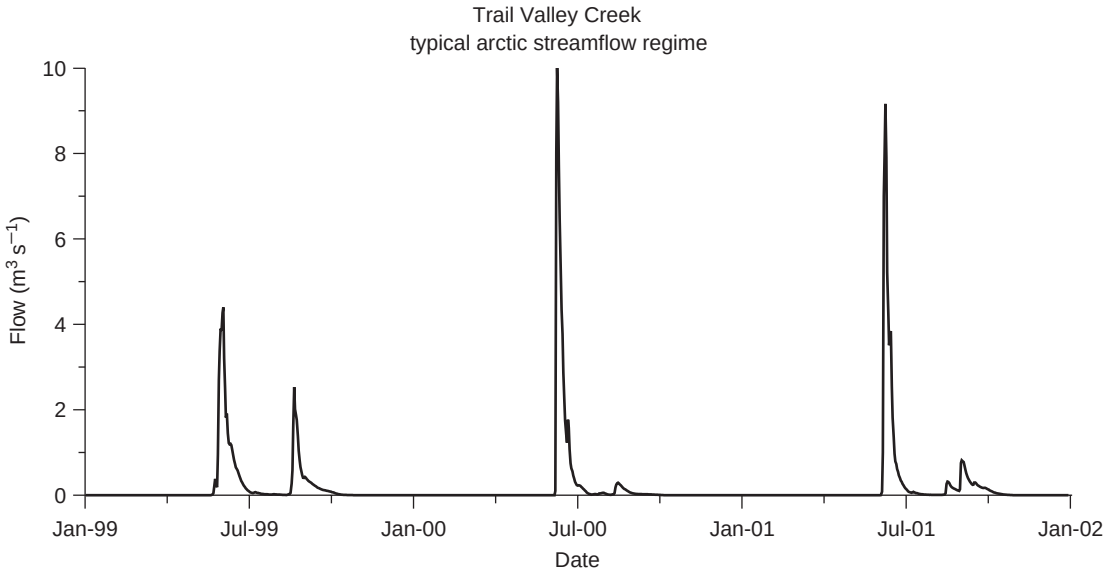

Figure 4 Typical arctic streamflow regime just North of Inuvik, Canada

alternating thick and thin layers. Maritime snow is warm and deep, typically characterized by common melt features such as ice layers and percolation columns. Maritime snow is usually course-grained due to its high moisture content. Ephemeral snow is a thin, extremely warm snowcover exemplified by one snowfall that melts away. Prairie snow is generally thin (except in drifts) and moderately cold, commonly with wind slabs and drifts. Mountain snow is highly variable, depending upon solar radiation effects and local wind patterns. Figure 5 (Sturm *et al.*, 1995) illustrates an estimate of the distribution of these snow classes for the Northern Hemisphere.

SNOW PHYSICS CONCEPTUALIZATION

The Conservation of Energy and Mass

In order to understand the hydrology of snowcovered catchments, it is important to understand the physics of snowmelt and other related phenomena that influence the temporal and spatial distribution of snow within a catchment. The snow pack energy balance and thermophysical process are thoroughly described in **Chapter 160, Energy Balance and Thermophysical Processes in Snowpacks, Volume 4**, and some key points are described in the following paragraph.

Melting of a snow pack is driven by the energy balance. Conservation of energy dictates that the change in snow temperature is balanced with the energy fluxes entering or leaving the pack on the basis of a system of partial differential equations and appropriate boundary conditions. Shortwave radiation penetration, water transport, phase changes resulting from water transport, and melt–freeze phase changes represent the energy fluxes within the pack. Sensible heat, latent heat, net long-wave radiation, and energy from liquid precipitation represent the energy fluxes at the upper boundary of the pack and ground heat flux represents the energy flux at the lower boundary. Most models assume that the pack is one-dimensional, considering only vertical transfers of energy and water. In reality, horizontal transfers also occur.

The canopy plays an important role in both the energy and mass balances of a snow pack on the ground. Figure 6 illustrates the energy balance under the influence of the canopy. The mass balance implications of a canopy are discussed later.

The canopy intercepts precipitation and changes the relative importance of the energy balance components. Incoming shortwave radiation is reflected or absorbed by the canopy, allowing less shortwave radiation to reach the ground surface. The absorbed shortwave radiation increases the temperature of the canopy, which in turn increases the emission of long-wave radiation from the trees, some of which reaches the snow surface. Trees and other flora alter the vapor gradient through transpiration and the physical presence of gaseous, liquid, or solid water in the canopy, thereby affecting the exchange of latent heat. Wind attenuation reduces the eddies responsible for turbulent mixing, reducing both the latent and sensible heat fluxes at the snow surface. As a result of the reduced latent and sensible heat fluxes in a forest, the turbulent exchanges of heat and water have often been ignored (Male and Granger, 1981). During the melt period, however, these fluxes can have a significant impact if melt is initiated by the movement of a warm air mass

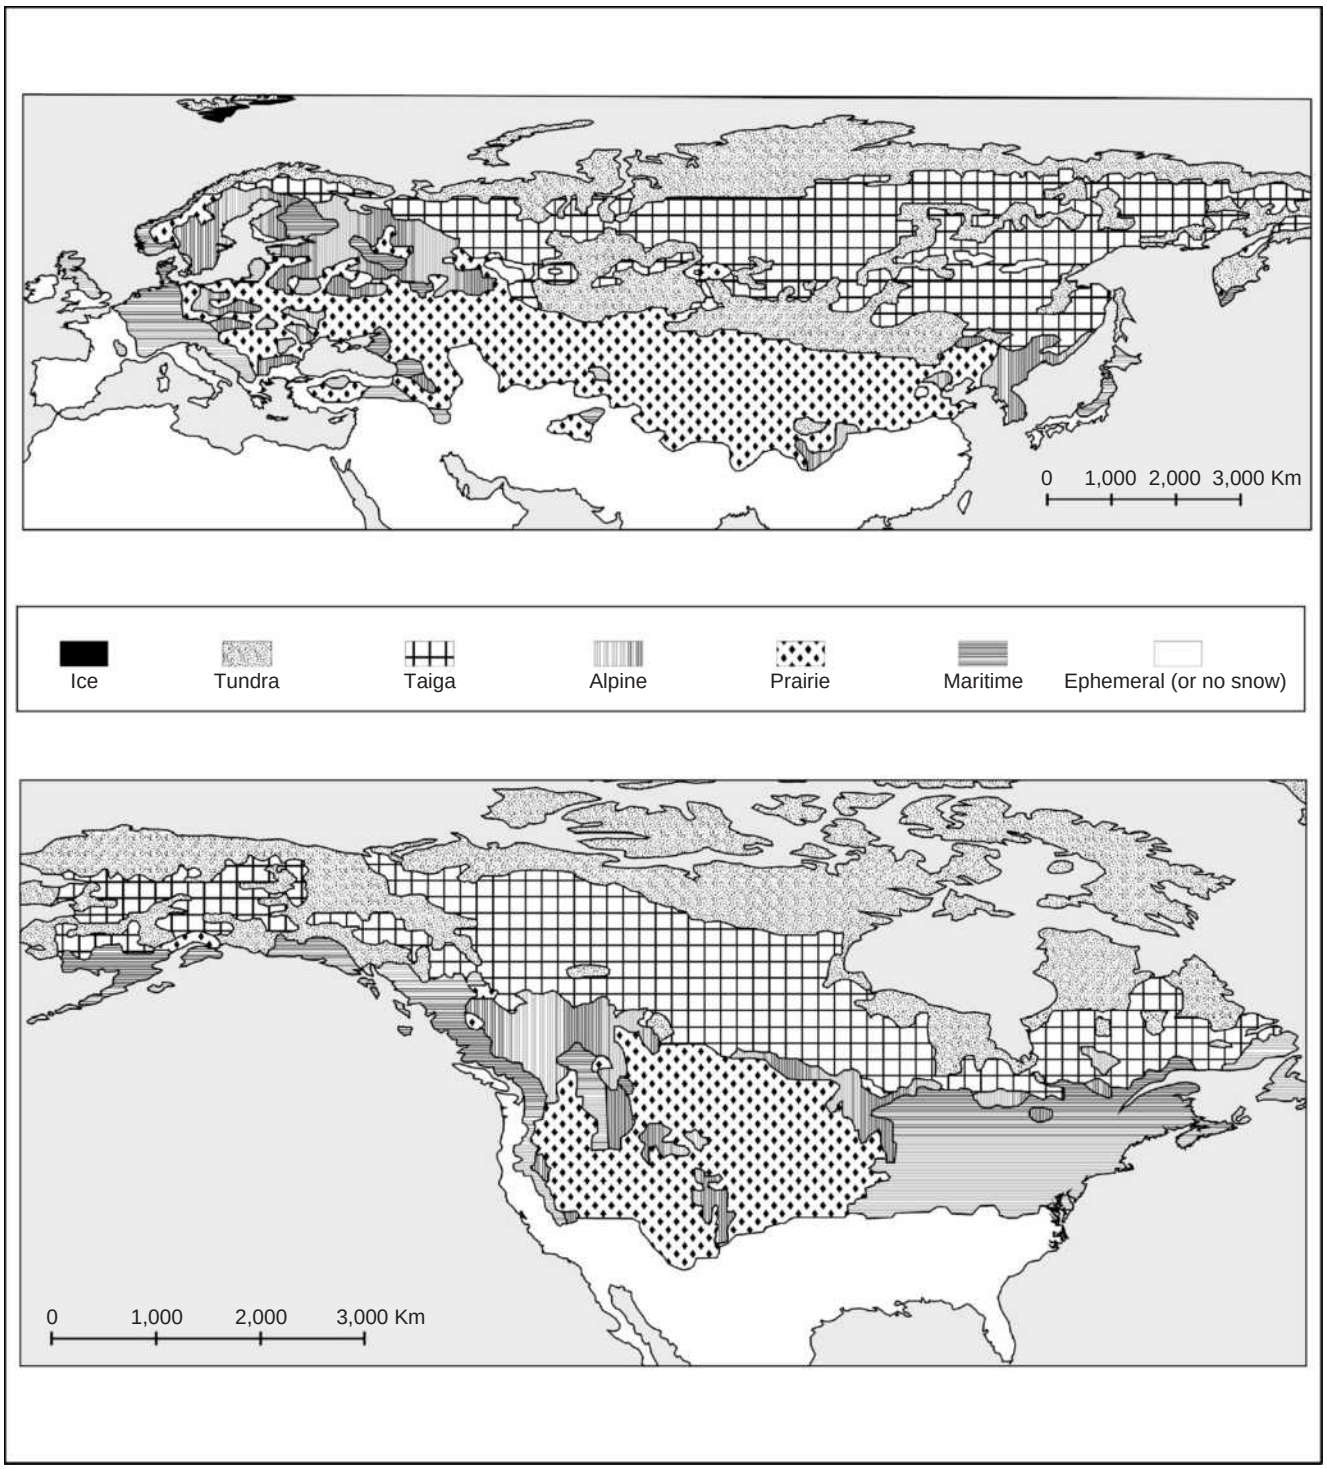

Figure 5 Estimated snow class distribution in the Northern Hemisphere

into an area (Male and Granger, 1981). The relative impact of the turbulent fluxes can also be greater due to the decrease in incoming shortwave radiation, which is only partially offset by the increase in incoming longwave radiation.

The conservation of mass within a snow pack can be described by equation (1).

$$I - O = \frac{dS}{dt} \tag{1}$$

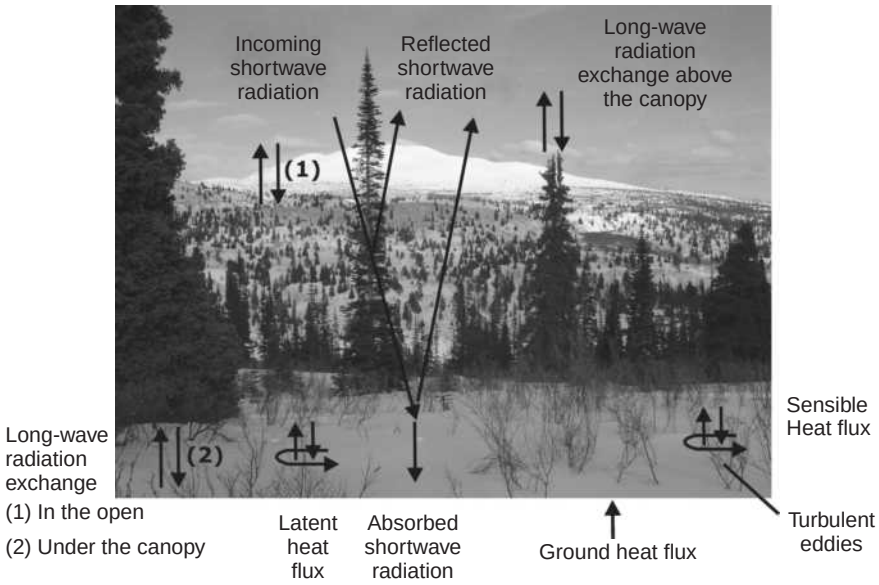

Figure 6 Snowpack energy balance including the canopy

As with any mass balance, equation (1) completely describes the mass regime. 'I' represents the inputs; 'O' represents the outputs and $\mathrm{d}S/\mathrm{d}t$ represents the instantaneous change in storage. Operational hydrologists usually work in units of millimeters or inches for all terms in equation (1) until the water reaches the stream, at which point $m^3\ s^{-1}$ (or $ft^3\ s^{-1}$) are used. Vapor and solid phases of water are always present in a pack and liquid can also be present. The inputs and outputs considered in equation (1) depend upon the purpose of the study. At the most basic level, the inputs are precipitation, condensation, and freezing surface water, while the outputs are sublimation and runoff. Greater detail is required when considering wind redistribution and canopy processes.

Wind redistribution is discussed in **Chapter 160, Energy Balance and Thermophysical Processes in Snowpacks, Volume 4** and will not be considered in detail in this article. Equation (1) can, however, be reformulated as in equation (2) to incorporate blowing snow and snow accumulation in wind-swept environments (Pomeroy and Brun, 2001).

$$Q_{\mathrm{surface}} = Q_{\mathrm{snowfall}} - \frac{\mathrm{d}Q_{\mathrm{T}}}{\mathrm{dx}}(\mathrm{x}) - Q_{\mathrm{E}} \qquad (2)$$

where Q_{surface} is the snow accumulation in ($\mathrm{kg\,m^{-2}\ s^{-1}}$); Q_{snowfall} is the snowfall rate ($\mathrm{kg\,m^{-2}\ s^{-1}}$); Q_T is the blowing snow horizontal transport flux ($\mathrm{kg\,m^{-1}\,s^{-1}}$); x is some distance along a fetch (m); and Q_{E} is the sublimation flux ($\mathrm{kg\,m^{-2}\ s^{-1}}$).

To relate the units of equations (1) and (2), 1 mm of water is the equivalent of $1\,\mathrm{kg\,m^{-2}}$. This relationship between mm and $\mathrm{kg\,m^{-2}}$ holds true for water because $1\,\mathrm{m^3}$ of water has a mass of 1000 kg. In addition, equation (2) is represented as a rate.

Snowfall canopy interception describes the process where snowfall is caught by the branches and foliage of a canopy. Some of the snow may get blown off the trees and reach the ground, but much of it sublimates. Snow can also drip from the trees as meltwater (Storck *et al.*, 2002). Hedstrom and Pomeroy (1998) estimated snowfall canopy interception (I) in equation (3) as:

$$\mathrm{I} = \mathrm{c_{suc}}(\mathrm{I^*} - \mathrm{I_0})\left(1 - \mathrm{e}^{-\frac{\mathrm{C_{can}R_s}}{\mathrm{I^*}}}\right) \qquad (3)$$

where c_{suc} is a dimensionless snow unloading coefficient; I^* is the maximum snow load in $\mathrm{kg\,m^{-2}}$; I_0 is the initial snow load in $\mathrm{kg\,m^{-2}}$; R_{s} is the snowfall for a unit of time in mm SWE or $\mathrm{kg\,m^{-2}}$; and C_{can} is the canopy coverage fraction.

Hedstrom and Pomeroy (1998) estimated c_{suc} to be 0.697 and the maximum snow load with equation (4) where S_{p} is a tree species coefficient; *LAI* is the leaf area index; and $\rho_{\mathrm{s}}(\mathrm{fresh})$ is the fresh snow density in $\mathrm{kg\,m^{-3}}$.

$$\mathrm{I^*} = \mathrm{S_p\ LAI}\left(0.27 + \frac{46}{\rho_{\mathrm{s}}(\mathrm{fresh})}\right) \qquad (4)$$

The above discussion and equations represent some of the complex physical constraints that control changes in the snow pack at a single point or within a small region. At the catchment scale, the complexity of these constraints increases and is reflected in the difficulties in capturing the movement, sublimation, and redistribution of snow, and in estimating the radiation balance at all points within the catchment. Because of these complexities,

conceptual methods for describing snow physical properties and subsequent melt at the catchment scale have been developed. These include temperature index melt models and snowcover depletion curves (SDC's), both of which are used in many operational hydrological systems to describe and predict the hydrological response of snow-covered catchments.

TEMPERATURE INDEX MODELS

The temperature index snowmelt algorithm (Anderson, 1973) is a well known algorithm used in many operational models and is given by equation (5):

$$\mathrm{M} = \alpha(\mathrm{T_a} - \mathrm{T_{base}}) \tag{5}$$

Where M is the daily snowmelt depth in mm; α is the melt factor (rate of melt per degree per unit time); T_a is the 2 m air temperature in °C; and T_{base} is the temperature at which the snow begins to melt (assumed to be fixed at 0 °C). This algorithm can be used on a daily or hourly time step. Some authors have suggested that hourly time increments should not be used for temperature index models as the hour-to-hour fluctuations in melting conditions are controlled largely by the radiation component of the energy budget (Rango and Martinec, 1995). However, recent studies using the temperature index model have shown that good results can be obtained in temperate climates such as southern Ontario, Canada, using landscape-based indices (see Donald, 1992; Seglenieks, 1994). The transferability of these parameters in time and space can be problematic, often leading to poor validation results, particularly in regions where radiation melt may dominate (Pietroniro *et al.*, 1996).

In addition to the standard temperature index algorithm, many of these index models also contain a snow pack heat balance accounting system that determines the snowmelt phase of the average snowcover (i.e. warming, ripening, or melt output) for each time step. Such algorithms were developed by Anderson (1973) for the NWSRFS (National Weather Service River Forecast System) Snow Accumulation and Ablation model (Figure 7) and take into account energy storage within the snow pack.

The radiation-temperature indexed model (equation 6) is a combination of the temperature index and the surface radiation budget as proposed by Martinec and de Quervain (1975), Ambach (1988), and Martinec (1989).

$$\mathrm{M} = \alpha(\mathrm{T_a} - \mathrm{T_{base}}) + rn \cdot \mathrm{R} \tag{6}$$

where rn is the conversion factor for energy flux density to mm of snowmelt ($\mathrm{kg\,W^{-1}}$); and R is the net all-wave radiation acting on the snow pack ($\mathrm{W\,m^{-2}}$). The first term in equation (6) attempts to conceptualize the turbulent energy components of the energy budget, namely, the sensible and latent heat exchanges through a simple index. The second term incorporates the surface radiation budget similar to that used in energy balance models. The WMO Guide to Hydrological Practices gives examples of basin-wide melt factors that range from $2\,\mathrm{mm\,C^{-1}}$–$7\,\mathrm{mm\,C^{-1}}$ for mountainous catchments in North America. A similar range of values has been estimated for lowland catchments in the former Soviet Union (WMO, 1994c).

In addition to the above discussion, the reader is referred to Hock (2003) for a comprehensive review of temperature index melt factors.

Snowcover Depletion Curves (SDCs)

The spatial distribution of snowcover is described by SDC's that summarize the percent areal coverage of the snow pack as it increases in average depth. Watershed-wide SDC relationships are currently used in lumped hydrological models such as NWSRFS (Anderson, 1973) to describe the snowcover distribution as the snowcover melts. These relationships are difficult to obtain and require calibration for each specific watershed. Despite the recognized limitations in the application of SDC's to large areas, such as elevation zones or entire watersheds, little progress has been made in the development and application of more stable snowcover representations for use in hydrological modeling. Research on the effect of surface cover on snow pack distribution in lowland regions (McKay and Gray, 1981; Adams and Roulet, 1982; Goodison, 1981; Schroeter, 1988) shows that vegetation roughness tends to determine snowcover distribution. Burkard *et al.* (1991) found that the response of the snow pack distribution to surface cover type could be summarized into three vegetation classes: little to no vegetation, such as ploughed field or pasture grassland; low vegetation such as corn stubble and marsh grasses; and high vegetation such as forests.

The simplest representation of snowcover is uniform snowcover, which is of constant depth and complete areal coverage. This ignores snowcover variability and results in a simulated snowcover that melts uniformly, creating an "instant bare ground" effect when the snowcover disappears. In reality, snowcover is highly variable within a response unit and the nature of the snowcover must be adequately characterized if distributed models are to improve hydrological modeling through improved representation of the state variables (Beven, 1989). The importance of different landscape units and topographical features in estimating the areal distribution of the snowcover is well established (McKay and Gray, 1981; Goodison, 1981; Adams and Roulet, 1982). Knowledge of the areal distribution of the snowcover within and between land units is required to make reasonable estimates of the total

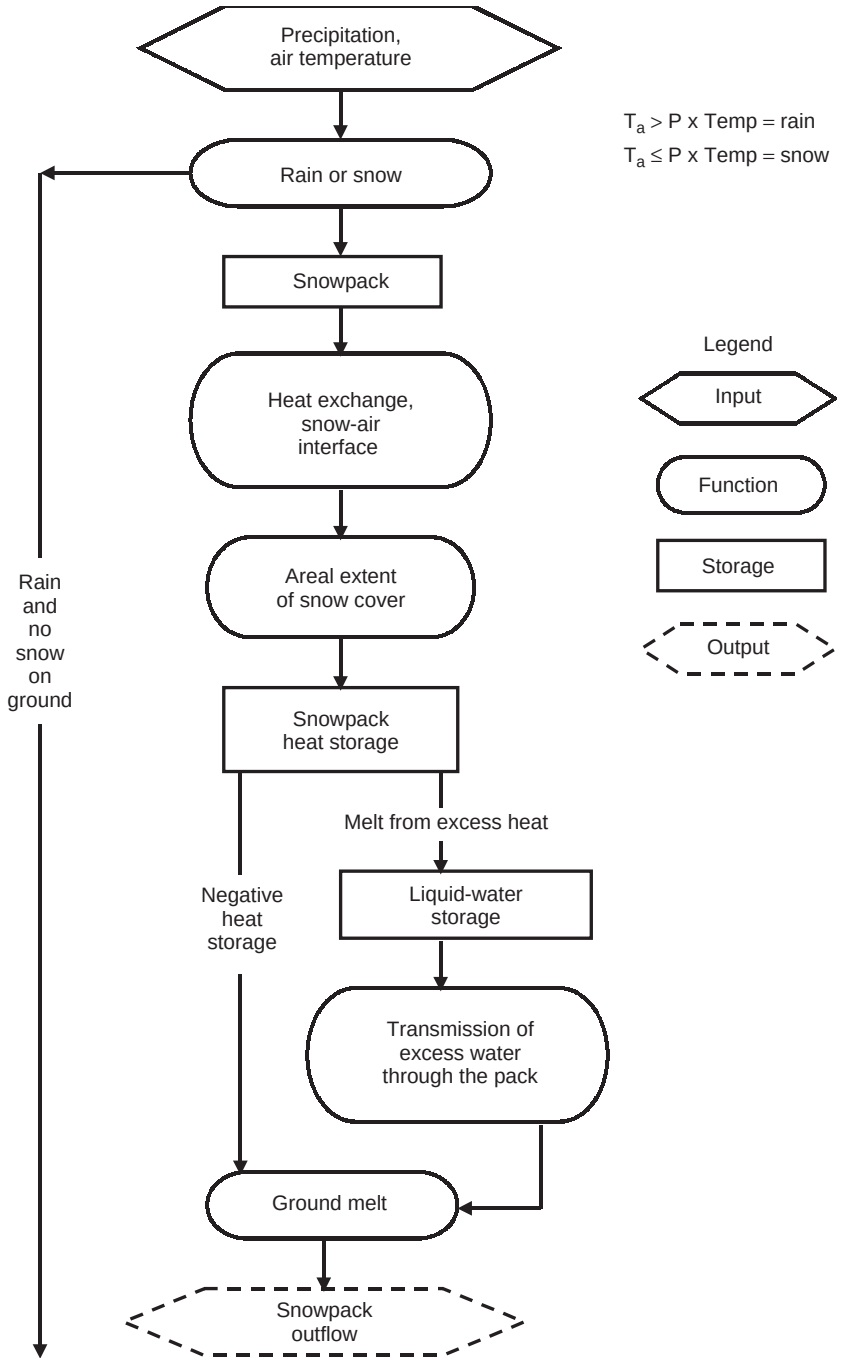

Figure 7 Flow chart of snow accumulation and ablation model

water available in the snowcover of a watershed (Goodison *et al.*, 1987). The areal distribution of the snowcover within a land unit type can be summarized in the form of an Areal Distribution Curve (ADC). An ADC is a summary of the state of the snowcover at a given time. Intense sampling programs are required to develop data sets for quantifying the snow distribution in the form of ADC's.

ADC's are frequency or cumulative frequency distributions of the occurrence of a given snowcover property, usually depth or water equivalent (see Goodison, 1981; Burkard *et al.*, 1991). An important observation in studies of the areal distribution of snowcover (e.g. Schroeter, 1988; Adams and Roulet, 1982; Willis, 1978) is the tendency for the snowcover to become aerodynamically shaped as snow accumulates due to the redistribution of the snowcover by

wind during and after initial deposition. This aerodynamic shape results in a limited capacity for ADC's in different cover types to be estimated from observation of the snowcover at maximum accumulation. The maximum accumulation depth is a function of vegetation height and topography. Another important observation in these studies is the tendency of the snow pack to follow consistent patterns from year to year. The spatial stability of the distributions at different locations within landcover units has not been as extensively studied. Burkard *et al.* (1991), however, indicate that no significant difference exists in land unit snowcover distributions from site to site in southern Ontario.

As noted, for hydrological purposes, it is not practical to physically model the distribution of snowcover (McKay and Gray, 1981). A generalized physically based mathematical model for areal snowcover accumulation and ablation is not yet formulated due to the complexity of the transport process in the natural environment. The development of statistical or empirical distribution relationships based on landcover types is a sensible approach to the problem, and again is accomplished by the use of the SDC, which summarizes the necessary information to model the snowcover depletion.

The scientific literature describes a number of different kinds of SDCs. In their discussion of the necessary resolution for the remote sensing of snowcover, Rango *et al.* (1983) presented a depletion curve where the percentage of snowcovered area (SCA) is plotted against time (see Figure 8). Conceptually, this approach is very easy to understand. In seasonal snow packs, the trend is for snowcovered areas to decrease from 100% to 0% over a period of time. Plotting this depletion curve with sufficiently regular satellite overpasses can result in an accurate calculation of the evolution of basin-wide SCA.

In work concerning the sub-grid parameterization of snow distribution for a lumped model, a second basin-wide SDC is presented by Luce *et al.* (1999) and Luce and Tarboton (2004) (see Figure 9). In this SDC, the SCA is plotted against the basin or element average SWE. The SCA fraction is assumed to be 1 at maximum SWE for the season. As a result, the SDC varies from year to year and from basin to basin with maximum seasonal SWE.

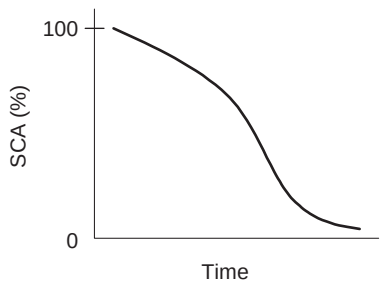

Figure 8 SCA versus Time SDC

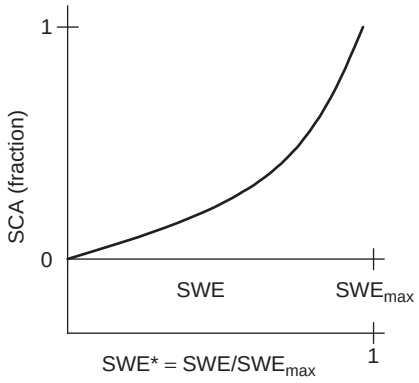

Figure 9 SCA versus. SWE SDC

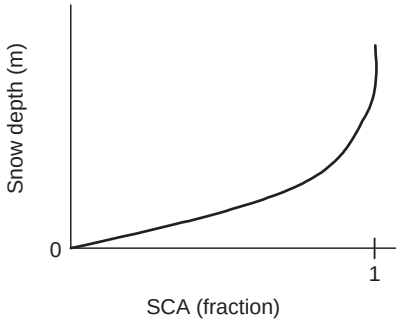

Figure 10 Snow Depth versus SCA SDC

Annual variability is addressed through the development of a dimensionless depletion curve by dividing the SWE by the maximum seasonal SWE. This assumes that the shape of the dimensionless curve is consistent for different values of maximum seasonal SWE. Luce and Tarboton (2004) show this assumption to be reasonable, implying that one basin-wide SDC is consistent from year to year.

A third method of representing snowcover depletion is described in detail by Donald (1992) and Donald *et al.* (1995) (see Figure 10). For this SDC, the average snow depth for the element is plotted against the SCA. The relationship between the SDC and the ADC is also described by Donald (1992) and Donald *et al.* (1995). Mathematically, the SDCs of Donald (1992) and Luce *et al.* (1999) are very similar. The differences between the two curves are subtle. Donald's curve is based on snow depth versus SCA, whereas Luce *et al.*'s is based on a dimensionless SWE term versus SCA. In addition, Donald's curve is landcover-based while Luce *et al.*'s curve is catchment-based. Both methods have their advantages and disadvantages, depending on the problem being solved.

Anderson (1973) discusses a number of ways that snowcover depletion curves can be developed for an entire watershed. In the context of the SCA versus Time SDC, the basin areal snow coverage is measured over a number

of years using aerial photography and related-to-average areal SWE estimated from ground surveys. Anderson recognized that such information was generally not available, nor could it be easily obtained. The same is true today.

Another suggested method, particularly suitable for the SCA versus average snow depth SDC (see Figure 10), is to make periodic measurements of the water equivalent at representative sites within each reasonably homogeneous geographical subarea of the watershed. Vegetation type, elevation, and aspect would be used for subarea selection criteria. Point estimations on the SDC would be possible as the subareas become bare because the percentage of bare area and basin-wide water equivalent would be known. If no data exist, as is often the case, the shape of the SDC must be arbitrarily selected. This SDC could also be modified by calibration during hydrograph simulation. Such watershed SDC's are watershed specific: they represent the characteristic response of the watershed to snow melt, which is a function of the specific surface cover and elevation characteristics within the basin.

The most recent work related to the topic of snowcover depletion curves can be found in Liston (2004), Essery and Pomeroy (2004), and Luce and Tarboton (2004).

ESTIMATING CATCHMENT SNOWMELT

Hydrological models, like all models, are an attempt to articulate an understanding of the complex and nonlinear interactions within the hydrological cycle using a rational mathematical approach. Since the advent of computers, there has been a dramatic explosion of modeling approaches in the literature, representing varying degrees of complexity and producing variable results. Landcover, hydraulic conductivity, surface soil moisture, and snowcover all vary tremendously at different spatial and temporal scales. For example, soil moisture can vary dramatically from one centimeter to the next and from one minute to the next. This has forced hydrological model developers to approach model development from a more conceptual paradigm, while retaining as much physics as possible. Landscape heterogeneity has forced hydrologists to conceptualize the physics and to seek effective parameter values (Pietroniro and Soulis, 2003). Hydrologists have traditionally used the integrated basin response of the hydrograph to test results and have used simple objective functions to describe complex terrain. However, as noted by Beven (1989), the relatively simple hydrologic comparison between observed and modeled streamflow can often lead to reasonable simulations with poor physical representation and/or parameterization. Within the context of snow models, Essery and Etchevers (2004) discuss this problem of parameterization with respect to a simple snow model. Nonetheless, it is useful to examine a number of snowmelt runoff models in the literature that are used operationally, as well as to highlight new approaches to dealing with snowmelt in models, particularly the more complex land-surface models currently being developed in atmospheric models.

Snowmelt runoff simulation models generally consist of a snowmelt model and a transformation function. The snowmelt model generates liquid water from the snow pack that is available for runoff and the transformation model is an algorithm that converts the liquid output at the ground surface to runoff at the basin outlet (Donald *et al.*, 1995). The snowmelt and transformation models can be lumped or distributed in nature. Lumped models use one set of parameter values to define the physical and hydrological characteristics of a watershed. Distributed models attempt to account for spatial variability by dividing the basin into subareas and computing snowmelt runoff for each subarea independently with a set of parameters corresponding to each of the subareas (WMO, 1994d). Snowmelt models generally include a snowcover representation that can range from a simple single-layered snow pack (e.g. Anderson, 1973) to a multilayer conceptual snow pack (e.g. Brun *et al.*, 1989). The snow pack representation has implications for the timing of the snowmelt runoff because of its ability to store water.

Many hydrological models were developed over the last 30 years in an attempt to characterize the behavior of snowcovered basins. Two of the most significant of these were the US NWSRFS (Anderson, 1973; Larson, 2002) and theStreamflow Simulation and Reservoir Regulation Model (SSARR) developed by the US Army Corps of Engineers (Singh, 1995; Croley, 2002). Other important models include the Martinec (1975) snowmelt runoff models developed for the Swiss Federal Institute for Snow and Avalanche Research and the Swedish HBV model (Bergström, 1975) developed at the Swedish Meteorological and Hydrological Institute.

This proliferation of models resulted from developments in computer technology and from a recognition of the increasing importance of managing storage of spring runoff for hydroelectric production, irrigation, water supply, or other consumptive or nonconsumptive uses. As computational efficiencies were realized and geospatial technologies such as geographic information systems and remote sensing were developed, snowmelt modeling was reinvented and several methods evolved to incorporate the distributed nature of a watershed and associated state variables into hydrological models (Donald *et al.*, 1995). The underlying concept in these methods is to discretize the watershed into zones, integrating hydrologically similar units into one larger unit for modeling purposes. An important function of watershed discretizations is to separate the runoff generation processes such as snowmelt, infiltration, and surface flow from stream flow routing. The distributed formulation of the watershed then accounts for the routing of water from unit to unit. Improvement in modeling is possible

by improving the characterization of the runoff generation processes that occur within each response unit. This can be accomplished through proper representation of the distributed nature of the hydrological state variables within the response units. Therefore, the approach to watershed discretization has important implications for snowcover representation.

The distributed representation used in most snowmelt runoff simulation models is the separation of the watershed into distinct elevation bands (WMO, 1986; Liston *et al.*, 1999; Essery, 2003). Elevation bands are appropriate in high-relief regions where snowmelt gradients are strongly related to elevation. For low-relief regions, elevation bands are not significant and for watershed discretization in distributed snowmelt models, it is important to emphasize physiographic differences such as vegetation that can significantly affect the snowcover. Collectively, the SCA and SDC are an attempt to conceptualize the snowmelt representation in both distributed and lumped models.

Catchment runoff is estimated using a number of possible algorithms that represent the physics of a melting snow pack. In many ways, melted snow is treated the same as rainfall, and infiltrated into the soil matrix using a number of possible infiltration algorithms. However, a melting snow pack can contain between 2 and 10 % of liquid water within the pack, resulting in a significant lag in meltwater production at the stream (WMO, 1994c). The melting of the snow pack is driven by the energy budget on the snow pack as described earlier. Although point estimates of all the forcing variables and parameters required to complete the energy budget and estimate the subsequent melt can be obtained through experimentation, in practice such complex treatments are often intractable. The integration of a reasonable snowmelt transfer function over relatively large catchments is extremely difficult without a highly sophisticated monitoring system. In light of these realities, the most widely applied algorithm for determining the melt rate of snow pack in a basin is the degree-day method, also known as the *temperature index method*.

INDEX METHODS FOR ESTIMATING BASIN RUNOFF

The success of a forecast is highly dependent upon how accurately the snow accumulation represents the basin conditions. According to WMO (1994d), there are at least two additional factors that may have some influence on runoff: antecedent groundwater storage and the amount of precipitation during the snowmelt season.

In high-relief areas, when sufficiently detailed measurements at multiple altitudes of the basin are available, the following formula can be used to calculate the weighted mean snow-accumulation index, I_n (WMO, 1994d):

$$\mathrm{I}_n = \frac{\mathrm{A}_1}{\mathrm{A}}\mathrm{w}_{n_1} + \frac{\mathrm{A}_2}{\mathrm{A}}\mathrm{w}_{n_2} + \cdots + \frac{\mathrm{A}_N}{\mathrm{A}}\mathrm{w}_{n_N} \qquad (7)$$

where $\mathrm{w}_{n1}, \mathrm{w}_{n2}, \ldots, \mathrm{w}_{nN}$ are the mean precipitation or SWE in millimeters at various altitudes, and $A_1, A_2, \ldots, A_N$ are the areas at these altitudes, and A is the total area.

Snow courses, which are located at various altitudes, are used to obtain data to establish a relationship between the SWE and the altitude, such that $\mathrm{w} = f(\mathrm{z})$. A different relationship is obtained for each year. Catchment runoff is then estimated using a number of possible algorithms that represent the physics of a melting snow pack.

As noted in the previous section, many snowmelt runoff models use some form of temperature index (degree-day) method to determine when snowmelt occurs and how much snowmelt may occur in a specific period of time. In the case of operational forecasts, the same approaches are used. An example of a well-established conceptual forecast model is the Snowmelt Runoff Model (SRM). This model has been applied in a range of conditions and for catchments of almost any size ($0.76–1\,22\,000\,\mathrm{km}^2$) and elevation range (305–7690 m a.s.l.) (Martinec and Rango, 1997). A model run starts with a known or estimated discharge value and can proceed for an unlimited number of days, as long as the input variables of temperature, precipitation, and snowcovered area are provided (Martinec and Rango, 1986).

Daily forecasts are estimated for the basin according to equation (8):

$$Q_{n+1} = [\mathrm{c_{Sn}}\cdot\mathrm{a}_n(\mathrm{T}_n + \Delta\mathrm{T}_n)\mathrm{S}_n + \mathrm{c_{Rn}}\cdot\mathrm{P}_n]\frac{A\cdot 10\,000}{86\,400}(1 - \mathrm{k}_{n+1}) + Q_n\mathrm{k}_{n+1} \qquad (8)$$

where Q is the average daily discharge ($\mathrm{m}^3\,\mathrm{s}^{-1}$); c is the runoff coefficient, expressing the losses as a ratio (runoff/precipitation), with $\mathrm{c_S}$ referring to snowmelt and $\mathrm{c_R}$ referring to rain; a is a degree-day factor ($\mathrm{cm}\,^\circ\mathrm{C}^{-1}\,\mathrm{d}^{-1}$), indicating the snowmelt depth resulting from a 1 degree-day; T is the number of degree-days ($^\circ$C d); ΔT is the adjustment by temperature lapse rate when extrapolating the temperature from the station to the average hypsometric elevation of the basin or zone ($^\circ$C d); S is the ratio of the snowcovered area to the total area; P is the precipitation contributing to runoff (cm), where a preselected threshold temperature, T_{crit}, determines whether this contribution is rainfall and immediate; A is the area of the basin or zone (km^2); k is the recession coefficient, indicating the decline of discharge in a period without snowmelt or rainfall: $k = (Q_{m+1})/(Q_m)$, (where m and $m + 1$ are the sequence of days during a true recession flow period); n is the sequence of days during the discharge computation period;

and 10 000/86 400 is the conversion from (cm km^2 d^{-1}) to (m^3 s^{-1}). Equation (8) is written for a time lag between the daily temperature cycle and the resulting discharge cycle of 18 h. In this case, the number of degree-days measured on the nth day corresponds to the discharge on the $n + 1$ day. Various lag times can be introduced by a subroutine. T, S, and P are variables to be measured or determined each day. C_r, C_s, delta T, T_{crit}, k, and the lag time are parameters that are characteristic for a given basin or, more generally, for a given climate. If the elevation range of the basin exceeds 500 m, it is recommended that the basin be subdivided into elevation zones of about 500 m each.

ENERGY BALANCE METHODS FOR ESTIMATING BASIN RUNOFF

In addition to lumped, temperature index models, detailed distributed models have also been developed and assessed. These Digital Elevation Model (DEM) grid-based models use the energy balance to calculate snowmelt and to predict runoff from input data on snow properties, terrain and region characteristics, precipitation, and climate. This approach is similar to those used by Anderson (1976) and Morris (1982), but designed to run on simpler, more generalizable inputs. A model of this type was initially presented by Marks (1988), described conceptually by Marks *et al.* (1992) and Marks and Dozier (1992), and then described in detail by Marks *et al.* (1998). The model approximates the snowcover as being composed of two layers and solves for snowmelt for each element of the DEM, taking into account local slope and aspect, and using estimated radiation inputs at the surface to close the energy balance (Susong *et al.*, 1999).

A recent addition to our ability to simulate snowcovered basins has come from the atmospheric research community. The first Global Circulation Models (GCMs) created by atmospheric scientists required some representation of land and ocean processes to provide the appropriate inputs to simulate the atmosphere. These early representations of nonatmospheric hydrologic subcycles first appeared in the late 1960s (Manabe, 1969) and were very simple for reasons of computational efficiency. Snow was lumped with soil, providing extra water storage and altering the energy balance through differing albedo and surface heat capacity. These land-surface schemes (LSS's) are often referred to as the first generation LSS's and many changes have been made in the second and third generation LSS's. With respect to snow, the work is occurring on two fronts. One approach uses the incorporation of better 1-D vertical component models into the LSS's, while the other method involves the incorporation of better 2-D process approximations. Many of the 1-D vertical point processes have been studied extensively in the scientific hydrology community. Work is underway to understand and describe the 2-D physical snow processes such as wind redistribution. Meanwhile, existing methods developed by the operational hydrology community are being incorporated into the LSS's.

SNOW MODEL INTERCOMPARISONS

A number of snow model intercomparison projects have been completed or are underway. In the mid-1980's, the WMO surveyed 11 snowmelt runoff models (WMO, 1986). Since that time, many more snow models have been developed and a more recent intercomparison is taking place with 30 land-surface models driven with meteorological data. This intercomparison is occurring through the Project for Intercomparison of Land-surface Parameterization Schemes (PILPS 2e) Arctic Model Intercomparison Study (Lettenmaier and Bowling, 2001; Bowling *et al.*, 2003). The PILPS 2d also considered a site with seasonal snowcover (Slater *et al.*, 2001). In addition, the International Association of Hydrological Sciences – International Commission on Snow and Ice (IAHS/ICSI) is helping facilitate an intercomparison (SnowMIP) of 40 snow models (Essery and Yang, 2001). These snow models are used for a wide variety of purposes, ranging from climate modeling and hydrology to research in snow physics, snow stability, and avalanche hazard forecasting. Results of this model intercomparison are discussed by Etchevers *et al.* (2004) and Essery and Etchevers (2004). In addition, ICSI has commissioned SnowMIP2 to assess the performance of snow models in forested environments.

CONCLUSIONS

Though the hydrology of snowcovered catchments has long been studied, the nature and character of the snow accumulation and ablation processes are still being explored. Progress in understanding the physical processes that control snowcover changes within a catchment is well in-hand, although there is still much uncertainty in the role of interception and sublimation in the overall water balance. It is clear that in order to understand catchment behavior, appropriate representation of SWE at the catchment scale is essential. Statistical methods, along with appropriate remote sensing techniques, may provide the only practical solutions to accurately estimating catchment SWE. Conceptual snowmelt models such as the SRM have provided the operational community with the necessary tools for robust forecasting in snowcovered catchments. These models, however, cannot explicitly resolve snow pack physics and are of limited use when assessing the energy balance of a system or the hydrology of smaller catchments. Detailed distributed models, using a

more physically based understanding of the melt and accumulation processes have yet to find their way into the operational community and are limited to small basin applications. The statistical characterization of snowcovered area and depletion provides an acceptable compromise to the detailed physical models, and allows for reasonable physics to be incorporated in the snowmelt models. These distributions are incorporated into current LSSs such as the Canadian Land Surface Scheme (CLASS; Verseghy, 2000), and may provide the best means for assessing both the water and energy balance of large catchments while retaining a physical basis for simulating snow accumulation and ablation.

This article reviews several aspects of snow hydrochemistry: the chemistry of snowfall including chemical incorporation in snowfall and snowfall chemistry variability, the chemistry of cold, dry snowcovers including snow redistribution, snow–atmosphere chemical exchange and in-pack chemical transformations, the chemistry of wet and melting snowcovers including solute leaching, particulate interactions and microbial activity, and snow-covered basin hydrochemistry with an emphasis on nutrient chemistry. The emphasis is on the processes of chemical transformation in seasonal snowpacks and meltwaters with strong attention to the broad ecosystem view of snow chemistry rather than solely focusing on acidification effects from snowmelt. The seasonal snowcover is shown to be a dynamic hydrochemical system with strong ecological interactions. Besides wet deposition by snowfall and rain, the processes of wind redistribution, dry deposition, volatilization, crystal metamorphism, photolysis, microbial uptake and release, solute elution, and meltwater movement strongly affect the chemistry of both the snowpack and meltwaters. Snowmelt chemistry alone is rarely directly responsible for major chemical fluctuations in water bodies, but meltwater has an important role in transporting ions from soils and organic material to water bodies.

INTRODUCTION

The seasonal snowcover plays a unique role in basin hydrochemistry by collecting and transforming chemicals over the snow accumulation season and then releasing them suddenly during melt. Chemicals in the snowcover are derived from dry and wet deposition and are preferentially flushed out, early in the melt season. When industrial pollutants are scavenged and deposited to snowcover, the resulting meltwaters provide a low pH contribution to aquatic and soil chemistry (Hendershot *et al.*, 1992; Galloway *et al.*, 1987). Tranter and Jones (2001) organized the processes, which influence the chemical composition of snow and meltwaters, into those involving

1. heat and mass fluxes that occur during sublimation and melting; and
2. chemical transformations.

During sublimation and melting, chemical species are considered conservative (excluding migration) in that they are not transformed. The physical properties of chemical species (e.g. solubility, vapor pressure) are therefore important in how these processes alter the chemical load of, and release from, the snow cover (Brimblecombe and Shooter, 1991). Chemical transformations occur by chemical reactions such as oxidation (Bales *et al.*, 1987) and photolysis (Beine *et al.*, 2002), or from microbiological activity (Hoham *et al.*, 1989). This review will consider hydrochemical processes in snow from snowfall formation to infiltration and runoff.

The Chemistry of Snowfall

Wet deposition to snowcovers primarily occurs through snowfall. The reader is referred to sections on rainfall chemistry for a discussion of the chemical inputs that can derive from rain-on-snow events (Stumm and Morgan, 1996).

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Chemical Incorporation in Solid Precipitation

Solid precipitation particle formation and fall through the atmosphere incorporate atmospheric chemicals via three main processes:

1. imprisonment during the initial formation of ice crystals;
2. capture of gases, aerosol, and larger particulates within clouds; and
3. scavenging of these materials below the cloud layers during snowfall (Barrie, 1991).

Cloud water droplets contain solute as a result of aerosol scavenging, and the diffusion of atmospheric gases into solution. The soluble species are mainly NH_4, SO_4, NO_3, Ca, K, and Mg, derived from natural and anthropogenic emissions, in addition to Na and Cl from sea-salt aerosol. In addition to solute, droplets contain sea-salt aerosols, particulate organic debris, and/or fine particulate clays (Kamai, 1976) that can form ice nuclei for freezing. The chemical content of the center of falling snow grains is often characterized by these compounds. During the droplet freezing process, however, most solutes are rejected to the outer edges of the crystal as they do not fit well into the ice crystal lattice (Colbeck, 1987).

Ice crystals then grow by vapor transfer from supercooled water droplets because of small differences in saturation vapor pressure over ice and water. Very little solute is transported by this process to the growing ice crystals (Hewitt and Cragin, 1994), however, small amounts of HNO_3 and HCl are absorbed. Direct collision between growing crystals and supercooled droplets results in rimed crystals and graupel, which contain relatively high solute concentrations compared to crystals formed mainly by vapor transfer (Cerling and Alexander, 1987).

Further scavenging of aerosols and other particulates occurs below clouds by adsorption and impact; snowfall more efficiently scavenges particulates than does rain because of its higher surface area to mass ratio, and lower terminal fall velocity (Raynor and Haynes, 1983; Nicholson *et al.*, 1991).

Relationships between crystal form and chemistry have been found because of the association between genesis and form, and the strong differences in chemical incorporation during various genetic processes. Lamb *et al.* (1986) found that the highest concentrations of solute were associated with the smallest unrimed crystals. Borys *et al.* (1983) showed the solute content of snow crystals to increase with the degree of riming. Hewitt and Cragin (1994) found that dendritic and stellar plates had similar chemical content for most species, except for Cl, which showed much higher concentrations in stellar plates than dendritic crystals.

Variability of Snowfall Composition

Snowfall chemical composition depends on factors such as the air mass origin, altitude, and meteorological conditions (Colin *et al.*, 1989; Davies *et al.*, 1992). Maritime air masses will give rise to snow containing mostly Na and Cl (Tranter *et al.*, 1986), while polluted air masses from industrial areas will deposit snow that is highly acidic because of the presence of strong acid anions (NO_3, SO_4) from fossil fuel combustion (Davies *et al.*, 1984; Landsberger *et al.*, 1989).

The spatial variability of snowfall chemistry shows length scales from meters to hundreds of kilometers (Tranter *et al.*, 1987; Pomeroy *et al.*, 1995; Turk *et al.*, 2001; de Caritat *et al.*, 2005), reflecting factors such as the proximity to pollution or ocean sources, the back trajectory of the air masses associated with the snowfall, and wind mixing of different snowfalls on the ground. Generally, snowfall at high altitudes contains lower chemical concentrations than at lower altitudes because of the shorter air column for the falling snow crystals to scavenge from. In addition, chemical concentrations during a snowfall event often decrease exponentially with time, as the store of species available for scavenging in the atmosphere depletes with cumulative scavenging. As a result, persistent storm tracks (e.g. lake effect, coastal) have characteristic spatial trends in snowfall chemistry. For instance, as air masses rise up the windward side of mountains, they generate heavy orographic snowfall. This snowfall progressively depletes aerosols over the increasing distance, resulting in more dilute snowfall chemistry with increasing altitude (Lyons *et al.*, 1991). Postdepositional changes and changes due to redistribution of snow are dealt with in the next section.

Chemistry of Cold, Dry Snowcover

Snowcovers at temperatures below 0 °C are defined as "cold", and because of low liquid water contents are termed "dry". The temporal and spatial variation in the chemical composition of snowfall and subsequent redistribution processes usually produce a snowcover that is chemically heterogeneous. The main processes of transformation (see Figure 1) are

1. redistribution by wind and vegetation;
2. surface-exchange at the snow-atmosphere interface (dry deposition and volatilization);
3. surface and subsurface chemical reactions;
4. snow-grain metamorphism within the pack; and
5. basal-exchange processes at the snow-soil interface (gaseous emissions from soil).

Snow Redistribution Processes

Snow is redistributed by wind via blowing snow transport (Pomeroy *et al.*, 1991), and by vegetation via snow

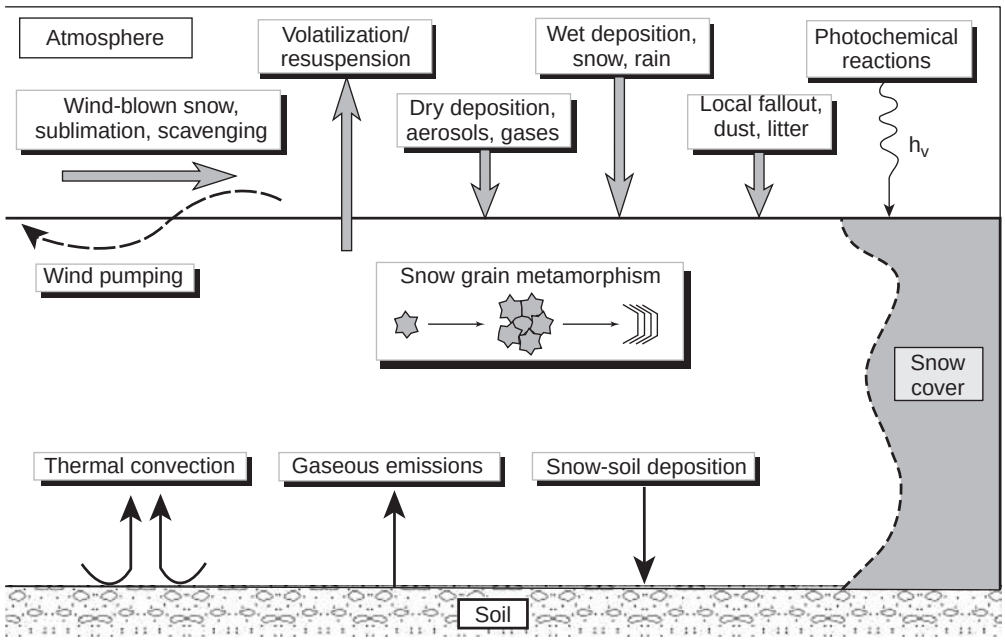

Figure 1 The main physical and chemical processes that influence the chemical composition of cold, dry snow cover during the accumulation season (After Tranter and Jones, 2001)

interception (Pomeroy *et al.*, 1999). Wind transport has the potential to change the chemical composition of snow due to three main physical processes, namely, sublimation of water vapor, scavenging of aerosols and gases from the atmosphere, and volatilization (Pomeroy and Jones, 1996). Direct wind redistribution of snow chemicals can move chemical species between basins, and both transport and sublimation increase the spatial variability of snow chemistry. In the Cairngorm Mountains of Scotland, Tranter *et al.* (1987) found that snowfall chemical concentrations had coefficients of variation (CV) from 0.03 to 0.04. However, CVs for ion concentration in wind redistributed snowcovers at this site varied from 0.1 to 0.74 (Pomeroy *et al.*, 2000). At the arctic treeline in NW Canada, Pomeroy *et al.* (1995) found that blowing snow redistribution was associated with a fivefold difference in chemical loading in snow within a 70 km^2 basin; this greatly exceeded the differences due to ion concentration for which the CVs ranged from only 0.06 to 0.12.

Interception by evergreen canopies can store over half the cumulative snowfall in midwinter (Pomeroy and Gray, 1995). Where chemical species are conserved, redistribution from trees occurs at scales of only a few meters and is generally unimportant. Dry deposition and volatilization are also affected by snow interception, and are discussed in the following section. Sublimation of intercepted snow increases the concentration of conserved ionic species up to sixfold, according to the loss of ice from intercepted snow clumps (Pomeroy *et al.*, 1999).

Processes at the Atmosphere-snow Surface Interface

Dry Deposition

Dry deposition is the direct deposition of chemical species from the atmosphere to the snow surface (Cadle, 1991). Aerosols and particulates may be directly deposited, while gaseous species may be adsorbed (Conklin, 1991). Because the aerodynamic surface roughness of snow is low (Cadle *et al.*, 1985), and liquid water layers are small to nonexistent in cold snow (Choi *et al.*, 2000), dry deposition to snow cover is much lower than to surfaces without snow or to forest canopies, and is small in relation to wet deposition from snowfall.

Bales *et al.* (1987) found that dry deposition rates to new snow were higher than those to old snow as a result of a reduction in the area of crystal surfaces during the metamorphism of snow. The importance of crystal form in dry deposition has also been reported by Ibrahim *et al.* (1983), who suggested that the interception of aerosols by ice needles in relatively fresh snow contributed significantly to the measured rates of dry deposition. Albert and Shultz (2002) show the effect of within-snowpack ventilation via diffusion and advection in enhancing dry deposition to snow.

Cadle *et al.* (1985) estimated deposition rates for HNO_3 to be one order of magnitude larger than those for SO_2. The difference was attributed to the relative solubility of the two gases in the liquid layers around the crystals, and also to other factors such as relative diffusion rates into

the ice lattice, and the rate of oxidation of SO_2 to SO_4 at the air–crystal interface (Bales *et al.*, 1987; Bales, 1991). The rate of deposition of HNO_3 is much higher to wet snow than to cold, dry snow (Cadle, 1991). Field studies in North America suggest that dry deposition contributes approximately 20–25% of the chemical composition of SO_4 and NO_3 in snowcovers (Cadle and Dasch, 1987; Barrie and Vet, 1984; Cadle, 1991).

Snow covers under forest canopies may receive greater contributions of dry deposition. Pomeroy *et al.* (1999) showed greater dry deposition of aerosols to intercepted snow, and subsequent unloaded snow in forest canopies. Dry deposition of gases and aerosols to forests is higher than to open snowfields because of enhanced aerodynamic roughness and absorptive needle/bark surfaces (Höfken *et al.*, 1983; Dasch, 1987). Species deposited to the canopy are subsequently redistributed to the snowcover via intercepted snow unloading, or rainfall interception and drip.

Aeolian dust and other particulate matter are continuously being deposited on snow covers. The result of dust deposition is usually a reduction in the acidity of the snow (Sequeira, 1991), particularly during melt periods (Clow and Ingersoll, 1994; Delmas *et al.*, 1996). Pomeroy *et al.* (1991) found enhancements of aerosol concentration in postdepositional and in-transit wind-blown snow during periods in which blowing snow particles developed strong electrical charges, and suggested that electrophoresis could attract small aerosols to blowing snow particles before deposition. The net effect of changes in aerodynamic roughness on dry deposition of gaseous species and distance from source of aerosols can be difficult to distinguish. An example of loadings of ions to basins with and without trees is shown in Figure 2.

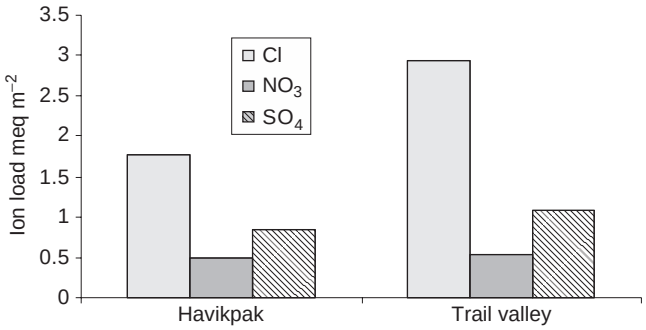

Figure 2 Ion loadings in snow to two basins in NW Canada; Havikpak Creek is sparsely forested and further away from the Arctic Ocean, Trail Valley Creek is dominated by tundra and 50 km closer to the sea. Differences in dry deposition of SO_4 and Cl are evident and because of the increased roughness of the Havikpak forests, and to the different availability of aerosol from the ocean (After Pomeroy *et al.*, 1995)

Snow will also accumulate nutrients by the deposition of biological debris, either as fallout from above the snow surface, or by direct incorporation into the snowpack. In forests, much of the deposition arises as litterfall from the canopy (Jones and Debois, 1987) and mammalian excrement (Jones, 1991). Invertebrate fallout from wind-borne arthropods and winged invertebrates may also contribute nutrients to snow, while vertebrate and invertebrate activity under and within the snow cover transforms and redistributes nutrients from the soil, upwards into the snow matrix. Jones (1991) attempted to calculate nutrient inputs to snow from different vertebrates by considering the spatial distribution of population densities, and the amount and chemical composition of animal excrement. Persistent spatial distributions of excrement were important to basin-scale estimates of N deposition. In the case of animals that herd (e.g. deer), deposition rates may be up to 200 g N ha^{-1} day^{-1} in areas of congregation. Solitary mammals, such as moose and hares, deposit only up to 2.5 g N ha^{-1} day^{-1}.

Volatilization

The dry deposition of aerosols to snow is often considered to be irreversible. However, some species may volatilize and be lost back into the atmosphere. Postdepositional loss of NO_3 has been observed in surface snow (Neubauer and Heumann, 1988; Beine *et al.*, 2002), and sublimating intercepted and blowing snow (Pomeroy *et al.*, 1991; Pomeroy and Jones, 1996; Pomeroy *et al.*, 1999). Volatilization of NO_3 in redistributed snow was proportional to ice sublimation losses over the winter, which is on the order of 35% in the boreal forest, 20% in arctic tundra, and 20–40% in the northern steppes. Figure 3 shows ion concentration enrichment as a function of sublimation loss of snow mass for NO_3, SO_4, and Cl in a boreal forest. SO_4 and Cl are conserved, as snow mass is decreased by sublimation; the loss of NO_3 is roughly proportional to the loss of snow mass, suggesting an association between volatilization and sublimation. These results are consistent with the observations of Stottlemyer and Troendle (1999) who observed increases in NO_3 in snowpacks and meltwater runoff, when evergreen forest basins were clear-cut in the Rocky Mountains, Colorado.

Oxidation and Photochemical Reactions in Surface Snowcover

Oxidation of certain species by atmospheric oxidants may take place on cold snow-grain surfaces, if a liquid film is present (Conklin and Bales, 1993). Bales (1991) has modeled the chemical oxidation of S(IV), SO_2, to S(VI), SO_3/SO_4, on the basis of the known oxidation rates by H_2O_2, O_3, and O_2. Whilst of great interest to ice core interpretations, this also has relevance to understanding S uptake in snow-covered catchments.

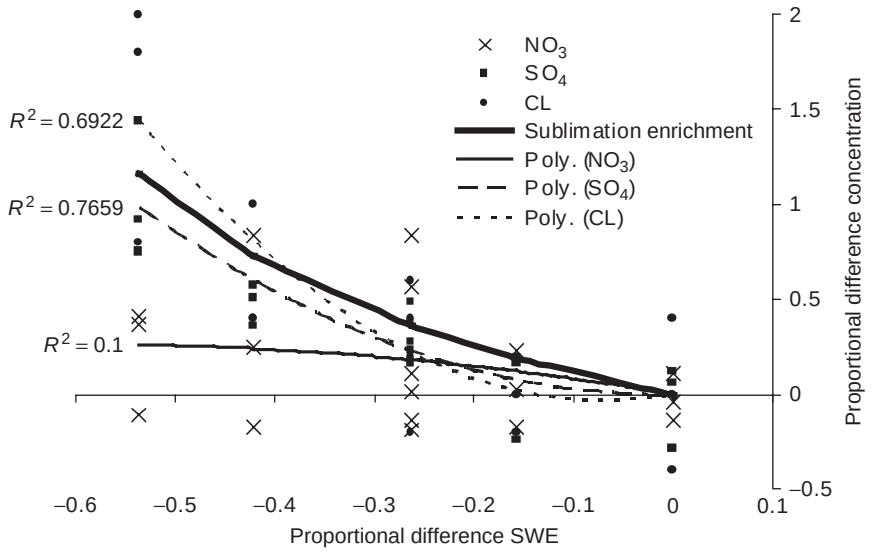

Figure 3 Enrichment of ion concentration because of sublimation of intercepted snow in the boreal forest. SO_4 and Cl follow the expected enrichment assuming conservation of ion, whilst NO_3 is depleted during sublimation. Snow mass is shown as snow water equivalent (SWE), and both SWE and ion concentration are referenced to levels that in a clearing experienced neither melt nor snow redistribution (After Pomeroy *et al.*, 1999)

Sigg *et al.* (1987) measured the decrease in concentrations of H_2O_2 in surface alpine snows, and proposed that photolysis was the primary mechanism. Neubauer and Heumann (1988) suggested that the apparent loss of NO_3 from Antarctic snow was due either to the photodegradation of HNO_3 to NO_2 by solar radiation, and/or to the volatilization of HNO_3 from snow during metamorphism, but were unable to distinguish between the two mechanisms. Beine *et al.* (2002) found that photolysis on a high Arctic snowpack caused HNO_3 transport to the snow surface.

In-pack Processes

Metamorphism

The processes of snow metamorphism are described in **Chapter 160, Energy Balance and Thermophysical Processes in Snowpacks, Volume 4**. It is currently accepted that the solute becomes redistributed to, and concentrated on, the snow-grain surfaces or in snow particle bonds during dry snow metamorphism, although direct observation of this process has not yet been made. The net effect of weak temperature gradient metamorphism is to concentrate the solute onto or near the surfaces of ice crystals (Bales, 1991; Colbeck, 1987; Davis, 1991). The solute may be located in a "quasi-liquid" surface layer, as discrete aerosol or as concentrated, "doped ice" pockets (Davis, 1991). Strong temperature or kinetic metamorphism is also accompanied by loss of ions. Ion losses are likely due to some form of transport, either to the base of the pack or to adjacent snow strata and the atmosphere. Laberge and Jones (1991) found that SO_4 was lost during depth hoar formation. In contrast, Pomeroy *et al.* (1993) found that SO_4 and Cl concentrations in depth hoar increased in proportion to the overall loss of water vapor from the depth hoar to adjacent snow layers. However, NO_3 concentrations remained approximately constant, indicating a concomitant loss of the species.

Chemistry of Wet Snow and Snow-meltwater Systems

The percolation of meltwaters through the snowcover (*see* **Chapter 161, Water Flow Through Snow and Firn, Volume 4**) causes the chemical composition of both the snow matrix and the meltwaters to change. The concentration and distribution of solutes in the snow-meltwater system is controlled by a wide variety of physical and biological processes (see Figure 4). These processes include

1. solute leaching from snow grains;
2. meltwater-particulate interactions; and
3. microbiological activity.

In addition, snow-atmosphere exchange is another factor as dry deposition rates of certain species (e.g. SO_2, HNO_3, HCl) to wet snow crystals increase significantly because of their solubility in water (Cadle, 1991). Rain on snow will also influence the chemistry of meltwaters due to its own chemical composition (Tranter *et al.*, 1992).

Solute Leaching

Fractionation of solute species between snow grains and meltwater occurs because of leaching of the melting snow

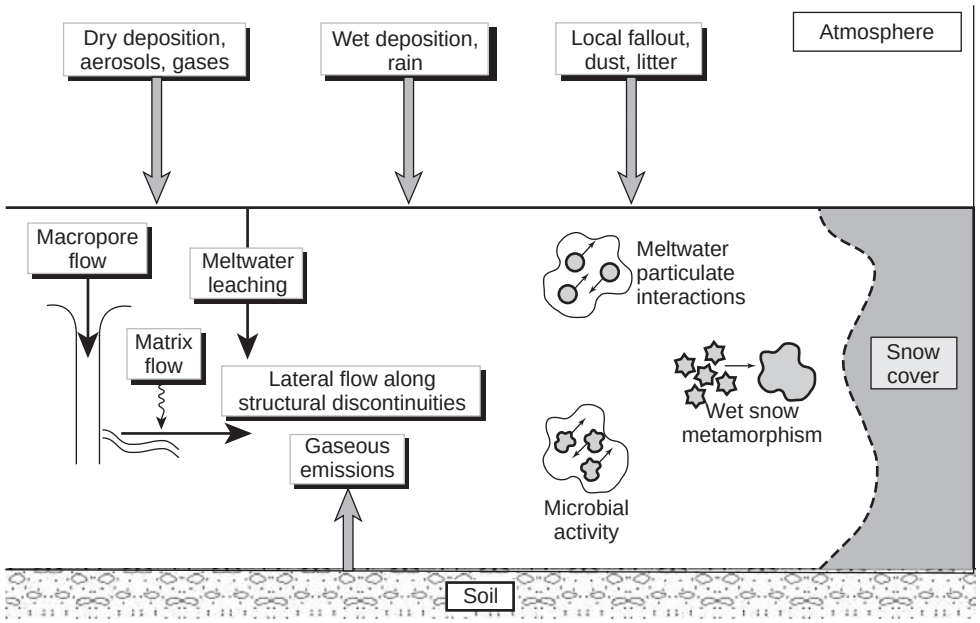

Figure 4 The main physical, chemical, and biological processes that influence the chemical composition of snow cover during melt (After Tranter and Jones, 2001)

grains. The result is that the meltwater front becomes progressively more concentrated as it moves through the pack (Johannessen and Henriksen, 1978; Colbeck, 1981). The degree of fractionation of any solute species, x, between snow and meltwater can be described by a nondimensional "concentration" factor, CF,

$$\mathrm{CF} = \frac{C_\mathrm{m}}{C_\mathrm{p}} \qquad (1)$$

where C_m is the ion concentration in any meltwater fraction, and C_p is the concentration in the parent snow prior to melt. Values of CF during the initial stages of meltwater discharge may range from 1 to 50, but a more typical range is 2 to 7 (Tranter, 1991). CF decreases with increasing melt and cumulative leaching to values of <0.1 in the final meltwaters. The efficiency of meltwater leaching (i.e. higher values of CF per volume of initial meltwater discharge) depends on the distribution of solute in snow grains, snowpack, and meltwater flow paths.

Wet snow metamorphism in the melt period is more rapid than dry snow metamorphism. It causes large grains to grow at the expense of small grains and solute to diffuse from grain boundaries into meltwater (Davis, 1991). The solute scavenging that results in fractionation is related to the rate of melt (Tsiouris *et al.*, 1985; Tranter *et al.*, 1988b) because it is affected by diffusion rates and the duration of snow-meltwater interaction. For example, Marsh and Webb (1979) reported the approximate doubling of initial snowmelt concentrations with the doubling of snow depth. Conversely, at high melt rates, solute scavenging is minimized. Diurnal changes in melt rate affect the CF of meltwaters, with the highest concentrations being found in the morning and evening, or during periods of shading, when melt rates are lowest.

Because of solute scavenging, meltwater flowing rapidly through snow macropores or "flow fingers" is more dilute than melt flowing through the snow matrix. The effects of heterogeneous flow on the spatial variability of fractionation are illustrated in Figure 5, where the CF is shown for two flow paths, one with the lowest (matrix) and one with the highest (macropore) measured flow rate (Marsh and Pomeroy, 1999). The CFs of both flow paths gradually converged over time, until all flow paths had similar values.

The mesoscale distribution of solute in snow cover will also affect the concentration of meltwaters. Discrete snowfalls or redistribution events cause snow strata to have differing composition. Solute-rich bands can arise from the exclusion of solute from ice lenses formed by the refreezing of meltwater, or rainwater in cold snow. The result of several diurnal melt-freeze cycles is often to increase the ionic concentrations in the first meltwaters issuing from the snowpack (Bales *et al.*, 1989; Williams and Melack, 1993). Both laboratory and field experiments have shown that solute-rich layers give rise to more concentrated meltwaters (Colbeck, 1981; Tranter *et al.*, 1986; Marsh and Pomeroy, 1999).

Modeling solute leaching and meltwater composition is extremely difficult because of uncertain processes, variable location of solutes in snow, and complex meltwater

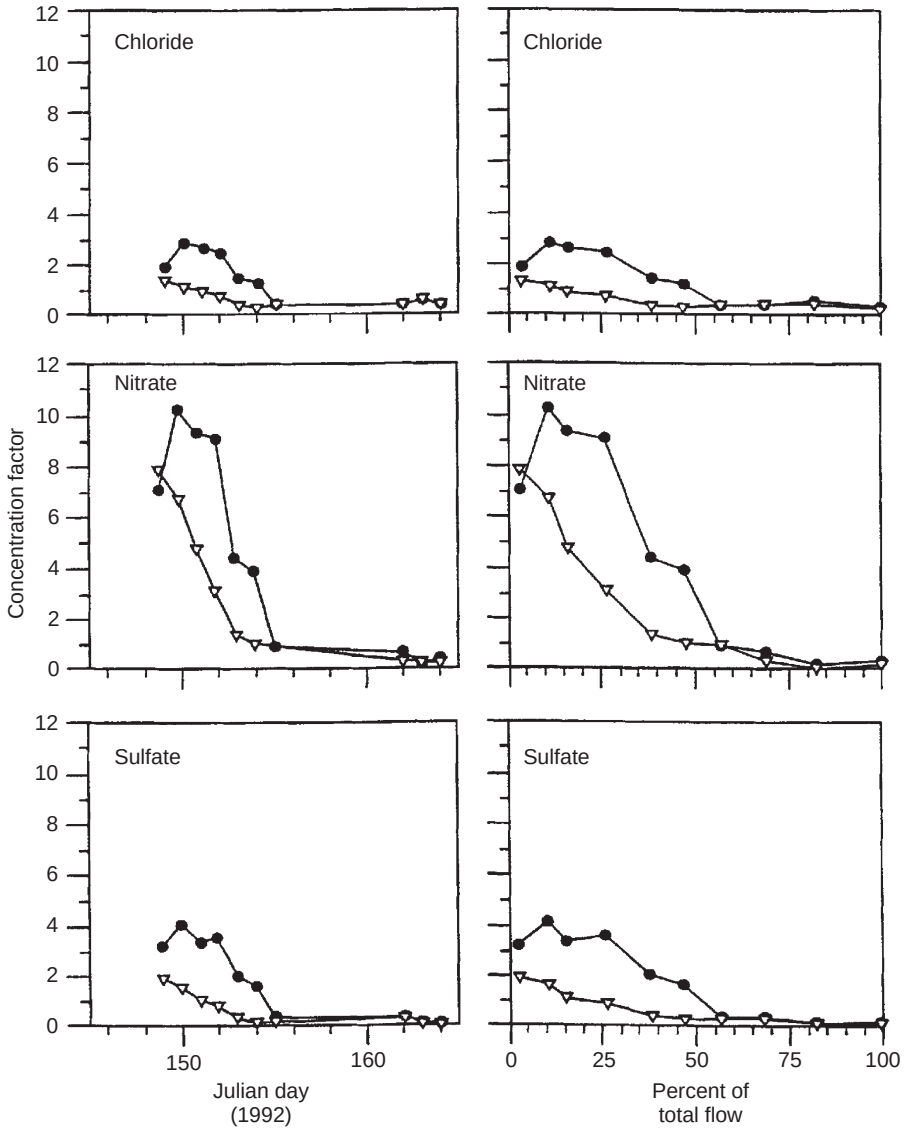

Figure 5 The impact of flow rate on the concentration factor of SO42-, SO3- and Cl- in snowmelt. The data is collected from a multiple compartment lysimeter under a tundra snowpack that samples both high and low meltwater flow zones of the melting snowpack. Open symbols and closed symbols denote the concentration factors from high and low flow chambers respectively

dynamics. Many early elution models were based on bulk transport, which in turn was based on snow depth and a bulk leaching coefficient (Stein *et al.*, 1986). The leaching coefficients were based on first-order removal of the solute from snow by meltwaters in advection-dispersion calculations (Hibberd, 1984). Recent models include metamorphism, preferential flow paths, and the solution of ions in snow, and are being used to explore the spatial and temporal distributions of water and solute flux (Iida *et al.*, 2000; Stagnitti *et al.*, 1999). Results suggest that solute should be partitioned into mobile and immobile fractions, whose interaction controls solute release into the meltwater flow (Feng *et al.*, 2001).

Snowmelt-particulate Interactions

Chemical reactions between meltwater and inorganic/organic particles can affect the concentration of solute in meltwater. Many studies have observed the neutralization of snow acidity by carbonaceous dusts from a variety of sources of either local (Colin *et al.*, 1987) or remote origin (Loye-Pilot *et al.*, 1986). Delmas *et al.* (1996) determined that the rate of chemical weathering of dusts in meltwaters depended on the location of the dust in the snow cover; dust in the lower strata of snow showed the highest rates of weathering due to increased partial pressures of CO_2 that arise during dust-meltwater interaction (see Figure 6).

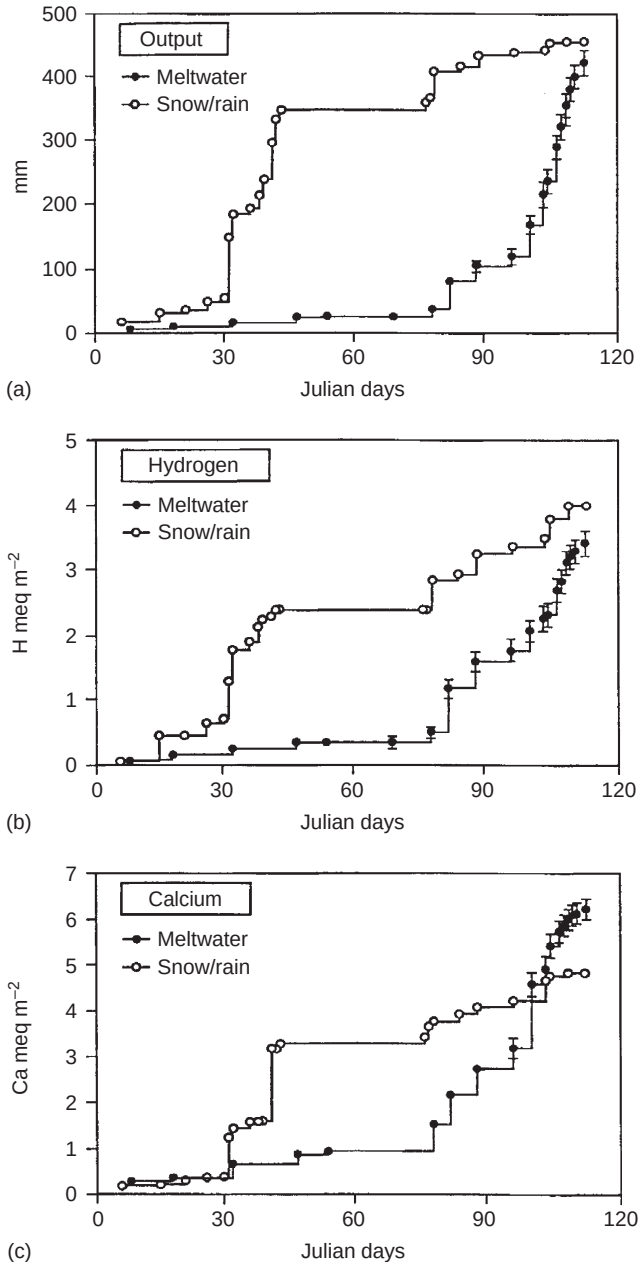

Figure 6 The neutralization of meltwater by calcareous dust in the French Alps. (a) The cumulative input of snow water equivalents and rain to the snowcover, and the cumulative output of meltwater. The water balance is approximately equal. (b) The cumulative input of H^+ to the snow cover, versus the cumulative output. There is a net loss of H^+ during the thaw. (c) The cumulative input of Ca^{2+} to the snow cover, versus the cumulative output. There is a net increase in Ca^{2+} during the thaw (After Delmas *et al.*, 1996)

These lower strata dust particles were, thus, the most efficient at neutralizing acidic meltwaters.

The leaching of litter in snow by meltwaters removes soluble organics and other chemical species (Jones and Sochanska, 1985; Stottlemyer, 1987). Surficial ionic exchange may also take place between meltwaters and the organic debris (Cronan and Reiner, 1983). Leaching experiments (Courchesne and Hendershot, 1988) show that large amounts of PO_4, K, Mn, Ca, and Mg are discharged from litter-laden snow covers, and a decrease in the acidity of meltwaters may arise from cation exchange.

Microbial Activity

During spring melt, the presence of liquid water and the increase in solar radiation stimulate microbiological and invertebrate activity in snow cover. Jones and Debois (1987) showed that meltwater production increased microbiological activity on canopy fallout in forest snowcover. The presence of meltwater also results in photosynthetic activity of truly motile algal populations within the snow cover (Hoham, 1987). Photosynthesis results in an increase in algal biomass at the expense of nutrient concentrations in the meltwaters. Decreases in the concentrations of NH_4 and NO_3 are particularly noted during the growth of algal populations, and may be of the order of 0.67 eq[N] ha^{-1} day^{-1} and 1.05 eq[N] ha^{-1} day^{-1} respectively (Jones, 1999). The loss of nutrients in snow meltwaters over the whole melt season may be appreciable, approaching 20–30% in some years (Jones, 1991).

Snow Nutrient Fluxes and Basin Budgets

Direct acidification from snowmelt remains a concern in many catchments with poor buffering capacity and proximity to certain industrial sources (Tranter *et al.*, 1988a). It is now realized, however, that many episodic stream and lake acidifications that had been associated with the melt of seasonal snowcover were, in fact, due to the mobilization of soil water that carried high ionic loads during the snowmelt period (e.g. Peters and Driscoll, 1987). The role of low ionic strength snowmelt waters is apparently to mobilize geochemical transport from soils in the basin (Hendershot *et al.*, 1992). The exception is where saturated frozen ground with macropores permits runoff with minimal soil interactions (e.g. Jones and Pomeroy, 2001; Quinton and Pomeroy, 2005). The direct delivery of nutrients from snow is now recognized as the primary snow-derived geochemical impact on basin hydro-ecology (Tranter and Jones, 2001). In basins that sustain a long snow-covered period, the major input of N and S to soils and water bodies arises in snow meltwaters in spring. The major output may also occur during the same period when export from the basin by streams is the greatest because of the meltwater runoff (Brooks and Williams, 1999; Brooks *et al.*, 1999). Where basins are poorly buffered, there is a dramatic drop in pH during snowmelt because of acids released directly from snow, and/or mobilized from soil. In either case, runoff during snowmelt has been linked to severe stream and

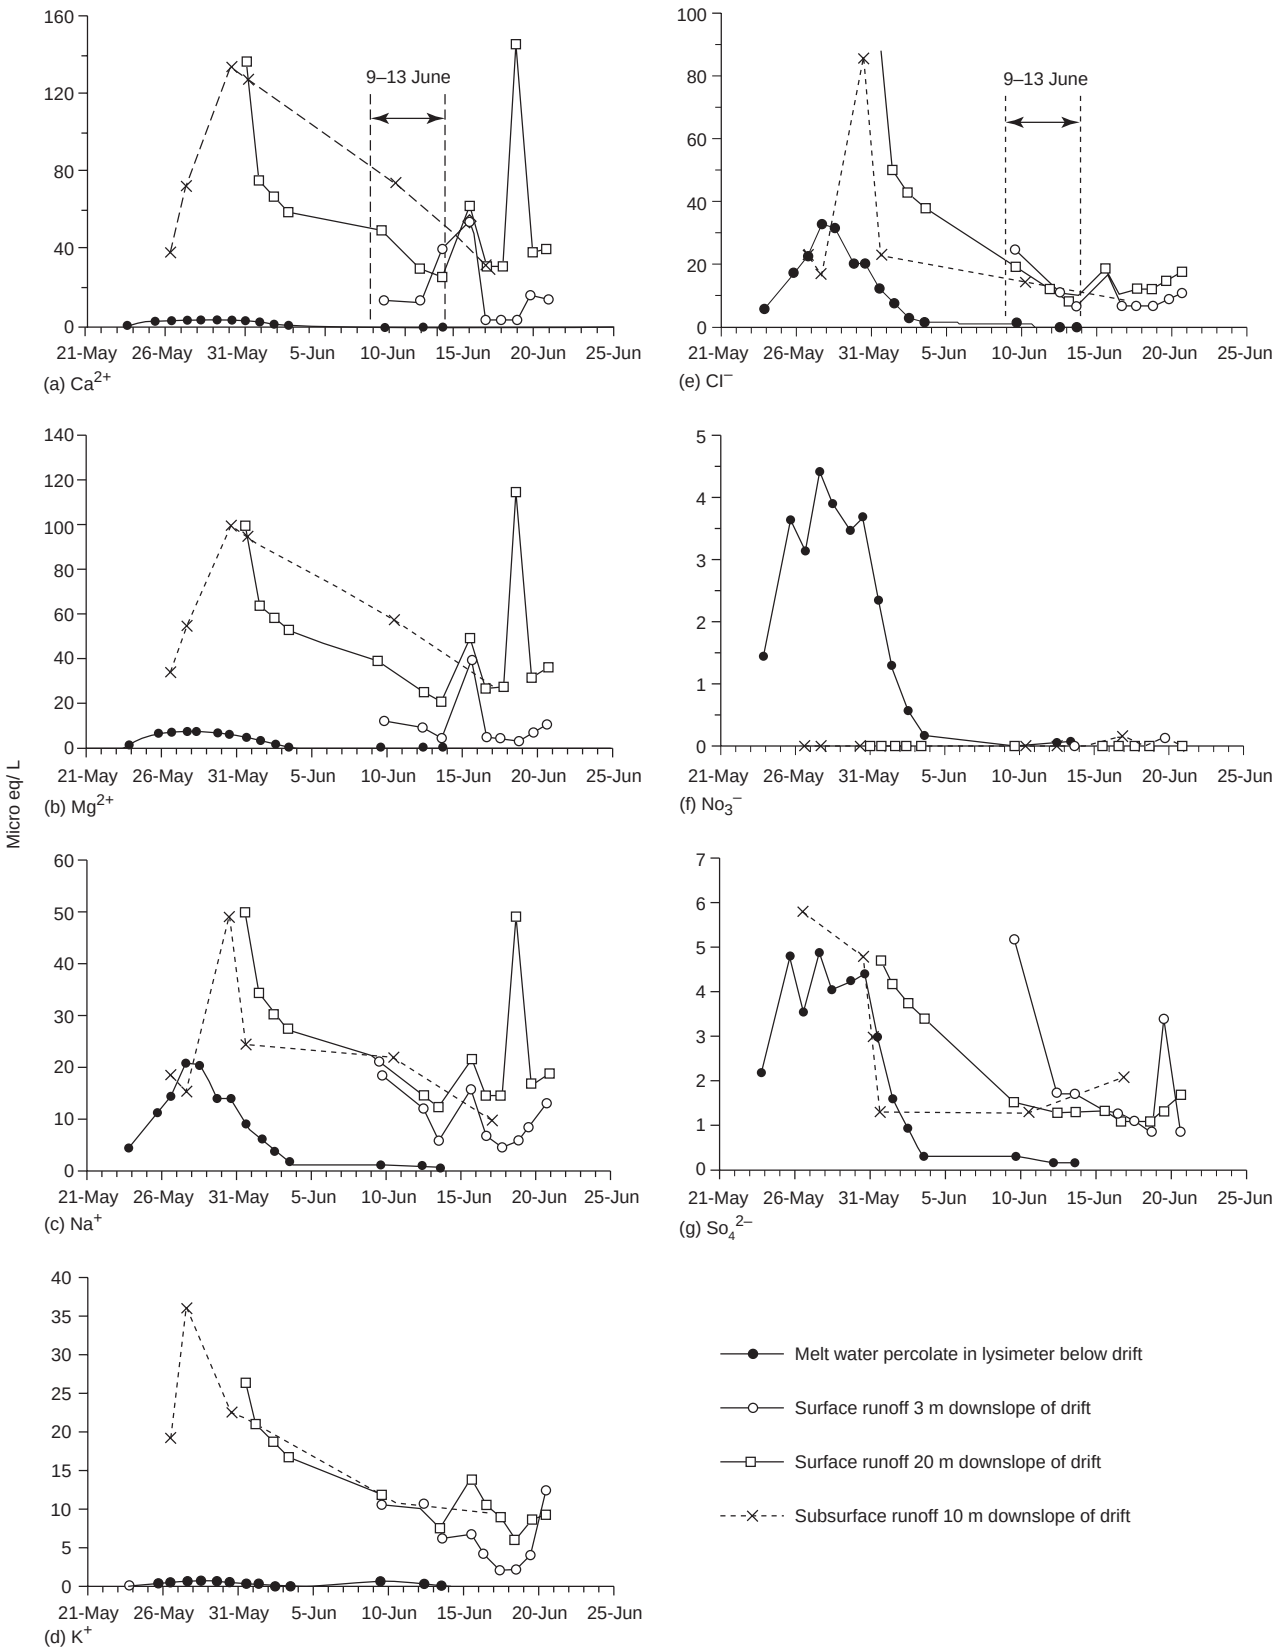

Figure 7 Ion concentrations in (i) meltwater, (ii) surface runoff 3 m downslope, (iii) surface runoff 20 m downslope, and (iv) subsurface runoff through 10 m of peat (After Quinton and Pomeroy, 2005)

lake acidification (Galloway *et al.*, 1987) (*see* **Chapter 95, Acidic Deposition: Sources and Effects, Volume 3**).

On an annual basis, the input and/or output of inorganic nutrients are relatively small, relative to the amount of nutrient that is being recycled within the basin itself. For example, values for the export of NO_3 by streamwater during melt in a boreal forest range from $0.65\,kg\,N\,ha^{-1}$ to $1.7\,kg\,N\,ha^{-1}$ (Tranter and Jones, 2001), which is small in comparison to organic pools of N. However, inorganic N has an extremely important role in primary productivity and is linked directly to carbon uptake by ecosystems. The contribution of inorganic N during snowmelt can be one of the largest inputs of this nutrient during the year (Jones, 1991)

The export of N as NO_3 originates both from the solute in the meltwaters (Williams *et al.*, 1993), and/or from the leaching of the species from soil after over-wintering nitrification of organic matter (Peters and Driscoll, 1987; Rascher *et al.*, 1987). In a study of a Colorado watershed, Lewis and Grant (1980) found that hydrological export of N as NO_3 increased significantly after winters over which the soil had frozen. This is supported by the work of Groffman *et al.* (1999) in a northern hardwood forest. The studies of Stottlemyer and Toczydlowski (1990), Stottlemyer and Toczydlowski (1999) indicated that nitrification occurs throughout the winter in organic soils when frozen soil conditions do not occur. Slow sustained meltwater discharge in winter, moves the mineralized N to lower inorganic horizons, where it cannot be taken up by microbiological activity. Some of the NO_3 can then be removed during the main melt period by macropore flow into surface water channels. Heuer *et al.* (1999) show that N dynamics in high altitude-basins are controlled by soil infiltration and transformation of N, and that soils can act as sources (alpine) or sinks (subalpine) of N during snowmelt.

Brooks *et al.* (1996) estimated that the winter/spring N losses by denitrification (N_2, N_2O) from an alpine basin were equal to the NO_3–N input by snowmelt, and represented 50% of the annual gaseous N loss. In this particular system, the loss of N via runoff was negligible during snowmelt. This latter result is in contrast with the hydrologic losses measured by Williams *et al.* (1993) at another alpine site, by Peters and Driscoll (1987) at a hardwood forest site, and by Jones and Roberge (1992) at a coniferous boreal site. These studies show the differing response of ecosystems to the input of N by snowmelt. The factors controlling the hydrologic export of N as NO_3 remain poorly understood.

An example of the effect of a nutrient-poor basin on the chemistry of snowmelt water, as it follows flow pathways to a stream is given by Quinton and Pomeroy (2005) for a frozen soil tundra site (Figure 7). Over flow pathways of from 3 to 20 m from a snow patch, enrichment of Ca, Mg, K, Cl, and Na was substantial. Concentrations increased from one to two orders of magnitude, indicating leaching from soil particles and surface vegetation, and possibly mixing with and flushing of soil water. SO_4 concentrations in meltwater were not strongly modified by hillslope flow, whilst NO_3 concentrations dropped to below detection limits shortly after exposure to the soil, indicating rapid microbiological uptake in the near-surface soil zones, despite below 0 °C soil temperatures.

Summary

Studies of the chemistry of snow-covered basins show that snow is not a passive reservoir of chemical species. Snow-atmosphere exchange by wind redistribution, dry deposition, and volatilization accompanied by various physical processes such as air and water movement, and snow metamorphism within the pack can increase or decrease the quantity of certain species, and/or lead to a redistribution of species within the snow cover. Chemical reactions such as photolysis also take place, while the presence of microorganisms in the snowpack will influence nutrient concentrations during the melt period. Inputs of inorganic nutrients to snow can be an important part of the annual cycling in the basin, particularly for N. Snowmelt chemistry alone is rarely directly responsible for major chemical fluctuations in water bodies, but the meltwater flux is important in mobilizing soil constituents and relocating soil water to the stream.

164: Role of Glaciers and Ice Sheets in Climate and the Global Water Cycle

MARTIN J SIEGERT

Bristol Glaciology Centre, School of Geographical Sciences, University of Bristol, Bristol, UK

Glaciers and ice sheets store nearly 70% of the world's freshwater and would raise sea level by around 70 m if they melted. They are, thus, an important component of the global water cycle. Their role in climate can be assessed through current responses to global warming and their influence on the environment during periods of glaciation. At the Last Glacial Maximum, ~21 000 years ago, the glacial cover caused sea level to be 115 to 130 m lower than at present. The climate of Ice Age Earth was affected in many ways by ice sheets. First, the expansion of ice sheets caused huge changes to the surface albedo and, hence, the radiation budget of the planet. Second, the orography of North America and Eurasia was altered significantly by large ice sheets, which had implications for atmospheric flow. Third, as the ice sheets grew and decayed, the influx of freshwater to the oceans, and in particular the North Atlantic, affected the ocean circulation, which in turn affected climate. The result of this ice–ocean–atmosphere interaction was large-scale short-term oscillations in air temperatures, which have been recorded in Greenland ice cores. The ice and climate processes identified for the glacial cycle are relevant today. For example, the Greenland ice sheet is currently melting at its southern margin, and releasing freshwater to the North Atlantic. Importantly, global temperatures were a few degrees higher in the previous interglacial, and the Greenland ice sheet was about half its current size. As global warming continues, the response of the Greenland ice sheet could be to return to its Eemian configuration. Although far smaller in volume, glaciers respond much quicker to climate change than do ice sheets. In the last century, most have experienced decay, and the runoff generated has been estimated to account for at least 10% of the 15 to 20 cm of sea-level rise measured (see ***Chapter 165, Mass and Energy Balances of Glaciers and Ice Sheets, Volume 4****). In combination, glacier and ice-sheet melting may send large quantities of water into the oceans, some of it rapidly. This could have serious implications for the climate of the North Atlantic and, through teleconnection, the world.*

INTRODUCTION

The global water cycle can be defined as the exchange of water between the land (including the biosphere), the hydrosphere, the atmosphere, and the cryosphere (Figure 1). Climate is inextricably linked to the water cycle, and glaciers and ice sheets play a central role within this cycle in defining the environmental conditions of the planet.

Processes critical to the water cycle are the evaporation of water into the atmosphere (predominantly from the oceans), atmospheric circulation, oceanic circulation, terrestrial runoff of fresh water, and processes leading to sea level and salinity changes. Glaciers and ice sheets, and their behavior in space and time, are key elements in each of these processes. They are essentially enormous stores of freshwater and their melting contributes to the freshwater input to the oceans. They have high surface albedos and so influence the surface heat balance, and they can grow to such a degree that they can change the hypsometry of a continent, which has implications for atmospheric circulation.

The global water cycle controls the amount of freshwater available for human use. As climate alters so too will the global water cycle and, thus, the availability of freshwater. It is therefore essential to ascertain how the global water cycle operates. This paper examines the role of glaciers

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

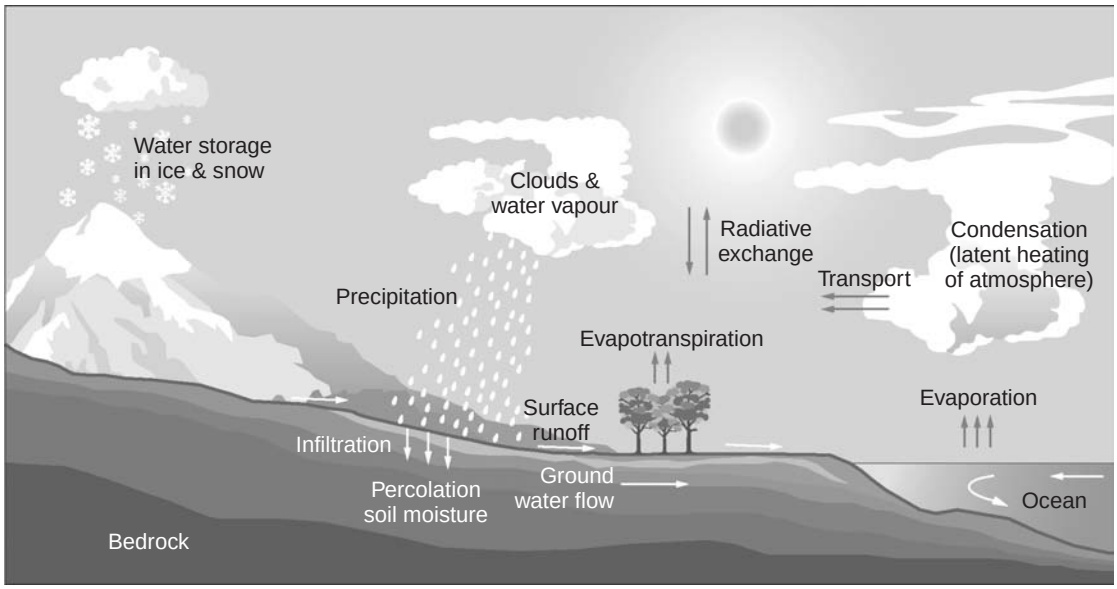

Figure 1 Schematic representation of the global water cycle

and ice sheets in the global water cycle, shows how past ice-sheet changes have had a marked influence on climate and water transfer processes, and discusses how ice sheets may respond to and influence climate today and in the future.

GLACIER VOLUMES

The oceans hold around 97% of all water on Earth (Gleick, 1996). Of the remaining 3%, around two thirds is held as ice within glaciers and ice sheets (the other third being in lakes, soils, rivers, and the atmosphere). Glaciers thus hold nearly 70% of the planet's freshwater. The distribution of glacier cover at present is provided in Table 1. By far the greatest ice volume is in Antarctica, where two ice sheets (the East and West Antarctic ice sheets) provide more than 25 million km^3 of ice, which, if melted, would raise global sea level by over 60 m. The next largest ice sheet is in Greenland, and this ice mass holds enough water to increase sea level by about 6 m. The remaining ice caps and glaciers in the world, if they too melted, would raise sea level by less than 0.5 m.

At the Last Glacial Maximum (LGM) at about 21 000 years ago, the spatial distribution of ice was much different from today (Table 2). Ice sheets at the LGM captured so much water from the oceans that global sea level was 115 to 130 m lower than its present-day level. Glacier expansion occurred predominantly in the high- to midlatitude Northern Hemisphere, where continental-scale ice sheets grew across North America and Europe. In North America, the Laurentide and Cordilleran ice sheets held as much ice as East Antarctica today. In some regions, such as Greenland and Antarctica, LGM ice sheets expanded from ice masses that had survived the preceding interglacial. The growth of ice was also witnessed in the Southern Hemisphere midlatitudes (e.g. Patagonia and New Zealand).

Table 1 Present-day volume of glaciers and ice sheets. The ice volumes for Greenland and Antarctica are for grounded ice only, and exclude ice shelves. As ice shelves are floating they have already displaced their weight in water and so if they melted sea level would not change as a consequence. The potential rise in sea level from ice sheets was determined by calculating the isostatic uplift that would occur if the ice were taken off, and allowing for the volume of seawater that would replace the ice in some areas. The sea level is therefore less than its ice volume equivalent (IPCC, 2001)

Geographic region	Volume (km^3)	Percent	Potential sea level rise (m)
Ice caps, ice fields, glaciers, and so on.	180 000	0.6	0.45
Greenland	2 850 000	10.0	7.2
Antarctica	25 710 000	89.4	61.1
Totals	28 740 000	100	68.75

However, outside of Antarctica, the lack of land surface (and continental shelf) limited the growth of ice in this half of the globe. The formation of Late Quaternary ice sheets caused alteration to the chemistry and circulation of the oceans, the flow of air (and moisture) within the atmosphere, the reflection of sunlight from the Earth's surface, and sea level. The environment of the planet was therefore very different at the LGM compared with today, and the global water cycle was an important control on this change.

GLACIER FLOW, MASS BALANCE, AND RESPONSE TIMES

Glaciers are fed with snow that, after a number of years of compression and firnification, turns to dense ice. The region in which ice accumulates is known as the *accumulation zone*, and is usually located in the highest, coldest regions of the ice mass. At the other end of the glacier, at lower elevations where it is warmer, ice is lost due to surface melting and, if the glacier terminates in water, iceberg calving. This region of net ice loss is known as the *ablation zone*. The line between these zones is where there is neither net ablation nor net accumulation of ice, and is called the *equilibrium line*. The altitude of this line is referred to as the "equilibrium line altitude" or, more commonly, the ELA. The flow of ice within glaciers acts to transport mass from the accumulation zone to the ablation zone (Figure 2). Thus, when the volume of ice accumulated equals the volume of ice ablated and the volume of ice transported from the accumulation zone to the ablation zone, the glacier is said to be "in balance". When a glacier is in balance, it remains in a stable, steady position, neither growing nor shrinking. In this case, the ELA is in a position that permits this "steady state" to exist. When the climate changes, the position of the ELA and the mass balance may alter. Glacier growth occurs when the annual mass balance is positive for a number of years. As a rule, ice accumulates in the

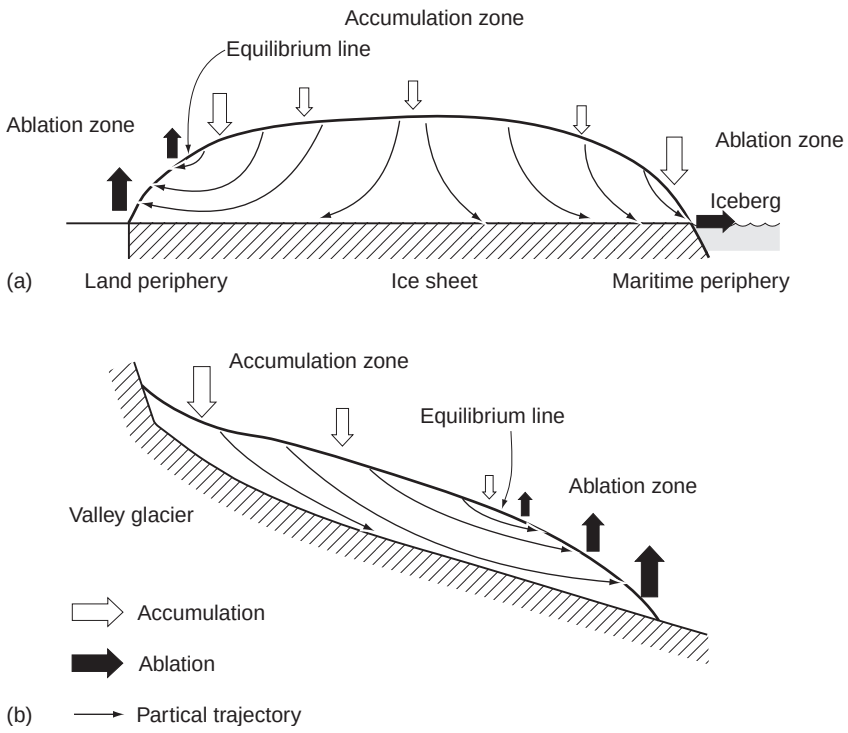

Figure 2 Glacier flow and the surface mass balance for (a) ice sheets and (b) glaciers. Reproduced from Siegert (2001) adapted from Sugden and John (1976) © Nature Publishing Group

winter and ablates in the summer. Generally, for glacier mass balance to become positive, the summer melt season needs to be cooler, resulting in less melting of ice. The net result of summer cooling is a lowering of the ELA. In this situation, the accumulation area is increased and the ablation area is decreased. This causes more flow of ice into the ablation region than gets ablated and, so, the glacier advances. Conversely, warmer conditions in the summer season result in a raising of the ELA, and more melting across a wider area of the glacier surface. If this happens for several years, the glacier will retreat.

This simple relationship between summer air temperatures, the ELA, and mass balance is true for large terrestrial ice sheets as much as it is for small glaciers. As the ELA is lowered, more and more land is available to be glacierized. It is therefore easy to comprehend how a reduction in summer air temperatures across a wide mountainous area would result in the large-scale expansion of glaciers. Further reduction in the ELA may cause these glaciers to coalesce and build up as single, large bodies of ice. And so it is that terrestrial ice sheets are initiated across mountain regions, when the ELA is forced down by a reduction in air temperature. Increase in summer air temperatures can cause an increase in the ELA and, therefore, an increase in net ablation. Thus, the growth and decay of ice sheets on land may be related to the position of the ELA and, because of this, to surface air temperatures. It should be noted, however, that in some cases, such as glaciers in Scandinavia, net accumulation occurs under warmer conditions because of the associated increase in precipitation. It should also be remembered that there is hardly any melting in Antarctica. Here, loss of ice is controlled predominantly by iceberg calving and sub-ice shelf melting.

If circumstances occur in which increased rate of ice flow causes more ice to be transported from the accumulation zone to the ablation zone than is supplied by accumulation, the advance of the glacier margin will eventually result in net ablation and subsequent retreat. This leaves the glacier with less ice than it had prior to the increase in ice flow. This unsteady flow of glaciers is called glacier surging and has been observed to occur in many glaciers and, recently, sections of relatively large ice caps (e.g. Sharp, 1988; Joughin *et al.*, 1996; Dowdeswell *et al.*, 1999).

Glaciers and ice sheets respond to climate change at different rates. The response time is "the time it takes a glacier to adjust to a change in its mass balance" (Paterson, 1994). The time taken for ice to flow from the accumulation zone to the ablation zone dictates the "response time" of an ice mass to climate change and is controlled by two parameters: the flow speed of ice and the glacier size. Fast-flowing small glaciers have a very low response time, while large slow-flowing ice sheets have much greater values. An estimate of the response time of a glacier (in which the deformation of ice dominates the total ice flow) is: $t = H/a_0$, where t is the time, H is the maximum ice thickness (at the divide if the base is flat) and a_0 is the ablation rate at the glacier margin (Paterson, 1994). For small temperate glaciers in maritime conditions, the response time is between 15 and 60 years, while for ice caps in the Canadian Arctic, which are larger and have a much cooler climate, the response time is between 250 and 1000 years. The greatest response times are in ice sheets, however. For example, in Greenland, Paterson (1994) estimates a response time of 3000 years. Thus, while ice sheets house the majority of the world's ice and freshwater, they have the largest response times. This makes them more robust in terms of withstanding short-term environmental variations than small temperate glaciers.

AGE OF GLACIERS AND ICE SHEETS

The response time of an ice mass is related generally to the age of ice within the ice mass. Near the center of a large ice sheet, or within the accumulation zone of a glacier, each annual layer of snow will lie on top of the previous layer. The deformation of this ice by vertical compression results in the thinning of ice layers. Thus, the age of ice becomes a function of depth and the accumulation rate of ice. An ice core taken from the center of an ice sheet will, therefore, comprise an ordered succession of ice from which climate records can be measured. Air bubbles within the ice trap the gaseous components of the atmosphere shortly after the time at which the original snow fell on the ice surface. Ice cores can be used to measure this gas and form a record of past concentrations of atmospheric constituents, such as carbon dioxide and methane. In addition, isotopes of oxygen and hydrogen can be measured from the ice itself, with values related to those of the snow from which the ice originates, to provide a proxy record of past air temperatures. The limit to the age of ice-core information is the age of the base of the ice sheet or glacier. Analysis of the Vostok ice core in central East Antarctica has provided knowledge not only of the last glacial climate, but of the previous four glaciations, spanning over 420 000 years. The oldest ice recovered from Antarctica is from the EPICA site at Dome C, where the ice is reported to be as old as 1 Ma at the base. The oldest water in Antarctica will be held as subglacial lakes, such as Lake Vostok (Siegert *et al.*, 2001), where water several million years of age could be present. For Greenland, ice cores such as GRIP and GISP2 provide a high resolution record of the glacial–interglacial cycle, and show major environmental instabilities during the last deglaciation (e.g. GRIP Project members, 1993; Grootes *et al.*, 1993; Stuiver and Grootes, 2000), but they rarely sample ice older than the last interglacial. Ice cores from other ice masses do not generally penetrate back to the LGM. They can often, however, provide detailed records of regional climate change over the last few thousand years.

Ice sheets, therefore, hold the majority of the planet's ice, have the greatest response times, and contain the oldest ice. They also have great potential for affecting climate and the hydrological cycle. Glaciers, on the other hand, contain far less ice, but they react quickly to climate change and so can be used as a means of assessing change.

GLACIERS, ICE SHEETS, AND CLIMATE CHANGE

Geological and glaciological data concerning the distribution of ice sheets at the LGM provide an excellent opportunity to assess how ice sheets both respond to and affect climate change. By examining the processes responsible for the buildup of ice at the LGM, we will uncover the ice-sheet processes critical to the global water cycle today.

Milankovitch Theory and the Forcing of Glaciations

By far the most cited theory relating climate change with ice-sheet growth was discussed initially by Croll (in the late nineteenth century) and later elaborated by Milankovitch in 1930. The theory is often referred to as the Milankovitch Theory (Figure 3). In this theory, cyclical changes in three of the Earth's orbital variants, namely, (i) orbital eccentricity, (ii) tilt of the axis (obliquity), and (iii) precession of the equinoxes, cause an alteration in solar radiation received at the Earth's surface and, hence, are thought to force air temperature changes.

The orbital eccentricity of the Earth varies in time between a highly elliptical orbit and a circular orbit. The periodicity of the cycle is 95 800 years (~100 ka). This is the most contentious of the orbital variations. Proponents of the theory claim it has the largest effect on ice-sheet growth, but it is actually responsible for only very small changes in solar insolation.

The tilt of the Earth's spin axis varies between 21.39° and 24.36°. The present value is 23.44°. The periodicity of this cycle is 41 000 years. Decreases in the axial tilt result in cooler summers in the more polar regions (high and midlatitudes), but do not change significantly the amount of solar radiation at low latitudes. Tilt variations do affect the degree of seasonal contrast at high latitudes, however, and higher obliquity results in increased seasonality.

The third orbital variation, caused by the conical rotation of the Earth's spin axis, affects the timing of perihelion and aphelion (the position where the Earth is closest and furthest from the Sun). The period of this movement is 21 700 years, over which time the Northern Hemisphere is tilted towards the Sun at successively different points in the Earth's elliptical orbit. At present, aphelion takes place during the Northern Hemisphere summer. This orbital variation causes an out of phase association in the degree of seasonality experienced by the two hemispheres.

Milankovitch analyzed, through the mathematics that describes the Earth's orbit around the Sun, the change in solar insolation caused by each of the orbital variations described above. These individual changes combine to yield the total modification in solar insolation due

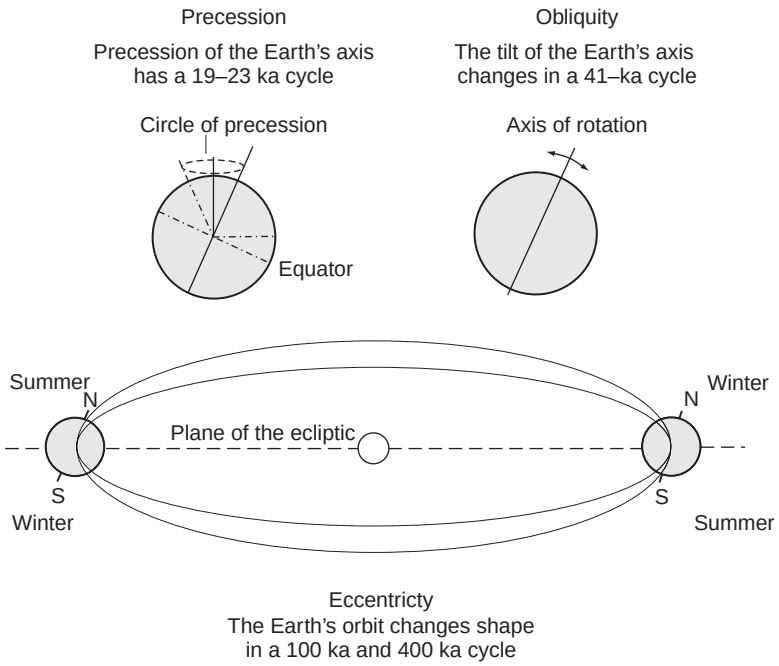

Figure 3 Milankovitch theory of orbital variations. Adapted from Siegert (2001)

to time-dependent variations in Earth's orbit. Ice growth (glaciation) occurs when a reduction in solar insolation in the Northern Hemisphere summer causes cooler temperatures and so less melting of snow and ice. This may be followed by a warm winter, when increased precipitation from the oceans falls onto high latitudes as snow. Ice recession (deglaciation) occurs when an increase in solar insolation in the summer causes relatively warm conditions, which result in an increase in the rate of ablation.

The most important season is the summer, when most melting can occur. Orbital calculations provide information on the variation of incident solar radiation as a function of season and latitude. From this, a complex relation between latitude and solar insolation through the last 130 000 years has been developed (Muller and MacDonald, 2000). On their own, the solar insolation changes predicted by Milankovitch are small, and not generally considered significant enough to initiate glaciations. Some sort of amplification of the climate response to orbital variation is therefore required. This is where ice sheets and glaciers can play a part in the global water cycle, climate modification and, consequently, their own existence.

There are several feedback mechanisms linking ice sheets, the oceans, and the atmosphere (Figure 4). A very good summary of the nature of these interactions is provided by Clark *et al.* (1999). They contend that ice sheets modulate ocean surface temperatures, the ocean circulation, the biosphere, surface albedo, and the continental water balance. In turn, these changes "feed back" and cause changes in ice-sheet configurations. Several of these feedback mechanisms are described below.

Amplifying Factors and Feedback Mechanisms

Sea Level

One important feedback mechanism allowing ice sheets to expand involves the link between sea level and ice-sheet volume. In this mechanism, ice growth in terrestrial regions causes sea-level reduction and, so, enables shallow marine regions such as the Barents Sea in the Northern Hemisphere or the Ross Shelf in Antarctica to become fully glaciated. The growth of ice in turn lowers the sea level further allowing additional expansion of marine-based ice. In addition, as sea level is lowered, the position of the ELA with respect to sea level will remain unchanged. However, the relative elevation of the land surface will increase. This can result in more land above the ELA, and an increase in the accumulation area of some glaciers. The subsequent growth of ice can then lead to further sea-level fall and the development of a simple feedback system. On the other hand, if accumulation decays with increasing distance from the ocean, then a reduction in sea level may result in less accumulation on certain glaciers.

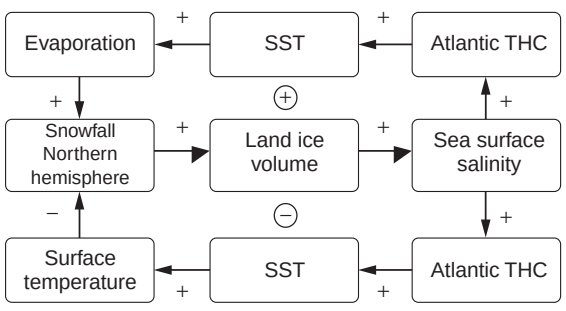

Figure 4 Flow diagram to describe the feedback processes associated with ice sheets, the oceans, and the atmosphere. Adapted from the IPCC (2001)

The decay of ice sheets during the last deglaciation was clearly associated with sea-level change. The melting of ice sheets into the oceans caused sea level to rise by 115 to 130 m. This may have caused marine-based ice sheets to become less stable since they would be more buoyant and more susceptible to basal motion. Ice-sheet melting would also have affected the salinity of the oceans, which would have implications for global climate. Ice–ocean interactions may have caused rapid changes in the climate during deglaciation; the likely processes involved are discussed in the Section "Evidence for rapid climate changes".

Surface Albedo

A second feedback system involves the reflective properties of the ice surface and the radiation budget of the Earth. The reflection of the Sun's radiation from the Earth's surface is related to the surface albedo. If the albedo is high, more radiation is reflected back into space. If the albedo is low, more radiation is absorbed by the planet's surface. Greater surface reflection of radiation results in a reduction in the amount of radiation absorbed. Snow and ice have extremely high albedo values. Therefore, as snowfields and ice sheets expand as a result of solar-insolation-induced adjustments in the air temperature, the increased surface albedo will cause an increase in the reflection of solar radiation and a further reduction in air temperature. Since this process will reduce the amount of summer warmth over snow-covered continents, it acts to reduce the rate of melting of ice. Cooler conditions also lead to the expansion of sea ice over the oceans and the length of time during the summer for which it persists. Sea-ice expansion lowers the albedo of the ocean surface considerably, and this contributes significantly to the feedback system. At the LGM, when large sections of the Northern Hemisphere were permanently covered with snow and ice and sea-ice extent was at a maximum, the surface albedo of the planet was drastically higher than it is today (although it is difficult to quantify by how much, a UK Meteorological Office model predicts a global rise in albedo of greater than 50%, from 0.15 at present to 0.26 at the LGM; Dan Lunt, personal communication, 2004).

As ice sheets decayed due to global warming, the albedo of the planet's surface decreased, causing the retention of heat at the Earth's surface and, hence, further warming.

Carbon Dioxide

Atmospheric carbon dioxide (CO_2) has an impact on climate because it absorbs/reradiates long-wave radiation emitted from the Earth's surface (i.e. the Greenhouse effect). For reasons not yet fully understood, when it gets colder, atmospheric CO_2 is depleted (Archer *et al.*, 2000). As the atmosphere cools in summer at the beginning of a glacial cycle (due to solar insolation changes), the CO_2 level drops and, because of this, so too does the absorption of long-wave radiation. Hence heat is lost from the Earth yielding further cooling. The influence of CO_2 on Late Quaternary ice sheets is currently not well understood. However, there are several potential climatic feedback mechanisms that involve CO_2 that may be relevant to the growth of ice sheets.

Levis *et al.* (1999) showed how CO_2 and surface albedo feedbacks may be linked, by running a model of the biosphere and climate at the LGM. The model results showed that CO_2 changes over a glacial cycle have an effect on the biospheric surface albedo. Their work indicated how a positive feedback, caused by changes to the gross albedo of the Earth's vegetation cover, might have contributed to cooling at the mid- and high latitudes at the LGM.

In addition, Antarctic sea ice would have covered a larger portion of the southern ocean during glacial times than today (Armand, 2000). Stephens and Keeling (2000) suggest that an expansion of southern ocean sea ice would reduce deep-water ventilation and inhibit the exchange of CO_2 between the ocean and atmosphere. They calculate that this process may be responsible for about 80% of the total CO_2 drop recorded in atmospheric proxy records during the last glacial.

Ice-sheet Elevation

As ice sheets grow, the surface area and elevation on which snow accumulates both increase. For example, the mean elevation of central East Antarctica is in excess of 2.5 km above sea level, as was the elevation of the Laurentide ice sheet in North America at the LGM. Because of this, ice growth can result in an increase in the area of the ice sheet above the ELA. The increase in the accumulation zone will result in further glacier growth. Such a change to the hypsometry of a continent will have a dramatic effect on the atmospheric circulation. This process was particularly relevant at the LGM across the Northern Hemisphere, when large ice sheets altered the elevation of the continents at mid to high latitudes. Kageyama and Valdes (2000) calculated the effect of the orography of the Laurentide ice sheet on the climate of the LGM. They used an Atmospheric General Circulation Model (GCM) with imposed ice-sheet dimensions. An additional experiment was undertaken where full LGM conditions were accounted for without any ice sheets present. By comparing the results of these two experiments, the effect of the Laurentide ice sheet topography on atmospheric flow and climate was evaluated. The height of the ice sheet was found to have a major effect on the climate over North America, the North Atlantic, and western regions of Europe. By subtracting the calculated rates of precipitation determined from the ice-free experiment from those from the full-LGM experiment, the influence of the Laurentide ice sheet on precipitation was identified. These model results suggest that the ice sheet was responsible for an increase in precipitation over Northern Canada, the northern North Atlantic, and Western Europe.

Ocean Circulation

Ocean circulation is important to glacier growth and climate change for three reasons. First, oceans are capable of transporting heat between latitudes. In the North Atlantic, for example, heat is transferred from low to high latitudes, providing moisture sources for northern hemisphere ice masses. Second, ocean thermal conditions are one of several factors affecting the growth of sea ice, which is an important albedo feedback. Third, ocean temperatures are a control on the rate of ice shelf melting, and possibly iceberg calving. Ocean circulation can be split into two components: surface currents and oceanic conveyor circulation.

Ocean surface currents are controlled by the direction and gradient of the prevailing winds, the rotation of the Earth (the Coriolis force) and by internal viscous dissipation giving rise to Ekman transport. As a consequence, gyres are set up with flow directions relating to their position on the globe, which can be disrupted (to a degree) by changes to wind field vectors and, in extreme polar environments, by changes in sea-ice extent (that can separate the ocean surface and the atmosphere).

The oceanic conveyor involves the formation, sinking, transfer, and upwelling of deep water due to changes in water density. In recent years, there have been several advances in the understanding of the global flow of the oceans (Figure 5). Oceanic convection is driven from the polar regions. Cold, salty water sinks to depth and moves equatorward. There are two main locations in the North Atlantic where this happens: the Labrador Sea between Greenland and America (known as the *Boreal region*) and the Norwegian–Greenland Sea (the Nordic region) (Imbrie *et al.*, 1992). The processes involved are evaporation of seawater, cooling of surface water through radiative and sensible heat loss, and formation of sea ice (e.g. the formation of the Odden Ice Tongue in the Norwegian–Greenland Sea), causing salty, high-density water to develop at the upper boundary, which then sinks

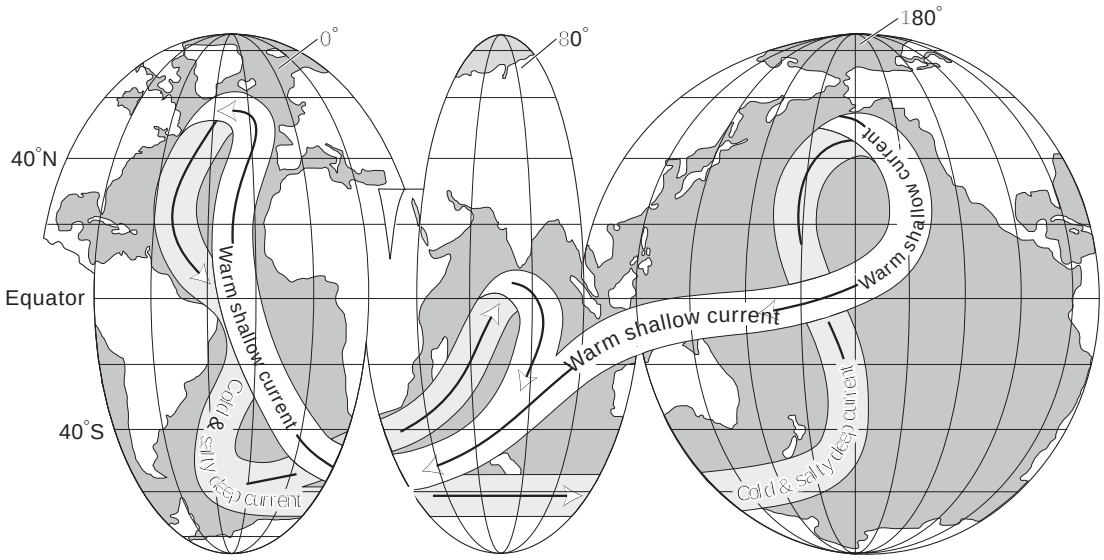

Figure 5 The global ocean conveyor system. Adapted from Siegert (2001)

to form "deep water". At present, North Atlantic Deep Water (NADW) meets the denser Antarctic Bottom Water (AABW) in the South Atlantic. These water masses then combine (at least in part) to flow into the Indian and Pacific oceans, where upwelling occurs and surface flow of water back to the Atlantic is initiated. The result is known as the *ocean conveyor belt*, which transports a flux of water more than 20 times greater than that of all the rivers combined (Figure 5). In the northern latitudes, oceans warm up between March and September and release heat in the rest of the year. In total, the amount of heat stored and released in the oceans is equivalent to about one-third of the heat received from the Sun. If the northward flow of warm water within the North Atlantic is halted, the ocean will cool and the heat supplied to Western Europe will be taken away. This would result in colder conditions over Europe and, hence, a reduction in the ELA.

One way of disrupting the ocean conveyor is to change the salinity of the ocean at the sites of NADW formation. For example, a decrease in sea-surface salinity caused by enhanced inputs of freshwater from rivers and glaciers may result in a reduction in NADW formation and, in turn, the effectiveness of deep ocean circulation (see the Section on "Evidence for rapid climate changes").

Imbrie *et al.* (1992) propose that the oceans were instrumental in the last deglaciation. In their model, the increase in summer insolation at the beginning of deglaciation caused warming of the atmosphere and oceans, which led to the snowfields shrinking. As the ELA increased, the Laurentide ice sheet melted in the south. The consequent effect on the wind field was to reestablish the Gulf Stream, and transport warm saline waters northward, increasing the exchange of waters within the Nordic regions. This heat helped to warm the atmosphere and, in turn, led to the melting of ice across Scandinavia and Eurasia. Deglaciation induced sea-level rise and, hence, the decay of marine ice sheets and then terrestrial ice sheets in the extreme north. The extra heat in the ocean increased the rate of evaporation, which in turn enhanced the effectiveness of the thermohaline system in the Norwegian–Greenland Sea.

Glaciers and Climate

Once a glaciation has started, a number of feedback processes can act to maintain the ice cover, regardless of the solar radiation inputs. It is interesting to note that, at the LGM, solar insolation values were similar to those at present (i.e. a deglacial period). It can thus be concluded that the climate at the LGM was greatly influenced, through feedback mechanisms detailed above, by the ice-sheet cover at that time. Moreover, as the planet warmed in the last deglaciation, ice sheets played an important role in regulating their own demise through their interaction with the atmosphere and oceans.

EVIDENCE FOR RAPID CLIMATE CHANGES

Greenland's GRIP and GISP2 cores hold a record of climate change as far back as the previous (Eemian) interglacial. The two cores, drilled about 30 km apart close to the summit of the Greenland ice sheet, yield a very similar palaeoenvironmental picture of the last 90 000 years or so (GRIP Project members, 1993; Grootes *et al.*, 1993). The ice-core records, with their very high temporal resolution, show that climate during the last deglaciation has been particularly variable and that alterations between warmer

and colder, and wetter and drier, conditions have been rapid. Fluctuations in the cores' oxygen isotope ratios suggest mean annual temperature variations of 10 to 15 °C, with shifts taking place rapidly over time periods on the order of decades. A doubling of accumulation at the beginning of the present interglacial also appears to have taken place over as little as three years. By contrast, the isotopic records from the Greenland ice cores demonstrate that climate variability during the present (Holocene) interglacial has been subdued by comparison, with changes of only a few degrees at most.

Ice sheets and glaciers are thought to be critical to rapid climate change of the last deglaciation. They can influence climate quickly by releasing large quantities of water, *via* melting or iceberg calving, into the oceans, so affecting ocean circulation and, thus, climate. Clark *et al.* (1999) focus on the causes of two periodic oceanic phenomena that may be related to cryospheric change: Dansgaard–Oeschger cycles and Bond cycles. Bond cycles are associated with a prolonged decrease in temperature (as recorded in Greenland ice cores) followed by an abrupt warming phase, and have a periodicity of around 7000 years (Alley, 1998). Dansgaard–Oeschger cycles, on the other hand, are millennial-scale periods of cooling and warming (Bond and Lotti, 1995; Bond *et al.*, 1997). Dansgaard–Oeschger cycles act in phase with Bond cycles during the transition between the cooling and warming, when large volumes of ice-rafted debris (IRD) are deposited across the North Atlantic by icebergs calved from the Laurentide ice sheet (so-called Heinrich events, see below) (Alley, 1998).

Alley and Clark (1999) suggest that changes in the ocean circulation caused by a Dansgaard–Oeschger event could be responsible for the Younger Dryas climate reversal at about 13 000 to 11 000 years ago. The idea is that a sudden switching off of the ocean conveyor caused sea-surface temperatures in the North Atlantic to become much colder, resulting in colder conditions over the adjacent land masses (e.g. Imbrie *et al.*, 1992; Clark *et al.*, 1999). This had the effect of reversing the deglaciation that had been going on since the LGM, and glaciers across most of Europe began to readvance. There is plenty of field evidence to show that this happened in Europe and many other parts of the Northern Hemisphere.

Heinrich Events and the Ice-sheet Binge-purge Theory

One theory fingers ice-sheet dynamics in North America as a possible cause of rapid ocean circulation and climate changes during periods of glaciation. The northeastern margin of the Laurentide ice sheet terminated as a calving ice wall along the Hudson Strait. Icebergs formed here would have drifted out into the North Atlantic where their sediments would have dropped to the ocean floor as IRD. Recent sedimentological investigations have revealed a series of IRD layers, corresponding to the 7000-year periodic production of huge volumes of icebergs. The sediments are known as *Heinrich layers* (see Figure 6). The cause of Heinrich layers is still debated. However, a commonly held view is that they were formed by periodic unstable dynamics of the Laurentide ice sheet (MacAyeal, 1993), the so-called binge-purge theory. The explanation for this theory is quite simple. The ice sheet slowly builds up over an essentially frozen base (the binge phase). Eventually, the basal temperatures reach the pressure melting value that initiates rapid basal motion (the purge phase). As ice flows out of the Hudson Strait it calves, and is advected across the North Atlantic. The drainage of so much ice depletes the reserves in the parent ice sheet such that it becomes thinner and eventually refreezes to the base, at which time the flux of ice to the Hudson Strait is decreased, and iceberg volume is reduced. This is then followed by ice regrowth. The cycle of binge and purge has been modeled by MacAyeal (1993) to be around 7000 years, which is a remarkably similar periodicity to that measured from IRD in the North Atlantic. The purge (surging) phase lasts for only a short time (around 700 years).

Meltwater Pulse 1A and the Bølling-Allerød Warm Period (14 600 years ago)

During the last deglaciation, the meltwater from decaying ice sheets and glaciers flowed to the ocean thus raising sea level. At around 14 600 years ago, so much water was transferred from the land that sea level increased by around 20 m in only a few hundred years. This huge, sudden input of freshwater to the ocean is referred to as "meltwater pulse 1A" (mwp-1A). The source of mwp-1A has been the subject of considerable debate. The traditional view is that the bulk of it came from the Laurentide ice sheet, with contributions from the Eurasian ice sheet. The cause of the decay was increased surface melting during the Bølling–Allerød warm period in North America and Europe. However, a rival theory has emerged in recent years linking mwp-1A to Antarctica (Weaver *et al.*, 2003). Both ideas are open to question. If the Laurentide ice sheet was responsible, it is not clear how a huge influx of cold freshwater to the North Atlantic is compatible with the Bølling–Allerød warm period as it may have led to a reduction in sea-surface temperatures (see the Section on "Proglacial lake outbursts and the 8200-year event" for an example of how freshening of the North Atlantic can result in climate cooling). There are two problems associated with the Antarctic ice sheet as the source. First, the ablation mechanism that would cause ice to melt rapidly is not obvious. Surface melting is an unrealistic candidate as there is virtually no runoff today. Temperatures would have to increase by several tens of degrees to cause enough water to melt from Antarctica to yield 20 m of sea-level rise, and there are no climate proxies to support such an event.

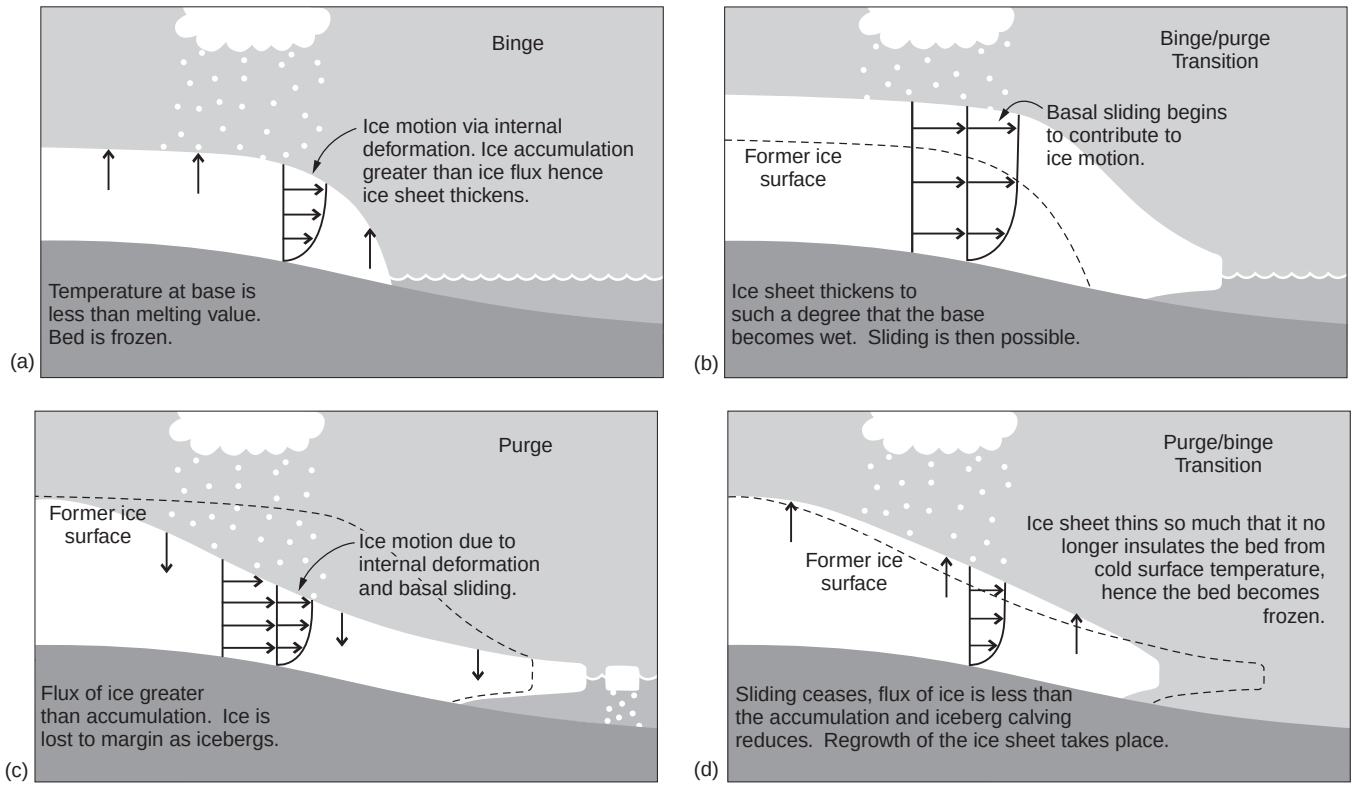

Figure 6 Binge-purge cycles of an ice sheet. (a) The binge phase. Ice-sheet growth occurs as a result of ice accumulation exceeding the flux of ice to the margin. Basal temperatures are cold as the only heat supply is from geothermal sources. (b) The binge/purge transition. As ice-sheet growth continues the base of the ice sheet warms due to enhanced heating from ice deformation and extra insulation from the ice above, until a critical threshold is reached at which the base becomes wet. (c) The purge phase. Once the subglacial conditions are warm basal sliding takes place (and this supplied more heat to the ice base), which leads to more ice transported to the margin than is replaced by falling snow and, hence, the ice sheet thins. (d) The purge/binge transition. As the ice sheet thins, the insulation effect of the ice diminishes and the base becomes cold. Once freezing conditions are reintroduced, sliding is no longer possible and the purge phase ends. As the accumulation of ice is once again greater than the flux of ice, the ice sheet begins to thicken and the binge phase begins again

Iceberg calving could be responsible, but only if this was associated with an increase in the flux of ice across the grounding line, which supposes a change to the interior ice-sheet dynamics. Second, numerical reconstructions of the Antarctic ice sheet show that its expansion involved an additional volume of ice less than that required to affect sea level by 20 m (Huybrechts, 2002). It is therefore unclear, how sea level could have risen by 20 m if the sole origin of mwp-1A was from Antarctica.

Proglacial Lake Outbursts and the 8200-year Event

The progressive retreat and thinning of the Laurentide ice sheet caused huge proglacial lakes to form along its southern margin. The largest of these was called *Lake Agassiz*. This massive lake fed freshwater into the Mississippi River between about 12 500 and 11 000 years BP (as is evident in the Gulf of Mexico isotope record). However, after 11 000 years BP lake waters were rerouted through the Great Lakes into the St. Lawrence. During its 4000-year history, Lake Agassiz played a significant role in the deglaciation of the Laurentide ice sheet. The lake reached its maximum extent between 9900 and 9500 years ago when it occupied an area of 350 000 km^2, within large regions of Ontario and Manitoba. At 8200 years ago, the ice sheet was too small to hold the lake water and so, catastrophically, Lake Agassiz drained into the Hudson Bay. Estimates put the volume of water involved in the instantaneous discharge at between 70 000 and 150 000 km^3, which would have been associated with an increase in global sea level of 0.2 to 0.4 m within a matter of days. Barber *et al.* (1999) match the sudden drainage of this lake through the Hudson Strait to a widespread cool period found in Greenland ice cores 8200 calendar years ago. Such an amount of freshwater must have affected the salinity of surface waters in the North Atlantic. In turn this

would have been disruptive to the formation of NADW and, thus, the thermohaline circulation. A decrease in the amount of warm northward-flowing mid-Atlantic surface water would have resulted in cooling of air temperatures in the higher latitudes and thus, a rapid climate change.

STABILITY OF ICE SHEETS AND IMPLICATIONS FOR FUTURE CLIMATE

The lessons being learned from the last deglaciation concerning ice sheets and their effect on climate are relevant today. The two largest ice sheets, in Greenland and Antarctica, have the potential to cause huge changes to the climate system, affecting the water cycle and society as a consequence.

Greenland

Palaeoclimatic records indicate that significant fluxes of freshwater as glacial runoff have caused dramatic cooling in the North Atlantic (Clark *et al.*, 2001) due to the freshening of Atlantic surface waters in regions of NADW formation. However, despite recognition from ocean models that the thermohaline circulation is sensitive to freshwater perturbations of as little as ~0.1 Sv (Manabe and Stouffer, 1994; Rahmstorf and Ganopolski, 1999), these models do not currently include the possible effects of significant freshwater input arising from changes in land ice sheets, which might well lead to bigger reductions in the thermohaline circulation (IPCC, 2001, p. 562).

The Greenland ice sheet is the largest store of freshwater in the Northern Hemisphere. The position, size, and topography of the southern Greenland ice sheet make it critical to future meltwater fluxes into the North Atlantic. It is well recognized that predicted global warming would likely be enhanced in high latitudes, with warming over Greenland likely to be up to three times the global average (IPCC, 2001). Runoff currently contributes ~50% of Greenland's annual ablation (Janssens and Huybrechts, 2000), concentrated along the southern margin of the ice sheet. The magnitude of runoff could be greatly enhanced in a warming world (Zwally *et al.*, 2002). The location of southern Greenland is particularly significant because it delivers runoff to key areas of NADW formation. The topography of Greenland also makes it highly susceptible to enhanced melting (Cuffey and Marshall, 2000). Greenland's ablation zone is currently relatively narrow (typically <100 km) but its topography (steep margins, shallow interior gradients) means that a modest climatic warming could rapidly expand areas of melt across the ice sheet surface. Since current temperatures already cause significant melting, any future warming will have a large impact on runoff, with the southern margin of Greenland being especially sensitive. Significantly, ice-sheet modeling and ice-core analyses suggest that the southern section of the GIS "collapsed" during the last interglacial period (Cuffey and Marshall, 2000), when temperatures were just a few degrees higher than at present.

As global temperatures rise to Eemian values, the Greenland ice sheet may return to its former configuration because of enhanced surface melting. Such change to the ice sheet would result in the direct input of huge volumes (2 to 3 m of global sea-level equivalent) of freshwater to the North Atlantic, with potentially significant consequences for the stability of the thermohaline circulation. The timescale over which such change might operate depends to a degree on the rate of meltwater supply. During the last deglaciation, when the rate of meltwater input to the oceans was at a maximum, such change occurred over decades. Gregory *et al.* (2004) predict that the Greenland ice sheet is likely to decay completely over the next 1000 years if the mean temperature of the region increases by 3 °C. Such change, if it happens, is bound to affect ocean conditions and, in turn, climate in a manner unprecedented in the last 8000 years.

Antarctica

In the 1970s, glaciologist John Mercer made two important observations. He discussed the prospect that the West Antarctic ice sheet was in danger of collapsing (Mercer, 1978). He also pointed out that the geography of West Antarctica was strikingly similar to the Eurasian Arctic: both involve a large continental shelf sea no more than a few hundred meters deep, and both have proximity to a pole and to a continental margin (Mercer, 1970). The major difference is that West Antarctica has a 2.5-km thick ice sheet over it, whereas the Eurasian Arctic is now comparatively free of grounded ice, having deglaciated after the LGM. The processes responsible for the decay of the Eurasian ice sheet are, thus, potentially important to understanding the stability of the present-day West Antarctic ice sheet.

In the last glaciation, the West Antarctic ice sheet was considerably larger than it is today. Grounded ice was probably in place across the whole continental shelf, just as it was in the Barents Sea. Ice decay in West Antarctica (from its maximum state to its present condition) was different to the decay of ice in the Eurasian Arctic in two ways. First, deglaciation began much later than in the Eurasian Arctic. Second, ice decay resulted in the formation of large floating ice shelves between the open ocean and the grounded ice sheet (i.e. the Filchner–Ronne and Ross ice shelves, each about 500 000 km^2 in area).

These differences suggest that two conclusions can be drawn about the stability of the West Antarctic ice sheet. First, the ice shelves may be influential in maintaining the stability of the ice sheet because they act as a buttress to support the grounded margin of the ice sheet, whereas in the Eurasian Arctic ice shelves were absent and the

grounded margin was actively involved in iceberg calving. Second, given the ice shelf buttressing effect on the ice sheet, the present sea level is not high enough to encourage ice decay in West Antarctica to the extent witnessed in the Eurasian Arctic.

One reassuring note relating to the latter conclusion is that during the Eemian interglacial, even though sea level was several meters higher than at present, the West Antarctic ice sheet did not decay. The majority of the water responsible for the Eemian sea-level rise probably came from Greenland (see above). The West Antarctic ice sheet is clearly capable of resisting substantial rises in sea level. The reason for this apparent stability could well be that the floating ice shelves in West Antarctica are key in maintaining grounded ice upstream. We should therefore be concerned with the stability of the ice shelves in West Antarctica. If these decay, the West Antarctic ice sheet will look much more like the former Eurasian ice sheet just before it broke up. In this situation, the processes that caused the break up of the marine portions of the Eurasian ice sheet may act over West Antarctica.

The oceans are critical to the stability of the ice shelves. Much of the mass loss from ice shelves is by subglacial melting (Jacobs *et al.*, 1992). If the ocean around Antarctica warmed, the ice shelf melt rates would increase, and the ice shelves could thin and ultimately disappear (provided melting exceeds surface accumulation).

The consequence of West Antarctic ice-sheet collapse would be a 6-m rise in global sea level, resulting in the inundation of many coastal and lowland areas of the world. Mercer called the situation a "threat of disaster". The glacial history of the Eurasian Arctic is an indicator that such ice-sheet collapse has occurred in the past.

West Antarctica and Heinrich Events

Although the southern ocean floors have not been cored as much as the North Atlantic, there is some IRD evidence from the southeast Atlantic to suggest that the West Antarctic ice sheet released regular pulses of icebergs during the last glacial cycle (Kanfoush *et al.*, 2000). Three sea-floor sediment cores reveal that IRD was deposited up to six times between 20 000 and 60 000 years ago, with a periodicity of between 6000 and 10 000 years. There are two main explanations for an IRD pulse in the southern oceans. The first is that the IRD was deposited by an increased number of icebergs. The second is that cooling of sea-surface temperatures may have allowed icebergs to survive transport across the southern ocean thus depositing their material in distal locations. However, one of the cores showing the IRD signal is taken from far north of the position of the LGM polar front, which seems to suggest that the former explanation may be relevant. Much work has still to be done to determine the true origin and significance of the southern ocean IRD pulses. However, there is a theory that the IRD reflects the instability of the West Antarctic ice sheet during the last 100 000 years (Kanfoush *et al.*, 2000).

GLACIER AND ICE SHEET RESPONSE TO RECENT CLIMATE CHANGE

Cogley (*see* **Chapter 165, Mass and Energy Balances of Glaciers and Ice Sheets, Volume 4**) reviews the various techniques by which the mass balance of large ice sheets can be assessed, and provides a summary of the results of mass balance investigations for a variety of glaciers and the ice sheets in both Greenland and Antarctica. A very brief overview of glacier and ice sheet response to recent climate change is provided below.

Glaciers

Global sea level has been rising by 1.5 mm yr^{-1} for the past hundred years or so, giving a total rise of approximately 15 cm (Warrick *et al.*, 1993). There are three main factors that affect global sea levels on timescales of decades to centuries. These are, first, the net loss of mass from glaciers and ice sheets to the oceans, second, the continued abstraction of groundwater aquifers, with the consequence that this water enters the global hydrological cycle and, third, the physical principle that the oceans will expand in a world, warmed by about one half of a degree over the last century. It is thought that a tenth or so of the observed annual rise in sea level could be a result of ablation from glaciers and ice sheets (IPCC, 2001).

The short response times of glaciers make it possible to assess their reaction to climate change by surveying them over a few decades. Net mass balance measurements from glaciers around the world show for the most part a consistent trend of negative mass balance over the last 30 years (Figure 7) and, in some examples where records permit, over the last 100 years (Haeberli *et al.*, 1996; Braithwaite, 2002). In Svalbard, for example, only four of the 44 measurements ($< 10\%$) of net mass balance show a positive annual increment. In the Canadian Arctic islands, over 70% of balance years are negative. However, it should be noted that these mass balance datasets have a relatively high interannual variability, although a number of the time series are statistically different from zero and indicate a negative mass balance. From the mass balance measurements of Arctic glaciers, distributed relatively widely across the polar North, it can be concluded that, during the last 30 to 40 years, glaciers from most areas of the High Arctic have shown no sign of building up, and have experienced either a negative or near-zero average mass balance. For glaciers at lower Arctic latitudes, the interannual scatter in the data is greater. This is presumably because of the higher turnover of mass, associated with greater precipitation and

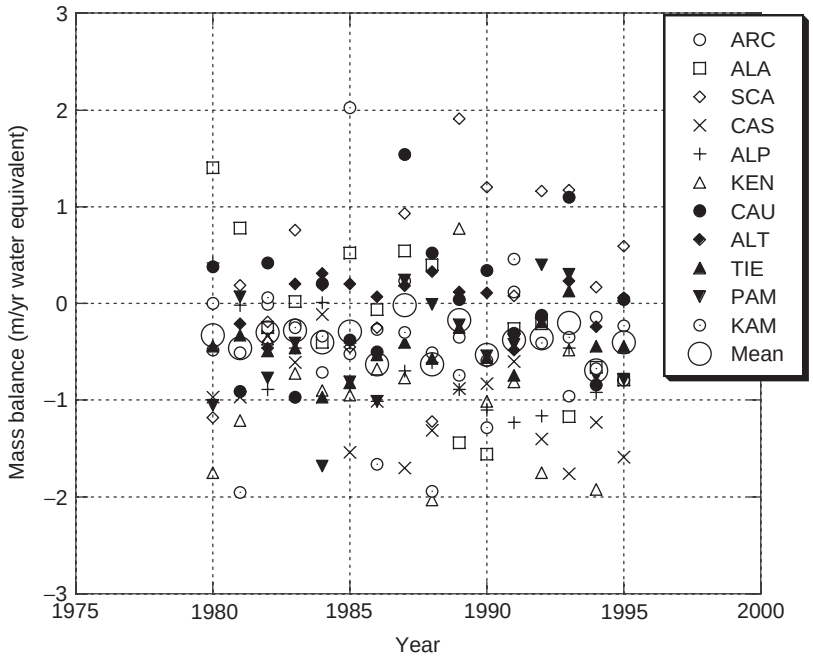

Figure 7 Glacier mass balance data from 11 locations over the 15 years (between 1980 and 1995). Data are from Braithwaite (2002) and Haeberli *et al.* (1996). The locations are denoted as follows: ARC (Arctic), ALA (Alaska), CAS (Cascades), SCA (Scandinavia), ALP (alps), KEN (Kenya), CAU (Caucasus), ALT (Altai), TIE (Tienshan), PAM (Pamir), and KAM (Kamchatka). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

stronger summer melting. Like their high latitude counterparts, most glaciers lower in the Arctic have experienced either a negative or a near-zero mass balance over the time period of observations, which is a maximum of 50 years. In Alaska, almost all the glaciers observed are in a state of negative mass balance and a few have mass balances close to zero over the period of observation (Arendt *et al.*, 2002).

Glaciers in maritime western Norway, such as Nigardsbreen, have had a clearly positive mean mass balance since measurements started in 1962 (Laumann and Reeh, 1993). A recent shift towards more positive annual balances has also been observed over almost the whole of Scandinavia since 1988 (Braithwaite, 2002). This region is a noticeable exception to the global trend of glacier retreat. It is thought that the region is influenced strongly by warming in North Atlantic, the positive phase of the North Atlantic oscillation and the northward deflection of winter storm tracks. Such conditions result in additional snowfall on the neighboring glaciers, which more than counters the negative effect of enhanced melting.

Glaciological investigations from a variety of glaciers within the tropics show most of them to be in a perilous state of decay (Thompson *et al.*, 2002; Kaser and Osmaston, 2001). In fact, the mass balance of glaciers such as those on Kilimanjaro in Tanzania is so negative that the glaciers could disappear entirely in as little as 20 to 30 years.

Ice Sheets

The long response times of ice sheets mean that it has traditionally been quite difficult to determine whether they are in positive or negative balance (*see* **Chapter 165, Mass and Energy Balances of Glaciers and Ice Sheets, Volume 4**). For example, Jacobs *et al.* (1992) estimated a negative balance for Antarctica of 469 Gt year^{-1}, based on measurements of accumulation, iceberg calving, sub-ice shelf melting, and runoff. However, the uncertainties associated with some of these measurements were between 20 and 50%.

Rignot and Thomas (2002) point out that there are three general ways of defining the mass balance of a large ice sheet. The first is by an assessment of the mass budget, as Jacobs *et al.* (1992) did for Antarctica. The second is from airborne and satellite measurements of the ice-sheet surface elevation (e.g. Wingham *et al.*, 1998), which, if data are acquired over a period of a few years, allow changes in ice thickness to be measured to centimeter accuracy. The third is by using satellite-based gravity measurements, since ice volume changes will have a measurable gravitational consequence (e.g. NASA's Gravity Recovery and Climate Experiment).

These techniques have been used to understand the current balance of the large ice sheets. In Greenland, NASA's Program for Arctic Regional Climate Assessment (PARCA) provided unprecedented data about the ice sheet's

state of health. This work showed that Greenland is melting, and thinning, across its southern margin. Importantly the surface meltwater finds its way to the ice base and acts as a lubricant to ice flow, so encouraging the ice to move faster, thus resulting in further thinning (Zwally *et al.*, 2002).

In Antarctica, the problem of mass balance remains hard to solve. Satellite altimeter data show that certain parts of West Antarctica are thinning (e.g. Pine Island and Thwaites glaciers). At the same time, however, the Siple Coast ice streams appear to be gaining mass. There is a connection between ice thickness changes and ice dynamics (i.e. as ice flow increases so the ice thickness will decrease), and this could explain the difference in elevation changes observed from different parts of the ice sheet. In the Siple Coast, for example, Ice Stream C has stopped flowing rapidly, and Whillans Ice Stream (formerly known as *Ice Stream B*) is slowing down (Joughin and Tulacyk, 2002). Similarly, the ice loss across the Pine Island sector could be result of increased velocities here, rather than an alteration to the surface balance.

SUMMARY

Glaciers and ice sheets comprise over two thirds of the world's freshwater and, if melted, could raise sea level by about 70 m. The distribution of ice around the planet is a function of today's climate and glacial history. Glaciers and ice sheets are thus intrinsically linked with climate.

Most glaciers are in a state of negative mass balance in response to climate warming over the last 100 years. Norway is an exception to this trend, where warmer conditions have led to enhanced rates of precipitation, which counter the extra melting experienced in summer. Glaciers have a short response time, and so are good barometers of climate change. Ice sheets, on the other hand, have much longer response times, and so their condition is not necessarily affected so much by recent changes.

Glaciers and ice sheets play a crucial role in the global water cycle as stores for freshwater on land. In the last glaciation, so much water was locked within ice sheets that global sea level fell by 115 to 130 m. Ice sheets at the LGM had a strong influence on the climate, in terms of their high albedo affecting the radiation budget, their orography affecting atmospheric circulation, and their runoff affecting the chemistry and circulation of the oceans.

During deglaciation the climate changed in a sporadic and rapid manner, switching from cold dry to warm wet conditions and back again within a few decades. Ice sheets were largely responsible for this rapid change in two ways. First, huge quantities of icebergs were released from ice sheets such as the Laurentide ice sheet in North America. These icebergs melted, causing IRD layers on the ocean floor (known as *Heinrich layers*) and the freshening of seawater. The reduction in salinity reduced the NADW formation and, hence, the thermohaline circulation which, in turn, cooled the climate of the North Atlantic region. A similar process may have been responsible for the Younger Dryas climate reversal at around 11 000 years ago that saw a regrowth of many Northern Hemisphere glaciers. Second, as the ice sheets melted large proglacial lakes were formed at their margins. One proglacial lake, named Lake Agassiz, outburst dramatically into the North Atlantic at 8200 years ago. The consequent release of freshwater directly into the Labrador Sea temporarily slowed the ocean circulation and a short cool period, recorded in Greenland ice cores, ensued.

The processes involving ice and climate during the last deglaciation could be relevant today. In particular, the southern margin of the Greenland ice sheet appears vulnerable to climate for two reasons. First, it is melting and retreating under the current climate. Second, in the previous (Eemian) interglacial, when air temperatures were only a few degrees warmer than at present, the Greenland ice sheet was far smaller than today. Hence, a future climate scenario could involve a much-reduced Greenland ice sheet. If so, the water melted from Greenland would be directed into the North Atlantic with potentially serious consequences for ocean circulation and climate.

Greenland is not the only ice mass capable both of affecting, and being affected by, future climate change. The majority of glaciers are currently in negative mass balance and are thought to be contributing at least 10% of the current rise in sea level (Meier, 1984; *see* **Chapter 165, Mass and Energy Balances of Glaciers and Ice Sheets, Volume 4**). Given their short response times to warming, they too could be influential to future climate and ocean processes.

The world's climate system is controlled to a large degree by the global water cycle. Glaciers and ice sheets are central to this cycle, and have the potential to affect it markedly over glacial–interglacial cycles. Moreover, their interaction with oceans and climate has often been an unsteady one and the processes involved in this interplay are relevant to our climate-changing world.

165: Mass and Energy Balances of Glaciers and Ice Sheets

J GRAHAM COGLEY

Department of Geography, Trent University, Peterborough, ON, Canada

Glaciers exchange energy and mass with the rest of the hydrosphere by snowfall, melting, vapor transfer, and the calving of icebergs. Melting and vapor transfer are significant in both the energy balance and the mass balance, which in consequence are intimately coupled. Glacier energy balances differ from those of other natural surfaces in having small or even negative net radiation. Emission of terrestrial radiation is limited, the surface temperature being no greater than the freezing point, but the surface albedo is always high. The limit on surface temperature, and the year-round tendency for net radiative cooling, means that sensible heat transfer is generally downward, while vapor transfer may be either upward or downward. Once conduction has raised a surface layer to the freezing point, further energy surpluses are used to melt snow or ice. In winter, the energy balance is dominated by radiative cooling. Apart from its close connection with the energy balance, the mass balance is also influenced strongly by glacier dynamics. Glaciers and the flowlines of which they are composed exhibit vertical zonation, with net accumulation at higher and net ablation (mass loss) at lower elevations. This imbalance drives, and is corrected by, the ice flow. The leading methods for the measurement of mass balance are the direct, geodetic, and kinematic methods. Direct measurement involves determining the accumulation and ablation in situ or by equivalent remote sensing, with separate treatment of calving where it occurs. Geodetic measurements require the determination of glacier thickness at two epochs; the change of thickness, approximately equal to the change in surface elevation, gives a volume balance that may be converted to a mass balance if the density of the mass gained or lost can be supplied accurately. In the direct and geodetic approaches, the ice flow is assumed to integrate to zero over any one flowline (correctly, if the entire flowline is measured). Kinematic methods are free of this restriction. They involve measurement of all of the terms in the balance and are therefore more difficult. The need for better understanding of mass balance, at socioeconomic scales from local to global, has stimulated intense study of ways to improve the measurements. Recent and impending methodological advances are coming from radar altimetry, laser altimetry, gravimetry, passive-microwave remote sensing, and interferometry using synthetic aperture radar. A subject requiring increased attention, as the measurements improve in precision and coverage, is improved quantification of the measurement errors. The best current estimates of global average mass balance are equivalent to $0.14–0.44\,\mathrm{mm\,a^{-1}}$ of sea-level rise, to be compared with the inferred total rate of about $1.9\,\mathrm{mm\,a^{-1}}$. This figure is a composite of estimates for "small" glaciers (those other than the ice sheets), whose balance has been growing more negative since the 1960s; the Greenland Ice Sheet, which seems to have a negative balance; and the Antarctic Ice Sheet, for which the sign of the mass balance remains in doubt although its magnitude is probably within a few $\mathrm{kg\,m^{-2}\,a^{-1}}$ ($\mathrm{mm\,a^{-1}}$ water-equivalent) of zero.

INTRODUCTION

Glaciers exchange energy with the atmosphere overlying them and with the earth or ocean beneath. While the surface energy balance of a glacier is not fundamentally different from that of a drainage basin or other hydrological unit, the fact that glaciers have a basal energy balance and a (typically small) internal energy balance sets them apart. A more obvious distinguishing feature of glaciers is that, because they are made of frozen water which is apt to

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

melt, their energy and mass balances are very intimately coupled. Mass balance is the glaciological analog of the *water balance* in hydrology. Most glaciers gain mass by snowfall and lose mass by melting, although for some glaciers, including the largest, the calving of icebergs is an important term in the balance.

Glacier energy and mass balances are important in the following unranked respects:

- Glacier meltwaters are dominant components of the water balance of semiarid regions downstream of glacierized mountain ranges (e.g. Su and Shi, 2002). Such regions include the Prairies of Canada, Central Asia, and the Himalaya, and much of Andean South America. They also constitute an important resource for hydroelectric power generation, notably in Norway; a source of revenue from tourism; and hazards (Richardson and Reynolds, 2000).
- On the global scale, glaciers exchange mass with the ocean. As it is currently understood, the water balance of the ocean fails to add up and an accurate knowledge of glacier mass balance is required if we are to explain the observed contemporary rise of sea level (Church *et al.*, 2001; Munk, 2003). Glacier mass balance also affects the salt balance of the ocean.
- Glaciers play a part both in bringing about climatic change and in helping us to document it. They are highly reflective and so reduce the magnitude of net radiation at the Earth's surface, and as their extents change so does their influence on the global energy balance and the general circulation. As independent sources of information about environmental change, they are a valuable supplement to the weather stations from which we derive information about temperature and other leading climatic variables.
- Gains and losses of glacier mass imply redistribution of the mass of the Earth, altering its moments of inertia with consequences for the evolution of such geophysical quantities as length-of-day, true polar wander and the geoid, and with implications for understanding of the viscosity profile of the Earth's mantle (Peltier, 1998).

DEFINITION OF TERMS

A Column of Ice

In Figure 1(a), a column extends through ice at the Earth's surface. Ice, a soft solid, deforms readily under stress, so we orient the column with respect to the resulting flow. We assume that net exchanges of energy and mass through the side-walls are negligible, an idealization which is acceptable for balance studies if not for studies of dynamics. The lower surface makes contact with either the solid earth or water. At its upper surface, the column will ordinarily be exposed to the atmosphere, but there may be a complicating mantle of rocky debris (Nakawo *et al.*, 2000). Melting and freezing are regarded as loss and gain respectively; that is, liquid water is "outside" the column, being assumed to run off or refreeze in a time shorter than the span over which we compute the mass balance (of ice). The column also has internal energy and mass balances; for example, changes of water phase are not restricted to the surface and the base.

Flowline

A *flowline* (Figure 1b) is a sequence of ice columns of infinitesimal cross section arranged so that each column gains mass by flow from an up-ice neighbor and loses mass to a down-ice neighbor. To a good approximation, flowlines may be identified by beginning at any point where either the slope changes sign – at a flow divide – or the ice thickness drops to zero, and following the direction of steepest ascent or descent to another such point. The first column in the sequence has zero flow through one boundary. Most importantly, the integral of the mass flux divergence over the entire flowline is zero: a loss by flow from one part of the flowline must be compensated by a gain somewhere else, which means that we can neglect the flow when estimating the mass balance of the flowline.

Glacier

A *glacier* is a collection of contiguous complete flowlines through snow and ice that persists on the Earth's surface for more than one year (Figure 1c). The two largest glaciers are called *ice sheets*: the Greenland Ice Sheet and the Antarctic Ice Sheet. An *ice shelf* consists of the floating parts of two or more glaciers. There are small ice shelves in northernmost Canada and Greenland, but otherwise ice shelves are found only in Antarctica. Ice shelves differ from sea ice, which is a few meters thick, in being tens to thousands of meters thick.

Glacier Types and Glacier Zones

Glaciers are at or below their *freezing point* T_f, which in the absence of impurities increases from 273.16 K at the surface at a rate of about $0.67\,\mathrm{K\,km^{-1}}$ of ice overburden. *Cold* or *polar glaciers* are those in which temperature T is below T_f except possibly in a surface layer, up to 10–15 m thick, during summer. *Temperate glaciers* are at $T = T_f$ throughout, except in the surface layer during winter. *Polythermal glaciers* have, in addition to the surface layer of seasonal fluctuations, a basal layer at $T = T_f$ and an intermediate layer in which $T < T_f$. Cold glaciers are also *dry-based glaciers*, while polythermal and temperate glaciers are, at least locally, *wet-based glaciers*. These types

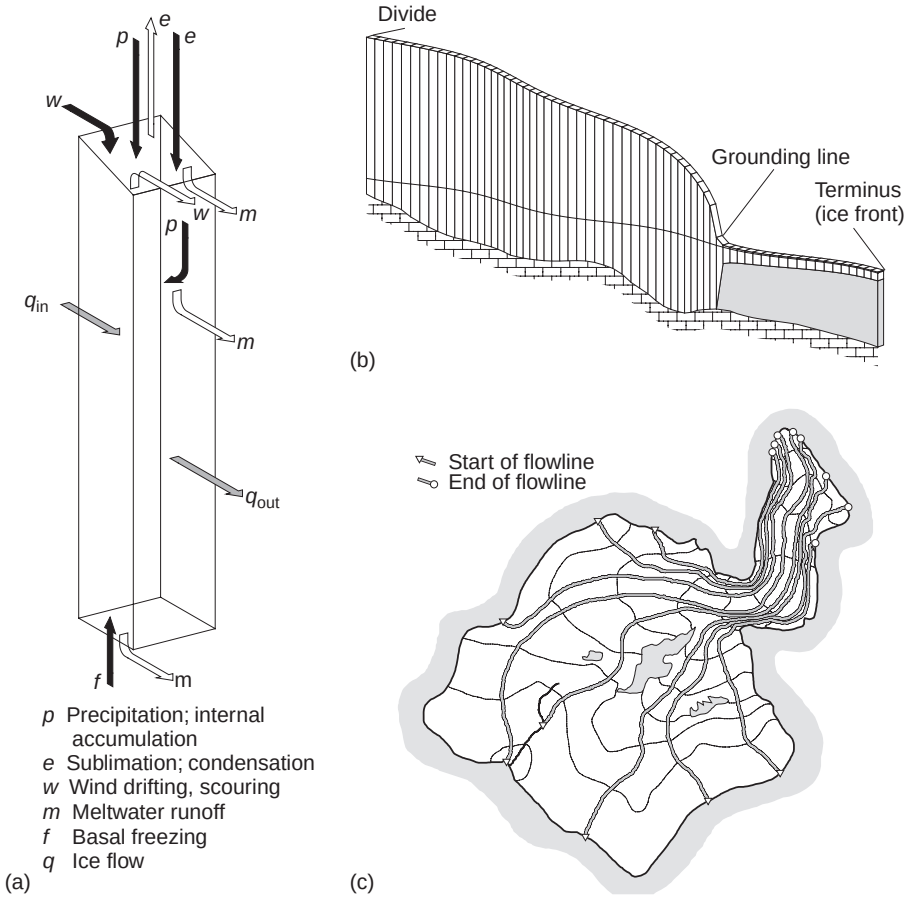

Figure 1 (a) A column of ice, showing leading mass-balance terms. Black arrows: accumulation (gain of mass); white arrows: ablation (loss of mass); grey arrows: throughflow. (b) A flowline considered as a sequence of ice columns. This flowline happens to have a floating terminal section. (c) Plan view of selected flowlines (thick) on a real glacier. Thin lines: contours (100-m interval)

can be misleading, for strictly the adjectives apply only to ice columns. Nevertheless, they are useful when considering energy and mass balances because the type determines whether, and if so where, melting and freezing may occur beneath the surface.

Because temperature decreases with increasing elevation at the surface, glaciers exhibit vertical zonation (Figure 2). This concept (Shumskiy, 1955; Benson, 1959) is the basis of most remote-sensing studies of energy and mass balances. *Snow* is solid condensates and precipitation, including freezing rain, added to the glacier during the current year. *Firn* is snow added in previous years. *Glacier ice* is firn that has been compacted to a density near that of pure ice. In the *dry-snow zone*, the temperature never rises to the freezing point and there is no melting. In the *upper percolation zone*, melting occurs at the surface in summer but the meltwater remains within the snow, while in the *lower percolation zone* some meltwater penetrates to the underlying firn before refreezing. This constitutes *internal accumulation*, which should be accounted for in the mass balance. The *slush zone* (Müller, 1962) is that part of the percolation zone in which at least some of the added snow is lost from the column, either as meltwater runoff or by slush avalanching. The *superimposed ice zone* represents either exposed, refrozen percolating meltwater or the product of slush avalanching. Ice is also found at the surface of the lowest zone, the *ablation zone*, but superimposed ice is newly gained mass while exposed glacier ice implies a loss of mass.

The surface volume balance of any column of the flowline is proportional to $z_1 - z_0 = z(t_1) - z(t_0)$ and, when we can neglect flux divergence and internal accumulation, the mass balance is simply this elevation difference multiplied by average density. The difference, and therefore the mass balance, is zero at the *equilibrium line* over the balance year (see Figure 2) or possibly some longer span. More generally, the whole flowline or glacier is said to be *in equilibrium* if the sum of its column balances is zero. Figure 2 hints, unrealistically, that the flowline will grow continually thicker in the accumulation zone and thinner in

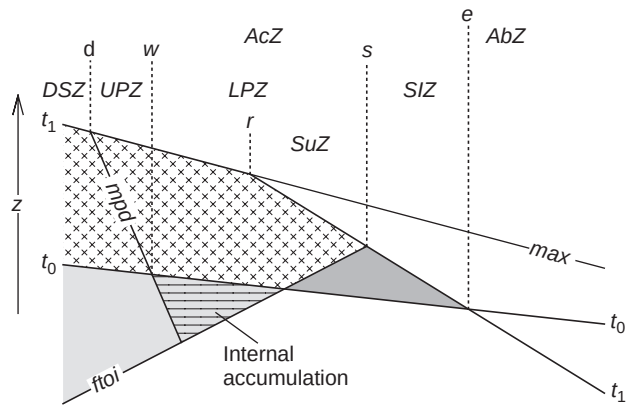

Figure 2 Cross section of a flowline, illustrating glacier zonation in elevation *z*. Broken cross-hatching indicates snow; firn is grey (the part vulnerable to internal accumulation being hatched), and superimposed ice is dark grey; glacier ice is unshaded. t_0, t_1: glacier surface at the start and end of the balance year; *max*: maximum elevation reached by transient glacier surface between t_0 and t_1; *ftoi*: boundary between firn and ice; *mpd*: maximum depth to which meltwater percolates before refreezing or reaching the effectively impervious (but not necessarily impermeable) barrier *ftoi*; d: dry-snow line (surface outcrop of *mpd*); *w*: wet snow line; *r*: runoff limit; *s*: snowline; *e*: equilibrium line. *DSZ*: dry-snow zone; *UPZ, LPZ*: upper and lower percolation zones; *SuZ*: slush zone; *SIZ*: superimposed ice zone; *AbZ*: ablation zone; *AcZ*: accumulation zone (the set of all zones above *e*)

the ablation zone. In fact, this pattern of thickness change and differential loading is what drives the glacier flow. The strongest definition of *equilibrium* is that it is the state that prevails when the flow is exactly that required to preserve the shape of the glacier unchanged, that is, for surface elevation z to remain constant everywhere. Figure 2 "works" only because of the hidden assumption that the surface z_1 transforms into the surface z_0 at the first instant of each new balance year, when snow turns into firn and superimposed ice into glacier ice.

Units

Glacier energy balances are usually reported in $\mathrm{W\,m^{-2}}$, which is the standard in climatology.

Mass balance is a rate per unit of projected horizontal area. It is nearly always reported for *balance years* (beginning at the start of winter) or their winter and summer components, so the appropriate units are $\mathrm{kg\,m^{-2}\,a^{-1}}$. Several other units are in common use. The most common are mm water-equivalent $\mathrm{a^{-1}}$, numerically identical with $\mathrm{kg\,m^{-2}\,a^{-1}}$ because 1 kg of water, with a density of $\rho_\mathrm{w} = 1000\,\mathrm{kg\,m^{-3}}$, is 1 mm deep when distributed over $1\,\mathrm{m^2}$. Care is needed when mass and volume balances are discussed together, for example when the measured quantity is a change of elevation or thickness. The thing to avoid is confusing ice thickness h (m) and water-equivalent "thickness" $(\rho_\mathrm{i}/\rho_\mathrm{w})h$ ($\mathrm{kg\,m^{-2}}$ or equivalently mm w.e.), $\rho_\mathrm{i} = 917\,\mathrm{kg\,m^{-3}}$ being the density of pure ice.

When discussing glacial contributions to changes of sea level a natural unit to use is mm sea-level-equivalent $\mathrm{a^{-1}}$. A glacier mass balance of B $\mathrm{kg\,m^{-2}\,a^{-1}}$ is equal to $-1000(S/S_\mathrm{o})B/\rho_\mathrm{w}$ mm s.l.e. $\mathrm{a^{-1}}$, S being the area of the glacier and $S_\mathrm{o} = 362.0\,\mathrm{Mm^2}$ the area of the ocean and ice shelves.

ENERGY BALANCE

Surface Energy Balance

The energy balance at the surface of a glacier is

$$K_\mathrm{s} + L_\mathrm{s} + H + \lambda E + G_\mathrm{s} + \mu M_\mathrm{s} = 0 \qquad (1)$$

where all the quantities are flux densities in $\mathrm{W\,m^{-2}}$. $K_\mathrm{s} = (1-\alpha)K\downarrow$ is net solar radiation, $K\downarrow$ being the incident solar irradiance and α the surface albedo. $L_\mathrm{s} = L\downarrow + L\uparrow$ is the net terrestrial radiation, the balance of gains from the upper hemisphere and the surface emittance $L\uparrow = -\varepsilon\sigma T_\mathrm{s}^4$. The surface emissivity, ε, is the ratio of surface emittance to that of a black body at the same temperature T_s, and $\sigma = 5.68 \times 10^{-8}\,\mathrm{W\,m^{-2}\,K^{-4}}$ is the Stefan–Boltzmann constant. Snow and ice are usually treated as black bodies, that is, $\varepsilon = 1$. H and λE are turbulent fluxes of sensible and latent heat from above respectively, and G_s is the conductive flux of heat from below; $\lambda = 2.835 \times 10^6\ \mathrm{J\,kg^{-1}}$ is the latent heat of sublimation. Finally, μM_s is the energy used for surface melting, with $\mu = 0.335 \times 10^6\ \mathrm{J\,kg^{-1}}$ the latent heat of fusion and M_s the surface meltwater flux ($\mathrm{kg\,m^{-2}\,s^{-1}}$).

General methods for the measurement of terms in the surface energy balance are described by Oke (1987), and adaptations to the peculiarities of glacier surfaces by Oerlemans (2001). Accurate microclimatological measurements are demanding, and much of the effort in glacier climatology is devoted to parameterizing the results of research campaigns so that they may be used in wider contexts. Some important generalizations may however be made readily.

First, the net solar radiation on glaciers is usually small because the albedo is large (Table 1). At optical wavelengths snow is the brightest of natural surfaces, although its albedo can in fact vary greatly with age, grain size, the abundance of impurities and of liquid water, the incidence angle of the irradiant flux, and other factors (Warren, 1982). Exposed glacier ice is always darker than snow. Fresh snow may absorb three times less solar radiation than the ice that it covers, and its disappearance is followed by a marked shift in the energy balance to a more absorbent regime in which, other things being equal, melting is accelerated.

Table 1 Typical observed energy balances of glacier surfaces

Fluxes, in $W\,m^{-2}$, are positive towards the surface (R_s is net radiation, $K_s + L_s$; melting is negative). Error estimates vary from a few to several tens of $W\,m^{-2}$. QML: Queen Maud Land, East Antarctica. Period: s, w denote winter and summer. Type: B, blue ice; G, glacier ice; S, snow.

The longwave (terrestrial) balance is constrained by the fact that $T_s \leq T_f$, which limits $L\uparrow$ to magnitudes no greater than about $-316\,W\,m^{-2}$.

Because the air above glaciers is often warmer than the freezing point in summer, and is a heat source fueling intense radiative cooling in winter and at night, the sensible heat flux H is generally directed downwards. The latent heat flux λE is often directed downwards also because, even when liquid water is present, the vapor pressure at the surface will be appropriate to saturation at a temperature near T_f. On the lower parts of glaciers, the turbulent fluxes are enhanced by katabatic drainage of cooled air from high elevations. The katabatic wind, as well as being persistent and directionally constant, can be extremely strong.

The heat exchanged with the interior of the glacier drives an annual variation of temperature which is confined to the upper 10–15 m. However, in summertime, once an isothermal surface layer at the freezing point has been established, the heat flux G_s must dwindle to zero, and any surplus from the atmospheric terms in equation (1) will be used for melting. This surplus is responsible for most of the ablation on most glaciers, exceeding -10 m w.e. a^{-1} (about $-100\,W\,m^{-2}$ over the year) at lower latitudes. It may also be responsible for advective heat transfer to the interior of the glacier if the meltwater refreezes at depth instead of running off.

Some representative energy balances are summarized in Table 1. Blue ice is glacier ice exposed at the surface because snow fails to accumulate. Apart from scouring (removal as blowing snow), the principal reason for this in Antarctica is sublimation. Bintanja (1998) estimates by modeling that sublimation of blowing snow may reach $-15\,W\,m^{-2}$, twice the rate of sublimation of *in situ* snow and ice, near the Antarctic coast.

Internal Energy Balance

The energy balance of a small volume within a glacier may be understood (Paterson, 1994) in terms of thermal diffusion, advection of heat by the ice flow, and energy sources due to strain heating, including the compaction of firn, and the refreezing of meltwater. The strain-heating terms are of order $10^{-4}\,W\,m^{-3}$ or less, and are negligible for balance purposes even when integrated over typical column thicknesses, but the refreezing of meltwater can be significant. It may be expressed as $\mu f c/Z$, where c is the surface accumulation rate, f is the fraction of c that refreezes in the firn, and Z the thickness over which it refreezes. $\mu f c$ is of order $0.1-1\,W\,m^{-2}$ over the year, but Z is at most 10 m so that detectable summertime warming of the firn is possible.

Basal Energy Balance

Glaciers

The energy sources at the bed of a glacier are frictional heat and geothermal heat. If the basal temperature is below

the freezing point, the heat is conducted upwards into the body of the glacier. The opposite situation, heat flow from the glacier into its bed, is possible, for example, when temperate ice advances over permafrost, but very unusual. If the bed is at the freezing point the available energy is used to melt ice.

Pollack *et al.* (1993) have compiled measurements of geothermal heat flux. Averages are $0.09\,\mathrm{W\,m^{-2}}$ for Antarctica and $0.04\,\mathrm{W\,m^{-2}}$ for Greenland, with similar values for other glacierized regions. Only Iceland and the Rocky Mountains have geothermal fluxes above $0.10\,\mathrm{W\,m^{-2}}$, equivalent to $-10\,\mathrm{kg\,m^{-2}\,a^{-1}}$ of basal melting. Frictional heating derives from the loss of potential energy in the ice column as it moves downslope. Its rate can be expressed as the product of basal velocity times basal shear stress, yielding typical fluxes of $0.01-1\,\mathrm{W\,m^{-2}}$. Although the basal balance quantities are small, they are only marginally negligible given the current accuracy attainable in surface mass-balance calculations. They are also heat sources without compensating sinks, so they tend to make cold glaciers steadily warmer.

Ice Shelves

Assuming that thermodynamic equilibrium prevails (Doake, 1976; Holland and Jenkins, 1999), the contact between shelf ice and seawater must be at the freezing point of the seawater, which depends on the pressure of the overlying shelf ice and the salinity of the water. But in general the seawater and shelf ice at some distance from the contact will not be at T_f, so there is a heat source or sink, and therefore melting or freezing, at the contact. We can write

$$H_b + G_b + \mu M_b = 0 \tag{2}$$

where H_b is the sensible heat flux from the seawater, G_b the conductive flux from the shelf and μM_b the latent heat flux; fluxes are positive towards the shelf base and melting is negative. There are two complications. First, salt is coupled to heat because freezing increases and melting decreases the salinity of the seawater, altering both T_f and the buoyancy of the water. Second, the water flow itself is driven substantially by variations of temperature and salinity.

Holland and Jenkins (1999) envisage a boundary layer in the water flow beneath the shelf. At some elevation below the base, the water is at a temperature T_o and salinity determined by the mesoscale ocean circulation, and the sensible heat flux depends on the difference between T_f and T_o. Thus, the principal controls on the basal energy balance are the properties "imported" by the mesoscale water flow. Direct measurements are very difficult, but Rignot and Jacobs (2002) measured basal melting rates indirectly at 23 shelf grounding lines (Figure 1b). These rates are well correlated with an indirect estimate of T_o, and are extremely high. They pertain to areas of only a few tens of $\mathrm{km^2}$ (the square of glacier width at the grounding line), but the greatest magnitude, $-425\,\mathrm{W\,m^{-2}}$ or $-44\,\mathrm{m\ ice\ a^{-1}}$, at Pine Island Glacier, is a record. The meltwater is buoyant because it is fresh, and flows upwards along the base of the rapidly thinning ice shelf to where a lesser pressure implies a smaller sensible heat flux (higher T_f). Sometimes, it enters a regime in which it is actually colder than T_f and ice begins to form, accreting as "marine ice" at the base of the shelf. The latent heat flux averaged over all the Antarctic ice shelves, however, is believed to be negative. Jacobs *et al.* (1996) estimate it (with an uncertainty of ±50%) as $-5.4\,\mathrm{W\,m^{-2}}$, that is, $-500\,\mathrm{kg\,m^{-2}\,a^{-1}}$.

If there is net freezing at the base, it is reasonable (Holland and Jenkins, 1999) to set the temperature gradient in the shelf ice, and the implied heat flux, $G_b = k_\mathrm{i}(\partial T/\partial z)|_b$, to zero. Where there is net melting, the shelf temperature gradient is coupled to the dynamics of the shelf ice, but if we neglect this coupling a crude solution is available in terms of the temperature difference between surface and base. Taking typical values, $T_\mathrm{s} - T_b = -30\,\mathrm{K}$ and thermal conductivity $k_\mathrm{i} = 2\,\mathrm{W\,m^{-1}\,K^{-1}}$, we find that G_b ranges from -0.2 to $-0.02\,\mathrm{W\,m^{-2}}$ for ice shelves of thickness 300–3000 m.

MASS BALANCE

Methods of Measurement

The mass balance b of an ice column is

$$b = c + a + c_\mathrm{i} + a_\mathrm{i} + c_b + a_b + \Delta q \tag{3}$$

where the c are accumulation rates (black arrows in Figure 1a), the a are ablation rates (white arrows) and $\Delta q = q_\mathrm{in} - q_\mathrm{out}$ is the flux divergence. Subscripts i and b denote the interior and base of the column. Ablation by calving at the terminus is a special case of equation (3) in which a_i is equal to minus the entire mass of the column. The mass balance of a glacier or glacier flowline of area S is

$$B = \frac{1}{S}\int_\mathrm{s} b\ \mathrm{d}s \tag{4}$$

When b is assumed to vary only with elevation, as is usual on valley glaciers, the measurements are grouped into elevation bands and equation (4) becomes a sum of band averages, each average being weighted by the area of its band.

Direct Measurements

Direct measurements of column mass balance take the form

$$b = c + a = \frac{1}{\Delta t}\int_{z_0}^{z_1} \rho\,\mathrm{d}z \tag{5}$$

The flux divergence is ignored because the column balances are to be integrated over the glacier, and the other terms in equation (3) are either ignored or estimated as corrections. If it occurs, calving must be measured separately. Standard methods of measurement are described by Østrem and Brugman (1991), and Trabant and March (1999) give a detailed account of a careful protocol for fieldwork. Glaciers are dangerous places; safety in the field is discussed by Selters (1999).

A direct measurement of b involves emplacing a stake and/or digging a pit. If the stake is vertical, and does not tilt, bend, or settle, measurements of stake top height above the surface at t_0 and t_1 are proportional to z_0 and z_1, neither of which need be known in an independent coordinate system. In the ablation zone (Figure 2), the lost mass may be assumed to have a constant density $\rho = 900\,\mathrm{kg\,m^{-3}}$ (slightly less than ρ_i to allow for solid impurities, bubbles, intergranular voids, and macropores), so the mass balance is $b = \rho\Delta z/\Delta t$. In the accumulation zone, the density of the mass gained must be measured in the walls of snow pits, augmented with spatially extended surveys of the variability of Δz by probing or of b by shallow coring and weighing.

The column mass balance should be determinable with a standard error of the order of $\pm 50\,\mathrm{kg\,m^{-2}\,a^{-1}}$, and usually better. Except when the measurement network is very dense, an additional error is made by extrapolating from points to the whole glacier. Cogley *et al.* (1996) and Trabant and March (1999) both adopt a standard error of $\pm 200\,\mathrm{kg\,m^{-2}\,a^{-1}}$ for elevation-band averages of b, on the basis of the ability of single measurements to reproduce elevation-band averages determined with dense networks. Cogley (1999) showed that the uncertainty in B is not significantly less than this, because measurements of b at different elevations are nearly perfectly correlated.

Internal accumulation is a worrisome bias on any cold glacier with a percolation zone. It is impractical to measure it, and models for estimating it are as yet quite crude. Internal ablation (Mayo, 1992) occurs because of the conversion to heat of the potential energy of meltwater flowing down englacial channels. When the glacier is known to be wet-based, the basal ablation can be estimated as a function of the basal heat flux and frictional heating, although usually both it and internal ablation are neglected. Beneath polythermal glaciers, some of it is cancelled out when meltwater freezes on reaching cold parts of the bed, although the heat thus released helps to maintain the temperate ice at its melting point. Extensive basal accumulation occurs only beneath some parts of ice shelves.

The winter and summer balances, b_w and b_s, are measured separately on some glaciers. They are defined by equation (5) with z_0 and z_1 taken at the endpoints of the appropriate season, and in most climates they separate the two main controls, winter wetness and summer warmth, of the annual balance $b = b_\mathrm{w} + b_\mathrm{s}$. This is valuable because, for example, both controls are likely to involve more water than in neighboring unglacierized terrain, and relatively small changes in either can have substantial implications for the regional water balance.

Geodetic Measurements

Geodetic measurements of mass balance have until recently been used mostly as checks on the reliability of more frequent direct measurements. They rely on pairs of dated maps or other representations of $\Delta z/\Delta t$ to give a volume balance that may be converted to a mass balance by making correct assumptions about density. Geodetic measurements require the separate determination of z_1 and z_0 in geocentric coordinates, which introduces a quite different set of concerns about accuracy. For example, the quantity which should be measured is actually the rate of change of thickness, $h = z - z_b$, and changes in bed elevation, z_b, arising from glacial isostatic adjustment and other causes need to be allowed for.

In the accumulation zone, if the density profile remains unchanged between t_0 and t_1, then *Sorge's Law* is said to apply: Density is a function only of depth beneath the surface. However, the compaction rate varies with the rate of surface loading by new snow, the temperature and, possibly, the rate of internal accumulation. Wingham (2000) modeled the compaction of dry isothermal firn, finding that the spatial scale of fluctuations in accumulation is of critical importance. Zwally and Li (2002) modeled the effect of seasonal fluctuations of temperature and accumulation loading, reproducing observed fluctuations of z with fair accuracy. Where melting occurs and the resulting meltwater refreezes in the form of ice lenses, the situation is much more complicated, and at present it is necessary to invoke Sorge's Law arbitrarily.

Kinematic Measurements

In kinematic measurements, q_in or q_out or both are measured at "gates" (cross-sections), in combination with up-ice or down-ice measurements of accumulation and ablation. The advantage is that the complete-flowline assumption can be relaxed. The disadvantage is that q_in and q_out cannot be measured inexpensively. They require knowledge of ice thickness across the gate and of the vertical distribution of ice velocity. In practice, only the surface velocity is known, and either it must be assumed that the glacier moves entirely by basal sliding, or the velocity profile must be modeled (Kostecka and Whillans, 1988). Hubbard *et al.* (2000) modeled glacier flow to generate a map of the flux divergence. This method is not likely to be applied widely because of the amount of boundary-condition information required by the flow model. An important recent advance, discussed below, is the ability to measure q at grounding lines by radar interferometry.

Hydrological Measurements

In the hydrological approach, precipitation and evaporation over the glacier are estimated along with the runoff of meltwater, and the water balance is solved. This is only done routinely for Aletschgletscher, Switzerland. Bhutiyani (1999) has published hydrological estimates for Siachen Glacier in the Karakoram. The uncertainty in the hydrological method is in practice much greater than in a typical direct measurement. For example, glacier runoff must be separated from that contributed by unglacierized parts of the catchment tributary to the discharge measurement station.

Surrogate Observations

Glacier mass balance B is well correlated with the elevation e of the equilibrium line at the end of the balance year (Braithwaite, 1984). This offers a means of inferring B from less expensive observations of e, possibly from space, but, apart from glaciers on which B is already measured, the only regular reports of e are those of Chinn (1999) for New Zealand glaciers. B is equally well correlated with the *accumulation area ratio*, which is the area of the accumulation zone divided by the area of the glacier (Slupetzky, 1989). These economical surrogates are valuable for extending knowledge of mass balance variability, but they are necessarily quite uncertain.

It is easier to measure the position of a glacier's terminus than to measure its mass balance. Terminus fluctuations are reported annually for several hundred glaciers, as against fewer than 100 reports of mass balance (Haeberli *et al.*, 1998). Unfortunately, the link between mass balance and glacier length is indirect. An observed annual change of terminus position is a response to balance forcing integrated over the glacier and over some indefinite span much longer than one year.

Developing and Emerging Technologies

Conventional measurement methods are labor-intensive and uncertain, but the need for better and more comprehensive estimates of mass balance has stimulated vigorous research into alternatives. Some of these are discussed briefly here.

Radar Altimetry Radar altimeters, mounted on aircraft or satellites, emit pulses towards the nadir (the point on the surface vertically beneath the sensor) and "track" the waveforms of the return pulses. Tracking involves prediction of future ranges (distances to the surface, convertible to elevations z) from ranges detected in the immediate past. Poor predictions, as when the surface is steep or undulating, result in loss of "lock" on the surface. A cross-track interferometer on the future CryoSat radar-altimetry mission will address this problem, which at present compromises the glaciological use of radar altimetry outside the interiors of the two ice sheets. In those regions, however, repeated radar altimetry has transformed our knowledge of accumulation. Accurate identification of orbit crossover points is essential, so orbital errors, discussed in detail by Davis *et al.* (2000), become important. Wingham *et al.* (1998) give a long list of corrections needed before the range differences may be interpreted as elevation changes. It is also assumed that the radar interacts with the glacier by surface backscatter, with extinction and subsurface volume backscatter being unvarying. This appears to be a good description of the interaction in dry-snow zones, but melting and internal accumulation complicate matters. Bamber *et al.* (2001) showed that the root mean square (rms) error of radar altimetry with respect to collocated estimates from airborne laser altimetry was ~ 7 m. The laser-altimeter measurements have decimeter-level accuracy (Krabill *et al.*, 1995).

Laser Altimetry Laser altimetry is the measurement of surface elevation by measurement of the two-way travel time of a pulse of optical radiation. Repeated measurements yield the change of elevation, leaving the density of the ice column to be supplied, for example, by Sorge's Law. The position of the laser must be known precisely, and it must be possible to reoccupy horizontal positions with an accuracy comparable to the radius of the "footprint" of the laser pulse. These problems have been solved by the integration of GPS measurements into altimeter systems. Neither laser altimeters nor radar altimeters can estimate the flux divergence, so it is necessary to accumulate a glacier-wide coverage of column measurements.

The first satellite laser altimeter, GLAS (the Geoscience Laser Altimeter System), was launched on ICESat in January 2003. Airborne laser altimetry was used by Krabill *et al.* (2000), who found significant thinning at lower elevations and overall balance at higher elevations on the Greenland Ice Sheet over a five-year span. Arendt *et al.* (2002) presented balance estimates for 67 glaciers in Alaska, relying on maps drawn from aerial photography flown in the 1950s and on laser-altimetric surveys in the 1990s. A notable methodological conclusion is that errors in the geodetic balance are dominated by the errors in the old maps. The old maps offer the chance of extending the historical span of the measurements, but their inaccuracy limits significantly what can be achieved.

Gravimetry Velicogna and Wahr (2002) have studied the joint resolving power of GLAS, GPS measurements, and the Gravity Recovery And Climate Experiment (GRACE). Launched in March 2002, GRACE is a pair of satellites flying about 200–250 km apart along-track. Each satellite ranges to the other using microwave phase measurements. When nongravitational accelerations are accounted for, the residual fluctuations in range may be used to map the gravity field with a horizontal resolution of a few hundred kilometers once every 30 days. With the aid of GLAS and GPS estimates of change in elevation, GRACE geoid changes are interpreted as a result of glacial isostatic

adjustment and of changes in ice mass. Errors in the latter of the order of $\pm 16\,\mathrm{kg\,m^{-2}\,a^{-1}}$ may be expected over 250-km spatial and 5-year temporal scales. This is quite large by comparison with the minimum accumulation in the interior of East Antarctica, but GRACE offers a substantial improvement over current coverage.

Ice-penetrating Radar and Ice Cores Radars with wavelengths in the meter range (frequencies of 10–500 MHz) can yield information on the depth to reflective horizons within the ice. The vertical separation between any two such horizons, if both horizons are isochronous and of known age, is a measure of volume balance. The same reasoning applies to horizons identified in ice cores. Only the accumulation at the core site can be measured, but the resolution in time is likely to be much better, at least in the upper core where annual layers are recognizable. When a well-dated core record can be tied to extensive radar surveys, a great increase in coverage results. It would be valuable if this capacity, at present largely restricted to century and longer timescales (e.g. Siegert, 2003), could be extended to shorter and more recent time spans and to smaller glaciers. Here, the aim is to find summer surfaces – the crusts that separate balance years. Pälli *et al.* (2002) estimated errors for a traverse in Svalbard with a 50-MHz radar. Most of the uncertainty was due to reflector-tracking error. For 13-year-old (Chernobyl) and 36-year-old (nuclear test) layers, with accumulation rates of 670 and $580\,\mathrm{kg\,m^{-2}\,a^{-1}}$, errors were ± 134 and $\pm 49\,\mathrm{kg\,m^{-2}\,a^{-1}}$.

Microwave Emission and Backscatter Passive-microwave radiometers sense the emission of surfaces at which they are pointed. Microwave emission from glaciers (Mätzler, 1987) is always reported in terms of the brightness temperature $T_\mathrm{B} = \varepsilon T - T_a$, where ε is the emissivity of the medium (a mixture of ice, air, and possibly water), T is its physical temperature and T_a, often neglected, is the brightness temperature of the downwelling sky radiation. In dry snow, the emissivity is determined by volume scattering at interfaces such as grain boundaries and larger structures such as buried hoar layers. Grain growth rate depends on both temperature and accumulation rate, and it is possible to exploit this (Zwally, 1977) to model accumulation rate as a function of T_B and T. Estimates of c from the Zwally model compare well with estimates from surface measurements (Vaughan *et al.*, 1999).

Scattering at air-water interfaces is much more effective than at air-ice interfaces, and, when melting occurs at the surface, volume scattering ceases to be significant and the emissivity approaches unity. Abrupt changes are observed in T_B as meltwater comes and goes, and have been used to estimate the extent and duration of melting over the ice sheets (Abdalati and Steffen, 2001; Mote, 2003). Ramage and Isacks (2003) have exploited the same behavior to determine the start and end of the melt season on Alaskan glaciers.

Active-microwave sensors (scatterometers and imaging radars) measure the backscatter from pulses which they themselves emit. Like radiometers, scatterometers have poor spatial resolution (tens of kilometers or worse), although it can be improved by temporal averaging. Drinkwater *et al.* (2001) reported standard errors of $50-70\,\mathrm{kg\,m^{-2}\,a^{-1}}$ for a linear regression between climatological estimates of accumulation and NSCAT scatterometer data in Greenland. In the percolation zone of western Greenland, Wismann (2000) showed an excellent correlation between seasonally integrated reduction of backscatter, with respect to a reference wintertime average, and positive degree-days. Because of its buried ice lenses, resulting from internal accumulation, the percolation zone is one of the most radar-bright surface types on Earth when cold and dry, and one of the darkest when wet.

Synthetic aperture radars (SARs), unlike scatterometers, can resolve surface features as small as 5–100 m. They cover much less ground per megabyte of data, so that complete one-time coverage of an ice sheet is a major undertaking (e.g. Jezek, 2002). In SAR studies of small glaciers, the emphasis, to date, has been on delineating zones and on searching for the equilibrium line (e.g. Demuth and Pietroniro, 1999). Cogley *et al.* (2001) demonstrated a different approach to SAR observations, relying on browse images to identify the seasonal course of melting as a function of elevation. There was a clear dependence of change in image brightness upon positive degree-days accumulated between same-day image pairs from summer days. In a similar way, Nghiem *et al.* (2001) were able to map the extent of melt and refreezing in Greenland, relying on diurnal variations measured by the Quikscat scatterometer.

Microwave estimates of accumulation in the dry-snow zone are already among the best available, and estimates of melting in the percolation zone have shown great promise. However, the ablation zone lacks a distinctive seasonal microwave signature.

Interferometric Synthetic Aperture Radar In a suitable configuration (e.g. Madsen and Zebker, 1998), two SAR images of a ground target can be used to estimate its elevation z by interferometry. More important payoffs of InSAR can be realized once the effect of topography is removed: the measurement of surface velocity and the mapping of grounding lines. When the images are separated by one day, as in the ERS tandem mission, 1995–1996, errors in surface velocity are of the order of meters/year. Vertical motions can be resolved as well, and near to grounding lines the contribution of tidal flexure to the vertical motion can be evaluated. The downstream change in flexure is largest just downstream of the grounding line, so the number of interference fringes is greatest there. Accurately located grounding lines are valuable because

at the grounding line the ice thickness is a function of z by hydrostatic equilibrium, and the discharge q may be estimated by integrating thickness times velocity across the gate. Speckle tracking (Gray *et al.*, 2001) is a less accurate but more robust way of measuring velocity. It is analogous to feature tracking in optical imagery, although the conditions for interferometry must still be satisfied.

Undersampling

Sparse information is a problem common to nearly all mass-balance methods. We wish to know the balance at M points in space during N spans of time, but have measurements only at a smaller number m of points for a smaller number n of spans. In whatever way m, n and M, N are related, interpolation or extrapolation will be required. How do spatial and temporal variability affect our ability to interpolate or extrapolate? This question can appear in different guises. Altimeter measurements of elevation change over a few years, and interferometric estimates of ice discharge over a few days, need to be compared with estimates of accumulation over much longer spans. In ice cores, measurements can be well resolved in time, but they may measure spatial as well as temporal variability if sastrugi and snow dunes have been migrating across the core site. Global estimates of small-glacier mass balance rely on observations spanning 1–50 years from at most a few hundred glaciers, and some of the unmeasured glaciers are thousands of kilometers from the nearest measured glacier. Information on time and space scales of variability is essential in each of these contexts if the measurements are to be interpreted meaningfully, that is, if they are to be given accurate error bars. This statistical problem is comparable in magnitude with the observational challenges being addressed by new technologies.

Results

Small Glaciers

Measurements of mass balance are reported to the World Glacier Monitoring Service (WGMS), Zurich, which publishes biennial bulletins (Haeberli *et al.*, 2001) and quinquennial summary volumes (Haeberli *et al.*, 1998). Not all measurements find their way into the WGMS database. Cogley and Adams (1998) and Dyurgerov (2002) are among those who have published more complete compilations. Dyurgerov's is the most comprehensive, and

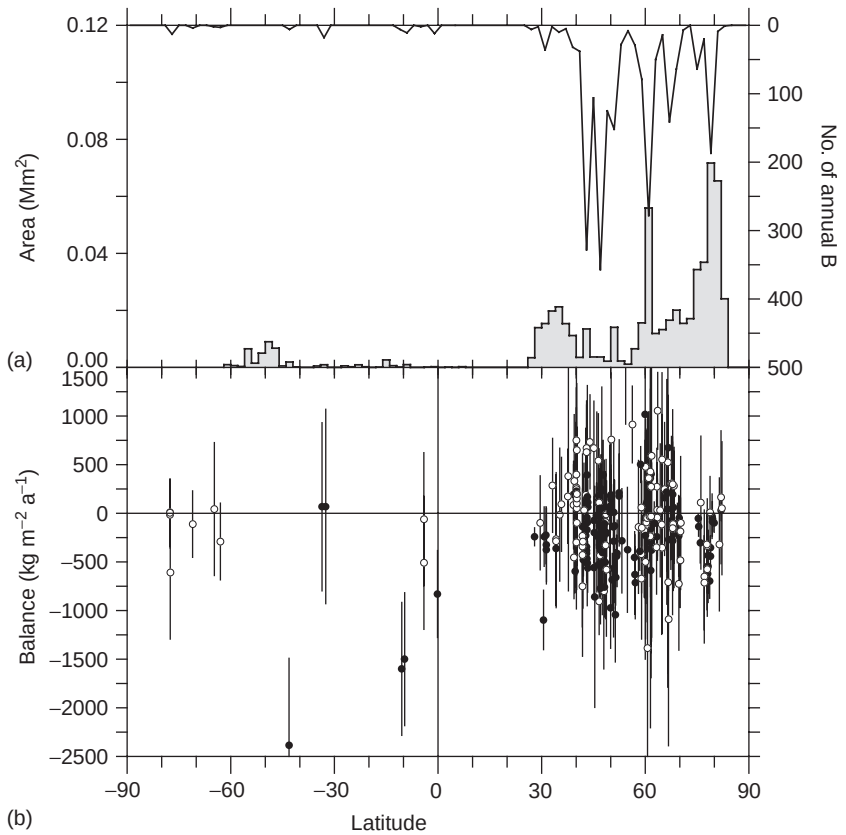

Figure 3 (a) Zonal distribution of small glaciers (shaded histogram, left axis; Antarctica excluded) and annual mass-balance measurements (thick line, right axis). (b) Average annual balances of measured glaciers, 1961–1990 (open circles: record length $n < 5$ years; solid circles: $n \geq 5$ years)

is available in spreadsheet form on CD-ROM. That of Cogley and Adams (1998; "CA" hereafter), covering only annual mass balance, may be obtained from **http://www.trentu.ca/geography/glaciology.htm.** Most reported measurements are direct measurements. Conventional geodetic measurements are unlikely to alter the picture greatly, although recent laser-altimetric measurements (Arendt *et al.*, 2002) have established more confidently that Alaska is a substantial contributor to sea-level rise.

Small glaciers occupy between 0.6 and 0.7 Mm^2, consisting of 0.539 Mm^2 plus about 0.070 Mm^2 in Greenland and an undetermined extent in Antarctica not belonging to the ice sheet. At present (2004) the CA dataset contains measurements from 310 glaciers dating back to 1885, although continuous measurements began only in the 1940s and a worldwide picture is only available after 1960. The spatial distribution of measured glaciers is uneven (Figure 3a), with high northern latitudes, Patagonia, and Tibet underrepresented at the expense of less remote regions (Europe and western North America). Glaciers with calving terminuses (19 of the 310) are not well represented. Most records are short. The modal length is 1 year, only 51 are 20 years or longer, and in no one year have as many as 100 glaciers been measured (Figure 4c). To set against this evidence of sparse coverage, there are about 2500 km^2 of ice per measured glacier, to be compared with about 30 000 km^2 of land per station for temperature climatologies. Moreover, CA note that three quarters of the small-glacier ice has at least one annual balance measurement within 400 km, and that the decorrelation distance for balance time series is about 600 km.

Spatial variations in mass balance are difficult to identify, at least at zonal resolution (Figure 3b). Allowing for uncertainties, most measurement series have averages indistinguishable from zero, but together they give a global arithmetic average of $-165 \pm 34\,kg\,m^{-2}\,a^{-1}$ for the reference period 1961–1990. (Here, and below, uncertainties are twice the standard error.) The error estimate is somewhat optimistic, and the balance estimate is biased by the neglect of internal accumulation in cold glaciers and of internal ablation in temperate glaciers, and other factors including possibly the spatial unevenness of the measurement network.

As records grow longer, however, the evolution of mass balance presents an increasingly coherent picture (Figure 4b). The world's small glaciers were close to equilibrium in the 1960s and have been losing mass since then at a growing rate. When spatial bias is corrected with an interpolation algorithm, the global average for 1961–1990 increases to $-123\,kg\,m^{-2}\,a^{-1}$, which is a best estimate.

Mass balance is well correlated with temperature (Figure 4a; $r = -0.79$ for the spatially corrected balance). The association would no doubt be closer if regional balances were matched to regional anomalies. Figures 4(a) and 4(b) help to justify the modeling of mass balance as a function of temperature (Wild *et al.*, 2003), and more importantly show that two independent measures agree in identifying the late twentieth century as a period of significant global change.

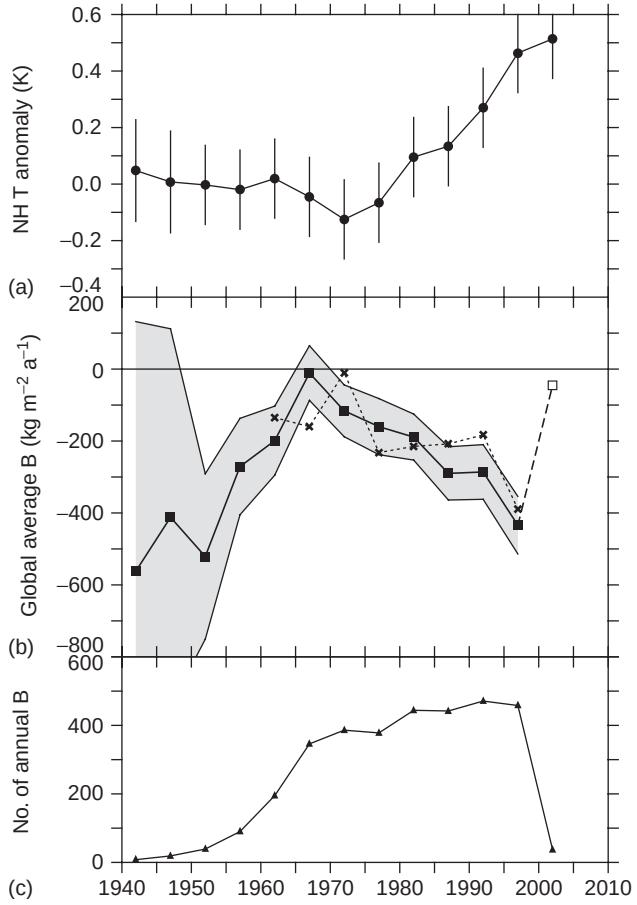

Figure 4 (a) Northern Hemisphere surface temperature anomalies; (b) small-glacier mass balance from the CA dataset, with shaded confidence region; crosses show effect of correcting for spatial bias; and (c) annual measurements contributing to each pentadal average balance (Jones and Moberg, 2003. © American Meteorological Society. **http://www.cru.uea.ac.uk/cru/data/temperature/**)

Greenland Ice Sheet

The ice sheets are too big for an integrated measurement of mass balance to be practical. Instead the aim is to compile the results of separate evaluations of each component.

For Greenland, accumulation is the best-known component. There are up to 400 column measurements, and three recent analyses interpolate to unmeasured parts of the ice sheet in different ways, hand contouring (Ohmura *et al.*, 1999) and kriging (Calanca *et al.*, 2000; Bales *et al.*, 2001). Figure 5 (Cogley, 2004) is constructed with another

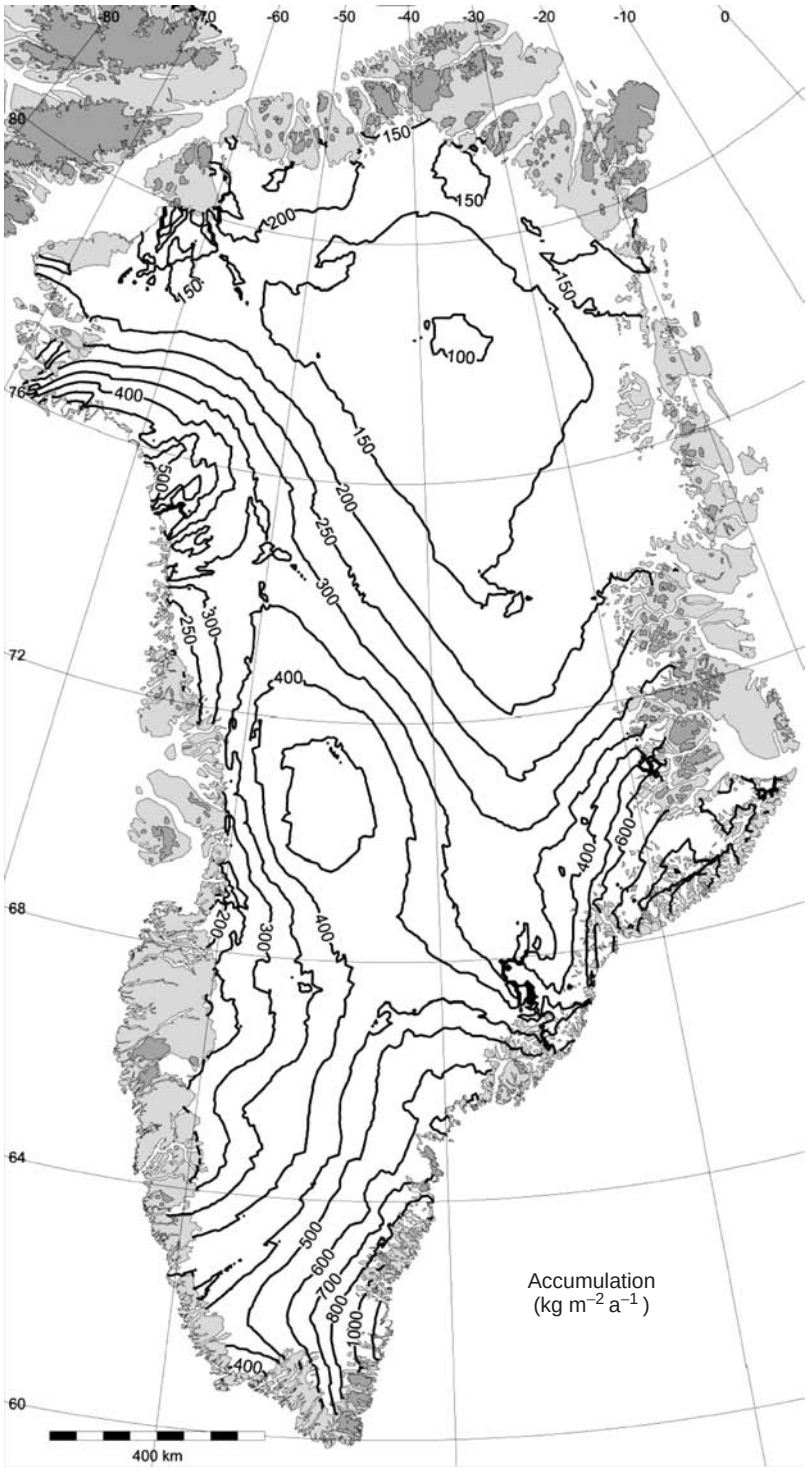

Figure 5 Accumulation on the Greenland Ice Sheet. The rate is below 100 kg m^{-2} a^{-1} in the northern interior and approaches 1400 kg m^{-2} a^{-1} in the southeast (Reproduced from Cogley (2004) by permission of American Geophysical Union)

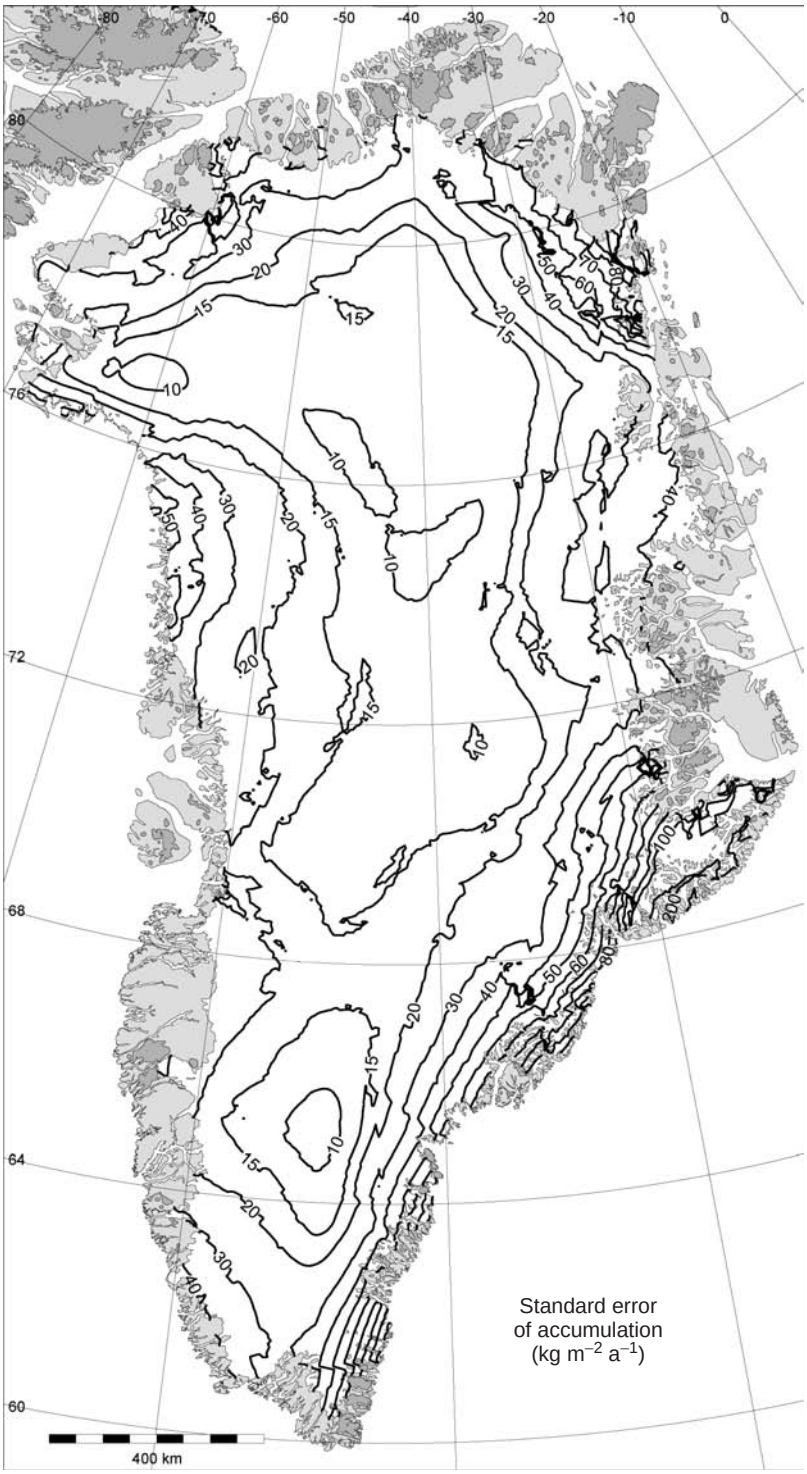

Figure 6 Standard error of accumulation on the Greenland Ice Sheet. Errors (for an assumed 30-year span) are as low as 8 kg m^{-2} a^{-1} in the interior and reach several hundred kg m^{-2} a^{-1} in places near the margin, where the interpolation algorithm falters for lack of information (Reproduced from Cogley (2004) by permission of American Geophysical Union)

interpolation algorithm. It is broadly similar to the other maps, but the algorithm has the advantage of generating formal estimates of the error at each interpolation point (Figure 6). The result is an accumulation estimate of $299 \pm 23\,\mathrm{kg\,m^{-2}\,a^{-1}}$, very close to the Ohmura, Calanca, and Bales estimates, 297, 290, and $305\,\mathrm{kg\,m^{-2}\,a^{-1}}$ respectively. Uncertainty is small in the interior of the ice sheet, where measurements are relatively abundant, and grows rapidly towards the edge where measurements are few (or nonexistent because the balance is negative and no snow survives).

The spatial and temporal variability of accumulation has of late received considerable attention (e.g. McConnell *et al.*, 2001), stimulated by advances in geodetic measurement technology which have led to improved estimates of surface elevation change (e.g. Krabill *et al.*, 2000; Davis *et al.*, 2000). The variability is such that the patterns of elevation change determined by altimetry can be understood mostly in terms of short-term fluctuations of the compaction rate and the accumulation rate (Braithwaite and Zhang, 1999) and spatial "glaciological noise".

According to the altimetry, average elevation change in the interior of the ice sheet is close to zero, implying $b = c + \Delta q \simeq 0$ because ablation a is near to zero. The kinematic measurements of Thomas *et al.* (2001) support this conclusion. The altimetry shows, however, that parts of the ablation zone are thinning rapidly.

The ablation zone occupies 10–15% of the Greenland Ice Sheet. Surface measurements are too few for a coherent picture to be drawn from them, and the most comprehensive current understanding of surface ablation derives from observations of melt extent and duration (Abdalati and Steffen, 2001) and from modeling. Mote's model (2003), which builds on passive-microwave observations of melt duration, yields a 12-year average of $-155\,\mathrm{kg\,m^{-2}\,a^{-1}}$ for meltwater runoff from the whole ice sheet. Wild *et al.* (2003) parameterized ablation as a function of temperature and surface elevation to obtain an equivalent estimate of $-152\,\mathrm{kg\,m^{-2}\,a^{-1}}$.

The estimates given so far imply a net surface mass balance of about $150\,\mathrm{kg\,m^{-2}\,a^{-1}}$. Zwally and Giovinetto (2000), using passive-microwave and thermal infrared satellite observations and a parameterization of meltwater runoff, estimated this quantity as $128\,\mathrm{kg\,m^{-2}\,a^{-1}}$, and summarized earlier estimates ranging between 97 and $211\,\mathrm{kg\,m^{2}\,a^{-1}}$.

It remains to evaluate the losses due to calving, or preferably the discharge q_{out} across the grounding line. Many outlet glaciers, particularly in north Greenland, have floating terminal sections. We would prefer the grounding-line flux because the floating ice has already made its contribution to sea-level rise, and because the basal mass balance of the floating terminuses is difficult to evaluate. Bigg (1999) estimated ablation due to calving using empirical relationships to predict calving velocity as a function of ice thickness or water depth. The latter were taken mostly from bathymetric charts. The estimates range from -73 to $-132\,\mathrm{kg\,m^{-2}\,a^{-1}}$ with an uncertainty estimated as $\pm 70\%$. Rignot *et al.* (1997) used InSAR to locate the grounding lines of 14 outlet glaciers of the northern Greenland Ice Sheet and to measure q_{out} as $136\,\mathrm{kg\,m^{-2}\,a^{-1}}$ from an area of $0.332\,\mathrm{Mm^2}$. The surface mass balance, estimated from a map of accumulation and a simple degree-day model of melting, was $113\,\mathrm{kg\,m^{-2}\,a^{-1}}$, so the total balance was $B = -25\,\mathrm{kg\,m^{-2}\,a^{-1}}$. The calving flux at the ice front was several times smaller than the grounding-line flux, requiring that basal melting of the floating ice be of the order of thousands of $\mathrm{kg\,m^{-2}\,a^{-1}}$. Rignot *et al.* (2001) found $B = -2\,\mathrm{kg\,m^{-2}\,a^{-1}}$ for a different but overlapping set of north Greenland glaciers. On 8 of 12 outlet glaciers, the grounding line retreated inland over 1992–1996. This is consistent with the laser-altimetric observations of near-coastal thinning, which also imply that the margin should be retreating where it is on land. There is some limited evidence for this (Sohn *et al.*, 1998).

Not all of the balance components are accompanied by detailed error estimates, but it seems likely that the mass balance of the Greenland Ice Sheet still cannot be distinguished reliably from zero. Krabill *et al.* (2000) estimated it as $-27\,\mathrm{kg\,m^{-2}\,a^{-1}}$, but this figure awaits analysis of errors and more complete documentation. Nevertheless priorities for future study are clear. Radar interferometry and laser altimetry both suggest that the closest attention should be given to lower altitudes of the ice sheet, where surface measurements are fewest and the energetics of melting and the dynamics of thinning need to be better understood.

Antarctic Ice Sheet

The Antarctic Ice Sheet is seven times the size of the Greenland Ice Sheet: $12.3\,\mathrm{Mm^2}$ of conterminous grounded ice as against $1.7\,\mathrm{Mm^2}$, plus about $1.6\,\mathrm{Mm^2}$ of ice shelf and ice rises.

Accumulation reaches less than $25\,\mathrm{kg\,m^{-2}\,a^{-1}}$ in the interior of East Antarctica and exceeds $2500\,\mathrm{kg\,m^{-2}\,a^{-1}}$ in the mountains of the Antarctic Peninsula (Turner *et al.*, 2002). Vaughan *et al.* (1999) compiled surface observations of accumulation and extrapolated them using a model based on microwave brightness temperature (Zwally, 1977) as a background field. They estimated accumulation to be $149\,\mathrm{kg\,m^{-2}\,a^{-1}}$ over the grounded ice and $166\,\mathrm{kg\,m^{-2}\,a^{-1}}$ over the entire ice sheet. Giovinetto and Zwally (2000) contoured the surface observations by hand and constructed from the contour map a grid of interpolates by eye. The resulting estimate of accumulation over the entire ice sheet was $159\,\mathrm{kg\,m^{-2}\,a^{-1}}$, to which they applied somewhat conjectural bulk adjustments totalling $-10\,\mathrm{kg\,m^{-2}\,a^{-1}}$ for loss by melting and deflation (wind scouring and sublimation) in coastal areas.

Although ablation by meltwater runoff is small in Antarctica, not all of the ice sheet has a positive surface balance. Bintanja (1999) reviewed the widely distributed areas of blue ice, where there is no snow at the surface. Mass balance minima range from $-350\,\mathrm{kg\,m^{-2}\,a^{-1}}$ in northern coastal areas where melting is significant to smaller magnitudes ($\sim -50\,\mathrm{kg\,m^{-2}\,a^{-1}}$) at higher elevations where sublimation is low because temperatures are low. Winther *et al.* (2001) estimated the extent of blue ice to be $0.12–0.24\,\mathrm{Mm^2}$. Over about half of this extent of the negative balance is due to melting and over the other half it is due to scouring and sublimation. These results suggest that blue-ice areas reduce the mass balance of the grounded ice sheet by perhaps $0.5–4\,\mathrm{kg\,m^{-2}\,a^{-1}}$, which is negligible given the present accuracy of accumulation estimates at the ice sheet scale. Surface ablation may not be negligible, however, in some of the smaller basins.

Rignot and Thomas (2002) reported ice fluxes obtained at grounding lines by InSAR and coupled these estimates with the Giovinetto–Zwally estimates of accumulation to yield the nearest approach to date to a whole-glacier estimate of B for catchments in Antarctica. The 33 catchments, labelled in Figure 7, cover $7.2\,\mathrm{Mm^2}$. Their ice discharges range from a negligible $3\,\mathrm{kg\,m^{-2}\,a^{-1}}$ (from the inactive Ice Stream C) to more than $1000\,\mathrm{kg\,m^{-2}\,a^{-1}}$ (Smith and DeVicq Glaciers in the Amundsen sector). Their balances (accumulation minus discharge) range from $131\,\mathrm{kg\,m^{-2}\,a^{-1}}$ (Ice Stream C) to well below $-500\,\mathrm{kg\,m^{-2}\,a^{-1}}$ (the small outlet glaciers in the Amundsen sector). The spatially variable picture thus presented is not the least significant contribution made by this work.

When pooled, the Rignot–Thomas measurements give a balance of $-3 \pm 4\,\mathrm{kg\,m^{-2}\,a^{-1}}$. If the Vaughan accumulation field is used in place of the Giovinetto–Zwally field, the balance becomes $6 \pm 4\,\mathrm{kg\,m^{-2}\,a^{-1}}$. It is not clear how much weight should be given to the reservations that led Rignot and Thomas to prefer the Giovinetto–Zwally field, and, by analogy with the error analysis for Greenland (Figure 6), the standard error of accumulation may not be as small as their chosen 5%. If it is larger, or if equal weight is given to the two accumulation fields, then the Rignot–Thomas results resemble all earlier estimates of Antarctic mass balance in showing no significant difference from zero. A further source of uncertainty, not considered by Rignot and Thomas, is the difference in time span between the accumulation maps, based on measurements covering up to several decades, and the quasi-instantaneous 1996 InSAR measurements of discharge. Too little is known about the temporal variability of the discharge of ice streams and outlet glaciers for us to be confident that the InSAR snapshots are good estimators of multidecadal averages; this is a question requiring more systematic attention.

Radar-altimetric surveys of thickness change (Wingham *et al.*, 1998; Davis *et al.*, 2001) agree with the InSAR/accumulation estimates in finding no significant change in the interior of East Antarctica. (This is a puzzle awaiting an explanation, for in a warmer world, as in Figure 4(a), the atmosphere should deliver more snow to Antarctica.) In the Amundsen sector of West Antarctica, the

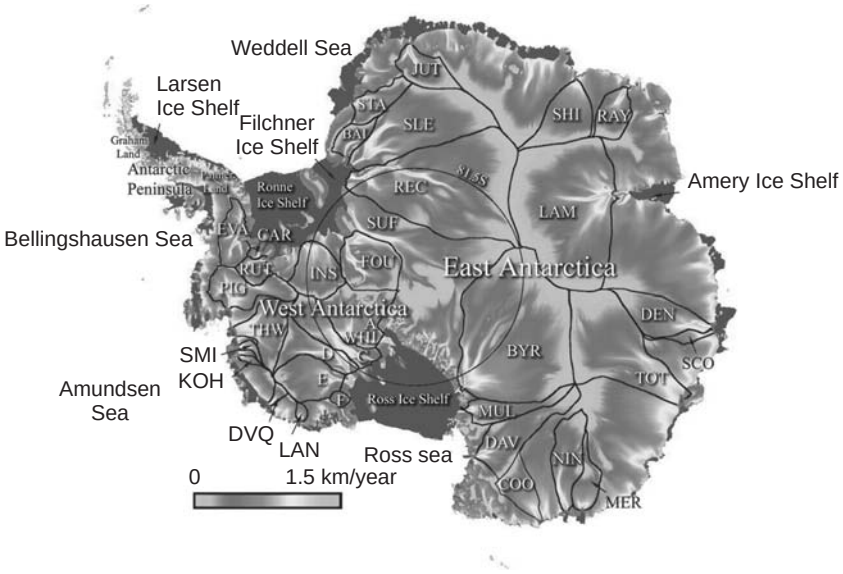

Figure 7 Major basins of Antarctica. The underlying field is the balance velocity (the column-averaged velocity $q_{\mathrm{out}}/\rho_{\mathrm{i}}$ which makes $b + q_{\mathrm{out}}$ zero in equation 3) (Reprinted from Rignot and Thomas, 2002. Mass balance of polar ice sheets. *Science*, **297**, 1502–1506. © 2002 American Association for the Advancement of Science). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

two methods also agree in finding a substantial negative balance. Shepherd *et al.* (2002) measured inland migration of the grounding lines and rapid thinning of Pine Island, Thwaites, and Smith Glaciers (Figure 7). They estimated the balances of Thwaites and Smith Glaciers as $-22 \pm 8\,\mathrm{kg\,m^{-2}\,a^{-1}}$ and $-233 \pm 34\,\mathrm{kg\,m^{-2}\,a^{-1}}$ respectively for 1991–2001, while Rignot and Thomas (2002) gave $-123 \pm 92\,\mathrm{kg\,m^{-2}\,a^{-1}}$ and $-698 \pm 222\,\mathrm{kg\,m^{-2}\,a^{-1}}$. The discrepancies obviously require investigation, but may be consistent with other evidence suggesting that the thinning began rather abruptly at some time during the 1990s. An abrupt onset would invite the speculation that the thinning is due to changes in ocean circulation leading to increased basal melting near the grounding line (Rignot and Jacobs, 2002).

The mass balance of the ice shelves is difficult to assess, mainly for lack of complete estimates of its components. The grounding-line flux estimates of Rignot and Thomas (2002) sum to $754\,\mathrm{Gt\,a^{-1}}$. If they account for the same fraction of shelf nourishment as the fraction of grounded ice from which they come, 59.3%, the total grounding-line flux would be $1271\,\mathrm{Gt\,a^{-1}}$. Vaughan *et al.* (1999) estimated the surface accumulation on the ice shelves as $478\,\mathrm{Gt\,a^{-1}}$. Several of the most northerly shelves have disintegrated in recent years, and surface melting has been implicated in these events, but quantitatively it makes little contribution to the balance; Jacobs *et al.* (1992) gave a crude estimate of $-36\,\mathrm{Gt\,a^{-1}}$. They also gave $-2016\,\mathrm{Gt\,a^{-1}}$ for the rate of calving, based mainly on iceberg censuses. From oceanographic observations, Jacobs *et al.* (1996) estimated the basal balance to be $-756\,\mathrm{Gt\,a^{-1}}$. The two inputs and the three outputs sum to $-1059\,\mathrm{Gt\,a^{-1}}$, or $-708\,\mathrm{kg\,m^{-2}\,a^{-1}}$.

Although there are scattered *in situ* and remotely sensed measurements, at present the only realistic way to get a broad view of the basal mass balance of an ice shelf is to model it using an ocean circulation model. For example, Williams *et al.* (2001) simulated the basal balance of Amery Ice Shelf to be $-254\,\mathrm{kg\,m^{-2}\,a^{-1}}$, which is substantially less negative than the Jacobs estimate of $-596\,\mathrm{kg\,m^{-2}\,a^{-1}}$. Nevertheless, the appropriate conclusion from the incomplete evidence appears to be that the ice shelves of Antarctica are losing mass at a rate that is very uncertain.

SUMMARY

Imprecise measurements, with insufficient spatial density and coverage, are a significant constraint upon what can be said about glacier mass balance in its global context. The cost of improving the methods and extending the scope of the measurements is high, but so are the probable costs of failure to understand mass and energy exchange between glaciers and the rest of the hydrosphere. For this reason, measurement technology is the subject of vigorous research and is improving rapidly. In the near future, the mass balance of the two ice sheets will become known with an uncertainty small enough to state with confidence whether they are growing or shrinking. At present the weight of evidence, some of it circumstantial, implies that both have negative mass balance, but the errors are not adequately quantified and for the Antarctic Ice Sheet, in particular, a conclusion about the sign of the mass balance would be premature. For the small glaciers, the picture is more clear. Their balances are negative on average and have been growing more negative since the 1960s, but here also there is scope for a more thorough assessment of errors.

The best balance estimates, in sea-level equivalents, are: for small glaciers, as calculated above, $0.21\,\mathrm{mm\,s.l.e.\,a^{-1}}$ with a poorly quantified uncertainty of the order of $0.06\,\mathrm{mm\,s.l.e.\,a^{-1}}$; for the Greenland Ice Sheet (Krabill *et al.*, 2000), $0.13\,\mathrm{mm\,s.l.e.\,a^{-1}}$ with no estimate of uncertainty; and for the Antarctic Ice Sheet (Rignot and Thomas, 2002; Vaughan *et al.*, 1999), between 0.10 and $-0.20\,\mathrm{mm\,s.l.e.\,a^{-1}}$ with an uncertainty of at least $0.13\,\mathrm{mm\,s.l.e.\,a^{-1}}$. The sum of these estimates, 0.14 to $0.44\,\mathrm{mm\,s.l.e.\,a^{-1}}$, is a small proportion of the contemporary rate of sea-level rise, 1.84–1.91 mm s.l.e. $\mathrm{a^{-1}}$ (Peltier, 2001; but see also Miller and Douglas, 2004, and references cited therein).

166: Surface and Englacial Drainage of Glaciers and Ice Sheets

PETER NIENOW[1] AND BRYN HUBBARD[2]

[1] *Institute of Geography, University of Edinburgh, Edinburgh, UK*
[2] *Institute of Geography and Earth Sciences, University of Wales, Aberystwyth, UK*

Supraglacial drainage occurs wherever snowpack, firn, or ice at the glacier surface is at the pressure melting point and supplied with additional energy, thereby generating melt water. Energy sources vary, but net radiation is usually the dominant source, although inputs of rainwater can also provide large volumes of surface runoff. The surface melt water is routed through the snowpack, firn, and across the glacier surface according to the local hydraulic gradient. In general, routing of water through snow and firn is slow (10^{-4}–10^{-5} m s^{-1}), contributing to a significant lag between melt water production and runoff at the glacier snout, whereas flow across exposed ice surfaces is typically 3–5 orders of magnitude faster. Under certain conditions where parts of the snowpack, firn, and/or ice surface are below the pressure melting point, the melt water will refreeze. Otherwise, the melt water will be routed supraglacially to the glacier margin unless intersected by a pathway from the glacier surface to the glacier interior. Such pathways include crevasses and moulins, and in temperate glaciers, microscale englacial veins. Flow rates through the englacial system vary considerably according to the hydraulic efficiency of the route taken. The routing of melt waters through both supraglacial and englacial drainage systems therefore affects the runoff response of an ice mass to rain and melt water inputs. During the course of a melt season, the efficiency of routing through both systems evolves, thereby altering the runoff response time to input variations.

INTRODUCTION

The routing of melt water through a glacial system is controlled by three interlinked subsystems – the surface, englacial, and subglacial drainage systems. The structure within each of these subsystems determines the efficiency and the route by which waters originating at the glacier surface are delivered to the glacier snout. The runoff response of a given ice mass to an externally forced melt or precipitation event is, therefore, controlled by the structure of these subsystems, which can vary both between ice masses and at a given ice mass over time and space.

The glacial drainage system can be envisaged as a cascade whereby surface melt waters are delivered to the glacier terminus either directly, via marginal streams, or via englacial and subglacial pathways. The distribution of snow, firn, and exposed ice and the hydraulic properties of each of these components determine the structure and efficiency of the surface or *supraglacial* drainage system. Flow rates vary substantially, from slow percolation through the snowpack and firn, to rapid channelized and sheet flow across exposed glacier ice (Krimmel *et al.*, 1973). The presence of a snowpack or firn layer, therefore, dampens the delivery of surface melt water to the glacier terminus (Fountain, 1989; Fountain and Walder, 1998). If the supraglacial melt water encounters a permeable pathway from the surface into the glacier interior, it will enter the englacial system. The rate of flow through the englacial system varies dramatically between the vertical shafts or "moulins" that can deliver water quickly to the glacier bed and the vein network in temperate ice where melt waters may flow at only a meter per year (Wakahama *et al.*, 1973) or less (Raymond and Harrison, 1975). In addition, water may be stored for significant periods in crevasses and englacial voids.

The flow of water through supraglacial and englacial drainage systems is important for a number of reasons. The structure within both systems critically affects the rate at which waters at the glacier surface are delivered to

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

the glacier snout. Both systems, therefore, modify the link between surface melt (and liquid precipitation) and runoff (Jansson *et al.*, 2003). This is clearly important where melt waters from glaciated catchments are used for hydroelectric power and irrigation or where flood prediction is desirable. The catastrophic release of large volumes of supraglacially stored water has caused substantial loss of human life, and the mechanisms responsible for these flood events need to be better understood (Richardson and Reynolds, 2000). Whether melt water generated in a given year at the glacier surface is routed to the terminus or refreezes within the snowpack/firn has significant implications for glacier mass balance and for long-term sea-level fluctuations (Pfeffer *et al.*, 1991). Finally, the proportion of surface-derived melt waters that access the englacial drainage system and the pattern by which these waters are subsequently delivered to the glacier bed will impact on the structure of the subglacial drainage system and therefore on ice dynamics, sediment evacuation, and solute acquisition.

Firnification

The presence of firn plays a critical role in the storage and release of surface-derived glacial melt waters (Fountain, 1996; Jansson *et al.*, 2003) because of its porosity. Firn represents an intermediate or metamorphic state between "first-year" snow and glacier ice, and the rate and processes controlling the transformation from snow to ice are determined by the local accumulation rate and thermal regime. Firn becomes ice when the density reaches $830\,\mathrm{kg\,m^{-3}}$ (Paterson, 1994) and the air spaces become isolated, but the time taken for and the depth at which this transition occurs varies dramatically between ice masses. Thus, in the dry-snow zone of ice sheets such as at the Vostok Station in Antarctica, the firn-ice transition occurs after $\sim$2500 years at a depth of 95 m (Barnola *et al.*, 1987). The extremely slow transition is the result of both very low temperatures and accumulation rates. By contrast, the firn-ice transition in temperate glaciers can take place in less than 10 years at depths of $<$15 m (Sharp, 1951).

One of the key factors controlling the rate of firnification is the presence of water in the snowpack. In all snowpacks, compaction of individual crystals occurs during the initial stages of transformation, resulting in a more efficiently packed structure and greater density. Also, '*pressure-sintering*' increases compaction and reorganization of the crystal structure with a resultant reduction in porosity and the associated increase in density. In snowpacks where melting occurs, the presence of water dramatically increases rates of firnification through processes of regelation, diurnal freeze-thaw cycles, and the refreezing of percolating melt waters. The presence of water also implies that the snowpack is warmer than dry snow, so all processes of metamorphism occur faster. The most rapid transformation of snow to ice occurs when melt waters from a single summer percolate to the base of the snowpack and refreeze at the cold ice surface as an annual layer of superimposed ice. This process is most important in High Arctic ice masses such as Greenland in the "superimposed ice zone" immediately above the equilibrium line (Benson, 1962).

Because of its porous nature, the presence and thickness of the firn in the accumulation area of an ice mass will affect the potential for water storage. The movement of melt water through the glacier system will be delayed by temporary storage within the firn, as outlined in the following section.

Water Flow and Storage in Snow and Firn Reservoirs

The supraglacial snowpack and firn are aquifers that store water and delay runoff from glaciers. The role played by these aquifers in the hydrology of glaciers has been discussed at length (Fountain, 1996; Fountain and Walder, 1998; Schneider, 2000; Jansson *et al.*, 2003).

Water Flow and Storage in Snow

Movement of water through snowpacks is often complex because of the heterogeneity of snowpack conditions and varies temporally and spatially on a glacier and between glaciers. The processes controlling snowpack hydrology are generally the same in glacial and extraglacial snowpacks – the one common difference being the presence beneath supraglacial snowpacks of glacier ice that presents either a virtually impermeable or completely impermeable surface at temperate and polythermal/cold glaciers respectively. Marsh (*see* **Chapter 161, Water Flow Through Snow and Firn, Volume 4**) provides a more comprehensive summary of water flow through snowpacks.

Supraglacial snowpacks are often highly heterogeneous because of the complex stratigraphy associated with microscale variations in ice grain structure and the presence of macroscopic layering, both of which affect the porosity and hydraulic conductivity. The presence of impermeable ice layers, in particular, can significantly inhibit infiltration (Lang *et al.*, 1977; Echelmeyer *et al.*, 1992). Surface melt waters therefore percolate through the snowpack at different rates according to the route taken (Colbeck, 1991). Percolation rates are controlled by gravity and local degree of water saturation (in unsaturated conditions) and approximate to Darcy's Law (Colbeck, 1973) with velocities typically in the range 10^{-4}–$10^{-5}\,\mathrm{m\,s^{-1}}$ (Wakahama, 1968). These slow percolation rates through the snowpack mean that its presence delays the delivery of surface-derived melt waters to the englacial drainage system when compared to conditions where snow is absent. The seasonal thinning and removal of the supraglacial snowpack in the ablation zone therefore plays an important role in decreasing flow times from the glacier surface to the snout.

Melt waters reaching the base of the snowpack in the accumulation area typically percolate into the unsaturated firn whilst, in the ablation area, waters may: (i) enter the englacial system directly through a crevasse or moulin; (ii) flow over the ice surface; or (iii) become ponded in a saturated aquifer. The thickness of the aquifer depends on snow thickness, ice surface slope, melt water flux from the surface and the distribution of moulins and crevasses that act as sinks. Where surface gradients are very low and crevasses infrequent, the snowpack may become fully saturated and supraglacial "swamps" or slush zones can develop (Holmes, 1955; Hagen *et al.*, 1991). Stenborg (1970) observed slush layers up to 2-m deep at Mikkaglaciären in Sweden. Saturated snowpacks can destabilize, generating slush flows or avalanches that remove large volumes of supraglacially stored melt water and create levee-bounded channels. Such flows can be particularly spectacular at cold glaciers where reduced surface macropermeability can result in the development of vast slush fields.

Water Flow and Storage in Firn

In the accumulation zone, melt water percolates through the snowpack and into the unsaturated firn before building up as a saturated layer above the underlying low permeability glacier ice. The saturated layer develops after the onset of spring melt, and the thickness reached is dependent on the flux of waters from surface melt and rainfall, the hydraulic gradient in the firn, and the spacing and, to some degree, size of crevasses.

The thickness of the saturated layer varies both across and between glaciers with maximum values, for example, of 2 m and 7 m observed at South Cascade Glacier (Fountain, 1989) and Aletschgletscher (Schommer, 1978) respectively. The volumes of melt water stored within the firn can be significant and reduce the amplitude of diurnal runoff variations at the glacier snout. At South Cascade Glacier, Fountain (1989) found that storage in the firn accounted for $\sim$12% of the total spring storage, whilst at Storglaciären, 44% of total water storage was in the firn (Schneider, 2000). The hydraulic structure of the firn results in percolation rates with velocities in the order of $10^{-5}\,\mathrm{m\,s^{-1}}$ (Schneider, 2000). These velocities, and the subsequent temporary storage of waters in the firn acquifer, can induce a lag of days to weeks between supraglacial melt water generation in the accumulation area and its arrival at the glacier snout (Lang *et al.*, 1979; Behrens *et al.*, 1982). The percolation rates also tend to dampen the effect of the surface melt-signal so that diurnal water level variations in the firn are limited (Jansson *et al.*, 2003). Once melt water inputs to the snowpack and firn cease at the end of the melt season, the saturated firn layer drains, contributing to runoff or storage elsewhere in the glacier in the early winter. The firn layer is typically fully drained by late November (Fountain, 1996).

Supraglacial Channel Systems and Lakes

Supraglacial Channel Systems

In the ablation zone, seasonal removal of the supraglacial snowpack exposes glacier ice that is essentially impermeable at the microscale. Melt water flows across exposed ice surfaces at much higher flow velocities than those that are observed in the firn or snowpack. Initially, waters may percolate slowly along crystal boundaries in the weathered surface ice, but they are then routed quickly across the surface in either a thin film akin to sheet flow or in supraglacial channels. Melt waters follow the line of steepest gradient and are routed to the ice margin, unless they first drain into crevasses or moulins. In temperate glaciers, a very small proportion of surface melt waters may drain into the englacial vein network.

The size and discharge of a given supraglacial stream is dependent on the surface melt rate and the area of the catchment basin, which itself is controlled by the surface topography and the distribution of crevasses and moulins. On temperate glaciers, supraglacial streams rarely flow for more than a kilometer before intersecting a crevasse. On cold or polythermal ice masses, large deeply incised (>3 m) supraglacial streams (Thomsen *et al.*, 1988; Bingham *et al.*, 2003) may flow for many kilometers because of the lack of crevasses, and individual catchment basins may reach up to several hundred square kilometers (Sugden and John, 1976). Because stream location is controlled by the surface topography of the ice mass, the position of the larger streams is relatively constant between melt seasons (Hagen *et al.*, 1991; Kohler, 1995). However, stream routing may change during a melt season if melt waters initially routed over crevasses or snow-plugged moulins are subsequently "captured" when englacial connections enable melt waters to drain into the glacier. This can result in the abandonment of down-glacier sections of the supraglacial drainage system.

Supraglacial channel networks often develop arborescent drainage patterns similar to terrestrial river catchments (Hagen *et al.*, 1991; Knight, 1999), and rectilinear patterns are also common resulting from structural control imparted by crevasse traces and longitudinal foliation (Sugden and John, 1976). Some workers suggest stream density decreases upglacier because of the decrease in ablation and thus runoff with increasing elevation and the up-glacier reduction in slope angles away from the glacier margin (Sugden and John, 1976). However, the spatially irregular removal of surface melt waters into crevasses and moulins ensures that there is no simple relationship between drainage density and location on most ice masses.

Supraglacial streams usually meander (Knighton, 1972) and have similar hydraulic geometries to those observed in terrestrial river channels (Ferguson, 1973) with some longitudinal sections analogous to pool-riffle sequences (Carver *et al.*, 1994). Channel roughnesses are very low

with Manning's "n" of 0.01–0.012 (Chow, 1973) reflecting the low friction of the smooth ice-walls, and flow velocities are correspondingly high at about $1-2\,m\,s^{-1}$. The rapid velocities in supraglacial melt water channels ensure that melt water fluxes into moulins and crevasses have the same diurnal pattern as supraglacial melt-rates (Kohler, 1995; Nienow *et al.*, 1996). As the melt season progresses and the thinning snowpack reveals increasing areas of glacier ice, the time between peak melt rate and peak runoff from the glacier snout decreases (Elliston, 1973). In addition, as the snowpack is removed, the impact of rainfall events on glacier runoff is enhanced because of the rapid routing of water over the exposed impermeable ice surfaces (Østrem *et al.*, 1967).

Supraglacial Lakes

Supraglacial lakes form where melt waters gather within topographic depressions on the ice surface. These depressions and associated lakes are most common on large polythermal or "cold" glaciers where the stiffness of cold ice promotes flow-induced surface undulations or topographic ramps in response to bedrock obstacles (Rabus and Echelmeyer, 1997) and the surface ice is largely impermeable. In addition, since average surface gradients typically decrease as ice mass/glacier length increases (Raper, 2001), the incidence of depressions occupied by supraglacial lakes increases with ice mass size (as long as melt waters are available to fill the lakes). Thus, in Greenland where surface gradients away from the ice-sheet margin are very shallow, supraglacial lakes are common (Holmes, 1955), especially in the "slush" zones around the equilibrium line (Greuell, 2000; Greuell and Knap, 2000). In this zone, individual lakes can cover several square kilometers and may survive between melt seasons. However, supraglacial lakes are often transient features formed during the early melt season before draining either supraglacially, as melt waters overtop their retaining topographic barrier, or englacially as crevasses or snow-plugged moulins open (Liestøl *et al.*, 1980; Hagen *et al.*, 1991; Bingham *et al.*, in press). Ice-marginal lakes may also drain across glacier surfaces if the water level overtops the retaining topographic ice barrier or if snow-plugged supraglacial outlet channels become reactivated when the temporary snow dam becomes saturated and fails. Ice-marginal lakes that drain onto glacier surfaces are most commonly found beside polythermal glaciers (Hambrey, 1994) where the ice margin is frozen to the bed, thereby inhibiting drainage of the lake waters by subglacial routes.

Surface melt waters often fill crevasses during the early melt season, prior to the development of drainage links into the englacial system. Ponding of melt waters in crevasses exerts extreme forces at the base of the crevasse (Van der Veen, 1998) and may induce hydrofracture and crack propagation to the glacier bed. Work at John Evans Glacier in the Canadian High Arctic suggested that over a period of days, water ponded in a crevasse induced a series of fractures before the crack reached the ice-bed interface, whereupon the ponded melt waters drained rapidly (Boon and Sharp, 2003).

In areas where debris-rich glaciers stagnate (including the "stagnating" snout of surge type glaciers immediately postsurge), differential surface melt often results in the formation of numerous supraglacial lakes or "glacier karst" (Clayton, 1964; Reynolds, 2000). In recent years, warming trends and glacier recession in alpine glaciated landscapes have resulted in a dramatic increase in the occurrence of such lakes, particularly in parts of the Himalayas and Andes (Ageta *et al.*, 2000; Richardson and Reynolds, 2000). Catastrophic drainage of these lakes as glacier lake outburst floods (or GLOFs) can lead to severe loss of life and destruction in downstream areas. Richardson and Reynolds (2000) estimate that 32 000 people have been killed by GLOFs in Peru alone in the last century. The precise mechanisms that initiate GLOFs remain poorly understood and consequently, their occurrence is hard to predict. Mitigation of the hazard potential of GLOFs is typically predicated on on-site monitoring programs (Richardson and Reynolds, 2000). However, advances in remote sensing have demonstrated the potential for remotely monitoring the evolution of these supraglacial lakes (e.g. Wessels *et al.*, 2002).

Controls on the Character of Supraglacial Drainage Systems

The character of supraglacial drainage systems is principally determined by the permeability of the glacier surface and the climate that controls the development of the snowpack, the thermal regime of the glacier, and the volume of melt water generated during a melt season. Crevasses and moulins are the most efficient way of draining melt waters from the glacier surface. The distribution of crevasses therefore controls the extent to which supraglacially derived melt waters are routed across the glacier surface prior to entering the englacial drainage system. Glaciers containing a cold surface ice layer typically have streams flowing over the surface for greater distances before the melt waters are routed to the glacier margin or access the englacial system via crevasses or moulins (Iken, 1972; Bingham *et al.*, 2003; Boon and Sharp, 2003).

The character of supraglacial drainage systems is temporally and spatially variable and critically dependent on when and where on an ice mass surface runoff is generated. The presence or absence of a snowpack exerts a fundamental control on supraglacial drainage characteristics, as do variations in hydrological conditions within the snowpack which itself typically undergoes a seasonal evolution. Seminal work by Benson (1962) described distinct snowpack facies in the accumulation area of the Greenland

Ice Sheet, which can be characterized by their physical and thermal properties. Benson's classification is applicable to other ice masses (e.g. Müller, 1962) and the different facies are characterized by different supraglacial drainage conditions because of variations in both the availability of melt water and the possible hydrological flow paths in each zone. The typical hydrological conditions present in each of Benson's zones at the height of the summer melt season are outlined in the following sections.

Dry-snow Facies This zone is generally only found high in the interior of the Greenland and Antarctic ice sheets and on some very high mountains at lower latitudes. In this zone, no melting occurs and there is thus no supraglacial drainage.

Percolation Facies At lower elevations, some melting occurs for a brief period during summer. The melt water generated percolates into the snowpack or firn, where it refreezes as ice lenses or in layers at a particular depth. Whilst refreezing releases latent heat, not enough melt water is generated to saturate the whole snowpack and raise the temperature to 0 °C. There is therefore no runoff from the percolation zone.

Wet-snow Facies Within this zone, summer melt is sufficient to raise the whole of the snowpack to 0 °C for at least part of the melt season. Melt water flow is characterized by vertical percolation through the snowpack and subsequent lateral flow across impermeable ice layers in the snowpack or across glacier ice. The volume of runoff increases with decreasing elevation as less of the melt water refreezes within the snowpack and firn. In this zone, extensive slush fields can develop (Greuell and Knap, 2000), and the depth of saturation is dependent on the volume of melt, the surface gradient, and the prevalence of crevasses. This zone is also characterized by large supraglacial lakes and surface streams that incise down into the underlying snowpack and firn, and the melt waters usually drain englacially via moulins and crevasses. Thick layers of ice commonly form through refreezing at the end of the melt season and if this occurs at the snow-ice interface, superimposed ice is formed.

Superimposed Ice Facies This zone is located where all of the winter snowpack is melted, but some of the melt water refreezes as superimposed ice when it reaches the cold glacier ice. The lower edge of the superimposed ice zone represents the equilibrium line. Hydrological conditions are very similar to the wet-snow facies until all of the snow is removed.

Ice Facies In the ablation zone, warming of the winter snowpack as the melt season progresses raises the whole snowpack to 0 °C. Percolation with some refreezing is characteristic of the early melt season, and as the snowpack becomes increasingly saturated, slush flows can play an important role in removing significant volumes of snow. Once the snowpack is removed, runoff follows the steepest gradient over the bare ice surface, and supraglacial stream systems rapidly route the melt water to crevasses and moulins or the glacier margin.

In temperate glaciers, only the wet-snow and ice facies occur because summer melting warms the entire snowpack to melting point. The extent of ice (ablation zone) and wet-snow (accumulation zone) facies at the end of a given melt season is clearly controlled by variations in annual mass balance. As the proportion of exposed ice increases during a melt season, the lag-time between peak melt rate and peak runoff decreases, as the efficiency of the hydrological pathways increases.

Water Supply to, and Flow through, the Englacial Drainage System

Supraglacial water will enter a glacier and flow englacially upon encountering a permeable pathway. At the largest scale, such pathways are provided by surface crevasses that open up and close as ice passes through a crevasse field. Once exploited by melt water, however, notches incised by melting into the up-glacier edges of crevasses may be transformed into vertical tubes or *moulins*, which can remain as flow pathways long after the crevasse itself has closed (Stenborg, 1969). Consequently, moulins frequently occur as linear trains reflecting the orientation of the original crevasse from which they developed. Individual moulins can vary in size from under a meter to over 10 m across. Subhorizontal englacial channels may also form as a result of the incorporation of water present along the base of crevasses into the underlying englacial ice (Fountain and Walder, 1998). Similarly, basal fractures and crevasses can also propagate upwards from the glacier bed, providing effective transport pathways for the interchange of englacial and basal melt waters (e.g. Röthlisberger and Lang, 1987). Although supraglacial melting has the capacity to supply large fluxes of water to this channelized englacial system, water can also be produced within the body of the glacier itself. Melt water, for example, can be generated by frictional heating resulting from ice deformation and, nearer the glacier bed, basal sliding. Further, sliding by regelation, whereby temperate ice melts and refreezes in response to the difference in pressure melting point around a bedrock hummock, can induce melting some distance above the glacier bed (Lliboutry, 1993).

Polycrystalline ice is permeable at the microscale because individual ice crystals are separated by a network of water-filled veins. These veins form where three adjacent crystals intersect (so-called *triple-grain junctions*) and the veins themselves meet at *nodes*, formed at the intersections of four crystals (Nye, 1989) (Figure 1). In general, the larger the ice crystals (and these can range from less than 1 mm to

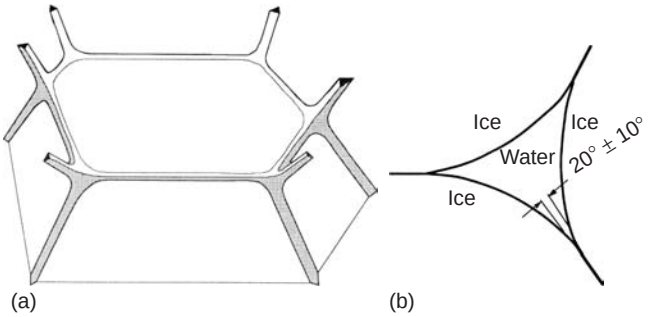

Figure 1 Ice crystals and inter-granular water veins and nodes illustrated conceptually (a) in three-dimensions and (b) in cross section (after Nye and Frank (1973) with the permission of the IASH)

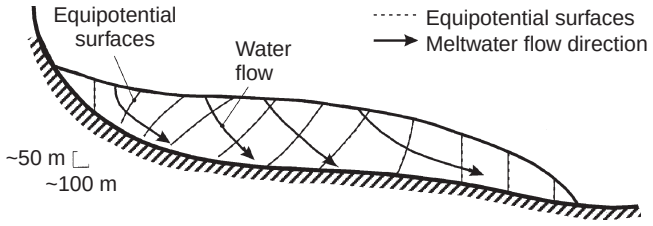

Figure 2 A conceptual glacier long section illustrating the general direction of englacial drainage (solid line) predicted from (Shreve, 1972) and hydraulic equipotentials (dashed lines) (after Paterson (1994) with the permission of Elsevier)

greater than 10 cm in diameter), the larger the veins between them. Veins are typically a few microns to tens of microns across. Laboratory-based research has been carried out on ice to measure the bulk permeability of vein-water systems at realistic temperatures. These studies generally indicate englacial flow rates in the region of 10^{-5} to 10^{-9} m s^{-1} (Wakahama *et al.*, 1973; Raymond and Harrison, 1975; Berner *et al.*, 1977). However, Lliboutry (1996) pointed out that these speeds are likely to be too high, since high confining pressures, the presence of debris and gas bubbles, and ice recrystallization will impede intergranular water flow in real glaciers relative to those measured in the laboratory. However, faster vein-water flow may occur near the glacier surface (where ice may be partially disintegrated because of melting and, below this, fine-grained) and near the glacier bed, where vein waters may be more saline and pressurized. For example, the bulk ionic concentrations measured in ice and vein water recovered from near the bed of Tsanfleuron Glacier, Switzerland, was ~11 times that typical of the overlying ice (Hubbard *et al.*, 2003). Further, relatively clear, bubble-free ice has been observed in cores recovered from close to the bed of many temperate glaciers. This *clear facies* ice is interpreted to result from gas expulsion along the intergranular vein system under the influence of intense deformation, indicating more active vein-water flow in this zone (Hubbard and Sharp, 1995). Hantz and Lliboutry (1983) identified an ~40-m thick layer of bubble-free "blue" ice in cores drilled to the base of Glacier d'Argentière, France. These authors also concluded from borehole water levels that bulk ice permeability increased substantially near to the glacier bed.

Despite the slow transfer speed of vein waters, this system is dense and widespread. Thus, although crevasses and moulins have the capacity to deliver large fluxes of melt water to the englacial drainage system, a more ubiquitous, but slower, delivery is achieved through the intergranular vein–water system. Indeed, the latter process may act as the only englacial meltwater source at glaciers on which little or no surface melting occurs.

Once present within the englacial system, melt waters generally flow towards the glacier bed and the glacier terminus. Arcone and Yankeilun (2000), for example, identified an englacial channel at Black Rapids Glacier, USA, which dipped consistently down-glacier at an angle of ~8° relative to the ice surface slope. Shreve (1972) argued that such flow is driven by two gravity-induced forces that can be combined to define a *water pressure potential* (ϕ). These forces are (i) the effect of gravity on the water itself (which drives "normal", unpressurized water flow) and (ii) the effect of gravity on the overlying ice which pressurizes the water flowing within the englacial channel. Application of this theory allows the 3-D equipotential surface, down which water is driven, to be defined from simple calculations based on glacier geometry (e.g. Sharp *et al.*, 1993) (Figure 2). One consequence of this analysis is that small surface englacial flow pathways may progressively capture water and enlarge into macroscopic flow pathways with depth (Raymond and Harrison, 1975).

If a glacier bed is overdeepened (i.e. the bed slope is reversed), the local pressure field may drive water away from the ice-bed interface and into an englacial position at the upglacier end of the overdeepening. This water would then reintersect the bed on the down-glacier lip of the overdeepening. In these cases, which are by no means rare (Fountain and Walder, 1998), basal water may become supercooled as it rises up (and possibly away from) the reverse slope of the overdeepening, resulting in the formation of refrozen basal ice (Alley *et al.*, 1998; Lawson *et al.*, 1998).

Although markedly more water is present in temperate ice than in cold ice, liquid water is by no means completely absent from the latter. Water, for example, is present in the intergranular vein system of ice whose bulk temperature is well below 0 °C (e.g. Mulvaney *et al.*, 1988). This is because the freezing point of vein waters is lowered as a result of the high concentration of soluble impurities within them. However, veins do close up as ice temperature decreases (e.g. Mader, 1992), and the porosity and permeability of cold ice are substantially lower than those of warm ice. One consequence of this contrast is that melt water flow

is inhibited at the boundary between warm ice and cold ice at polythermal glaciers. This thermal and hydrological contrast has been identified by airborne and surface radar (e.g. Bamber, 1987; Moore *et al.*, 1999) and may be closely associated with the location and propagation of surge waves at polythermal surging glaciers (e.g. Murray *et al.*, 2000).

Englacial Water Storage and Release

Clearly, any temperate or polythermal glacier's englacial drainage system is capable of storing a large amount of water at any given time. Our understanding of storage in intergranular veins and channels indicates that this is probably between 1 and 5% of the total volume of temperate ice within a glacier (Murray *et al.*, 2000; Moore *et al.*, 1999). In addition, evidence for temporal variations in storage is provided by water balance studies, which compare water inputs to a glacier with the outputs from it. Stenborg (1970), for example, calculated by this method that water was stored at Mikkaglaciären, Sweden, during the early summer and released during mid summer. Similar studies at other glaciers (e.g. Tangborn *et al.*, 1975; Willis *et al.*, 1993) also indicate early summer or summer storage. Importantly, Fountain and Walder (1998) calculated that subglacial storage could not account for the total volume of water stored at South Cascade Glacier, USA. These authors concluded that a substantial proportion of the total volume of water stored within the glacier is stored englacially. Such stored water is generally released through the winter or spring, sustaining outflow at times of negligible surface melting. The delivery of such water may be important not only hydrologically but also for glacier dynamics. Lingle and Fatland (2003), for example, argued that surges may be initiated by the delivery of stored water to a constricted basal drainage system during late winter or spring.

Methods of Investigating Englacial Drainage

Investigating englacial drainage is severely hampered by the limited access to the glacier interior. Thus, very little is known about the sizes and directions of englacial flow pathways or of the manner in which those pathways interact. However, a variety of techniques has contributed to our understanding of the character of englacial drainage.

Direct Observations

At the glacier surface, melt water can be observed to flow over the ice surface and to descend into crevasses and moulins (Figure 3). Thus, we know that these features transport large fluxes of water rapidly during the melt season. The integrity of a glacier's surface ice layer can also be observed to disintegrate to a depth of some tens to hundreds of millimeters under the influence of summer melting thereby bringing large volumes of melt water into contact with the upper surface of the englacial vein system.

Figure 3 Supraglacial melt water entering one of a train of moulins formed along a closed transverse crevasse on the surface of Mont Miné Glacier, Switzerland

However, while the capacity of the underlying vein system to transport this water has been measured on ice samples in the laboratory, it has not been measured directly in the field.

Moulins investigated by Holmlund (1988) descended almost vertically for some tens of meters below the glacier surface. Here, they ended in plunge pools and deviated laterally. Further exploration, however, was not possible as the channels narrowed. On the other hand, stones dropped from the glacier surface, particularly into large moulins, commonly indicate considerable depths of >100 m. The overall degree of lateral deviation of a moulin system was investigated by Iken (1972) on White Glacier, Axel Heiberg Island, Canada. The author lowered a pressure sensor into the water column in a moulin and simultaneously recorded both the length of line and the head of water above the sensor, and determined that the moulin dipped at a fairly consistent angle of $\sim 25^\circ$ from the vertical between the depths of 40 and 80 m below the ice surface.

Finally, in the ablation zone of glaciers, englacial channels occasionally intersect the ice surface as a result of ice ablation. Channels revealed in such situations are commonly some decimeters in diameter (Figure 4).

Figure 4 Englacial melt water conduit exposed in cross section by ablation at the surface of Llaca Glacier, Peru

Borehole-based Investigations

Over the past 30 years, numerous glaciological research teams have drilled boreholes into the glacier bed – allowing simultaneous access to the englacial and basal zones at multiple locations. Several techniques have been employed down such boreholes to investigate the character of the englacial drainage system.

Borehole Video TV footage has been recorded from video cameras moved along glacier boreholes. Pohjola (1994) reported on the basis of such a study at Storglaciären, Sweden, that ~1.3% of the glacier's thickness was composed of decimeter- to meter-scale englacial channels and voids. Later, Harper and Humphrey (1995), and Copland *et al.* (1997) drew similar conclusions on the basis of borehole video observations at Worthington Glacier, Alaska, and Haut Glacier d'Arolla, Switzerland, respectively.

Borehole Hydrology Many borehole-based studies used measurements of the head of water within individual boreholes to draw inferences about the water pressure in the subglacial drainage system to which it is connected (using the borehole as an open manometer). If these pressure data are associated with repeated electroconductivity (EC) profiles along the borehole water columns being measured, then englacial water sources and sinks can be identified and quantified. This is because water that has entered the borehole and englacial system from the glacier bed is generally of high EC while that entering the borehole and englacial system from the ice surface is generally of low EC. Gordon *et al.* (2001) used this approach at Haut Glacier d'Arolla, Switzerland, identifying complex patterns of interaction between the englacial and subglacial drainage systems. As a result of this study, the authors were able to identify five different types of borehole hydrological behaviour, or "borehole plumbing". Borehole behaviour patterns identified ranged from those that were characterized by a static, unchanging water column ("unconnected") to those that were simultaneously hydraulically connected to both the subglacial and the (channelized) englacial drainage systems ("basally connected").

Electrical Resistivity Tomography Electrical resistivity tomography (ERT) enables the internal resistivity distribution of a medium to be reconstructed from multiple resistance measurements made at its boundaries. Although the technique is best known for medical (Webster, 1990) and hydrogeological applications (e.g. Daily *et al.*, 1992), it has been used to image englacial drainage. Thus, Hubbard *et al.* (1998) identified an englacial hydraulic connection between two boreholes at Haut Glacier d'Arolla, Switzerland, by ERT.

Ice Radar

Ice radar involves transmitting waves of radio frequency into the glacier and investigating the properties of the waves that return, having been reflected off boundaries between materials with different *dielectric constants* or *relative electrical permittivities* within the ice. While ice has a permittivity of 3 to 4, freshwater has a permittivity of 80, making it is possible for ice radar to be used to locate major englacial water bodies and flow pathways. However, the presence of water throughout temperate glaciers means that radar signal penetration into such ice is poor relative to cold ice, although a small number of studies have successfully used ice radar to locate englacial (and subglacial) channels. For example, Jacobel and Anderson (1987) used stationary ice surface radar to identify temporal changes in the behaviour of englacial channels at Variegated Glacier, USA, while Arcone and Yankeilun (2000) identified and traced a single englacial channel using high frequency airborne radar at Black Rapids Glacier, USA.

Variations in the velocity of a propagating radar wave can be interpreted in terms of the water content of the ice through which that wave passes – allowing the bulk vein-water content of ice to be calculated. Murray *et al.* (2000) combined borehole and ice surface radar measurements at Falljökull, Iceland, and identified four ice layers with bulk water contents that varied between 0.2 and ~4%.

Tracing

Tracing studies involve injecting a tracer (normally fluorescent dye, although salt can be used) into the glacier's drainage system and recording its delivery from the glacier in its proglacial stream. If the recorded tracer concentration is plotted against time, the resulting *concentration breakthrough curve* yields information on the character of the flow pathways followed by the tracer. Properties of breakthrough curves include the time of arrival of peak tracer concentration and tracer dispersion. The former yields a travel time, which can be used to calculate average water velocity. The latter yields a measure of the

nature of the flow pathways followed, with more dispersed and multiple-peaked breakthrough curves reflecting more complex and/or multiple flow pathways. Many field-based studies have investigated these properties, but isolating the properties of the englacial drainage system from the subglacial drainage system is problematic. However, Stenborg (1969) and Behrens *et al.* (1975) isolated velocities of some tens of centimeters per second through the englacial drainage component, indicating the presence of channelized flow pathways from the glacier surface to the bed.

Ice Analysis

The physical character of ice recovered from either field cores or formed in the laboratory can also provide useful information relating to the nature of englacial drainage. For example, Wakahama *et al.* (1973), Raymond and Harrison (1975), and Berner *et al.* (1977) all carried out laboratory tests on ice to investigate the rate at which water flows through the intergranular vein system (reported previously). At a larger scale, Raymond and Harrison (1975) observed tubular conduits of some millimeters diameter in core samples recovered from 10 to 20 m beneath the surface of Blue Glacier, USA. Unfortunately, no further research of this kind has been carried out since this pioneering study.

Character of Englacial Drainage: Summary

As a result of combining the techniques and approaches outlined in this article, it is possible to draw some inferences about the character of englacial drainage systems. At the broadest scale, these systems can be classified in a manner similar to subglacial drainage – as discrete or distributed. Wherever water enters the ice surface through discrete channels, it continues to flow englacially at speeds similar to those of open-channel flow ($\sim 10^{-1}$ m s^{-1}). Much of this water enters the englacial drainage system during the melt season via moulins. Some of these form splash pools at a depth of some tens of meters and deviate laterally, while others appear to dip more regularly down-glacier. Little is known about the dynamics of englacial channels, but it is likely that they shrink as a result of ice deformation and grow (and tend towards the vertical) as a result of thermal erosion by melt water. The nature of individual englacial channels may therefore depend principally on local glacier dynamics and melt water flux. Since both controls vary seasonally at many glaciers, it is quite possible that moulin-fed englacial channels do so as well. A third probable control over the direction taken by englacial channels is that of the internal structure of the glacier. However, the association remains unknown.

Distributed englacial drainage comprises water present everywhere within the intergranular vein network, possibly supplemented by microscale channels at depth within the glacier. The vein-water system itself cannot transport water faster than some tens of centimeters per year, and cannot therefore be responsible for removing the bulk of surface-generated melt water at temperate glaciers. Although microscale channels have been observed in ice cores and decimeter-sized englacial voids have been identified from borehole studies, the coalescence of vein passages to form increasingly large channels with depth remains a tantalizing, but unproven hypothesis. Deep in the glacier, evidence suggests that waters can move away from a basal location into an englacial location through englacial channels, moulins and crevasses, and through the intergranular vein–water system. The latter system may open up in this zone as a result of the presence of pressurized water and higher ionic concentrations, both of which are strongly controlled by the character of the subglacial drainage system (*see* **Chapter 167, Subglacial Drainage, Volume 4**).

167: Subglacial Drainage

MARTIN SHARP

Department of Earth and Atmospheric Sciences, University of Alberta, Edmonton, AB, Canada

Subglacial drainage can occur wherever ice at a glacier bed reaches the pressure melting point. The subglacial drainage system is fed from a mixture of surface, englacial, subglacial, and groundwater sources that differ in terms of their spatial distribution and characteristic patterns of temporal variability. Subglacial drainage systems are not readily accessible, and knowledge of their characteristics is derived from a range of indirect methods including radio-echo sounding, the use of artificial tracers, monitoring, and manipulation of subglacial conditions via boreholes, and monitoring of glacial runoff properties. Subglacial water flow is driven by gradients in hydraulic potential, and occurs through either fast/channelized or slow/distributed systems located at the ice-bed interface, or through subglacial aquifers. Water can be stored subglacially in cavities, in the pore space of subglacial sediments, or in subglacial lakes. Drainage system structure evolves continually on various timescales in response to changing water inputs, evolving glacier geometry, and changes in glacier flow dynamics. Major hydrological events in such systems include the spring and fall transitions, outburst floods, and structural changes related to glacier advances and glacier surging. In the absence of variable water inputs from the glacier surface, subglacial drainage systems may be sensitive to forcing by earth, ocean, and atmospheric tides.

INTRODUCTION

Whenever ice at the base of a glacier or ice sheet reaches the pressure melting point, water may be present and a subglacial drainage system can develop. Subglacial water flow is of interest for a number of reasons, including its role in modulating glacier runoff, its potential as a source of geo-hazards, its influence on ice flow dynamics, and its role in chemical weathering (*see* **Chapter 168, Hydrology of Glacierized Basins, Volume 4** and **Chapter 169, Sediment and Solute Transport in Glacial Meltwater Streams, Volume 4**). If meltwater produced at the glacier surface penetrates to the glacier bed, the rate at which it is transported to the glacier terminus is determined in part by the character of the subglacial drainage system, which therefore mediates the relationship between surface melting and runoff. This is an important issue where glacier runoff has economic value (e.g. for the production of hydroelectricity) since efficient harvesting of the resource depends upon the ability to forecast runoff (Willis and Bonvin, 1995). Subglacial drainage systems may receive sudden inputs of large volumes of water from the drainage of supraglacial, ice-marginal, and subglacial lakes (Nye, 1976). The escape of this water from the glacier can be a significant hazard to population centers. Subglacial drainage can also exert a strong influence on glacier flow dynamics. Basal water reduces the friction at the ice-bed interface, affecting the rate of glacier flow by sliding (Iken, 1981) and the strength and deformation rate of unconsolidated subglacial sediments (Clarke, 1987a). Spatial variations in subglacial drainage system character may help explain the location of ice streams within large ice sheets (Bentley, 1987), and temporal variations have been implicated in the mechanics of glacier surging (Kamb, 1987). Subglacial water has access to abundant supplies of freshly ground and highly reactive "rock flour", creating a unique chemical weathering environment (Raiswell, 1984; Tranter *et al.*, 1993) (*see* **Chapter 169, Sediment and Solute Transport in Glacial Meltwater Streams, Volume 4**). The investigation of subglacial drainage has therefore become a major research focus in glacier hydrology.

SOURCES, SINKS, AND DIRECTION OF SUBGLACIAL DRAINAGE

Water Sources

Subglacial water has four main sources: surface, englacial, and basal melt, and subglacial groundwater. The relative

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

importance of these sources depends upon the climatic regime at the ice surface, the temperature of the glacier ice, ice flow dynamics and the nature of the glacier bed. On annual timescales, surface melt is usually the dominant source in "temperate" glaciers, where ice is almost all at the pressure melting point. Basal melt may, however, be the dominant subglacial water source in large areas of Antarctica where surface air temperatures never rise above the freezing point but ice temperatures reach the pressure melting point near the glacier bed. It may also be important in areas of high geothermal heat flux, such as Iceland. Englacial melt due to strain heating may be a significant water source in fast flowing glaciers such as Jakobshavn Isbrae, Greenland. Groundwater inputs have received little study, but they may be significant where a glacier rests on an underlying aquifer, especially in winter when surface melt ceases.

The Distribution and Magnitude of Water Inputs

The distribution of water inputs to a glacier bed depends upon the water source and thermal structure of the glacier. Basal melting (driven by geothermal heat and by frictional heat produced as the glacier slides over its bed) occurs throughout warm-based areas of a glacier, where ice at the bed is at the pressure melting temperature. This usually results in a relatively uniform distribution of melt inputs, because spatial variations in the geothermal heat flux usually occur on length scales greater than the size of individual glaciers. In some areas, like Iceland, however, there can be large spatial variations in the basal melt rate related to the distribution of active geothermal areas. There can also be significant spatial gradients in basal melt rate due to sliding friction or strain heating. Water produced within the glacier may drain to the glacier bed via a network of veins located at crystal boundaries in temperate ice (Nye and Frank, 1973). This also results in a relatively uniform distribution of water inputs to the bed. Most surface melt, however, becomes channelized subaerially and penetrates to the bed via crevasses or vertical shafts known as *moulins* (Holmlund, 1988) (*see* **Chapter 166, Surface and Englacial Drainage of Glaciers and Ice Sheets, Volume 4**). These localized inputs of water may be restricted to limited regions of the bed, depending upon the distribution and density of crevasses and moulins. This is especially true for nontemperate glaciers, where crevasses are often rare due to low rates of ice flow (Hodgkins, 1997).

The magnitude and variability of surface water inputs will depend on the density and exposure of input sites and on the nature of the melting surface. Surface snow and firn reservoirs have considerable potential to store water, and they act to delay melt-induced runoff and damp diurnal and meteorologically driven variations in meltwater flux (Fountain, 1996). These reservoirs produce slowly varying water inputs. Ice surfaces have comparatively little storage capacity, such that water inputs to the glacier bed from bare ice surfaces track the surface melt rate (Willis *et al.*, 2002). An exception to this generalization occurs on some cold glaciers, where there can be significant surface storage in lakes and channel systems (Liestøl *et al.*, 1980). This stored water may drain rapidly to the glacier bed as a result of water-pressure induced propagation of water-filled crevasses (Van der Veen, 1998; Boon and Sharp, 2003).

The Location and Direction of Subglacial Drainage

Subglacial drainage can occur either at the interface between ice and the underlying substrate, or within subglacial sediments. The pattern of water flow is influenced by the topography of the subglacial surface, and by horizontal and vertical gradients in water pressure. In general, this pattern is strongly influenced by the geometry of the overlying ice because basal water often supports a substantial fraction of the ice overburden. Where the substrate is permeable, vertical gradients in water-pressure influence the magnitude and sign of water exchange between substrate and ice-substrate interface. For the case of a glacier resting on an impermeable substrate, water flow will be perpendicular to contours of equal hydraulic potential at the glacier bed. One simplified view of subglacial drainage assumes that the drainage system is a hydraulically connected water sheet, in which water pressure is equal to the ice overburden pressure (Shreve, 1972). In this case, the hydraulic potential can be written:

$$\Phi = \Phi_0 + \rho_I g(z_s - z_b) + \rho_w g\ z_b \qquad (1)$$

Where Φ_0 is a reference potential, ρ_I and ρ_w are the densities of ice and water, g is the acceleration due to gravity, and z_s and z_b are the elevations of the ice surface and glacier bed, respectively. Shreve's model predicts that the slope of subglacial equipotential surfaces is $\sim$11 times the ice surface slope, but in the opposite direction. This implies that subglacial water can flow uphill out of overdeepened sections of glacier bed, so long as the magnitude of the water-pressure gradient exceeds that of the elevation potential gradient. Bedrock obstacles that are extensive in a direction transverse to ice flow will, however, likely cause substantial lateral diversions of water flow (Flowers and Clarke, 2002a), and water may refreeze if it emerges supercooled and quickly enough from over-deepenings (Alley *et al.*, 1998). Subglacial equipotential surfaces may contain depressions that define a closed interior drainage basin and become a focus of drainage, allowing the formation of subglacial lakes (Björnsson, 2002). Such depressions may be associated with localized sources of basal melting such as volcanoes. Changes in glacier geometry change the form of the subglacial hydraulic potential surface, allowing drainage capture and restructuring of subglacial drainage

catchments (Fountain and Vaughn, 1995). The assumption on which Shreve's formulation of the hydraulic potential is based may, however, break down in practice because subglacial drainage systems do not consist of hydraulically connected sheets. In reality, they contain discrete elements, such as channels, in which water pressure may differ from the ice overburden pressure and vary with discharge (Röthlisberger, 1972; Walder, 1986).

THE INVESTIGATION OF SUBGLACIAL DRAINAGE SYSTEMS

Direct observations of active subglacial drainage systems are limited because these systems are typically located beneath tens of meters to kilometers of glacier ice. A variety of remote sensing and other approaches has therefore been employed to determine their character and behavior.

Characteristics of Recently Deglaciated Surfaces

Observations of recently deglaciated glacier beds have shown that glaciers can rest on both rigid bedrock and unconsolidated, permeable, and potentially deformable sediments that vary substantially in terms of key hydrologic parameters such as thickness, continuity, hydraulic conductivity, and porosity. Studies of deglaciated carbonate surfaces (Figure 1) have provided information on the size, morphology, density, and network characteristics of formerly subglacial channel systems eroded into bedrock (Walder and Hallet, 1979; Hallet and Anderson, 1980; Sharp *et al.*, 1989). They have provided evidence for extensive ice-bed separation (cavity formation) on the downglacier side of bedrock bumps and steps (Figure 1), and revealed the widespread presence of laminated crusts composed of secondary calcite (Figure 1). These crusts are typically found on the lee side of small bedrock protuberances and are believed to have precipitated from a thin water film as a result of either refreezing of film waters or degassing of CO_2 rich solutions in the low-pressure region downstream of bed obstacles. The maximum size ($\sim$50 μm) of bedrock fragments trapped within individual laminae in the crusts sets an upper limit on the likely thickness of the water film (Hallet, 1976, 1979).

Such observations have motivated the development of several theoretical models of subglacial drainage (Walder, 1982, 1986; Kamb, 1987; Flowers and Clarke, 2002a,b). They are, however, limited in that they provide a temporally integrated view of drainage system structure and little insight into interactions between the various components of the drainage system (e.g. channels, cavities, film). Furthermore, the high solubility of carbonate minerals may mean that the structure of drainage systems developed on carbonate substrates is very different to that of systems developed on more resistant rock types.

Figure 1 Recently deglaciated carbonate bedrock surface at Glacier de Tsanfleuron, Switzerland, showing: (1) Roughened surface associated with an area of ice-bed separation (or cavity) on the downstream side of a bedrock obstacle. (2) Calcite deposits precipitated from the subglacial regelation water film. (3) A small Nye or ''N'' channel with solution scallops on its walls. (4) A polished and striated surface indicative of intimate ice-bedrock contact. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Radio-echo Sounding

Given the inaccessibility of active glacier beds, there has been considerable interest in remote sensing approaches to mapping their characteristics. Radio-echo sounding (radar) has been used to map the distribution of warm and cold-based ice using variations in the strength of the radar echo from the bed. The echo strength depends upon the dielectric contrast between ice and substrate, and is much greater for an ice-water interface than for an interface between ice and rock or dry, unfrozen sediment (Bentley *et al.*, 1998). Within warm-based areas of a glacier, the spatial pattern of bed reflection power may be indicative of the relative abundance of water at the bed (Copland and Sharp, 2001). To date, attempts to locate and map the distribution of individual channels at the glacier bed have only been successful in relatively thin ice (Moorman and Michel, 2000).

Radar has played a key role in mapping the size, shape, and distribution of subglacial lakes in Antarctica (Robin *et al.*, 1970; Oswald and Robin, 1973). Lakes are identifiable on radar records from a very strong, mirrorlike bed reflection that is constant in strength along track, suggesting a very smooth basal interface. In Iceland, radar mapping of ice thickness and bedrock topography

has allowed the reconstruction of subglacial equipotential surfaces beneath ice caps (Björnsson, 1982). Subglacial lakes, such as that in the Grimsvötn caldera beneath Vatnajökull, are located within internal drainage basins that can be identified from these surfaces.

Investigations with Artificial Tracers

Various tracers have been used to characterize subglacial drainage systems. These include salt solutions and fluorescent dyes, such as rhodamine or fluorescein (Burkimsher, 1983; Kamb *et al.*, 1985; Seaberg *et al.*, 1988; Willis *et al.*, 1990; Hock and Hooke, 1993; Nienow *et al.*, 1998). Where multiple streams enter and leave a glacier, the drainage catchment structure of the glacier can be mapped by delineating those areas of the glacier surface from which tracer inputs are recovered in each individual outflow stream (Sharp *et al.*, 1993). Measures of drainage system efficiency include the time of travel from input point to the glacier terminus, and the travel distance divided by the travel time (an index of flow velocity). If the discharge during the tracer test is known, the ratio of discharge to tracer velocity provides an index of the cross-sectional area of the drainage system. Since neither the channel sinuosity nor the water fluxes through individual channels are usually known, however, it is not possible to derive true measures of velocity or cross-sectional area. Nevertheless, the relationship between the indices of velocity and cross-sectional area may provide insight into the dynamics of the drainage system because the timescale of geometric adjustment of channels can be longer than that of water input variations. Thus, in a permanently water-filled conduit, variations in water flux on short timescales would be accommodated almost entirely by variations in flow velocity, while cross-sectional area would be relatively constant. By contrast, in a channel that was not full at low flows, the flow cross section would increase as discharge rose. Water flux increases would therefore be accommodated by a combination of increases in flow velocity and the cross-sectional area of the flow, resulting in a less sensitive relationship between flow velocity and discharge (Nienow *et al.*, 1996).

Continuous monitoring of dye concentrations in an outflow stream allows the construction of a dye return curve. This provides additional information about the character of the drainage system through which the tracer has passed. Curves with a single well-defined peak indicate that most dye was advected through a single major channel, whereas multipeaked curves are indicative of a more complex, multipath configuration (Willis *et al.*, 1990). Often, there is a correlation between peak shape and transit velocity, with single-peaked curves being associated with rapid transport and multipeaked curves with slower transport. Integration of the dye flux as a function of time allows calculation of the fraction of injected tracer that was recovered at the point of outflow. Typically, this fraction is much less than 1, indicating either significant retention of tracer within the glacier drainage system, or that much of the tracer emerged at concentrations below the fluorimetric detection limit. Retention may reflect diversion of water into subglacial storage or sorption of dye to fine-grained sediment (Bencala *et al.*, 1983).

As a tracer cloud passes through a drainage system, it becomes dispersed due to vertical and horizontal variations in water velocity and diversion of packets of tracer into storage sites such as backwater eddies. Dispersion results in reduced peak heights and increased peak widths. The rate of dispersion is described by the *dispersion coefficient*, D ($m^2\,s^{-1}$), but a more useful descriptor of peak characteristics is the *dispersivity* d(m), which is the ratio of the dispersion coefficient to the tracer velocity (Fischer, 1968). The dispersivity describes the rate of peak spreading relative to the rate of peak advection, and provides a characteristic length scale for the drainage system. Flow through major channels typically results in $d < \sim 10$ m, while more complex, less efficient systems result in much higher values ($> \sim 50$ m) (Seaberg *et al.*, 1988; Nienow *et al.*, 1998).

Borehole Manipulation and Monitoring

Boreholes, drilled with high-pressure hot water, provide direct access to glacier beds and are routinely employed in investigations of subglacial drainage. This has allowed measurements of the minimum thickness of subglacial sediment layers (by penetrometry; Hooke *et al.*, 1997; Harbor *et al.*, 1997), and *in situ* estimation of parameters that are important determinants of the hydraulic behavior of these sediments. These parameters include the porosity, hydraulic diffusivity and conductivity, and compressibility of the sediments. The techniques employed to measure them include analysis of the horizontal and vertical propagation and attenuation of natural pressure waves through subglacial sediments (Fountain, 1994; Hubbard *et al.*, 1995; Fischer *et al.*, 1998) and impulse-response tests (Stone and Clarke, 1993; Stone *et al.*, 1997; Kulessa and Murray, 2003).

Boreholes also provide an opportunity to measure water pressure and water quality within subglacial drainage systems. Boreholes sealed by freezing allow direct measurement of water pressure in the subglacial drainage system connected to the borehole. Water levels in open boreholes have also been used as a measure of subglacial water pressure on the assumption that the borehole functions as a manometer. Although there are potential problems with this assumption, a number of studies have recorded spatially coherent patterns of water level variation across arrays of open boreholes, suggesting that at least some boreholes do behave approximately as manometers (Hubbard and Nienow, 1997).

The behavior of borehole water levels during and after the time when the drill contacts the glacier bed has

been used to characterize different morphologies of the subglacial drainage system. Boreholes differ in terms of their base water levels, the amplitude, and timescale of water level oscillations, and the phase relationship between these oscillations and glacier runoff (Murray and Clarke, 1995; Hubbard *et al.*, 1995; Smart, 1996; Gordon *et al.*, 1998). Boreholes that are close to drainage channels often display low minimum water levels and high amplitude diurnal water level fluctuations that are almost in phase with runoff. Boreholes sampling hydraulically resistant elements of the drainage system typically exhibit high background water levels with minimal variability. Water level fluctuations in such boreholes may be out of phase with those in boreholes located close to channels, indicating diurnal transfer of mechanical support for the glacier between areas close to and remote from major channels as channel water pressure varies (Murray and Clarke, 1995; Gordon *et al.*, 1998).

In situ measurements of basal water quality have focused on the electrical conductivity (EC) and turbidity of borehole waters (Stone *et al.*, 1993; Hubbard *et al.*, 1995; Stone and Clarke, 1996; Kavanaugh and Clarke, 2001). High conductivity is usually associated with waters that have a long subglacial residence time, while low conductivity and low turbidity are associated with surface meltwater. High turbidity indicates basal water and/or high flow velocities. Temporal variations in conductivity and turbidity can thus provide insight into interactions between drainage system components (Hubbard *et al.*, 1995) and processes of drainage reorganization (Gordon *et al.*, 1998; Kavanaugh and Clarke, 2001). For open boreholes in particular, interpretation of measurements made at the base of boreholes demands an understanding of the system geometry and patterns of water exchange between the borehole and the subglacial drainage system (Gordon *et al.*, 2001). There have also been attempts at *in situ* hydrochemical characterization of borehole waters (Tranter *et al.*, 1997, 2002). Such measurements provide an alternative means of identifying different components of the subglacial drainage system, on the assumption that different modal water chemistries reflect differences in parameters such as the degree of water-rock contact and access to supplies of dissolved gases.

Properties of Glacial Runoff

Several studies have used the characteristics of glacial runoff to make deductions about subglacial drainage systems. The form of the diurnal discharge hydrograph from a glacier changes systematically over the melt season (Röthlisberger and Lang, 1987). Advances in the timing of the daily discharge peak and increases in the amplitude of the diurnal cycle reflect increased efficiency of water transfer through the glacier (Richards *et al.*, 1996). In part, this is a consequence of removal of the supraglacial snowpack and its delaying effect on runoff of surface meltwater, but it may also reflect the development of large drainage channels at the glacier bed. In some cases, the two processes may be closely connected (Nienow *et al.*, 1998) (*see* **Chapter 168, Hydrology of Glacierized Basins, Volume 4**).

Glacial runoff typically shows strong seasonal variations in solute concentration and composition (Tranter *et al.*, 1993). Solute concentrations in water leaving glaciers are enhanced relative to concentrations in the snowpack and supraglacial streams, indicating significant solute acquisition from water-rock interaction at or near the glacier bed. The nature and extent of this interaction depend upon the duration of water-rock contact, the rock:water ratio in the drainage environment, the extent to which water has access to supplies of gaseous O_2 and CO_2, and the availability of other potential sources of protons such as organic carbon and sulfide minerals (Raiswell, 1984; Tranter *et al.*, 1993). Glacial runoff appears to acquire solute in two distinct types of environment. Environments characterized by long transit times, high rock:water ratios, and proton supply from oxidation of sulfides and/or organic carbon result in water with high solute concentrations. This water type dominates runoff in the winter, the early melt season, and periods of recession flow in summer, and may also be characteristic of sudden outbursts of subglacially stored water at any stage of the melt season (Anderson *et al.*, 1999; Wadham *et al.*, 2001). Such waters are inferred to have drained via a predominantly distributed drainage system (see below; Tranter *et al.*, 1993). More dilute waters that have acquired significant amounts of solute by rapid reactions with suspended sediment are characteristic of periods of high flow later in the melt season (Brown *et al.*, 1994). These waters appear to have drained primarily and rapidly through large subglacial channels, though they may have mixed with and diluted waters of the more concentrated type in the process (*see* **Chapter 169, Sediment and Solute Transport in Glacial Meltwater Streams, Volume 4**).

The suspended sediment content of meltwaters also provides insight into subglacial drainage system structure. Waters that pass slowly through distributed drainage systems are unable to entrain significant amounts of sediment even though it may be abundant within the drainage environment. Water passing through large channels may have more limited contact with sediment but is better able to entrain what is available. Thus, sediment evacuation increases as channelized drainage becomes established in summer, but sediment exhaustion may occur towards the end of the melt season (Swift *et al.*, 2002). Sudden releases of sediment may result from outburst events and reorganization of drainage systems at the glacier bed (Humphrey and Raymond, 1994; Wadham *et al.*, 2001) (*see* **Chapter 169, Sediment and Solute Transport in Glacial Meltwater Streams, Volume 4**).

TYPES OF SUBGLACIAL DRAINAGE SYSTEM

Two types of subglacial drainage system have been widely recognized, though each can assume a diversity of forms. These have been characterized as *distributed* or *slow* systems, and *channelized* or *fast* systems (Fountain and Walder, 1998; Raymond *et al.*, 1995). In addition, some glaciers rest on permeable sediments that function as a groundwater aquifer (Boulton *et al.*, 1995; Flowers and Clarke, 2002b).

In distributed/slow systems, drainage pathways are tortuous, anastomosing, and widely distributed across the bed. Such systems are hydraulically resistant, and changes in water flux result in large changes in flow cross section but little change in flow velocity, which is generally low. By contrast, in channelized/fast systems most of the water flux passes through a few major channels that have an arborescent structure and occupy only a small fraction of the bed. Such systems offer much less resistance to water flow, and changes in water flux result in major changes in flow velocity. In the steady state, distributed systems exhibit an inverse relationship between water pressure and discharge, while the reverse is true for channelized systems (Walder, 1986; Kamb, 1987; Walder and Fowler, 1994; Röthlisberger, 1972). Both drainage morphologies can exist beneath the same glacier, and they will interact with each other (Hubbard *et al.*, 1995; Alley, 1996). The relative importance of the two systems in transmitting the imposed water flux may change on timescales ranging from hours to decades (Kamb *et al.*, 1985; Nienow *et al.*, 1998).

Distributed/Slow Subglacial Drainage Systems

One of the earliest configurations proposed for a subglacial drainage system was a pervasive *water film* (Weertman, 1964). Such a film might transport water produced at the bed by geothermal heating and sliding friction, or waters involved in regelation (pressure-induced phase change) around small obstacles on the glacier bed (Hallet, 1979). Weertman (1972) argued that the film might be the primary means of subglacial drainage because the pressure distribution around incipient channels at the glacier bed would impede their ability to capture water from the film. Since this argument only holds for a bed that is planar, impermeable, and free of debris, however, it is probably not applicable in reality. Thin water films are inherently unstable in the face of perturbations in film thickness because rates of viscous energy dissipation increase with film thickness, enhancing the local melt rate of the overlying ice, and causing a tendency towards channelization of the flow (Nye, 1976; Walder, 1982). Thus, while films are likely components of many subglacial drainage systems, their role in water transport is probably minor.

Where a glacier slides over a rough substrate, ice may separate from the bed to form cavities downstream of bedrock obstacles (Lliboutry, 1968) (Figure 1). Two types of cavity have been recognized: *autonomous cavities*, which contain ponded meltwater but transmit no water flux, and *interconnected cavities* which form an active part of the subglacial drainage system (Lliboutry, 1976). The status of individual cavities probably changes over time in response to changes in the imposed water flux and ice dynamics (Iken and Truffer, 1997). Nonarborescent cavity networks, linked by small bedrock (or *Nye*) channels oriented parallel to ice flow and incised up to 0.2 m into the glacier bed, have been mapped on recently deglaciated bedrock surfaces (Figure 1) (Walder and Hallet, 1979; Hallet and Anderson, 1980; Sharp *et al.*, 1989). Analyses of the hydraulics of linked-cavity systems demonstrate that cavities open by sliding of the overlying ice and close by ice deformation (Walder, 1986; Kamb, 1987). Melting of the ice roof by energy dissipated by flowing water makes only a minor contribution to the enlargement of cavities. The major stimulus to cavity growth is a discharge-induced rise in water pressure within the cavity system. The positive relationship between water flux and water pressure in cavity systems (and other forms of distributed system) has the consequence that water tends to be at higher pressure in larger cavities than in smaller cavities. It thus tends to drain from large to small cavities. This equalizes water pressures and ensures that there is no tendency for master channels to develop within the cavity network, thus acting as a negative feedback on the development of efficient (fast) drainage systems. The tendency for cavities to grow in response to rising water fluxes means that cavity-based drainage systems have significant potential to store water.

Glaciers often rest on unconsolidated sediments, rather than bedrock. The subglacial sediment layer may vary substantially in thickness and continuity, and the sediment characteristics can range from coarse gravel to fine-grained silt and even clay. Porous and permeable subglacial sediment functions as a confined aquifer that can drain of some of the water that penetrates to or is produced at the glacier bed. Measured hydraulic conductivities of *in situ* subglacial sediments are in the range 10^{-4} to 10^{-9} m s^{-1} (Fountain and Walder, 1998). With these hydraulic conductivities, most calculations suggest that Darcian flow through aquifers of thickness $\sim$0.1 m under a hydraulic gradient of $\sim$0.1 is unable to transport discharges of the magnitudes typical of the summer melt season, or even the winter period (Boulton and Jones, 1979; Alley, 1989; Fountain and Walder, 1998). Thus, the aquifer may become saturated and a drainage system will develop at its upper surface. Elution of fines from the upper layers of the sediment (Hubbard *et al.*, 1995) may form a *macroporous horizon* at the surface of the sediment layer (Stone and Clarke, 1993; Fischer and Clarke, 1994). Alternatively, a network of interconnected *microcavities* may form on the downstream sides of larger particles protruding up through the sediment surface (Kamb, 1991).

Such a system could have an effective hydraulic conductivity several orders of magnitude higher than the values quoted above (Fountain and Walder, 1998), and would be capable of adjusting its porosity by dilation in response to water flux variations (Clarke, 1987a).

Alternatively, a system of *canals* may coexist with the subglacial aquifer (Walder and Fowler, 1994). It may be fed directly by englacial conduits, in which case much of the surface-derived runoff would drain through the canal system without entering the aquifer and the aquifer would play a limited role in overall drainage. The canals would have an ice roof and a sediment floor, and would grow by roof melting or basal erosion, and close by deformation of ice or sediment. Canal systems could adopt two very different configurations: an arborescent network incised upwards into the ice, or a nonarborescent network incised into the sediment. The type of system that develops depends upon the magnitude of the effective pressure within the canal system ($P_e = P_{ice} - P_{water}$) relative to some critical value (P_{crit}) which depends upon the hydraulic gradient and the relative creep properties of ice and sediment. Nonarborescent networks are expected when the hydraulic gradient is low (as under ice sheets and ice streams), while arborescent networks are more likely beneath valley glaciers where hydraulic gradients are high. A canal network may exist beneath Ice Stream B, Antarctica (Engelhardt and Kamb, 1997).

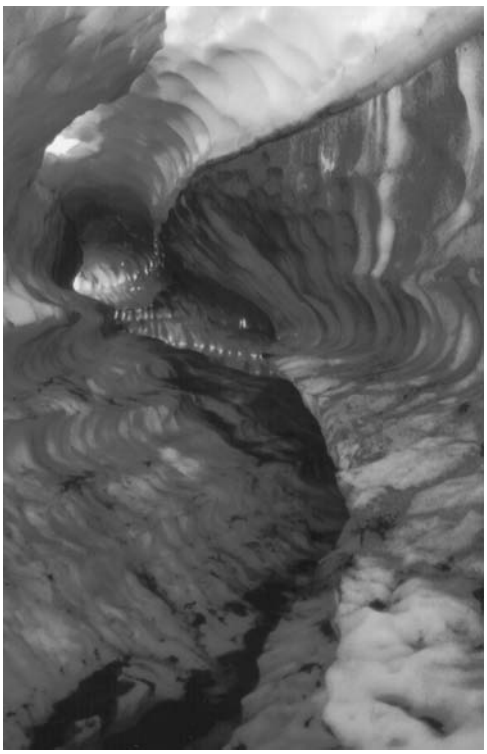

Figure 2 Röthlisberger or ''R'' channel at Matanuska Glacier, Alaska. Note scalloping and sediment deposits on the channel walls. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Channelized/Fast Subglacial Drainage Systems

Large ice-walled conduits (*Röthlisberger or "R" channels)* are the major component of channelized or fast subglacial drainage systems (Figure 2). They form where the rate of wall melting due to viscous dissipation of energy in flowing water outstrips the rate of creep closure of the overlying ice. The original analysis of the hydraulics of R-channels assumes steady water flow through conduits of semicircular cross section (Röthlisberger, 1972). This analysis predicts an inverse relationship between the water flux through an R-channel and the pressure gradient that drives the water flow. This implies that when two parallel conduits transporting different water fluxes coexist, the water pressure at a given distance from the glacier terminus along the conduits will be greater in the conduit with the lower water flux. Water from the smaller conduit will therefore tend to be captured by the larger conduit, a process that can account for the arborescent character of R-channel networks.

In reality, flow through R-channels fed by surface melt is unlikely to be steady as discharge varies with surface melt rates on timescales that are shorter than those on which channel cross section can adjust by a combination of wall melting and creep closure. Thus, R-channels may cease to be water-filled at low flows, and water pressures may rise to values in excess of the local ice overburden pressure during peak discharges (Hubbard *et al.*, 1995). Although there have been attempts to calculate the conditions under which open channel flow might occur within subglacial conduits (Hooke, 1984), there are few data with which to validate the calculations. In general, however, open channel flow is most likely where ice is thin and steeply sloping, and at times when discharge has dropped substantially from a preceding period of high flow.

There is also evidence that the cross-sectional shape of R-channels may not be semicircular. Attempts to forecast the distribution of water pressure within subglacial conduits using Röthlisberger's (1972) analysis have often predicted water pressures substantially below measured values. This might be explained if channels are broad and low in cross section, since such channels would tend to close more readily than semicircular channels, resulting in higher average water pressures (Hooke *et al.*, 1990). Conduits with this geometry might be expected because ice melt would be concentrated low down on channel walls at times of low discharge. In addition, creep of ice into partially full channels would be most rapid at the tunnel ceiling (especially when channels are only partly full), rather than at the base of the tunnel walls where creep is resisted by friction with the glacier bed. These arguments are supported by modeling of the evolution of channel cross section in response to time-varying water fluxes (Cutler, 1998).

Subglacial Groundwater Systems

In some cases, a complex hydrostratigraphy exists beneath a glacier, consisting of interbedded layers of contrasting grain size and hydraulic conductivity. Some of these layers may function as aquifers and others as aquitards. Water flow will tend to be predominantly horizontal within the aquifers and vertical across the aquitards (Flowers and Clarke, 2002a). In such cases, groundwater flow may represent an important sink or source for subglacial water.

A common case is that of a low conductivity till aquitard overlying a higher conductivity sand or gravel aquifer. For such a system, the pressure and elevation gradients across the aquitard drive the exchange between the glacier bed and the aquifer. Upward flow of groundwater commonly occurs where the glacier bed profile is concave (Tulaczyk *et al.*, 2000) and at the glacier margin (Flowers and Clarke, 2002a). The magnitude of the water flux into the aquifer is very sensitive to the aquifer conductivity, and it decreases as the aquitard and aquifer conductivities decrease. The mean water pressure and water fluxes at the glacier bed are therefore strongly influenced by the hydraulic conductivities of both the aquitard and the aquifer, decreasing as the conductivities rise. Thus, these properties of the subglacial sediments act as valves that control the routing of subglacial water. For most reasonable values of till conductivity, fluctuations in water pressure and flux recorded at the ice-bed interface will be transmitted to the aquifer, but with a discernible lag (Flowers and Clarke, 2002a).

Subglacial Lakes

Subglacial lakes can represent a significant form of subglacial water storage. 77 subglacial lakes have been identified beneath the Antarctic Ice Sheet (Siegert *et al.*, 1996). These are mostly located beneath regions of low surface slope close to ice divides, with major clusters in the Dome C and Ridge B regions. Those located away from ice divides are found close to regions where enhanced ice flow begins. The largest lake so far identified is the 230-km long Lake Vostok in East Antarctica (Kapitsa *et al.*, 1996), which has an estimated depth of at least 510 m, an area of $\sim$14 000 km^2, and a volume of 1500 to 7000 km^3. The mean observed length of the 77 lakes identified is, however, only 10.8 km (Siegert, 2000), and the total water volume stored in Antarctic subglacial lakes is likely in the range 4000–12,000 km^3 (Dowdeswell and Siegert, 1999). It is not known whether these lakes formed *in situ* beneath the ice sheet as a result of the progressive accumulation of water produced by basal melting, or whether they represent preglacial water bodies that were overridden by the growing ice sheet in the past. Little is known about whether and how these lakes drain under present-day conditions.

Subglacial lakes are common beneath ice caps in the volcanically active region of Iceland (Björnsson, 2002). High rates of heat flow associated with subglacial hydrothermal systems result in rapid melting of basal ice and a local depression in the ice cap surface. This can create closed depressions in the subglacial equipotential surface in which water can accumulate. Some lakes, such as Grimsvötn beneath Vatnajökull, fill caldera depressions in the bedrock, but the lake water level may rise above the caldera rim so long as the potential gradient continues to direct water flow towards the lake from surrounding areas. Other lakes form more rapidly as a result of extreme rates of basal melting during subglacial volcanic eruptions. These Icelandic subglacial lakes drain by episodic outburst floods (*see* **Chapter 168, Hydrology of Glacierized Basins, Volume 4**).

MAJOR EVENTS IN SUBGLACIAL DRAINAGE SYSTEMS

Spring Transitions

Where surface melting represents a significant input to subglacial drainage systems, there tends to be a strong seasonality to the magnitude of the water input. Subglacial drainage systems adjust to these variations in water flux and may thus have very different configurations in summer and winter. Thus, the subglacial drainage system will undergo major periods of evolution in spring and fall.

The driving force behind drainage evolution in spring is the progressive increase in the amount of surface meltwater delivered to the glacier bed. The temporal pattern of water inputs depends upon the end of winter snowpack distribution, meteorological conditions at the glacier surface, and the ease with which water can penetrate to the bed. Snow, with its high albedo, melts relatively slowly in comparison to glacier ice, and it acts as a potential storage site for water. As snow is removed from the glacier surface, a flood can result from the release of water stored in the snowpack (Flowers and Clarke, 2002b). Where drainage pathways from surface to bed are not immediately available, water is stored in supraglacial lakes, channels, and crevasses at the start of the melt season, and may be delivered to the bed very suddenly (Flowers and Clarke, 2000; Boon and Sharp, 2003). As glacier ice is exposed and subjected to surface melting, both the total daily runoff and the amplitude of the diurnal variation in runoff increase (Willis *et al.*, 2002). These changes in water input drive the evolution from a slow/distributed subglacial drainage system that is characteristic of winter, to a system that is usually dominated by fast/channelized components (Nienow *et al.*, 1998).

Drainage development in spring seems to occur in two phases. Because the drainage system is initially underdeveloped, the first water to penetrate to the bed forces

increased separation between ice and substrate not exclusively, but primarily, downstream from points where it reaches the bed (Mair *et al.*, 2002). This generates an increase in the subglacial drainage system volume that acts as a preferred pathway for subglacial drainage, and may allow significant water storage at the bed (Nienow *et al.*, 1998). As ice is exposed and surface meltwater production increases, water fluxes to the bed increase, water backs up in the drainage system, water pressures tend to rise, and major subglacial channels develop rapidly within regions of preferred drainage (Nienow *et al.*, 1998; Gordon *et al.*, 1998; Cutler, 1998). Rainstorms during this period may be a major stimulus to channel growth (Cutler, 1998; Gordon *et al.*, 1998), which is accompanied by the onset of strong diurnal water-pressure cycling in areas close to channels (Gordon *et al.*, 1998). Locally, channel growth is probably directed down-glacier from each point of water input. At a larger scale, however, the subglacial channel network extends upglacier over time at a rate that mirrors the retreat of the transient snowline. Where crevasses and moulins are distributed widely across a glacier, this can be a relatively smooth process. Where they are sparsely distributed, however, the process can be more episodic, with large areas of glacier bed developing channelized drainage in relatively short periods of time.

Where a frozen glacier margin effectively dams the outflow of basal water, a wave of high subglacial water pressures may spread upglacier from the margin in response to surface water input. Eventually, these high pressures are dissipated by either increased water flux into the subglacial groundwater system (Flowers and Clarke, 2002b), or by a sudden release of water at the glacier terminus (Skidmore and Sharp, 1999; Flowers and Clarke, 2000). In this case, channel development may follow the outburst.

End of Summer Transitions

The end of summer is marked by a decline in available melt energy. As water inputs decline, channels cease to be water-filled and begin to contract by ice creep (Cutler, 1998). Initially, water pressures tend to fall, allowing drainage of water previously stored in other components of the subglacial drainage system (Flowers and Clarke, 2002b). Eventually, the drainage system (both fast and slow components) contracts to the point that water pressures begin to rise again (Hubbard and Nienow, 1997), and the distributed/slow components come to dominate the system. In some areas, there is evidence that both the upstream and downstream ends of major channel systems may freeze shut very rapidly when surface melt ceases (Skidmore and Sharp, 1999; Copland *et al.*, 2003). This can preclude further input of surface water and trap water at the glacier bed. In other areas, including Svalbard, drainage continues throughout the winter (Hodgkins, 1997).

Hydrological Changes During Glacier Surges

Glacier surges involve periodic, abrupt one to three order of magnitude increases in glacier flow velocity that are sustained for months to years and separated by periods of quiescence lasting years to decades (Meier and Post, 1969; Raymond, 1987). Ice builds up in a reservoir area during quiescence and then is transferred rapidly down-glacier during surges. Rapid flow during surges is usually attributed to an increase in the basal velocity of the glacier. This results from a reduction in ice-bed coupling due to the buildup of high-pressure water at the bed (Clarke, 1987b). Two models have been proposed to explain how changes in ice flow dynamics might be associated with a reorganization of subglacial drainage (Clarke *et al.*, 1984; Kamb, 1987; Raymond, 1987), though available observations are currently insufficient to validate either model. In both models, transitions in drainage system character between the quiescent and surge phases are linked to the evolution of glacier geometry over a surge cycle. The buildup of ice in the reservoir area during quiescence results in local thickening of the glacier, an increase in the mean surface slope, and a rise in shear stress at the glacier bed (Raymond and Harrison, 1988).

One model of surging assumes the glacier rests on a largely impermeable substrate, and suggests that rapid surge phase motion occurs primarily by basal sliding. This model proposes that during surges, the basal drainage system is distributed in character and may consist of linked cavities (Kamb, 1987). During quiescence, this distributed system is replaced by a low-pressure system dominated by major subglacial channels. This temporal switching of drainage morphologies is analogous to seasonal changes but operates on longer timescales. This model of surging proposes that thickening of the reservoir area during quiescence increases the rate of closure of subglacial channels by ice creep. This drives up the channel water pressure (especially over winter when water fluxes are low) until it exceeds the mean water pressure in the surrounding drainage system. Once this happens, the channels lose water to the cavity system, initiating a positive feedback whereby decreasing water flux results in a further increase in water pressure and further water loss from the channels (Raymond, 1987). This process may be facilitated if the glacier contains sufficient englacial water storage capacity that downward drainage of englacially stored water over winter eventually overwhelms the constricted subglacial system and initiates rapid sliding (Lingle and Fatland, 2003). If the cavity system is sufficiently stable to withstand the following melt season's discharge perturbation, rapid sliding may be sustained (Kamb, 1987). If the surge is propagating down-glacier into thinner ice, water inputs into the drainage system under the surging region increase, and episodic releases of water occur (Kamb *et al.*, 1985). Initially, rapid ice creep shuts down channels that start to form during

these releases, but eventually the ice becomes too thin to allow this. Permanent drainage of water stored beneath the surging region occurs and the channel system becomes reestablished. Subglacial water pressure is lowered and the surge phase of motion comes to an abrupt end (Kamb *et al.*, 1985).

The second model assumes the glacier rests on an unconsolidated, permeable bed, and that rapid motion is due in part to deformation of water-saturated sediments (Clarke *et al.*, 1984). Sediment deformation may be negligible during quiescence if the sediment is drained by canals at the till surface, or a network of pipes within the sediments. Such types of system promote more efficient drainage, a reduction of sediment pore water pressure, and an increase in sediment strength. In this model, the rise in basal shear stress due to the evolution of glacier geometry during quiescence may initiate or increase the rate of sediment deformation. Although this might induce dilation of the sediment, increasing its porosity and hydraulic conductivity, it could also destroy pipes and surface canals, reducing the bulk transmissivity of the drainage system, driving up pore water pressures and weakening sediments (Clarke *et al.*, 1984). As the sediments weaken, they will deform more rapidly, initiating the surge phase of motion. Eventually, the down-glacier transfer of ice by the surge results in thinning of ice and a reduction in surface slope in the reservoir region, and a decrease in the basal shear stress acting on subglacial sediments. The basal shear stress may become too low to deform the sediments, and the cessation of deformation may allow drainage pipes and canals to become reestablished. This will further reduce pore water pressures and increase sediment strength, bringing an end to the surge motion.

Glacial Outbursts

Sudden releases of stored water are a common feature of the discharge regimes of glacier-fed rivers. The most common water sources for these "glacier outbursts" are ice-dammed lakes along glacier margins, but releases from supraglacial, subglacial, and englacial sources are also known. Often, these outbursts are routed through the subglacial drainage system and can be a major stimulus for changes in its character (Nye, 1976; Stone and Clarke, 1996; Flowers and Clarke, 2000; Björnsson, 2002). For the case of drainage of an ice-marginal lake, drainage commonly begins when the lake water level approaches that required to float the ice dam. Once water starts to leak into the subglacial drainage system, channel development likely occurs in a manner similar to that described for the spring transition. In some cases, channel development is initiated close to the ice dam and channels grow in a downstream direction over a period of days to weeks. In other cases, initial drainage may take the form of a turbulent sheet flood and channel development first occurs near the glacier margin. This facilitates drainage in this region, and provides a positive feedback for channel growth by reducing back-pressure in the system (Flowers *et al.*, 2004). When there is insufficient water in the lake to keep the channel full, the channel begins to shrink and eventually closes. This terminates the flood, which has a characteristically asymmetric hydrograph, with a gradual rise to peak discharge and abrupt termination. The flood characteristics depend upon the volume of water in the lake, the lake hypsometry, lake water temperature, ice overburden pressure, hydraulic gradient, and wall roughness of the tunnel (Clarke, 1982).

Outbursts from supraglacial and englacial water pockets may have a very different form, with a more abrupt and symmetric hydrograph (sudden break outbursts, Haeberli, 1983). This may reflect the sudden delivery of water to the subglacial drainage system as a result of water pressure-induced propagation of fractures from the void that contains the water pocket (such as a crevasse) to the glacier bed (Van der Veen, 1998). Abrupt increases in water delivery to the bed result in over-pressuring of the subglacial drainage system and hydraulic uplift of the surrounding ice. This in turn permits the disturbance to propagate away from its point of origin (Engelhardt and Kamb, 1997). This may activate new areas of the bed, increase the connectivity of the drainage system and allow flushing of stored water. Such events tend to propagate down-glacier and will eventually culminate as an outburst at the glacier margin. Connections created by these events may persist after the outburst, resulting in a more efficient drainage system (Flowers and Clarke, 2000). In some polythermal Arctic glaciers, such outbursts are the normal means by which subglacial outflow begins in spring (Skidmore and Sharp, 1999).

Tidal Forcing of Subglacial Drainage

Variability in subglacial water pressure and electrical conductivity on diurnal timescales is typically attributed to forcing by inputs of meltwater from the glacier surface. Such variability has, however, also been recorded in winter and in environments that are too cold for surface melting to occur. Semidiurnal fluctuations have also been observed in these environments. This may result from forcing of the subglacial drainage system by earth, atmospheric, or ocean tides. Diurnal variations in basal water pressure of Haut Glacier d'Arolla, Switzerland, in winter resulted from water flow between a borehole and the subglacial drainage system that was forced by deformation of the glacier substrate and the glacier ice induced by the luni-solar diurnal earth tide (Kulessa *et al.*, 2003). Diurnal velocity variations of Ice Stream D, Antarctica, appear to be driven by the ocean tide beneath the Ross Ice Shelf, into which the ice stream flows (Anandakrishnan *et al.*, 2003).

SUMMARY

Subglacial drainage can occur wherever ice at a glacier bed reaches the pressure melting point. The subglacial drainage system is fed from a mixture of surface, englacial, subglacial, and groundwater sources that differ in terms of their spatial distribution and characteristic patterns of temporal variability. Subglacial drainage systems are not readily accessible, and knowledge of their characteristics is derived from a range of indirect methods including radio-echo sounding, the use of artificial tracers, monitoring, and manipulation of subglacial conditions via boreholes, and monitoring of glacial runoff properties. Subglacial water flow is driven by gradients in hydraulic potential, and occurs through either fast/channelized or slow/distributed systems located at the ice-bed interface, or through subglacial aquifers. Water can be stored subglacially in cavities, in the pore space of subglacial sediments, or in subglacial lakes. Drainage system structure evolves continually on various timescales in response to changing water inputs, evolving glacier geometry, and changes in glacier flow dynamics. Major hydrological events in such systems include the spring and fall transitions, outburst floods, and structural changes related to glacier advances and glacier surging. In the absence of variable water inputs from the glacier surface, subglacial drainage systems may be sensitive to forcing by earth, ocean, and atmospheric tides.

168: Hydrology of Glacierized Basins

IAN WILLIS

Department of Geography, University of Cambridge, Cambridge, UK

The presence of snow and ice and the lack of vegetation and soil make the hydrology of glacierized basins very different to that of equivalent nonglacierized basins. This article discusses how the characteristics of glacierized basins control their runoff regime and its interannual, intraannual, and intraseasonal variability. The magnitudes and patterns of seasonal water storage and release associated with the snowpack, firn layers, and englacial and subglacial drainage systems are also considered. The controls on flooding in glacierized catchments are discussed with specific reference to the catastrophic drainage of ice-dammed subglacial and ice-marginal lakes, moraine-dammed proglacial lakes, and drainage of water from the englacial/subglacial drainage network that may be triggered by high surface melting or rainstorms. Finally, the effects of climate change on runoff regimes, water storage, and floods are assessed. The similarities and differences between the hydrological regimes of mid-, high-, and low-latitude basins containing glaciers with different thermal regimes are highlighted.

INTRODUCTION

The hydrology of glacierized basins differs from that of equivalent nonglacierized basins because of the presence of snow and ice and lack of vegetation and soil. Whereas rainfall is often the dominant water input to nonglacierized basins, snow and ice melt provide important inputs to glacierized basins (Röthlisberger and Lang, 1987; Chen and Ohmura, 1990). Vegetation interception and evapotranspiration are important hydrological processes in many nonglacierized catchments, but are of negligible importance in glacierized basins. Similarly, soil porosity and permeability are usually important influences on runoff from nonglacierized basins, while the porosity and permeability of snow and firn are key in glacierized basins. The routing of water vertically and laterally through snow and firn and laterally across ice surfaces are important processes in glacierized catchments, but soil throughflow and overland flow play more dominant roles in nonglacierized basins. Furthermore, englacial routing of water through ice in small veins and pipes or, more importantly, along crevasses and large conduits, is unique to glacierized basins. Subglacial routing of water at the base of ice through thin films, sediment pores, linked cavities, or channels incised upward into ice and/or downward into rock or sediment, is a unique feature of glacierized basins.

The distinctive characteristics of glacierized catchments have important implications for (i) runoff regimes; (ii) water storage and release; (iii) the incidence of flooding; and (iv) the effects on these of climate variability and change. The hydrology of glacierized basins has been studied mainly in midlatitudes in catchments containing temperate glaciers (especially in the European Alps; Norway; Iceland; New Zealand; USA and Canada) or mainly temperate polythermal glaciers (e.g. northern Sweden). Less work has been carried out in glacierized basins at lower latitudes (e.g. Central and South Asia; Africa; South America). Only recently has the hydrology of high-latitude basins containing cold or mainly cold polythermal glaciers begun to be explored (e.g. Nunavut, Canada; Spitsbergen, Svalbard; McMurdo Dry Valleys, Antarctica). This bias toward temperate glaciers in the midlatitudes is necessarily reflected in this review. However, reference is made to basins in other areas where appropriate, and similarities and differences between these catchments and those in the more commonly studied regions are highlighted.

INTERANNUAL VARIATIONS IN GLACIER WATER (MASS) BALANCE

Although they constitute only ~0.4% of all freshwater on the Earth, glaciers and ice caps respond rapidly to climate

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

change, made an important contribution to sea-level rise over the last century (Meier, 1984) and will continue to do so in the future (Houghton *et al.*, 2001). Glaciers and ice caps are often regarded as natural reservoirs, storing water as snow and ice during wet, cool years and releasing it during dry, warm years. Thus, a glacier's water (mass) balance is more positive during wetter, cooler years, and more negative during drier, warmer years.

Several authors have synthesized the many mass balance records from around the world (Dyurgerov and Meier, 1997; Cogley and Adams, 1998; Haeberli *et al.*, 2000; Braithwaite, 2002; see also **Chapter 165, Mass and Energy Balances of Glaciers and Ice Sheets, Volume 4**). During the latter part of the twentieth century, most small glaciers and ice caps shrank in response to global climate change, although there were marked differences between regions. Thus, between 1980 and 1995, glaciers in the Cascades and Kenya underwent almost continuous and rapid shrinkage, glaciers in the Alps, Arctic, and Tienshan underwent fairly continuous but moderate shrinkage, and those in Alaska, the Pamirs, and Kamchatka had years of both positive and negative mass balance with a moderate shrinkage overall. Glaciers in the Caucasus and Altai, however, had periods of positive and negative mass balance but a slight increase in size overall, while those in Scandinavia also had periods of positive and negative mass balance and a moderate increase in overall size.

Global climate change is manifested as regional changes to atmospheric circulation patterns, which may be described by negative and positive atmospheric pressure anomalies (e.g. Leather *et al.*, 1991). Regional scale climate controls glacier mass balance through its effects on local scale precipitation, cloudiness, humidity, and air temperature. Therefore, teleconnections exist between atmospheric circulation patterns or pressure anomalies and glacier mass balance, terminus position, or equilibrium line altitude (Table 1). The increased rate of glacier shrinkage since the mid-1970s coincided with shifts in atmosphere/ocean, temperature/pressure patterns such as El Niño Southern Oscillation (ENSO) (e.g. Francou *et al.*, 2000) and Pacific Decadal Oscillation (PDO) (e.g. Moore and Demuth, 2001).

Detailed understanding of the links between local scale climate and glacier mass balance is best achieved through the use of numerical models in which ablation is calculated using energy balance techniques (e.g. Oerlemans and Fortuin, 1992; Oerlemans, 1993; Hofinger and Kuhn, 1996). Alternatively, where the energy balance components cannot be determined, ablation may be calculated using simpler approaches involving "seasonal sensitivity characteristics" (e.g. de Ruyter de Wildt *et al.*, 2003) or "positive degree days" (e.g. Laumann and Reeh, 1993; Rabus and Echelmeyer, 1998; Braithwaite and Zhang, 2000). All these modeling approaches show that glacier mass balance is dependent on both air temperature and precipitation but that the sensitivity of mass balance to these variables varies with climatic setting. For example, glaciers in maritime settings are more sensitive to air temperature changes than those in continental locations (e.g. Oerlemans and Fortuin, 1992; Laumann and Reeh, 1993). This is because higher air temperatures not only increase ablation but also decrease accumulation by reducing the proportion of precipitation falling as snow. This lowers mass balance both directly and indirectly because reduced snow accumulation allows glacier ice to be exposed for a longer period in summer. This increases ablation because the albedo of ice is lower than that of snow. Energy balance modeling studies show that glacier mass balance may be sensitive to variables other than precipitation and air temperature. For example, Oerlemans (1993) showed that a decrease in glacier albedo of just 0.03 might have the same effect on glacier mass balance as an increase in air temperature of 1 °C.

INTERANNUAL VARIATIONS IN GLACIER RUNOFF

Year-to-year variations in regional climate control not only variations in glacier mass balance, but also runoff from glacierized basins (Ribstein *et al.*, 1995; Depetris and Pasquini, 2000; Lawler *et al.*, 2003). Years with a strongly negative Southern Oscillation (SO) index are associated with high annual runoff from Zongo Glacier, Bolivia because of their association with warm dry weather and high melt rates (Ribstein *et al.*, 1995). Runoff from three glacierized basins in Iceland decreased between 1973 and 1992, particularly in spring, because of marked cooling and reduced melting, and in autumn, because of fewer heavy rainstorms (Lawler *et al.*, 2003). Spring cooling was associated with an increase in the North Atlantic Oscillation (NAO) Index and the weakening of southwesterly circulation over Iceland, whereas autumn rainstorm reduction was linked to a decrease in the NAO index and reduction in zonal airflow. Depetris and Pasquini (2000) analyzed interannual variations in stream flow between 1956 and 1994, downstream of Lake Argentino, an upstream arm of which is periodically dammed by the Perito Moreno Glacier, Argentina. Spectral analysis of the discharge series revealed significant peaks in the 33–36-month and the 42–58-month ranges, corresponding with similar periodicities in the position of subtropical Pacific anticyclones and the intensity of ENSO respectively. Further analysis of the 42–58-month periodicity showed that anomalously low and high discharges were associated with La Niña and El Niño years respectively. Furthermore, the high discharges associated with El Niño years were due to lake damming by the Perito Moreno Glacier. El Niño conditions led to glacier advance (due to positive mass balance) and high rainfall, both of which led to larger lake

Table 1 Teleconnections between global atmospheric circulation and glaciers

Atmospheric index	Glacier index	Correlation	Glacier	Year(s)	Cause(s)	Reference
Mean sea level pressure & 500 hPa height over North Atlantic (winter and summer)	Winter and summer mass balance	High (low) winter accumulation = strong (weak) Azores to Iceland pressure gradient & weak (strong) Siberian high; High (low) summer ablation = low (high) pressure from Southern Greenland to Gulf of Bothnia & high (low) pressure over Barents Sea	Storglaciären, Sweden	1946 to 1992	(a) Strength of prevailing westerlies; (b) winter precipitation; (c) summer temperature	Pohjola and Rogers (1997)
SOI	Advanced terminus position	Negative	Franz Josef Glacier, New Zealand	1954 to 1994	(a) Pressure anomalies over New Zealand in ablation season; (b) prevailing wind direction; (c) precipitation; (d) summer temperature	Hooker and Fitzharris (1999)
Decadal ENSO-like phenomena & PDO	Winter and net mass balance	Negative with three glaciers, positive with one	Four glaciers, Washington, USA & BC, Canada		(a) Precipitation & storminess; (b) temperature	Bitz and Battisti (1999)
Decadal ENSO-like phenomena & PDO	Winter and net mass balance	Positive	Wolverine Glacier, Alaska		(a) Precipitation & advected moisture flux; (b) winter temperature	Bitz and Battisti (1999)
Multivariate ENSO index (monthly)	Monthly mass balance	Negative	Chacaltaya Glacier, Bolivia & Antizana Glacier, Ecuador	1991 to 1999	Summer ablation	Francou *et al.* (2000)

(*continued overleaf*)

Table 1 (*continued*)

Atmospheric Index	Glacier index	Correlation	Glacier	Year(s)	Cause(s)	Reference
NAO (Oct–Apr) & (Dec–Mar)	Winter and net mass balance	Positive	Ten glaciers (especially maritime), southern Norway		Winter precipitation	Nesje *et al.* (2000)
SOI (Oct–Mar)	End of summer snowline altitude	Negative	Sajama Volcano Glacier, Bolivia	1963 to 1998	(i) Rainy season precipitation; (ii) temperature of warmest month	Arnaud *et al.* (2001)
PDO (Nov–Apr)	Winter mass balance	Negative	Place Glacier, British Columbia, Canada	1965 to 1999	Winter precipitation	Moore and Demuth (2001)
PDO (Nov–Apr) SOI (Nov–Apr)	Net mass balance	Negative Positive				
SOI	Net mass balance	Positive	Zongo Glacier, Bolivia	1991 to 1998	(i) precipitation; (ii) temperatures; (iii) sublimation; (iv) melting.	Wagnon *et al.* (2001)
PDO NP	Advanced terminus position	Negative Positive	Six glaciers, Mount Baker, North Cascades, Washington, USA	1940 to 1990	(i) Winter precipitation; and (ii) summer temperatures	Kovanen (2003)

volumes above the dam and bigger flood discharges when the dam broke.

As with glacier mass balance, regional scale climate controls annual runoff, largely through its effects on local precipitation and air temperature. However, the effect of local climate variability on annual river flows depends on the sensitivity of the runoff regime to both these variables. Thus, an increase in air temperature and decrease in precipitation may result in increased runoff in a glacier melt-dominated river but decreased runoff in a rainfall-dominated one. For example, annual runoff from glacierized catchments in central Tien Shan, China, increased by 7% between the 1950s and the 1990s corresponding with air temperature and precipitation increases, although it was not obvious whether the runoff increases were due to increased melt, rainfall, or both (Jingshi and Fukushima, 1999).

Interannual runoff variability also depends on the percentage of the catchment that is glacierized (Kasser, 1973; Fountain and Tangborn, 1985; Braithwaite and Olesen, 1988; Chen and Ohmura, 1990; Moore, 1992; Pelto, 1996; Hopkinson and Young, 1998). Variability is at a minimum for catchments that are ~40% glacierized and goes up as the glacierized percentage both increases and decreases (Figure 1). The reason is that in catchments where runoff is controlled by both rainfall and glacier melt, low rainfall in warm, dry years is offset by high melt, while low melt in cold, wet years is offset by high rainfall. This "compensating effect" is greatest where catchment runoff is controlled approximately equally by rainfall and glacier melt (Röthlisberger and Lang, 1987). For example, in the period 1985–1993, summer stream flows in the North Cascades, Washington, USA, were lower than their long-term averages. The biggest reductions occurred in the least

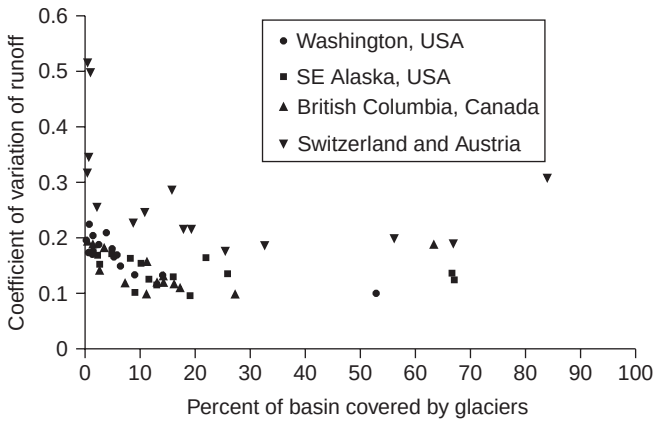

Figure 1 Coefficient of variation of runoff versus the percentage of the catchment that is glacierized. Data shown are annual runoff variability for Washington and Alaska, USA (Fountain and Tangborn, 1985), and British Columbia, Canada (Moore, 1992), and August runoff variability for Switzerland and Austria (Röthlisberger and Lang, 1987)

glacierized catchments, where glacier ice melt compensated to some extent for the lower runoff associated with reduced summer snowcover and rainfall (Pelto, 1996). Similarly, Hopkinson and Young (1998) showed that the "compensating effect" is measurable even in catchments with a low percentage glacier cover. Working in the 3% glacierized Bow River Basin, Alberta, Canada, where the runoff regime is dominated by snow melt and rain inputs, they compared annual water yields with annual glacier volume changes over the period 1952 to 1993. Glacier volumes tended to increase during high-flow years with high snowmelt and rainfall, and decreased during low-flow years. On average, glacier melt contributed ~2% of basin yield, but this increased to ~13% for the lowest-flow year. Interestingly, there were several years when this general trend was disrupted, showing that glaciers do not always augment river discharge during low-flow years. In an extreme case, basin yield during a very low-flow year was reduced by up to 4% because of an increase, rather than a decrease in glacier volume.

Interannual runoff variability depends not only on the magnitude of air temperature and rainfall changes but also on their timing during the year. For example, Liu *et al.* (1999) studied air temperature, precipitation, and runoff changes in eight glacierized catchments in western China between 1953 and 1993. Mean annual air temperatures were 0.5 °C higher and precipitation was 10–20% higher after the late 1970s than before. However, annual stream flow decreased over time because rises in temperature were concentrated in winter and spring, while precipitation increases were spread throughout the year. The effects were to increase winter accumulation but not summer melt. Summer runoff increased slightly, because of increases in rain rather than melt.

Secular trends in climate can affect annual river flows indirectly through their effects on glacier mass balance and geometry. Thus, an increase in air temperature may increase runoff in a glacier melt–dominated stream in the short term but decrease it over the longer term because of glacier shrinkage. Pelto (1996) analyzed stream flow variations in five glacierized basins in the North Cascades, Washington, USA. Between 1985 and 1993, mean summer temperatures were higher, mean winter precipitation totals were lower, and mass balances were more negative than their long-term means. Summer runoff was also lower by an average of ~23% because of lower winter snowcover, earlier spring snow melt, and reduced glacier area.

Changes in the relative areas of snow, firn, and ice on a glacier surface can also affect river flows. For example, Braun and Escher-Vetter (1996) examined year-to-year variations in proglacial stream discharge below Vernagtferner, Austria, in relation to documented changes in mass balance. Between 1979 and 1990, the total glacier area shrank by ~0.46 km^2 but summer discharges increased.

This was attributed to an increase in the area of ice relative to snow and firn, which reduced the overall glacier albedo and increased melt rates. Conversely, a similar study of Place Glacier, BC, Canada showed that the glacier shrank by $\sim 0.24\,km^2$ between 1970 and 1984, that August discharges were negatively correlated with winter snow accumulation and positively correlated with August air temperatures, and that once these controls had been accounted for, August discharges showed a negative trend through time (Moore and Demuth, 2001). The areas of snow and firn remained fairly constant at Place Glacier so the area of ice relative to snow and firn decreased, glacier albedo increased, and melt rates decreased.

INTRAANNUAL VARIATIONS IN RUNOFF

The annual runoff regime of glacierized basins depends largely on the annual distribution of radiation, air temperature, humidity, cloudiness, and precipitation and therefore varies with geographical setting.

Midlatitudes

The midlatitudes have marked annual variations in solar radiation and air temperature and small to moderate variations in precipitation (Figure 2a and b). Consequently, in midlatitude glacierized catchments (e.g. Alps, North America, Scandinavia, Iceland, New Zealand, Greater Himalayas, India), the year can be divided into a winter accumulation season and a summer ablation season. (Catchments in the Greater Himalayas are included here as most of the precipitation falls during the winter months and the summer monsoon has little influence (Singh *et al.*, 1995). Catchments in the Outer and Middle Himalayas, where most of the precipitation falls during the monsoon with only negligible amounts during the winter, are included in the low latitude section). During winter, precipitation falls mainly as snow and glacier melt is negligible. During summer, precipitation falls mainly as rain, especially at lower elevations, and glacier melt is high. Such glaciers are known as *winter accumulation type* (Ageta and Higuchi, 1984), and tend to store water as snow and ice during the winter, and release it as water during the summer. Consequently, there are three important characteristics of the runoff regimes of midlatitude glacierized basins (Figure 3a). First, there is a long summer melt season, coinciding approximately with the period when mean daily temperatures are above $0\,^{\circ}C$. Second, there is a large annual variation in runoff as summer melting coincides with rainfall across the lower elevations of the catchment. For example, ~90% of the annual runoff from Vernagtferner, Austria, occurs between June and October (Escher-Vetter and Reinwarth, 1994). Scandinavian glaciers discharge ~85% of their annual runoff between June and August (Østrem, 1973). Approximately 70% of the runoff in the Satluj River, Western Himalayas occurs between June and September (Singh and Jain, 2002). Third, there is a delay in the timing of maximum annual flow relative to equivalent nonglacierized basins. This is caused by temporary storage of spring meltwater, and by peak meltwater production in midsummer (Fountain and Tangborn, 1985).

High Latitudes

The high latitudes have even greater annual variations in solar radiation and air temperature than midlatitudes, with long periods of the year when air temperatures are below freezing point (Figure 2c and d). They also have moderate variations in precipitation, but lower precipitation totals than midlatitudes (Figure 2c and d). High-latitude glaciers in maritime areas (e.g. Svalbard) may be described as *winter accumulation type*, but those in more continental regions (e.g. Arctic Canada) may be thought of as *summer accumulation type* (Ageta and Higuchi, 1984). All these glaciers release water in the summer but the melt season is shorter than in midlatitudes (Figure 3b and c). For example, ~97% of the annual runoff from Austre Broggerbreen, Svalbard, occurs from June to August (Repp, 1988), while ~94% of the annual runoff from Quviagivaa and Nirukittuq Glaciers, Ellesmere Island, Canada, occurs in July and August (Wolfe and English, 1995). The lower radiation receipts and air temperatures mean that the annual variation in runoff is, typically, less than in equivalent midlatitude basins (Figure 3b and c).

An extreme case is Canada Glacier, Taylor Valley, Antarctica, where the entire annual runoff is typically confined to a six to eight week period in December and January (Lewis *et al.*, 1999) (Figure 3c). Runoff in the ice-marginal streams occurs only when air temperatures near the glacier terminus are above freezing point. Melting occurs at other times, because of high radiation energy, particularly on the vertical cliffs of the terminus, but the water refreezes before it reaches the streams. For their area (~2% of the ablation zone), the vertical ice cliffs are more important than the horizontal glacier surfaces in supplying meltwater to the streams (~15–20% of the annual glacier runoff). This is because the cliffs often have a higher net short-wave radiation flux than the horizontal surfaces, as they cannot accumulate snow and therefore have a lower albedo. They also have a higher net long-wave radiation flux because of radiation from the bare ground beneath the cliffs. Finally, the lower elevation of the cliffs means that air temperatures are higher, specific humidity is higher, and sublimation rates are negligible. Thus, virtually all the energy receipt on the cliffs is used for melting, whereas only ~20–60% of the energy is used for melting on the horizontal surfaces, the rest being used for sublimation (Lewis *et al.*, 1999).

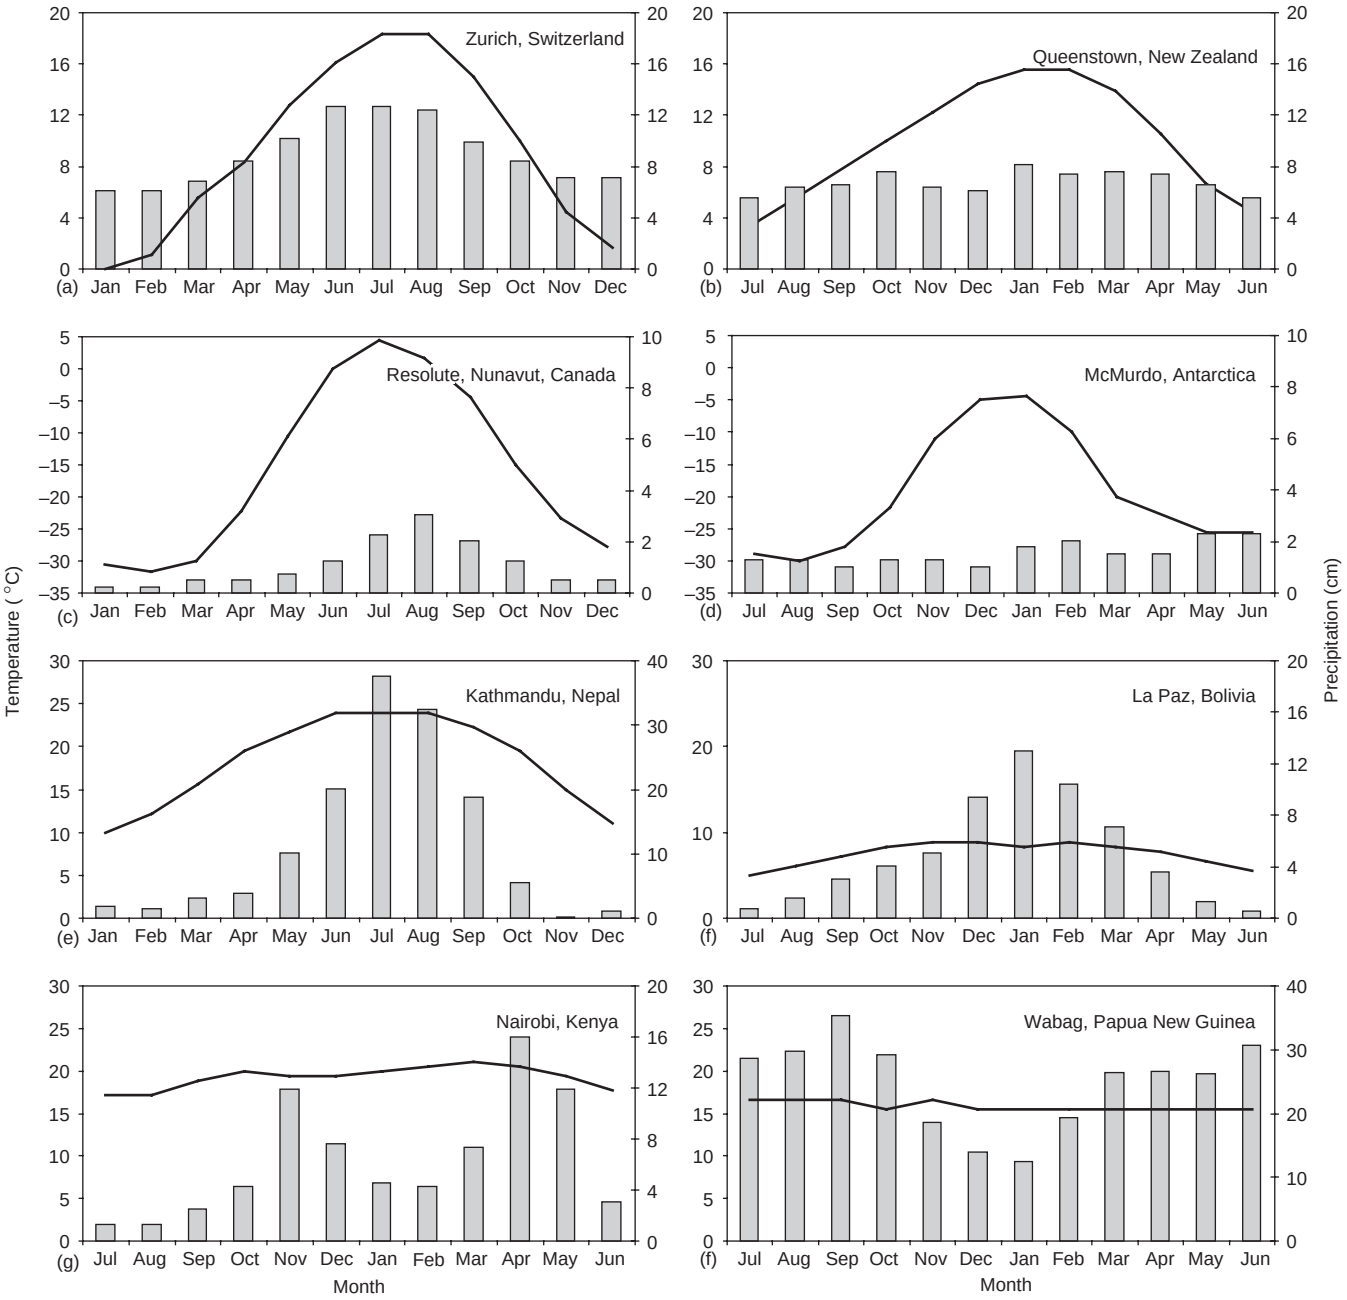

Figure 2 Monthly air temperature (line) and precipitation (bars) near glacierized basins in midlatitudes (a and b), high latitudes (c and d), low latitudes with ''summer accumulation'' regime (e and f), and low latitudes with ''year-round ablation'' regime (g and h)

Low Latitudes

The low latitudes have relatively small annual variations in upper atmosphere solar radiation receipt and air temperature, but annual fluctuations in the Inter Tropical Convergence Zone produce large variations in humidity, cloudiness, and precipitation (Figure 2e–h). Low latitude glaciers can be described as either "summer accumulation type" or "year-round ablation type" (Ageta and Higuchi, 1984).

Summer accumulation type glaciers occur at high altitudes, with cold, dry winters and marked summer precipitation maxima. Such areas include the monsoon-dominated parts of the Outer and Middle Himalayas in India and Nepal (Higuchi *et al.*, 1982); the Pamiro-Altai in Tadjikistan (Konovalov and Shchetinnicov, 1994); the Karakoram, Pamirs, Tien Shan, Altai, Kunlun and Qilian mountains of Pakistan, Tadjikistan, Kazakhstan, and China (Xie and Lui, 1993; Aizen *et al.*, 1995; Xie *et al.*, 1999; Liu *et al.*,

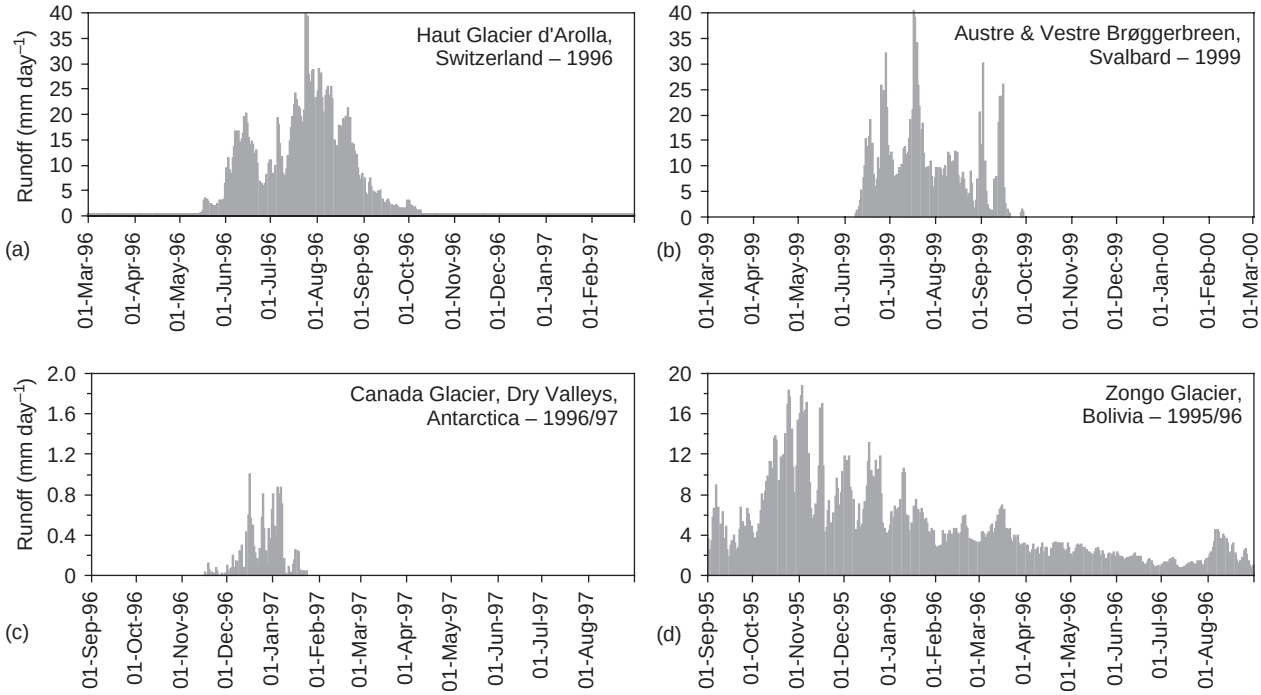

Figure 3 Daily specific runoff from (a) Haut Glacier d'Arolla, Switzerland; (b) Austre and Vestre Brøggerbreen, Svalbard; (c) Canada Glacier, Taylor Valley, Antartcia; (d) Zongo Glacier, Bolivia

1999); and the high Andes of Peru and Bolivia in the outer tropics (Francou *et al.*, 1995; Hastenrath and Ames, 1995; Ribstein *et al.*, 1995; Ames and Hastenrath, 1996; Kaser, 1999, 2001; Kaser and Osmaston, 2001). In these regions, there is very little winter precipitation and in the summer, precipitation falls mainly as snow at high elevations and rain at lower elevations (Figure 2e and f). Upper atmosphere solar radiation receipt and air temperatures are fairly constant throughout the year (Figure 2e and f), and annual variations in ablation are controlled mainly by variations in cloudiness and humidity (Kaser and Georges, 1999; Wagnon *et al.*, 1999a,b; Kaser and Osmaston, 2001). Ablation occurs throughout the year, but the majority of winter ablation is by sublimation due to the dry air. Conversely, the humid summer air means that sublimation is negligible, and most of the ablation is by melting.

As both accumulation and melting are concentrated in the summer, low latitude glaciers tend not to store and release water with the same seasonal rhythm as mid- to high-latitude glaciers. However, glacierized catchments in these regions are subject to large annual variations in runoff, with high runoff corresponding with the wet season when both rainfall and glacier melting are high (Fukushima *et al.*, 1987; Collins, 1999; Hasnain and Thayyen, 1999). For example, virtually all of the annual runoff from Langtang Glacier, Nepal occurs between May and October (Tangborn and Rana, 2000), and 70–90% of runoff in glacierized basins in western China occurs between June and September (Liu *et al.*, 1999). Similarly, ~60% of the annual runoff from Lirung Glacier, Nepal occurs during the monsoon period (mid-June–mid-September) (Bhatt *et al.*, 2000), and ~65% of the May–October runoff occurs during the monsoon months of July and August (Hasnain and Thayyen, 1999). At Zongo Glacier, Bolivia, runoff is more evenly distributed throughout the year. Only ~50% of annual runoff occurs during the warm summer period (December–March), and precipitation-induced runoff associated with the passage of cold fronts is not uncommon during the winter months of June and July (Ribstein *et al.*, 1995) (Figure 3d).

Year round ablation type glaciers occur in high-altitude areas in the inner tropics where radiation and air temperatures are high and their annual variations are negligible (Figure 2g and h). Precipitation also occurs throughout the year, although distinct peaks may coincide with one or two wet seasons. Glaciers in these regions are subject to fairly even accumulation and ablation throughout the year although, as with summer accumulation type glaciers, both accumulation and melting may be slightly higher during the wetter months. Glaciers with one wet month are found on Mount Jaya, Papua New Guinea, Mount Kilimanjaro, East Africa, and the volcanoes of Ecuador (Hope *et al.*, 1976; Hastenrath, 1981) (Figure 2g). Those with two wet months are located in the Ruwenzori Mountains and on Mount Kenya, East Central Africa (Whittow *et al.*, 1963; Hastenrath, 1984; Hastenrath and Kruss, 1992) (Figure 2h). As accumulation and ablation occur fairly evenly throughout the

year, runoff also tends to be distributed throughout the year.

Effect of Catchment Size and Percentage Glacier Cover

The annual runoff regime of glacierized catchments depends not only on geographical setting but also on catchment size, hypsometry, and percentage glacier cover. In the midlatitudes (Kasser, 1973; Fountain and Tangborn, 1985; Röthlisberger and Lang, 1987; Young and Hewitt, 1993) and low latitudes (Kaser *et al.*, 2003), annual runoff variation is at a minimum for basins with ~30–40% glacier cover. Higher annual runoff variation occurs in basins with both lower and higher glacier cover. Catchments with a high percentage glacier cover tend to be small upland catchments with a low elevation range. Liquid water inputs are very low during winter (due to precipitation falling as snow and negligible melt) but very high during summer (due to rainfall and high melt). Consequently, annual runoff variability is high, as discussed earlier. Conversely, catchments with a low percentage glacier cover tend to be large, extend into the lowlands, and have a high elevation range. Here, liquid water inputs are highest during the winter and lowest during the summer (due to the majority of precipitation falling across the catchment as rain, and the relatively insignificant effect of glacier accumulation and high melt in the catchment). Thus, annual runoff variability is again high but with maximum discharges in the winter and low flows in the summer. Between these extremes, in catchments with ~30–40% glacier cover, melt-dominated glacier runoff from the upper parts of the catchment compensates for the low rain-induced runoff from lower elevations during the summer. Conversely, reduced runoff from the upper parts offsets higher rain-induced runoff from lower elevations in winter. The net effect is a relatively even distribution of runoff throughout the year.

Finally, in midlatitude catchments, the time of maximum summer runoff is increasingly delayed with increasing glacier cover (Meier and Tangborn, 1961; Stenborg, 1970, Fountain and Tangborn, 1985; Pertziger, 1990). Furthermore, the relationship between runoff peak timing and percentage glacier cover appears to be nonlinear. For example, in the North Cascades, Washington, USA, maximum runoff was delayed by 1 month from mid-June to mid-July as glacier cover increased from ~5% to ~25%. It was delayed by a further 2 weeks to late July as glacier cover increased to ~50%, but by only 1 more week as cover increased to ~100% (Fountain and Tangborn, 1985).

INTRASEASONAL VARIATIONS IN RUNOFF

Glacierized basins not only have pronounced year-to-year and season-to-season runoff variations, but major intraseasonal runoff fluctuations too. This is especially true during the spring and summer months for midlatitude glaciers and, to a lesser extent, for high-latitude glaciers. It appears to be less true for low-latitude glaciers.

Midlatitude Glaciers

Midlatitude glaciers undergo major changes in their hydrology during the spring and summer months because of seasonal changes in both water inputs and water routing.

Seasonal Changes in Water Inputs

Over the ablation season, water inputs increase as the transient summer snowline migrates upglacier largely because of increases in net short-wave radiation but also increases in sensible and latent heat (Arnold *et al.*, 1996; Fountain, 1996; Willis *et al.*, 2002). As the snowpack melts, metamorphoses, and thins, its albedo drops because of (i) higher water content; (ii) larger snow crystals; (iii) higher dust concentration at the snow surface; and (iv) the presence of underlying ice, which, typically, has a lower albedo than snow and influences the albedo of the overlying snowpack (Wiscombe and Warren, 1980; Brock *et al.*, 2000). Once ice is exposed, the albedo of the glacier surface often drops dramatically, mainly because ice has larger crystal sizes and higher debris concentrations than snow (Mattson *et al.*, 1993; Brock *et al.*, 2000). Thus, as albedo falls during spring and summer, surface melt rises because of increases in net short-wave radiation. Furthermore, ice surfaces are typically rougher than snow surfaces (van de Wal *et al.*, 1992; Duynkerke and van den Broeke, 1994). Surface roughness scales directly with the aerodynamic roughness lengths for wind, air temperature and vapor pressure (Munro, 1989). Thus, as surface roughness increases during spring and summer, surface melt rises because of increases in sensible and latent heat transfer between the atmosphere and the glacier surface.

Seasonal Changes in Water Routing

The speed at which water is routed through glacierized catchments increases over the spring and summer (Hock and Noetzli, 1997; Arnold *et al.*, 1998; Willis *et al.*, 2002). There are three aspects to this: (i) supraglacial routing (vertically through snow, laterally through snow, and across ice); (ii) routing through firn; and (iii) englacial/subglacial routing (down crevasses and moulins, through pipes and conduits, and along the subglacial drainage system).

As the snowpack melts, metamorphoses and thins, the hydraulic conductivity (velocity of water movement) of the upper unsaturated layers increases for four main reasons. First, the snow crystals enlarge, increasing the saturated permeability (Shimuzu, 1970). Second, the melt rate and water content increase, raising the percentage water saturation (Colbeck, 1978). Since the hydraulic conductivity of

snow depends on its effective permeability, which depends on both its saturated permeability and its percentage water saturation, bigger crystal sizes and more melt mean higher vertical velocities (Colbeck and Anderson, 1982). Third, the development of preferential flow paths due to lateral heterogeneity (e.g. discontinuous layers or ice lenses), or heterogeneous infiltration patterns (e.g. heterogeneous surface melt) will speed up water movement (Marsh and Woo, 1984). Fourth, a thinning snowpack means decreasing vertical distance to travel, which also reduces the travel time of water movement to the base of the snowpack.

The speed at which water is routed laterally in a saturated layer at the base of the snowpack depends on snow crystal size, water content, and surface slope (Colbeck, 1978). As these are fairly constant during the ablation season, the lateral hydraulic conductivity of saturated snow may not change significantly. However, lateral water velocities at the base of supraglacial snowpacks may depend less on grain scale phenomena and more on larger scale processes. Observations at Haut Glacier d'Arolla, Switzerland suggest that water flows in a thin layer at the base of the snowpack along preferential flowpaths in rills and small channels incised into the ice. If the hydraulic efficiency of these increases over time, the speed at which water moves laterally at the base of the snowpack may also increase. Also, if the depth of saturated snow increases in some areas more than others, hydraulic gradients may increase lateral water velocities beyond those determined by surface slopes alone.

Vertical and lateral routing of water through firn is analogous to vertical and lateral movement through snow (Fountain, 1996; Schneider, 2000). Water tends to drain from firn layers during the winter. During spring and summer, water reaching the base of a snowpack overlying firn infiltrates the firn, moving at speeds determined by crystal size and water content. Once the water reaches the firn-ice transition, a firn water table builds up and lateral water movement is governed by elevation and pressure head gradients. Average vertical and lateral water velocities through firn vary over similar ranges of $\sim 0.1 - 0.35\,\mathrm{m\,h^{-1}}$ (Schneider, 2000). Seasonal changes in water velocities through firn have not been measured, although they may be expected to increase during spring and summer as the water content of the unsaturated zone increases, and hydraulic gradients in the saturated aquifer rise.

Seasonal changes in englacial and subglacial drainage pathways also increase the speed at which water is routed through glacierized catchments (*see* **Chapter 167, Subglacial Drainage, Volume 4**). Englacial pipes and conduits, and subglacial channels tend to close during the winter as the discharge of water flowing through them drops. In spring, once water reaches the base of the winter snowpack, the flux of water through crevasses and englacial pipes and conduits increases, and they enlarge through melting and become more hydraulically efficient. Eventually, water reaches a distributed hydrological system at the bed, which enlarges mechanically because of sliding and hydraulic jacking (Iken, 1981), and thermally because of ice melting (Kamb, 1987). If the flux of water reaching the bed is large enough, a distributed hydrological system will be unable to transmit the water, and parts of the system will enlarge to form channels, which have a greater hydraulic efficiency (Kamb, 1987; Nienow *et al.*, 1998). This switch from predominantly distributed to channelized drainage may be triggered by high melt rates or rainstorms, and may be associated with the release of water stored englacially and/or subglacially (see the following section).

Seasonal Changes in Runoff

Seasonal changes in water inputs and routing in midlatitude glacierized basins have a big impact on the shape, peak magnitude, and timing of diurnal discharge variations in proglacial streams (Elliston, 1973; Collins, 1982; Röthlisberger and Lang, 1987; Fountain, 1992; Gurnell *et al.*, 1992, 1994; Willis and Bonvin, 1995; Hannah *et al.*, 1999, 2000). Figure 4 shows how diurnal discharge hydrographs change through an ablation season. Discharges increase from May to August, and then drop during September because of variations in water inputs driven by changing patterns of net short-wave radiation and sensible and latent heat fluxes. Between May and September, the diurnal discharge range increases progressively, the lag between minimum and maximum discharge steadily declines, and the gradients of the rising and falling limbs of the hydrographs systematically increase. These changes reflect increasing hydraulic efficiency of supraglacial, englacial, and subglacial pathways associated with the gradual depletion of the snowpack and the evolution of the englacial and subglacial drainage system.

Seasonal changes in surface conditions and water routing can also affect a glacier's response to rainfall events (Collins, 1995; Denner *et al.*, 1999). A snowpack and a hydraulically inefficient englacial/subglacial drainage system in early summer can significantly dampen the effects of rainstorms on proglacial stream discharges. In late summer, large areas of ice and hydraulically efficient englacial/subglacial drainage mean that proglacial discharges respond much more rapidly to rainstorms.

Several recent studies have used statistical techniques to divide melt seasons into distinct periods on the basis of proglacial stream hydrograph characteristics (Hannah *et al.*, 1999, 2000; Lafreniere and Sharp, 2003). Hannah *et al.* (1999) used Principal Component Analysis and Cluster Analysis to identify diurnal hydrographs with distinct shapes and magnitudes during the 1995 and 1996 summers at the Taillon Glacier, France. The temporal sequencing of hydrographs with distinct characteristics was used to divide the melt seasons into different periods. The differences

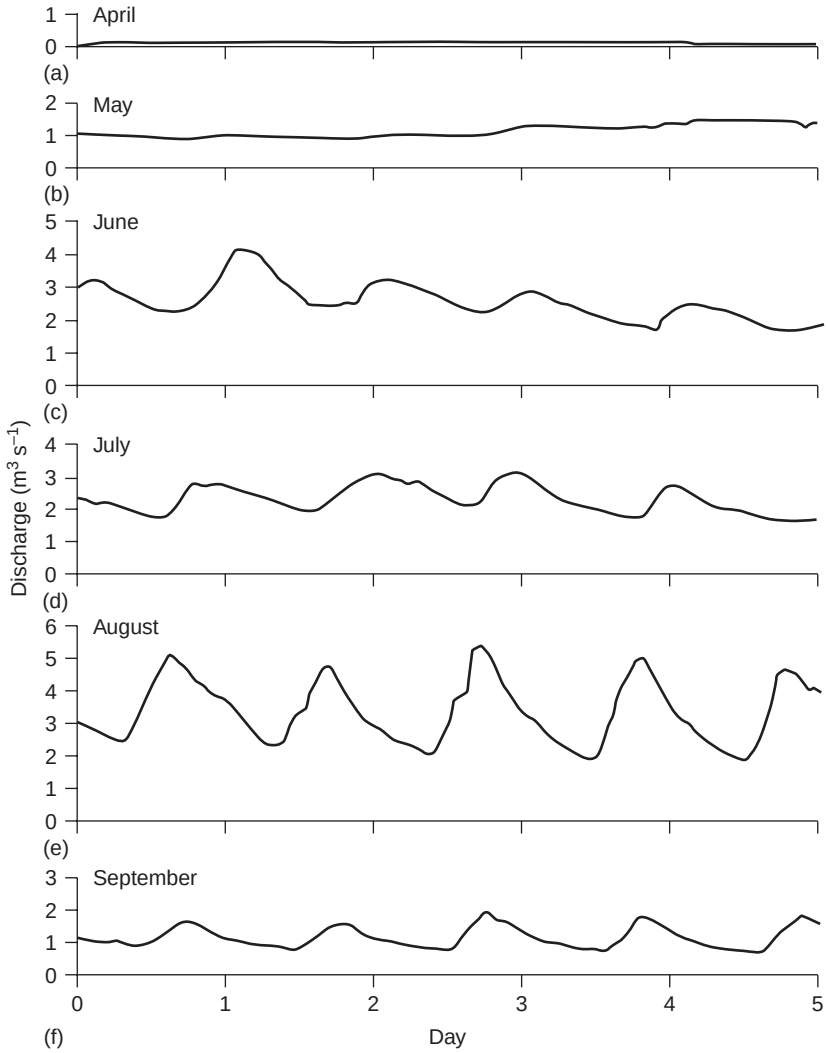

Figure 4 Changing shape of proglacial stream hydrographs from Haut Glacier d'Arolla, Switzerland in 1993 (from Willis and Bonvin, 1995)

in hydrograph characteristics, together with differences in energy receipt, ablation, and rainfall between the periods were interpreted in terms of temporal changes in both surface water inputs and the characteristics of the glacier's drainage system. During the 1995 summer, there was a progressive change from "building", "low magnitude" hydrographs, representing early season snowmelt and slow routing and high storage in the snowpack, through "low-intermediate peaked" hydrographs, reflecting increasing exposure of ice, rising melt rates and more rapid glacial routing of water, to "high-intermediate" and "high peaked" hydrographs signifying maximum exposure of ice, high melt and rainfall inputs, fast glacial routing, and low water storage. During the 1996 summer, however, there was a less obvious progressive change in hydrograph characteristics, reflecting a greater dominance of rainfall inputs and a less distinct evolution of the glacier's drainage system.

Lafreniere and Sharp (2003) used Wavelet Analysis to determine individual and cross wavelet spectra for air temperature, rainfall, and discharge time series from glacierized and nonglacierized catchments feeding Bow Lake, Alberta, Canada, during four summer melt seasons. The differences between the catchments were most marked in 1998, a strong El Niño year with low winter precipitation and high spring and summer air temperatures. In this year, the 24-h power in the discharge series was particularly low for the nonglacierized catchment and unusually high for the glacierized catchment, reflecting the lower snow melt contribution in the former and higher ice melt contribution in the latter compared with other years. In the glacierized catchment, there was a strong and persistent short scale ($\sim$12 h) power in the discharge series during July and August and a shift in the phase lag from $\sim$7 h to 4.5 h in early July, suggesting snowpack depletion and the evolution

of the glacier's drainage system. A low phase difference between air temperature and discharge also showed that the routing of diurnal melt cycles through the glacier was more hydraulically efficient in 1998 than in the other years. In the nonglacierized catchment, the relatively weak 24-h power in the discharge series was maintained throughout the summer in 1998 but largely disappeared during July and August in other years. This suggests that patches of ice were exposed in 1998 but not in normal years. The variability in discharge at short scales (<24 h) and rapid changes in the temperature–discharge phase difference suggest that precipitation was a more dominant component of runoff and was routed more quickly through the nonglacierized catchment than through the glacierized one.

High-latitude Glaciers

Compared with midlatitude temperate glaciers, very few studies have investigated seasonal variations in water inputs, routing, and runoff from high-latitude cold and largely cold polythermal glaciers (Hodgkins, 1997).

Seasonal Changes in Water Inputs and Routing

The few studies from the Arctic confirm that, as at midlatitude glaciers, water inputs increase over the summer largely because of decreases in albedo and increases in net short-wave radiation (e.g. Arendt, 1999). However, there are important differences in the way water is routed through catchments containing cold and polythermal glaciers and the ways in which this routing changes over the summer.

First, the end-of-winter snowpack is typically much colder than midlatitude glaciers. As water infiltrates the snow, large volumes refreeze to form ice lenses and superimposed ice layers (Repp, 1988; Bøggild, 2000; Wadham and Nuttall, 2002). The associated release of latent heat is the main way in which the snowpack warms up. Once the snowpack reaches 0 °C, some water is used to supply the irreducible water saturation (water retained by capillary forces). A depth of water, equivalent to >50% of the winter snowpack depth may be needed to raise the temperature to 0 °C and satisfy the irreducible water saturation (Marsh and Woo, 1984; Reeh, 1991). The effect is to increase the delay between initial melt and arrival of meltwater at the snowpack base compared with midlatitude glaciers. On John Evans Glacier, Ellesmere Island, Nunavut, Canada, for example, the delay is about 2 weeks on the lower glacier and over 3 weeks on the upper glacier where snow depths are only ~0.1 m w.e. (Boon *et al.*, 2003).

Second, once water has reached the snowpack base, it tends to pond in surface depressions, since cold ice is largely impermeable (Liestøl *et al.*, 1980; Hagen *et al.*, 1991; Boon *et al.*, 2003). On Austre Brøggerbreen, Svalbard, lakes appear between late May and early June, last between 2 and 10 weeks, reach volumes of up to ~9500 m^3, empty quickly over 1 or 2 days as supraglacial streams filled by snow or superimposed ice become unblocked, and then drain to ice-marginal channels (Liestøl *et al.*, 1980; Hagen *et al.*, 1991). Similar lakes appear and drain on John Evans Glacier, although others drain after moulins open up ~4 km from the glacier terminus, allowing water to reach the bed (Boon *et al.*, 2003).

Third, cold glaciers such as Austre Brøggerbreen and Scott Turnerbreen, Svalbard, are essentially impermeable and surface water flows largely in supraglacial and ice-marginal streams (Hagen *et al.*, 1991; Hodgkins, 1997; Hodson and Ferguson, 1999). Tracer tests from a meandering supraglacial stream and a boulder-strewn marginal stream at Hannabreen produced slow, dispersed returns, suggesting that routing of water at cold glaciers is likely to be hydraulically inefficient (Vatne *et al.*, 1995). Moulins feeding englacial and ice-marginal channels may be present, although these may be incised supraglacial streams or crevasses, which have been enclosed by ice creep but remain open due to heat advection and dissipation of flowing water. Tracer tests conducted from such moulins on Austre Brøggerbreen had high throughflow velocities, suggesting that englacial routing of water may be hydraulically efficient (Hagen *et al.*, 1991). However, cold glaciers do not have much of an englacial drainage system and they lack a subglacial drainage system altogether. Thus, the drainage system cannot evolve through the summer as it can on temperate glaciers.

By contrast, largely cold polythermal glaciers with a warm-based core and cold-based margins do have an englacial/subglacial drainage system. Such glaciers include Midre Lovénbreen, Erikbreen, Finsterwalderbreen, Kongsvegen, Hannabreen, and Bakaninbreen, Svalbard (Vatne *et al.*, 1992, 1996; Hagen *et al.*, 1993; Hodson and Ferguson, 1999; Wadham *et al.*, 2001; Murray and Porter, 2001; Rippin *et al.*, 2003) and John Evans Glacier, Ellesmere Island, Nunavut, Canada (Skidmore and Sharp, 1999; Boon *et al.*, 2003). Very little is known about this system or how it evolves through time. Flow separation techniques using proglacial stream discharges and electrical conductivities suggest that 30–40% of water is routed slowly, possibly subglacially, through Hannabreen (Vatne *et al.*, 1996). Furthermore, concentrations of sulfate in the proglacial stream showed no change through time, implying a relatively stable subglacial drainage system. Tracer tests from moulins on Erikbreen had low throughflow velocities and high dispersivities, suggesting that the glacier is underlain by a distributed drainage system which does not evolve significantly over the summer (Vatne *et al.*, 1995). One of the most important aspects of the hydrology of many largely cold polythermal glaciers is the sudden emergence of subglacially routed water at the glacier terminus in the form of pressurized fountains on the glacier or, more commonly,

Figure 5 Artesian fountain observed ~0.5 km from the terminus of John Evans Glacier, Ellesmere Island, Nunavut between 29th June & 5th July 1998 (Reproduced from Copland *et al.,* 2003 by permission of International Glaciological Society; Photo credit: Martin Sharp)

pressurized proglacial upwellings (Figure 5). These demonstrate that a subglacial drainage system is present beneath the warm-based core of the glacier and that this is able to extend beneath the cold-based margins of the glacier at some point during the summer. At John Evans Glacier, the breaching of the "thermal dam" occurs after hydrofracture events allow the sudden transfer of supraglacially stored water into the subglacial drainage system (Copland *et al.*, 2003). This phenomenon also involves the storage and release of subglacial water and small floods in proglacial streams (see later sections).

Seasonal Changes in Runoff

The three important differences between the hydrology of midlatitude and high-latitude glaciers produce distinct differences in the runoff regimes of their proglacial streams (Hodson *et al.*, 1998; Hodgkins, 2001; Irvine-Fynn *et al.*, 2005). First, the delay between the onset of melt and the rise in proglacial discharge is often greater at high-latitude glaciers because of the greater volumes of water stored supraglacially, ice-marginally and at polythermal glaciers, englacially and subglacially. Second, diurnal variations in proglacial discharge are often absent or more subdued at high-latitude glaciers, particularly early in the summer, because of the delaying and dampening effects of supraglacial slush and ponds, hydraulically inefficient meandering supraglacial and boulder-strewn marginal channels, and at mainly cold polythermal glaciers, subglacial water storage above the thermal dam. Third, the relatively sudden release of water from supraglacial ponds and, on mainly cold polythermal glaciers, from subglacial locations above the thermal dam produces a marked flood hydrograph, often lasting a few days.

Low-latitude Glaciers

There have been very few investigations into the hydrology of low latitude glaciers. Tracer experiments and flow separation techniques based on proglacial stream discharge and electrical conductivity measurements led Wagnon *et al.* (1998) to conclude that Zongo Glacier, Bolivia had a more "highly developed" englacial/subglacial drainage system than similar sized midlatitude glaciers. They suggested that year round ablation maintained the hydrological system, preventing conduits and channels from closing down, as occurs on mid- and high-latitude glaciers during the winter. Dye tracer experiments at Dokriani Glacier, India, suggest that the glacier is underlain by efficient channelized drainage in July, distributed drainage in August, and channelized drainage again in September (Hasnain *et al.*, 2001). However, the results are equivocal since they are based on only 10 experiments from three locations.

SEASONAL WATER STORAGE

As mentioned previously, glaciers in mid- and high latitudes store water as snow in winter, and release it as snow and ice melt during the summer. However, glaciers can also store and release liquid water on a variety of timescales (Jansson *et al.*, 2003). On several glaciers, seasonal variations in liquid water storage and release have been examined using a water balance approach, by comparing time series of surface water inputs (from melt and rainfall) with proglacial stream outputs (Figure 6). Most studies show that water is stored during spring and early summer and then released. The exception is Scott Turnerbreen, which showed initial release followed by storage, although this might reflect the short period of measurement. The maximum amount of water stored varies between glaciers, from <0.1 m (averaged over glacier area) at Haut Glacier d'Arolla, Scott Turnerbreen, and Midre Lovenbreen to ~0.4 m at Unteraargletscher (Figure 6). The timing of maximum storage also varies between glaciers, from early June on South Cascade Glacier to late August on Midtdalsbreen, although this may, at least in part, reflect the different measurement start dates. Several studies (Mikkaglaciären, South Cascade Glacier, Haut Glacier d'Arolla, Midre Lovénbreen) show that the amount of water released is greater than that stored, implying that additional water must have been stored before measurements began. Others (Midtdalsbreen, Unteraargletscher) show that the amount released is less than that stored, suggesting that more may have been released after measurements finished or that there are significant errors in the calculations. Only Storglaciären showed an approximate net balance over the entire measurement period. Unfortunately, none of these studies has covered an entire hydrological year, and none has examined interannual water storage variability by investigating more than one season (Jansson *et al.*, 2003).

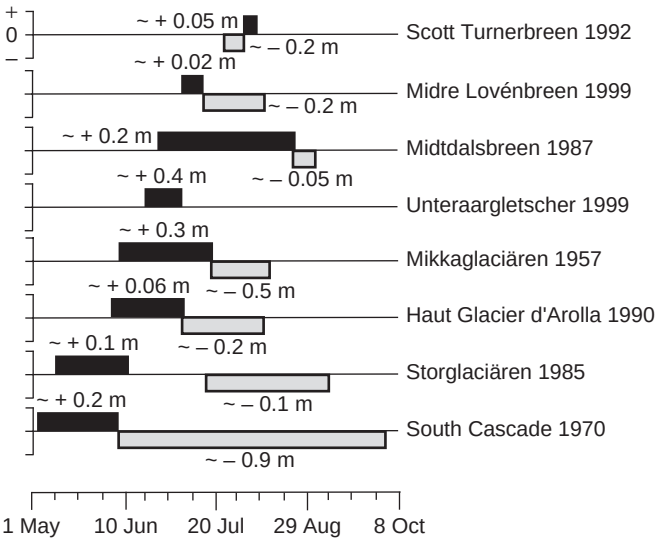

Figure 6 Patterns of storage gain (positive, black) and loss (negative, white) for several glaciers discussed in the text. (based on Figure from Jansson *et al.*, 2003)

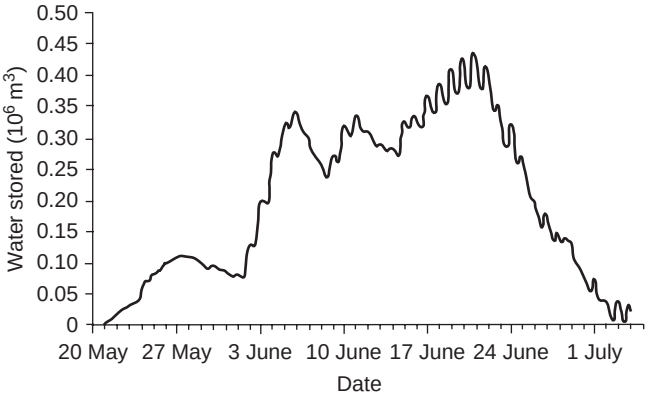

Figure 7 Cumulative total snowpack water storage calculated using a physically based distributed model for Haut Glacier d'Arolla, Switzerland in the year 2000 (Courtesy of Andrew Fox)

All the studies listed above have calculated bulk water storage and release for entire glaciers by comparing water input and water output time series. Such an approach does not reveal where the water is stored, and there is still uncertainty about the relative importance of supraglacial, englacial, subglacial, and ice-marginal storage, and whether the relative importance of these stores varies through the summer. These issues are discussed further in the following sections.

Supraglacial Storage

Large volumes of water may be stored in snow, particularly at the start of the melt season (Willis *et al.*, 1993; Fountain, 1996). This is particularly important on high-latitude glaciers where cold ice is largely impermeable and large slush zones develop (Liestøl *et al.*, 1980; Hagen *et al.*, 1991; Hodgkins, 2001; Boon *et al.*, 2003). This water tends to be released gradually during the summer as the snowpack melts, although it may drain rapidly in the form of slush avalanches (Smart *et al.*, 2000). On cold and polythermal glaciers, water may also be released rapidly as supraglacial and ice-marginal channels are unblocked, or as moulins open up (Boon *et al.*, 2003). This has important implications for both seasonal runoff (see the earlier section) and flooding (see the following section) in high-latitude glacierized basins. Some water may continue to drain from the remaining snowpack during the early winter. Some may refreeze during the winter to form superimposed ice, which accounts for 6–25% of the annual accumulation on Midtre Lovénbreen, Svalbard (Wadham and Nuttall, 2002).

Recent hydrological modeling work at Haut Glacier d'Arolla has calculated the temporal patterns of water storage in the supraglacial snowpack from late May to early July 2000 (Fox, 2003). A distributed snow energy and mass balance model was used to calculate spatial patterns of melt and vertical routing through the unsaturated snowpack. A modified groundwater model was then used to determine spatial patterns of lateral water routing and water storage in the saturated snowpack. Figure 7 shows the cumulative volume of water stored in the saturated snowpack. The daily water balance is usually positive between late May and mid-June with short periods of negative balance that last a few days. The cumulative balance reaches a maximum on 21 June when ~0.1 m of water averaged over the glacier is stored in the snowpack. This represents ~17% of the total meltwater production up to 21 June, and is more than the maximum volume stored seasonally in 1990 (Richards *et al.*, 1996). This water then drains from the snowpack over the next 2 weeks as the snowpack thins, and the snowline migrates rapidly upglacier. Figure 8 shows the spatial patterns of water storage in the saturated snowpack on 10 June, shortly before the time of maximum storage. Thus, most water is stored along valleys in the glacier surface where water tends to pond.

Firn Storage

Appreciable volumes of water can also be stored in and released from firn (Fountain, 1996; Fountain and Walder, 1998; Schneider, 2000; Jansson *et al.*, 2003). The firn zone is essentially an unconfined aquifer. The water table height depends on the surface recharge rate, the hydraulic properties of the firn, and the rate of drainage from the base, which is governed by the surface slope and the distribution of crevasses. Measurements on three glaciers, Aletschgletscher, Switzerland, South Cascade Glacier, Washington, USA, and Storglaciären, Sweden, show that the firn aquifer reaches thicknesses of

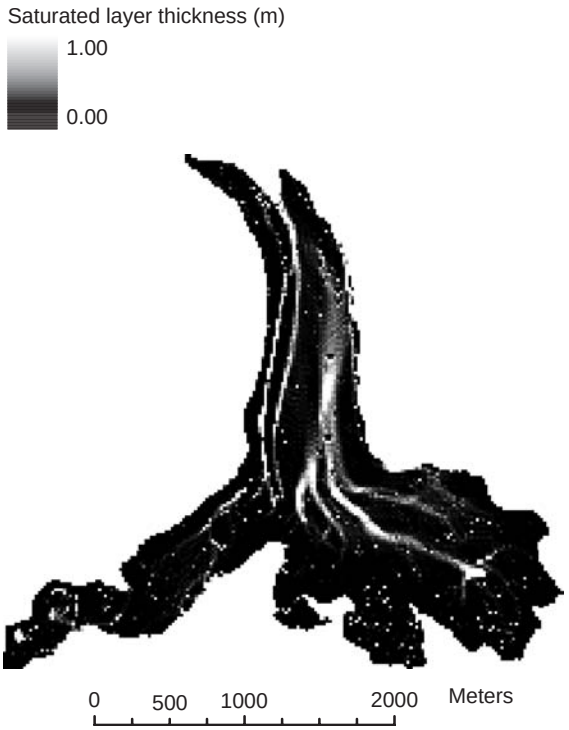

Figure 8 Spatial distribution of modeled snowpack water storage at Haut Glacier d'Arolla, Switzerland on 10th June 2000 (Courtesy of Andrew Fox)

~3–7 m during the summer. The firn tends to gain water during spring and drain during late summer. Day-to-day variations in melt and rainfall cause damped water-level fluctuations of 1–2 m lasting days to weeks, superimposed on the seasonal trends. As with water in the snowpack, some water in firn may refreeze during the winter, accounting for 7–64% of annual accumulation for different glaciers in Alaska (Trabant and Mayo, 1985), and ~4% of annual accumulation on Storglaciären (Schneider, 2000). Measurements of firn area, porosity, and water saturation at South Cascade Glacier suggested that ~12% of the maximum volume stored seasonally at this glacier may be stored in the firn (Fountain, 1989). Similar measurements suggest the equivalent figure maybe ~44% at Storglaciären (Östling and Hooke, 1986).

Englacial Storage

In addition to firn storage, Östling and Hooke (1986) suggested that englacial reservoirs such as crevasses might be important storage sites on Storglaciären. Fountain and Walder (1998) argue that the majority of water storage on temperate glaciers is probably englacial. They refer to borehole-video studies, which show that englacial voids and conduits represent a macroporosity of ~1%, and to radar studies and work measuring water levels in moulins, which show how englacial passageways fill and drain in response to variations in water inputs. This macroporosity is easily able to accommodate the maximum depths of seasonal water storage measured on several glaciers (Figure 6).

Subglacial Storage

Glacier surfaces often rise and fall in response to weather-related variations in surface water inputs and/or changes in the morphology of the subglacial drainage system (Iken *et al.*, 1983; Iken and Bindschadler, 1986; Kamb and Engelhardt, 1987; Jansson and Hooke, 1989; Raymond *et al.*, 1995; Mair *et al.*, 2002). Although some of this movement may be due to strain-induced variations in ice thickness, some is also due to the growth and shrinkage of subglacial cavities and associated changes in subglacial water storage. Fountain and Walder (1998) estimate that linked cavities may account for ~10–30% of the volume of water stored seasonally in several glaciers (Figure 6). They also estimate that subglacial till may account for up to ~40%, but probably much less. Tangborn *et al.* (1975) suggested that most water is stored in subglacial locations beneath South Cascade Glacier, although they had no direct evidence for this. They suggested that a subglacial conduit system closes down in places during periods of low or zero surface water inputs during the winter, and then fills with water during the spring and early summer before reopening and releasing the stored water later in the summer. A similar mechanism was advocated to explain patterns of water storage and release at Haut Glacier d'Arolla (Richards *et al.*, 1996). These authors linked storage/release patterns to rates of water input and the evolution of the subglacial drainage system as determined by dye tracing experiments (Nienow *et al.*, 1998).

Similarly, Schuler *et al.* (2002) observed that over most of Unteraargletscher, the snowpack was already saturated in mid-June when water balance calculations began. They concluded that between mid-June and early July, water storage occurred within and at the base of the glacier. This was supported further by observations of a rainfall-induced rise in water pressure measured in a borehole ~3 km from the glacier terminus, followed by a flood in the proglacial stream. The rainstorm caused more water to back up in the englacial/subglacial drainage system causing water pressures to rise. This triggered a reorganization of the subglacial drainage system, leading to the release of water stored in and beneath the glacier.

Rippin *et al.* (in press) showed how the dynamics of the mainly cold polythermal Midtre Lovénbreen are affected by patterns of water storage and release. The upper tongue accelerated during times of water storage but the lower tongue accelerated during a time of water release, which also coincided with the emergence of a pressurized proglacial upwelling. This implied that at least some

of the water was stored subglacially behind the "thermal dam", marking the boundary between warm-based and cold-based ice. The water was then released as it forced its way beneath the cold-based lower tongue. Similar behavior was observed at the mainly cold polythermal John Evans Glacier (Copland *et al.*, 2003). Early season velocity events affected large areas of the glacier tongue, and occurred when supraglacially stored waters connected to the subglacial drainage system, and triggered the release of subglacially stored water. High pressures above the thermal dam were shown by the emergence of an artesian fountain on the glacier surface (Figure 5) in addition to a pressurized proglacial upwelling.

Summary

Previous research into seasonal patterns of water storage suggests that most glaciers store water in spring and early summer and release it during the late summer. Snow is an important location for stored water, especially early in the melt season, and may account for up to 100% of the stored water in the spring. As the snowpack melts, the stored water is released. It may drain directly from cold glaciers or may enter firn, englacial, or subglacial locations on temperate and polythermal glaciers. Firn may account for ~10–40% of the maximum volume of stored water. Similarly, ~10–40% may be stored subglacially. However, especially on temperate glaciers, englacial water storage in pipes, conduits, crevasses, and moulins is likely to be more important than subglacial storage during mid- to late summer. Recent work from two polythermal glaciers suggests that water is stored subglacially beneath the warm-based core in early summer and then released as the water penetrates the cold-based margin.

Reviewing several studies of glacier water storage, Willis *et al.* (1993) suggested that there may be two main controls on seasonal patterns of water storage and release depending on the relative importance of snow/firn storage verses englacial/subglacial storage. On Midtdalsbreen, and possibly Storglaciären, most storage was in snow/firn, and release from storage tended to occur in response to declining water inputs. By contrast, on South Cascade Glacier and possibly Mikkaglaciären, significant storage occurred in englacial/subglacial locations, and the seasonal evolution of the glacier's drainage system dominated the pattern of water release. Recent work at Haut Glacier d'Arolla and Unteraargletscher suggests that they too fit into this latter category. Recent work on Arctic glaciers suggests that two more categories may be needed. On cold glaciers (e.g. Scott Turnerbreen), the release of water may occur relatively early in the melt season because of the depletion of the supraglacial snowpack and the water it contains. The release of water from mainly cold-based polythermal glaciers (e.g. Midre Lovénbreen and John Evans Glacier) may be driven largely by the timing of the breakthrough of subglacially stored water through the cold margin.

FLOODS IN GLACIERIZED BASINS

Floods are a common feature of many glacierized basins and a major natural hazard responsible for damage to human structures and loss of human life (Tufnell, 1984). A rare type of flood occurs when volcanic eruptions beneath or adjacent to glaciers produce hot gases, ash, or lava, causing exceptionally rapid melting and generating large volumes of water that immediately produce runoff (Trabant *et al.*, 1994; Smellie, 2002). For example, severe flooding in the proglacial stream of Drift Glacier, Alaska occurred when the 1989–1990 eruption of Redoubt Volcano melted over $100 \times 10^6\,m^3$ of snow and ice on the glacier, and a further $\sim 35 \times 10^6\,m^3$ of snow in the valley downstream (Trabant *et al.*, 1994). The absence of high-water marks in depressions and of ice-collapse features in the glacier showed that the melted water ran off immediately and was not stored in lakes.

A more common type of flood arises from the sudden drainage of lakes. The "catastrophic" floods produced by lake drainage are usually referred to by the Icelandic term jökulhlaups, although they are also known as débâcles in parts of Europe, aluviones in South America and chhugyümha in Nepal (Tweed and Russell, 1999). The most common types of lake producing jökulhlaups are either ice-dammed (subglacial or ice-marginal) or moraine-dammed (usually proglacial).

A final type of flood, usually smaller than those mentioned above, can be triggered by high meteorologically driven melt rates, rainfall, or the release of water stored in a glacier's englacial/subglacial drainage system.

Ice-dammed Subglacial Lakes

The most dramatic and best-documented subglacial lake floods involve the sudden drainage of lakes beneath the Icelandic ice caps of Vatnajökull (Thorarinsson, 1953; Björnsson, 1974, 1975, 1992, 1997; Guðmundsson *et al.*, 1995, 1997; Snorrason *et al.*, 1997; Roberts *et al.*, 2000, 2001) and Myrdalsjökull (Thorarinsson, 1957; Tómasson, 1996; Sigurðsson, 1999; Björnsson *et al.*, 2000; Roberts *et al.*, 2002, 2003). The elevated geothermal heat fluxes in the Grimsvötn and Katla calderas and occasional volcanic eruptions produce high subglacial melt rates. Hydraulic potential gradients cause water to collect in large subglacial lakes known as *cupolas*. A surface depression often forms over the cupolas, causing supraglacial meltwater to collect there too. Jökulhlaups associated with the drainage of Grimsvötn are particularly well studied. Water from the cupola drains beneath Skeiðarárjökull, an outlet glacier on the south side of Vatnajökull, every 6 years or so,

releasing up to 4.5 km^3 of water at maximum discharges of up to 50 000 $m^3 s^{-1}$ (Guðmundsson *et al.*, 1995). Less predictable floods are produced during times of particularly intense volcanic activity such as the fissure eruption in 1996 at Gjalp, just north of Grimsvötn (Snorrason *et al.*, 1997). Flood volumes and maximum discharges tended to decrease during the twentieth century because of declining geothermal and volcanic activity (Guðmundsson *et al.*, 1995), although such activity has been increasing recently and so jökulhlaups may become bigger once again (Björnsson, 1997).

Subglacial lakes are traditionally assumed to drain through a single subglacial conduit that exits the glacier terminus. According to the most widely cited model (Clarke, 1982; based on earlier work by Spring and Hutter (1981) and Nye (1976)), rising lake levels cause water pressures to approach ice overburden (~91% of ice depth), allowing the ice dam to be breached. Once water starts to leak through the dam, the advection of heat from the lake water and the dissipation of potential energy allow a conduit to develop. Initially, rapid melting causes the conduit to enlarge, allowing more water to escape by a positive feedback process. As the lake level drops, the conduit effective pressure (ice overburden minus water pressure) declines. Conduit closure due to ice creep exceeds enlargement due to melting, and eventually the conduit closes, the ice dam is reestablished, and the flood stops.

A limitation of the model is that subglacial lake drainage often starts before water levels reach ice overburden pressure at the dam. Grimsvötn floods usually start when lake levels are 20–50 m less than ice overburden pressures (Björnsson, 1992), although the 1996 jökulhlaup was one of the few triggered at ice overburden pressures (Björnsson, 2003). Several explanations have been advanced:

- Crevasses reduce the ice density above the dam (Thorarinsson, 1939).
- Drainage occurs through hydrofractures created in the ice above the dam (Glen, 1954; Higgins, 1970).
- Ice flexure means ice acts like a cantilever over the dam (Nye, 1976).
- A conduit always links the lake to the subglacial drainage system below the lake, but hydraulic gradients route water to the lake at low lake levels. Once the lake level is high enough and if the pressure drops low enough in the drainage system below the lake, a siphoning mechanism pulls water out of lake, although this mechanism can only pull ~10 m of water (Whalley, 1971; Fisher, 1973; Knudsen and Theakstone, 1988; Knight and Russell, 1993; Schöner and Schöner, 1997).
- Subglacial drainage below the dam switches from flow through sediment pores to flow in a broad low conduit (canal) as the lake level rises; this happens at a level less than the ice overburden pressure (Fowler and Ng, 1996).
- The pressure at which the dam breaks depends on the hydraulic gradient at the caldera rim and the speed at which the lake level rises (Fowler, 1999). A conduit always links the lake to the subglacial drainage system below the lake. At low lake levels, the dam occurs along the conduit some distance below the caldera rim and the hydraulic gradient routes water upglacier from the dam to the lake. As the lake level rises, the dam migrates upglacier toward the lake. If the lake level rises slowly (weeks–months) and if the dam is "strong" (large hydraulic gradient at rim), the lake level reaches ice overburden before the dam reaches the lake, and a flood is initiated due to flotation. If the lake level rises slowly but the dam is "weak" (small hydraulic gradient at rim), then the dam reaches the lake while the lake level is still below ice overburden, and a flood is initiated by conduit enlargement at the dam. Finally, if the lake level rises quickly (days–weeks), the dam migrates upglacier more slowly, so overburden pressures are more likely to be reached before a flood is initiated.

Hydrographs of Subglacial Lake Drainage Floods

According to Clarke's (1982) model, the flood hydrograph shape and its peak magnitude and timing are determined by three factors: (i) the temperature, volume, and hypsometry of the lake; (ii) the ice overburden pressure where the lake meets the dam/conduit; and (iii) the roughness and hydraulic gradient of the conduit. Largest peaks occur when the lake temperature is high, channel enlargement is dominated by the lake's thermal energy, and frictional dissipation is small. Floods draining through a subglacial conduit should have hydrographs with a long gentle rising limb (as the conduit gradually enlarges) and a steep abrupt falling limb (as the conduit closes or the lake is emptied). These characteristics match many observed flood hydrographs (Thorarinsson, 1957; Whalley, 1971; Mathews, 1973; Mottershead, 1975; Theakstone, 1978; Clarke and Waldron, 1984; Sugden *et al.*, 1985; Russell, 1989; Björnsson, 1992) (Figure 9a).

However, some jökulhlaup hydrographs are very different in shape and peak magnitude and timing from the predicted ones. Recent observations in Iceland provide a possible explanation. Björnsson (1998) compared jökulhlaup hydrographs before, during, and after the 1991 Skeiðarárjökull surge. After the surge, the hydrograph showed a gradual rise to a peak discharge of ~2000 $m^3 s^{-1}$ and a rapid decline, matching the pattern of lake water outflow calculated from measurements of ice subsidence above it (Figure 10a). During the surge, however, the hydrograph showed a gradual rise to a peak discharge of just ~300 $m^3 s^{-1}$, and a very gradual decline (Figure 10b). It did not match the pattern of lake outflow, and it involved the subglacial storage and release of up to ~200 $\times 10^6$ m^3 of water as it travelled toward the terminus (Figure 10b).

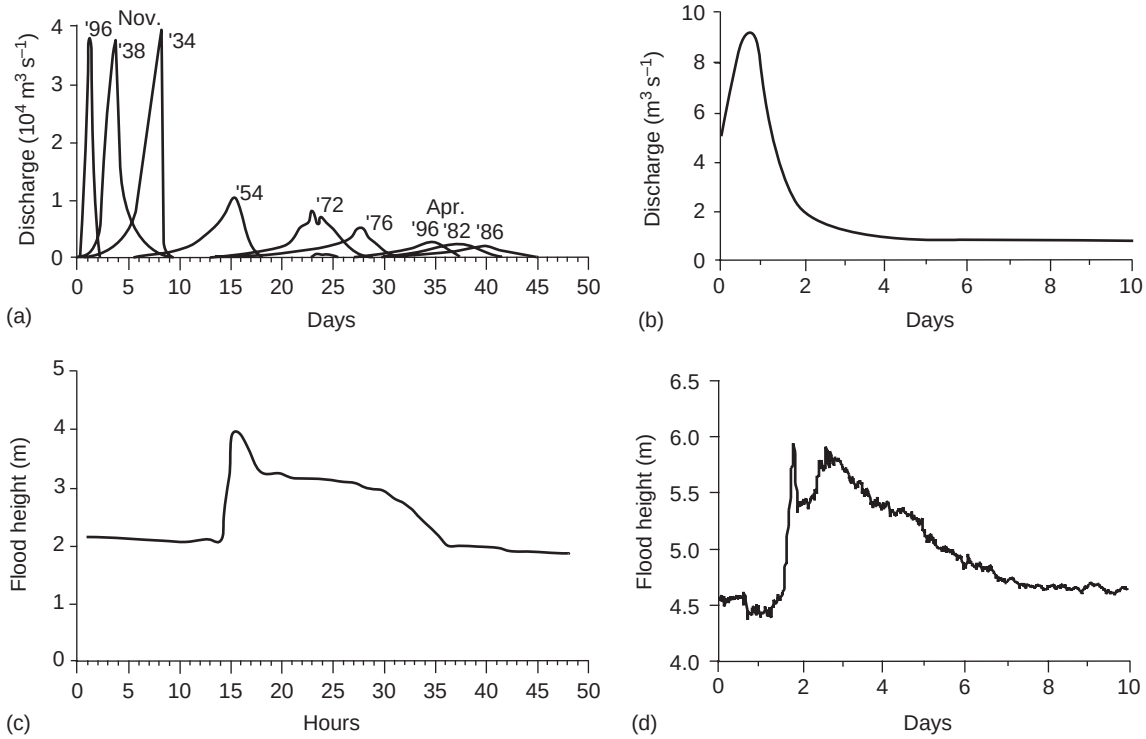

Figure 9 Hydrographs of floods from (a) Grímsvötn, Vatnajökull, Iceland in 1934, 1938, 1954, 1972, 1976, 1982, 1986 and 1996 (from Björnsson, 2003); (b) Aurora Lake, Black Rapids Glacier, Alaska in June 1993 (from Raymond and Nolan, 2000); (c) Luggye Tsho, Bhutan in October 1994 (from Richardson and Reynolds, 2000a); d) Franz Josef Glacier, New Zealand in February 2003 (from Goodsell *et al.*, 2005). All hydrographs are measured except for (b) which is modeled to fit daily measurements

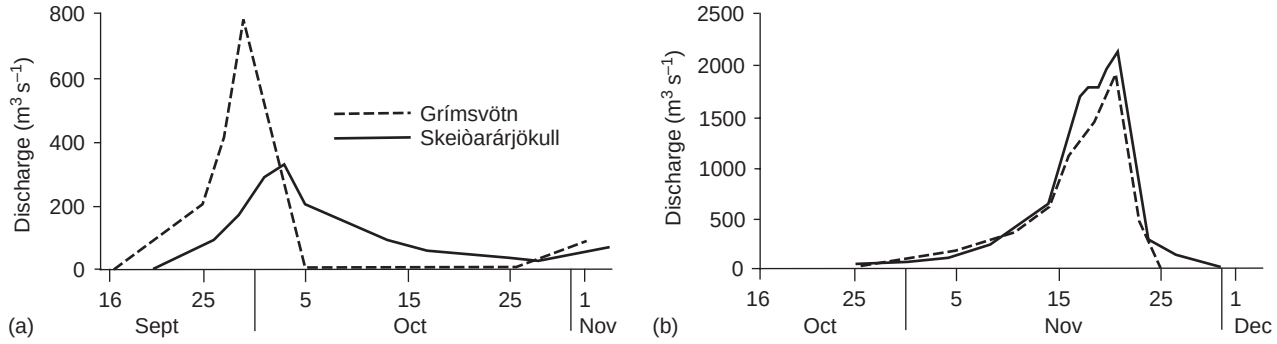

Figure 10 Drainage of outburst flood water from Grimsvotn and Skeiðarárjökull (a) during and (b) after the 1991 surge of Skeiðarárjökull (after Björnsson, 1998)

Since surging of at least some glaciers is associated with distributed linked cavity drainage (Kamb *et al.*, 1985), Björnsson (1998) concluded that the flood during the surge was routed through linked cavities, not a single conduit.

Recent observations during and after jökulhlaups at both Skeiðarárjökull and Sólheimajökull suggest that distributed drainage may occur beneath glaciers that are not surging, at least around glacier margins (Roberts *et al.*, 2000). Floodwater is partially evacuated from numerous ice-marginal and supraglacial outlets that change position over time, indicating hydraulic jacking and ice fracturing as subglacial water pressures vastly exceed ice overburden pressures. Thus, floodwater is distributed widely over the bed, as subglacial drainage pathways enlarge mechanically and not just thermally. Water may also be stored and released in locations other than subglacial cavities during flooding. During the 1999 Sólheimajökull jökulhlaup, subglacial water purged to ice-marginal locations and "retro-filled"

relict ice-dammed lake basins, before draining back into the glacier (Roberts *et al.*, 2003).

Flowers and others (2004) have developed a new model that accounts for some of the discrepancies between some observed jökulhlaups and calculations made with the original Clarke (1982) model. Floodwater initially propagates as a turbulent subglacial sheet, which feeds an enlarging system of conduits. The model was compared with the observed flood hydrograph in Skeiðarárjökull associated with the 1996 Gjalp eruption (Figure 9a). It successfully accounts for the ~10.5-h lag between lake drainage onset and the flood water arrival at the terminus, the lag between maximum rate of lake drainage and maximum stream discharge, and the high subglacial water pressures in the early stages of the flood.

Ice-dammed Marginal Lakes

Ice-marginal lake floods are widely reported in the literature (Thorarinsson, 1939; Liestøl, 1956, 1977; Stone, 1963; Maag, 1969; Björnsson, 1976; Young, 1980; Hewitt, 1982; Dawson, 1983; Clement, 1984; Sturm and Benson, 1985; Sugden *et al.*, 1985; Hagen, 1987; Desloges *et al.*, 1989; Mayo, 1989; Russell, 1989; Liu, 1992; Zhang, 1992; Del Valle *et al.*, 1995). Ice-marginal lakes form in three locations: (i) where a trunk valley glacier blocks the drainage of a glacier-free side valley; (ii) where a side-valley glacier extends across a glacier-free trunk valley; and (iii) at the confluence of two valley glaciers (Benn and Evans, 1998). They are especially common next to cold or mainly cold polythermal glaciers, where ice is frozen to its bed and water cannot drain englacially/subglacially.

Ice-marginal lakes are traditionally assumed to drain through either a subglacial conduit (see the earlier section) or a subaerial breach between the glacier and the valley side. It was originally thought that subaerial breach drainage would be uncommon since flotation and subglacial drainage would occur before lake levels reached the height of the glacier surface to initiate a breach (Miller, 1952; Liestøl, 1956). However, subaerial breach drainage is now recognized as an important mechanism for lakes next to cold or mainly cold polythermal glaciers where ice is frozen to the bed and flotation is more difficult (Howarth, 1968; Maag, 1969; Costa and Schuster, 1988). It may also be important on glaciers with high debris contents, as this will also make flotation more difficult (Tweed and Russell, 1999). Drainage may begin in a valley-side conduit where ice is thin, but a subaerial breach may develop subsequently if the conduit roof collapses or is melted completely by flowing water (Fountain and Walder, 1998).

Hydrographs of Ice-marginal Lake Drainage Floods

Walder and Costa (1996) produced a model for breach drainage outburst floods, assuming that channel widening occurs by sideward ice melting (ignoring the possible role of ice calving) and ignoring the negligible role of ice creep on channel closure. Like Clarke's (1982) model for subglacial conduit drainage (see the earlier section), the flood hydrograph shape depends mainly on the temperature, volume, and hypsometry of the lake and the roughness and hydraulic gradient of the channel. Again, like Clarke's (1982) model, largest peaks result when the lake temperature is high, channel enlargement is dominated by the lake's thermal energy, and frictional dissipation is small.

Raymond and Nolan (2000) described the drainage of an ice-marginal lake at Black Rapids Glacier, Alaska, that drained across the surface of the glacier through a supraglacial ice spillway. Their spillway drainage model accounts for spillway lowering by ice melt. A jökulhlaup (rapid unstable discharge) occurs if the spillway elevation melts down faster than the lake level falls, otherwise stable discharge occurs. According to the model, a jökulhlaup occurs when the lake area exceeds some critical value, governed by the lake temperature and the slope and width of the spillway as it leaves the lake. For typical spillway slopes of ~0.1 and widths of ~3 m, a lake area of $>1\,\mathrm{km}^2$ is required to initiate a jökulhlaup if lake temperatures are 0 °C. If temperatures are slightly higher than 0 °C, a jökulhlaup can occur for much smaller lake areas.

Floods along ice-marginal channels or supraglacial spillways typically possess a more symmetrical steep rise to and fall from peak than subglacial conduit floods. They tend to last just a few minutes to hours, but may last days if the lake volume is large (Thorarinsson, 1939; Haeberli, 1983; Dawson, 1983; Raymond and Nolan, 2000) (Figure 9b).

Moraine-dammed Lakes

The drainage of moraine-dammed proglacial lakes has been widely reported in the literature (Lliboutry *et al.*, 1977; Haeberli, 1983; Buchroithner *et al.*, 1982; Hewitt, 1982; Clague *et al.*, 1985; Fushimi *et al.*, 1985; Ives, 1986; Vuichard and Zimmermann, 1986, 1987; Carling and Glaister, 1987; Costa, 1988; Costa and Schuster, 1988; Clague and Evans, 1994, 2000; Ding and Liu, 1992; Yongjian and Jingshi, 1992; Mathews and Clague, 1993; O'Connor and Costa, 1993; Yamada and Sharma, 1993; Mool, 1995; Popov, 1997; Reynolds, 1998; Yamada, 1998; Cenderelli, 2000; Richardson and Reynolds, 2000a; Cenderelli and Wohl, 2001, 2003; Haeberli *et al.*, 2001; Huggel *et al.*, 2002). Such lakes form where a glacier terminates on ground that slopes back toward the glacier. A typical situation is where retreat of a glacier allows a lake to form behind a terminal moraine.

Proglacial lakes may drain catastrophically through a subglacial conduit or subaerial breach next to the glacier, in which case they behave like ice-marginal lakes described previously. However, floods from proglacial lakes usually

occur through the moraine dam. This may involve progressive groundwater flow and piping through the dam leading to simple mechanical failure, but it often involves the melting of ice if the moraine is ice cored (Buchroithner *et al.*, 1982; Fushimi *et al.*, 1985; Richardson and Reynolds, 2000b). One of the most common triggering mechanisms involves lake water overtopping part of the dam, initiating rapid and accelerating incision. This may be caused by catastrophic drainage into the lake from ice-marginal or subglacial sources upglacier, by rapid glacier advance, or by large waves caused by glacier calving or snow, ice, or rock avalanching (Lliboutry *et al.*, 1977; Grabs and Hanisch, 1993; Ives, 1986; Vuichard and Zimmermann, 1986, 1987; Clague and Evans, 1994).

Hydrographs of Moraine-dammed Lake Drainage Floods

There are virtually no recorded hydrographs associated with moraine-dammed lake floods. An exception is the flood from Luggye Tsho, Bhutan, in 1994, for which a complete stage hydrograph measured ~100 km downstream is available (Richardson and Reynolds, 2000a) (Figure 9c). It shows a rapid one-hour rise to peak stage, followed by a moderate fall and then a more gradual fall. The entire flood lasted ~22 h. Another fairly well-documented moraine-dammed lake flood occurred in 1985, when the terminus of Langmoche Glacier, Nepal, collapsed into a proglacial lake. A wave travelled along the lake, and overtopped the moraine dam, initiating dam erosion and ultimately failure. The initial flood discharge was ~2000 $m^3 s^{-1}$, with an average discharge of ~500 $m^3 s^{-1}$ over 4 h, draining a total volume of ~6–10 $\times 10^6$ m^3 of water (Vuichard and Zimmermann, 1986, 1987). This 1985 flood was not the first from the lake. Cenderelli and Wohl (2001) used a step-backwater model together with geomorphic evidence downstream of the Langmoche Glacier to estimate the seasonal peak discharges associated with rainfall and snow and ice melt, and those associated with the repeated lake drainage. Peak discharges from rainfall and melt ranged from 7 to 205 $m^3 s^{-1}$; those from the proglacial lake floods were up to 60 times greater and ranged between 400 and 2350 $m^3 s^{-1}$.

Because of their damage potential, mitigation schemes have been introduced at some lakes known to be prone to such floods in an attempt to keep lake levels below critical thresholds (e.g. Grabs and Hanisch, 1993; Ames, 1998; Reynolds, 1998; Reynolds *et al.*, 1998; Haeberli *et al.*, 2001).

Drainage from the Englacial/Subglacial Drainage System

Although the most dramatic outburst floods are caused by catastrophic drainage of subglacial, ice-marginal, or proglacial lakes, floods can also be caused by the release of water stored in the englacial/subglacial drainage system and are often associated with high melt rates and/or rainstorms. Such floods have been described from both temperate and mainly cold polythermal glaciers.

Temperate Glaciers

On temperate glaciers, floods are most prevalent in spring, shortly after melt onset (Beecroft, 1983; Haeberli, 1983; Driedger and Fountain, 1989; Warburton and Fenn, 1994; Walder and Driedger, 1995; Barrett and Collins, 1997; Collins, 1998; Anderson *et al.*, 1999; Schuler *et al.*, 2002). If the water is stored englacially, the release mechanism may involve the forced connection of isolated englacial voids, pipes, and conduits to the subglacial drainage system (Fountain and Walder, 1998). However, there is strong evidence to suggest that at least some of the water is stored subglacially and that its release involves the rapid conversion of a distributed subglacial drainage system with low transmissivity and high storage potential to a channelized system that transmits water more rapidly and stores less water.

Rapid surface water inputs cause high subglacial water pressures, initiate instabilities at the glacier bed, and lead to a reorganization of the subglacial drainage system (Stone and Clarke, 1996; Barrett and Collins, 1997; Gordon *et al.*, 1998; Kavanaugh and Clarke, 2001). The conversion may involve the unstable enlargement of links between basal cavities through melting (Walder and Driedger, 1995; Nienow *et al.*, 1998), a mechanism initially advocated to explain the termination of some glacier surges (Kamb, 1987). However, many spring floods are also associated with increases in glacier surface velocities, surface uplift, reductions in basal drag, increases in basal sliding and the evacuation of subglacial sediment (Collins, 1989; Iken *et al.*, 1983; Hooke *et al.*, 1989; Anderson *et al.*, 1999; Mair *et al.*, 2001, 2002, 2003; Swift *et al.*, 2002). Taken together, these phenomena are referred to as *spring events* (Röthlisberger and Lang, 1987). Thus, conversion from distributed to channelized drainage must also involve mechanical enlargement of cavities through hydraulic jacking (Röthlisberger and Iken, 1981), in addition to thermal enlargement of the links between them.

Several mechanisms appear to explain a series of rainfall-induced floods observed at Franz Josef Glacier, New Zealand since the 1920s (Davies *et al.*, 2003; Goodsell *et al.*, 2003, 2005). There appear to be four distinct types of flood, which are not restricted to the spring and early summer. The first three occur at or near the glacier snout and involve the blockage of a main subglacial conduit by coarse sediment (Davies *et al.*, 2003). Depending on the conduit gradient, water discharge, and sediment characteristics, this may lead to (i) overflow of water in ice-marginal moulins and then along ice-marginal channels; (ii) the bursting of water from the glacier portal as the blockage is removed;

(iii) widespread uplift of the glacier margin and the discharge of water along the width of the terminus. The fourth type of flood involves the blockage of a subglacial conduit by ice at the base of an icefall near the centerline of the glacier ~2 km from the terminus (Goodsell *et al.*, 2003). Water is forced to flow supraglacially and then ice-marginally to the glacier snout. The first three flood types may be more common when the glacier is in an advanced or advancing position since this would promote the blockage of subglacial conduits near the glacier snout (Davies *et al.*, 2003). The flood described by Goodsell *et al.* (2003, 2005) occurred while the glacier was retreating, and this flood type may be favored by glacier recession, which might promote ice collapse around the icefall.

Very few floods associated with drainage from englacial/subglacial stores have been documented. Those that have suggest hydrographs can be highly variable. The flood from Bas Glacier d'Arolla, Switzerland, was symmetrical and lasted 2 days (Warburton and Fenn, 1994). The flood from Bench Glacier, Alaska, involved a ramped increase in flow with a declining limb lasting several days with erratic short-term pulses of very high flow superimposed on top (Anderson *et al.*, 1999). The hydrographs associated with the fourth flood type at Franz Josef Glacier also had a very rapid rise to peak within a few hours, followed by a more gradual decline lasting several days (Goodsell *et al.*, 2005) (Figure 9d).

Polythermal Glaciers

Small floods associated with drainage from the englacial/subglacial drainage system appear to be a common feature of mainly cold polythermal glaciers that have a warm-based core and cold-based margins (Baranowski, 1973; Skidmore and Sharp, 1999; Hodson and Ferguson, 1999; Wadham *et al.*, 2001; Rippin *et al.*, 2003). Water is trapped beneath the warm-based core by the "thermal dam" at the boundary with the cold-based margin. Once pressures reach some critical level behind the thermal dam, water escapes from beneath the cold-based margin producing small floods associated with supraglacial geyser-like spouts (Baranowski, 1973; Skidmore and Sharp, 1999), proglacial upwellings (Skidmore and Sharp, 1999; Hodson and Ferguson, 1999; Rippin *et al.*, 2003), or enhanced flow in ice-marginal streams (Wadham *et al.*, 2001). The precise mechanisms whereby water escapes through the margin are not known, but possibilities include flow through fissures within the sediments beneath the permafrost, through hydrofractures in the basal ice, or by hydraulic jacking between the basal ice and frozen sediments (Rippin *et al.*, 2003).

On John Evans Glacier, burst-through events occur in late June/early July and are initiated when supraglacial streams connect to moulins located in a major crevasse field ~4 km from the glacier terminus (Boon *et al.*, 2003; Copland *et al.*, 2003). This allows water to drain from the surface to the bed, and the burst-through event usually starts within 24 h of the moulins opening. Initially, outflow consists of highly solute-rich waters that have likely been stored subglacially over winter, but solute concentrations drop rapidly within 3 to 4 days as these "old" waters are diluted by the new season's melt (Skidmore and Sharp, 1999). In the relatively warm summers of 1998–2000, subglacial outflow was continuous once initiated, similar to the situation that has been observed on other mainly cold polythermal glaciers (Hodson and Ferguson, 1999; Rippin *et al.*, 2003). However, during the cooler summers of 1994 and 1996, subglacial outflow occurred as a series of floods, with the subglacial drainage system closing down in intervening periods (Skidmore and Sharp, 1999; Boon *et al.*, 2003). Wadham *et al.* (2001) report similar findings from Finsterwalderbreen, Svalbard. Floods were observed in mid-August 1995 and mid-July 1999, once the snowline had retreated, allowing surface meltwaters to reach a subglacial reservoir beneath the upper glacier. The chemistry of the floodwaters suggested that they consist mainly of subglacially stored snowmelt. The floodwaters were routed to an existing ice-marginal stream rather than an existing proglacial upwelling, and there was no evidence for supraglacial fountains.

CONCLUSIONS

Summary

The presence of snow and ice, and the lack of vegetation and soil make the hydrology of glacierized basins very different to that of equivalent nonglacierized basins. These differences have important implications for the runoff regime, water storage and release, and incidence of flooding in glacierized catchments.

Many studies have shown how regional and local climates control individual glacier mass (water) balance. Studies are starting to identify how regional and local climate influence year-to-year variations in runoff from glacierized catchments. Interannual runoff variability depends on the sensitivity of catchments to different climatic variables, particularly air temperature and rainfall. This sensitivity partly depends on the percentage glacier cover. Interannual runoff variability depends on the seasonality and magnitude of climate variability. Finally, the nature of interannual runoff variability may change over the long-term in response to changes in snow, firn, and ice extent.

Regional and local climate affect season-to-season variations in runoff from glacierized catchments with big differences between catchments in mid-, high, and low latitudes. Glaciers in midlatitudes have pronounced accumulation and ablation seasons with low runoff in the winter and high runoff in the summer. Glaciers in high latitudes also have pronounced accumulation and ablation seasons, but

have shorter ablation seasons with high summer runoff in maritime areas and low summer runoff in continental regions. Low latitude glaciers usually have accumulation and ablation that are distributed more evenly throughout the year and show less marked runoff variability between the seasons.

There are also significant differences in the behavior of glaciers in mid-, high, and low latitudes in terms of their runoff regime during the spring and summer. Temperate glaciers in mid-latitudes show marked changes in the magnitude and shape of diurnal hydrographs over spring and summer in response to seasonal changes in meltwater production, snowpack cover and supraglacial, englacial, and subglacial routing. Cold and mainly cold polythermal glaciers in high latitudes show less marked diurnal hydrograph changes due to lower melt rates and fewer changes in glacial routing. Similarly, temperate glaciers in low latitudes also appear to undergo fewer changes in meltwater production due to the occurrence of both snowfall and melting throughout the year, maintaining a relatively stable englacial and subglacial drainage system.

Glaciers in mid- and high latitudes store and release water on a seasonal basis. Water is stored in snow, firn, and within the englacial and subglacial drainage system. Temperate glaciers that develop a hydraulically efficient subglacial drainage system store water in the spring and early summer and release it as the snow melts and the subglacial drainage system develops during the summer. Those with a less well-developed subglacial drainage system store and release water in response to weather-related inputs. Mainly cold polythermal glaciers store water in spring and early summer. This water may be released dramatically in the form of ice-marginal fountains or pressurized proglacial upwellings as the water is forced from the warm- based core through the cold-based terminus. Cold glaciers have little capacity for storing water, but store water in the snowpack in spring, release it relatively quickly in early summer as the snow melts, and may store water in ice-marginal channels during mid- to late summer.

Floods are prevalent in glacierized catchments. Most large floods result from the catastrophic drainage of ice-dammed subglacial or ice-marginal lakes, or moraine-dammed proglacial lakes. Smaller floods can occur in response to rapid surface melting or rainstorms, and may be associated with the release of water stored in the englacial / subglacial drainage system.

Effects of Future Climate Change

Global climate change has the potential to alter the hydrology of glacierized basins in major ways. The effect of global climate change on glacier mass balance is difficult to quantify. Most estimates involve sensitivity tests of local glacier mass balance models to uniform changes in air temperature and precipitation. But global climate change may have more subtle effects on regional and local climate through, for example, changes in the timing and intensity of weather systems. Glaciers may be more sensitive to these changes than to a uniform increase in annual air temperature or decrease in annual precipitation. It is also, important to recognize the different mass balance regimes discussed by Ageta and Higuchi (1984). As a rise in temperature will decrease the amount of precipitation falling as snow, midlatitude glaciers will be more sensitive to temperature increases in the winter months (Oerlemans, 1993), whereas low latitude glaciers may be more sensitive to changes in summer months (Ageta and Kadota, 1992). Similarly, low latitude glaciers may be more sensitive to changes in humidity than midlatitude glaciers, especially during dry winter months, since humidity controls the partitioning between sublimation and melting.

The effect of climate change on runoff from glacierized basins is even more difficult to quantify. Annual or melt-season runoff may either increase or decrease in the short-term (years) depending on the magnitude and timing of climate change, particularly air temperature and rainfall, and the effects this has on patterns of snow accumulation and snow and ice melt. In the longer term (decades), the effects of changes in glacier geometry will play an increasingly important role. There are very few modeling studies that have tried to quantify the effects of climate change on glacierized basin river flow. Singh and Kumar (1997) used the UBC watershed model to examine the effects of air temperature and precipitation changes on snowmelt runoff, glacier melt runoff, and total stream runoff in the 2.5% glacierized Spiti River catchment, western Himalayas. Annual snowmelt, glacier melt, and total runoff increased linearly with increases in temperature between 1 °C and 3 °C, but the effects were greatest on glacier melt runoff. For example, a temperature increase of 2 °C increased annual snowmelt, glacier melt, and total runoff by an average of 12%, 35%, and 9% respectively. Changes in precipitation produced linear changes in runoff, but the relationships were direct for snowmelt and total runoff, but inverse for glacier melt runoff. Braun *et al.* (2000) modeled the effects of declining glacier cover on the runoff from Alpine basins. Larger discharge peaks will occur when higher melt rates coincide with more intense rainstorms. Boon *et al.* (2003) discuss how global climate change may increase the incidence of synoptic conditions favorable to extreme melt events, which will increase the incidence of flooding in Arctic streams, particularly if they occur during late summer.

Climate change may also alter the patterns of annual water storage and release, if the thickness and extent of the snowpack and firn layers change. Furthermore, increased melting and rainstorms may encourage the development of hydraulically efficient englacial and subglacial drainage

pathways, which will also alter a glacier's water storage capacity. Finally, significant changes in water storage and release may occur in the Arctic if changes in climate and glacier geometry alter the distribution of cold and polythermal glaciers.

Floods associated with the drainage of ice-dammed or moraine-dammed lakes are likely to increase in number, frequency, and size at least in the short to medium term as glaciers retreat in response to climate change (Haeberli, 1983; Fujita *et al.*, 1997; Ageta *et al.*, 2000; Richardson and Reynolds, 2000a). However, many potentially hazardous lakes have not yet been identified as they are situated in remote locations. Thus, increased use is being made of remote sensing techniques to map the distribution of proglacial lakes so that their hazard potential can be identified. For example, Huggel *et al.* (2002) use a combination of satellite imagery to map lake areas, aerial photographs, and analytical photogrammetry to derive digital elevation models (DEMs), and empirical equations to derive lake volume and potential flood discharges, and run out distances. They applied their approach to modeling the 1993 flood associated with the drainage of Sirwolte Lake, Switzerland.

Acknowledgments

I thank Jean-Michel Bonvin, Grande Dixence SA, Switzerland; Lars-Evan Pettersson, NVE, Norway; Andrew Fountain, Portland State University, USA; and Pierre Ribstein, Université Paris, France for the data shown in Figure 3. This paper was written while I was on sabbatical leave at the Department of Geography, University of Canterbury, New Zealand, and I thank the staff there, especially Wendy Lawson and Ian Owens, for their hospitality. Extra special thanks go to Ragazza Glaciale. The paper benefited from my useful discussions with Luke Copland and Becky Goodsell, the constructive reviews of two anonymous referees, and editorial help from Martin Sharp. Phil Stickler and Andy Fox helped produce the Figures.

169: Sediment and Solute Transport in Glacial Meltwater Streams

MARTYN TRANTER

Bristol Glaciology Centre, School of Geographical Sciences, University of Bristol, Bristol, UK

This review documents the suspended sediment and major ion concentrations of glacial runoff, with a view to understanding the controls on sediment and solute fluxes from glaciated catchments. The sediment yield from glaciated catchments (those with >30% glacial cover) is often an order of magnitude greater than those of similar, nonglaciated catchments. Remarkably, sediment yield from glacier basins scales with basin area, most likely as a consequence of thicker ice thicknesses and ice fluxes, which increase the rate of subglacial erosion. The rate of glacial erosion usually exceeds the rate of transport of material from the catchment, so that following deglaciation sediment yield remains high for periods of 10^3–10^5 years. The concentration of ions in glacial runoff is typically less than that of temperate river waters, yet the solute yield from glaciated catchments is similar to that of temperate catchments when scaled by specific runoff. Glaciers are particularly efficient in dissolving carbonates, sulfides, fluid inclusions, and the surfaces of silicate minerals. This is a consequence of the production of fine-grained, geochemically reactive sediments in subglacial environments and the high water flux through many glaciated catchments. Subglacial chemical weathering is microbially mediated. Hence, glacier beds act as refugia for microbial life, which spans the range from fully oxic to fully anoxic conditions.

INTRODUCTION

Glaciers are the largest freshwater reservoir on earth (Knight, 1999), containing some $28 \times 10^6\,km^3$ of water (Table 1), and are acknowledged as powerful agents of physical erosion (Paterson, 1994; Hallet *et al.*, 1996). It is known that globally significant volumes of sediment are transferred by glacial runoff into the oceans (Syvitski *et al.*, 1987; Jones *et al.*, 2002), although the annual runoff of glacial meltwaters to the oceans is poorly known, particularly the contribution made by valley glaciers. Similarly, glacial chemical erosion is also poorly documented (Sharp *et al.*, 1995; Anderson *et al.*, 1997), but is of less significance to global cycles than the products of physical erosion. Globally significant quantities of solute may be transported by glacial runoff only during relatively brief periods ($\sim 10^2$ years) during deglaciation (Tranter *et al.*, 2002a). This review expands on these statements, commencing with a discussion of the annual runoff of glaciers, since this has a first-order control on the quantity of both the sediment and the solute that is exported from glaciated catchments. Summary of current physical and chemical erosion rates in glacial catchments (*see* **Chapter 168, Hydrology of Glacierized Basins, Volume 4**) follows, together with a discussion of the principal controls on these values. This review concludes with an assessment of the role of glaciers in global sediment and chemical cycles, and how chemical and physical erosion by glaciers impacts on certain types of ecosystems.

GLACIER HYDROLOGY, HYDROGRAPHS, FLUXES, AND SPECIFIC RUNOFF

Interest in the magnitude, duration, and variability of glacier runoff arose for two main reasons. First, glacial runoff is an important source of water to a variety of environments and anthropogenic activities (Röthlisberger and Lang, 1987; Fountain and Walder, 1998), and second, there is an intrinsic link between glacier hydrology and glacier dynamics (Copland *et al.*, 2003; Mair *et al.*, 2003; Paterson, 1994). For example, water derived from glaciers is used for agricultural irrigation (e.g. in NW China; Liu *et al.*, 1999), is fundamental to the longevity of certain

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Table 1 Volumes of terrestrial ice contained in ice sheets and other ice masses (after Knight, 1999)

Region	Current volume (10^6 km^3)	Volume at LGM (10^6 km^3)
Antarctica	26	26
Greenland	2.6	3.5
Laurentide	–	30
Cordilleran	–	3.6
Scandinavian	–	13
Other ice masses	0.2	1.1
Total	28.4	77.2

semiarid and arid ecosystems (e.g. the polar deserts of the Dry Valleys, Antarctica; McKnight *et al.*, 1998, and is stored for hydroelectric power generation (e.g. in the European Alps; Knight, 1999). Glacial runoff may be an environmental hazard, since glaciers often flood with a range of timescales from hours to weeks (Björnsson, 1998; Knight, 1999). The magnitude of runoff can be very high. For example, jökulhaups from Vatnajökull, in SE Iceland, discharge up to 4 km^3 over 15 days, with a peak discharge of 10^4 m^3 s^{-1} (Rist, 1955; Drewry, 1986), and during deglaciation in North America, a super flood from glacial Lake Agassiz is believed to have discharged 23 000 km^3 via the St Lawrence at 11 000 BP, and 75–150 000 km^3 via the Hudson Strait, contributing 6.4 and 19–42 cm equivalent sea level rise respectively (Dyke and Prest, 1987; Dawson, 1992).

Most of the work on the hydrology of glaciers has been conducted on smaller valley glaciers rather than ice sheets because of logistical and technical constraints. For example, the peak discharge from many outlet glaciers on the Greenland Ice Sheet may be of the order of 10^2–10^3 m^3 s^{-1}, and many discharge directly into coastal waters. Any attempt to construct an annual hydrograph from these outlet glaciers will be both expensive and reliant on specialist technology. By contrast, it is a more practical challenge to monitor small valley glaciers with peak discharges of the order of 10 m^3 s^{-1}. Figure 1 shows that the hydrographs of glaciers in the Alps, the High Arctic and Greenland exhibit characteristic midablation season peaks, when the receipt of solar radiation is greatest and the snow line is at its highest. Ice has a lower albedo than snow, and so there is more melt per unit incoming solar radiation. An example of the classical hydrograph of an Alpine valley glacier is shown in Figure 1(a), where prominent diurnal variations in discharge during the ablation season are evident. Diurnal variations are less evident in the hydrograph of the valley glacier in the High Arctic (Figure 1b), where there is midnight sun during summer, and less diurnal variation in the receipt of solar radiation. The basic hydrograph shape is more sensitive to the passage of cold and warm air masses across the catchment (Hodson *et al.*, 1998a,b).

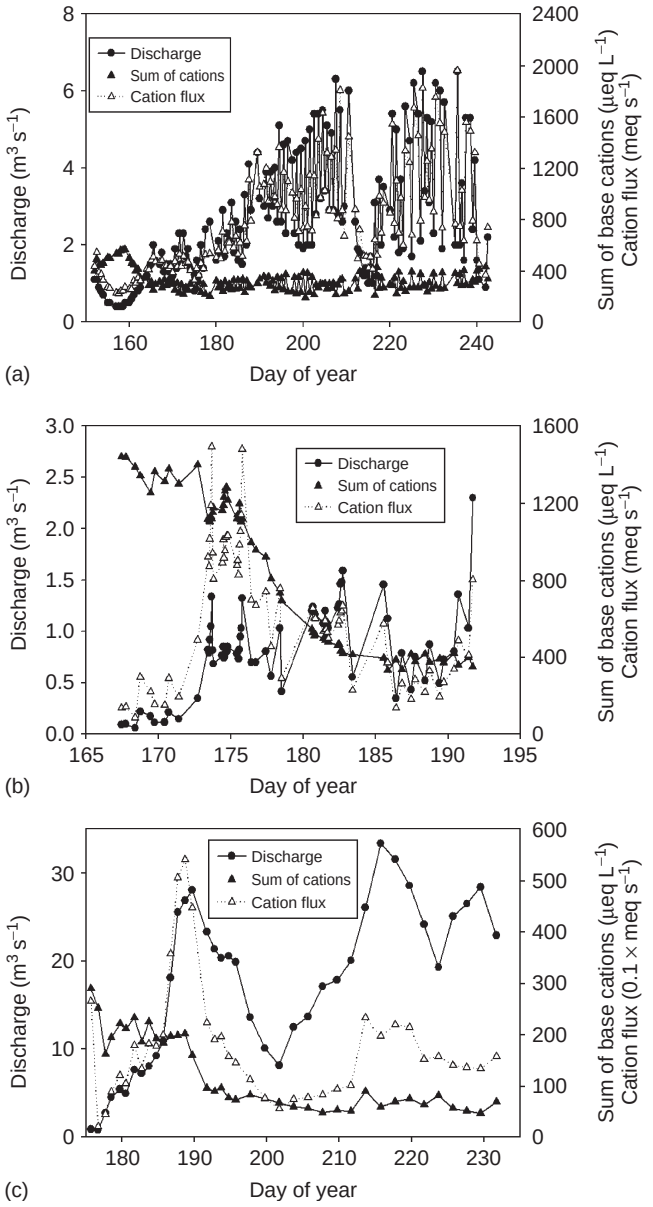

Figure 1 Hydrographs and time series of the sum of base cations and the cation flux for three glaciers with different thermal regime. (a) Haut Glacier d'Arolla, a small warm-based, valley glacier in the Swiss Alps (Brown *et al.*, 1993). Data are for 1989. (b) Scott Turnerbreen, a small, cold-based valley glacier on Svalbard (Hodgkins *et al.*, 1997). Data are for 1993, and only cover the early part of the ablation season. (c) Manitsoq Glacier, a small, polythermal-based outlet glacier to the SW of the Greenland Ice Sheet (Skidmore *et al.*, in press). Data are for 1999

The hydrograph of the outlet glacier from the Greenland Ice Sheet (Figure 1c) is dominated by an early season flood of basally stored water and the midablation season high. The large size of the potential drainage system,

which can extend back some 50 km from the ice margin, mitigates against large diurnal variations in discharge. It is evident from Figure 1 that glacial runoff exhibits considerable variation on intra-annual timescales. There may be considerable inter-annual variations also, arising from factors such as climate, precipitation regime, and glacier dynamics (Drewry, 1986).

Hydrographs for small valley glaciers are often derived from water depth monitored by pressure transducers, which are sampled at a resolution of 15–30 min. By contrast, samples for the determination of suspended sediment and solute concentrations are often collected at much longer intervals (i.e. with poorer resolution). Annual sediment and solute budgets are therefore constructed from estimates of how sediment and solute concentrations map onto the hydrograph. For example, the annual discharge can be multiplied by the volume-weighted solute concentration to give an annual load (Wadham *et al.*, 1997), or regression of discharge versus solute load can be used to convert the hydrograph into an estimate of solute load variations throughout the ablation season (Sharp *et al.*, 1995). Summation of the latter gives the annual load.

It is evident from the brief summary above that there are considerable variations in both the size of glacial catchments and the magnitude and variability of annual runoff. This could create fundamental problems in comparison of the voracity of physical and chemical erosion in different glaciated catchments. Comparison of annual solute yields among temperate catchments is often achieved by determining the specific runoff, which is the total annual runoff divided by the catchment area (Holland, 1978). The specific runoff of glacial catchments is also a useful comparative index (Anderson *et al.*, 1997; Hodson *et al.*, 2000), but it should be noted that a considerable area of the glacier bed may be hydrologically inactive beneath glaciers that are polythermal- or cold-based (since, by definition, all or a proportion of the glacier bed is frozen to the bedrock). Additionally, the catchment areas of outlet glaciers from ice sheets are hard to define, since the extent to which water is sourced from the ice sheet interior is difficult to assess (Skidmore *et al.*, in press). The specific runoff of glaciers varies from a few cm $year^{-1}$ in Antarctica (Fountain *et al.*, 1999) to several m $year^{-1}$ in lower latitudes (Hodson *et al.*, 2000), and, despite the potential drawbacks identified above, the specific runoff is currently one of the more useful metrics with which to compare solute yields from different glacial catchments (Anderson *et al.*, 1997; Hodson *et al.*, 2000). Figure 2(a) gives an illustration of the association between solute yield and specific runoff for glaciers worldwide. By contrast, Figure 2(b) shows that basin area is a poor metric with which to compare solute yields, contrasting sharply with the excellence of this metric when comparing sediment yields (Figure 3).

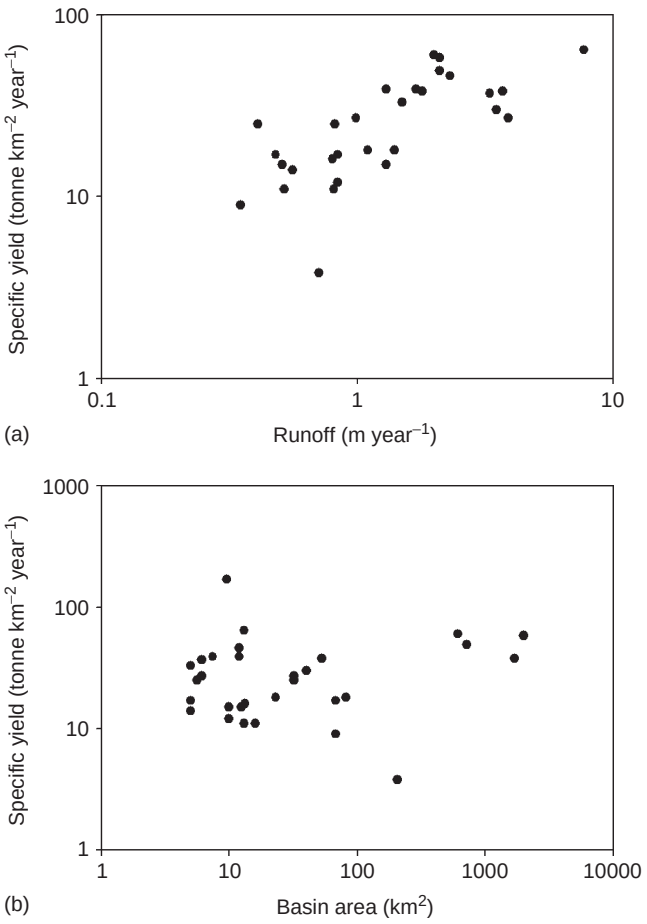

Figure 2 Scatter plots of the specific yield of solute versus (a) specific runoff and (b) basin area for worldwide glacier basins (data from Hodson *et al.,* 2000)

SUSPENDED SEDIMENT CONCENTRATIONS, BED LOAD, SEDIMENT FLUXES, AND YIELDS

Mechanisms of glacial erosion are dominated by abrasion, which produces fine sediment, and fracture/traction, which includes plucking, quarrying, crushing, and joint block removal and produces coarser sediment in general (Knight, 1999). Much of the finer material produced by subglacial erosion is transported by meltwater (Hallet *et al.*, 1996) for glaciers terminating on land. As a consequence, glacial meltwater streams are characteristically turbid, containing high concentrations of predominantly silt-sized sediment. Suspended sediment concentrations typically range from 0.2–10 kg m^{-3} (Gurnell, 1987). There is often a crude increase in suspended sediment concentration with discharge (Swift *et al.*, 2002), as shown in Figure 4, although the specific association between these variables is often complex (Gurnell, 1987; Lawson, 1993; Hodgkins, 1999). Suspended sediment concentrations are influenced on diurnal timescales by factors such as the type of subglacial

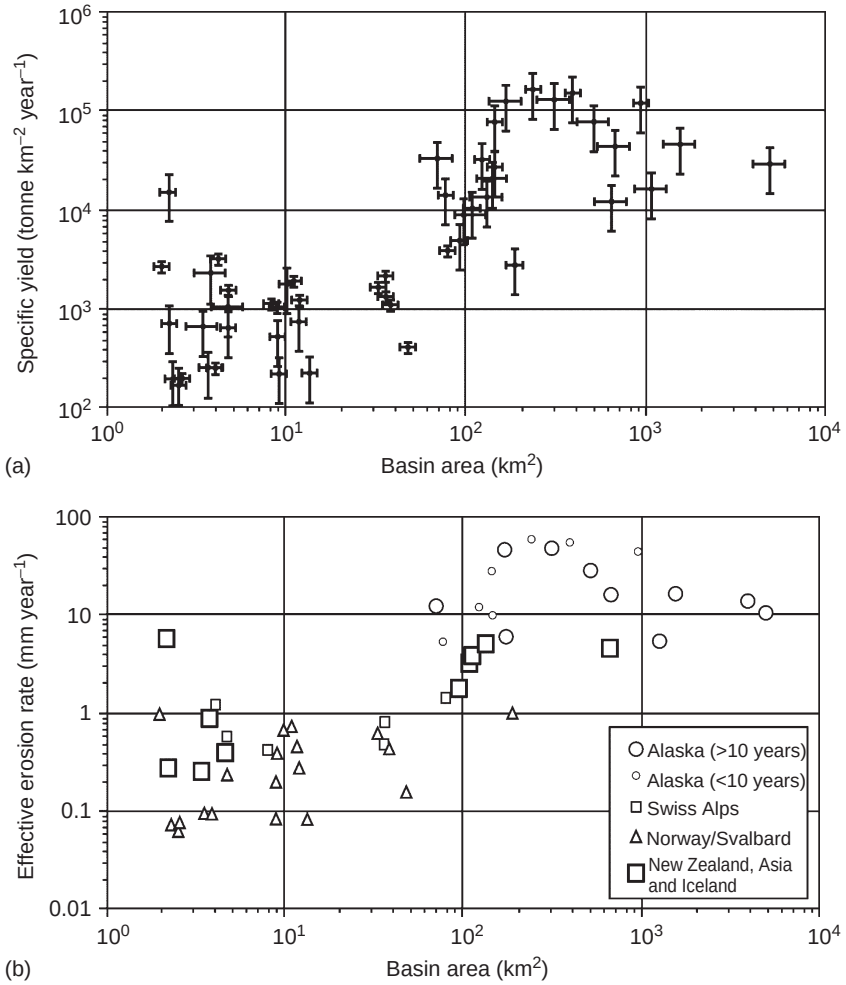

Figure 3 Scatterplots of (a) specific yield of sediment and (b) effective erosion rate versus basin area for worldwide glacier basins (after Hallet *et al.,* 1996)

drainage system (Swift *et al.*, 2002; Hodgkins, 1999), channel bank collapse, rainstorms, and periods of high snowmelt (Orwin and Smart, 2004). Very high concentrations of suspended sediment occur during outburst floods (Hodgkins *et al.*, 2003) and jökulhaups (Knight, 1999). Usually, sediment concentrations are greater on the rising limb of a hydrological event than the falling limb, since readily available sediment sources are used up or exhausted by the rising discharge, and there is often hysteresis in time series of suspended sediment concentration and transport versus discharge (Gurnell, 1987; Lawson, 1993). Figure 5(a) shows examples of hysteresis in runoff over timescales of weeks and Figure 5(b) shows hysteresis during a flood from small valley glaciers in Norway.

Bed load is seldom measured in glacial runoff channels, because of the logistical problems associated with channel migration and large seasonal changes in discharge. Where bed load has been measured, the flux of sediment at the bed is of a similar magnitude (~20–80%; Lawson, 1993)

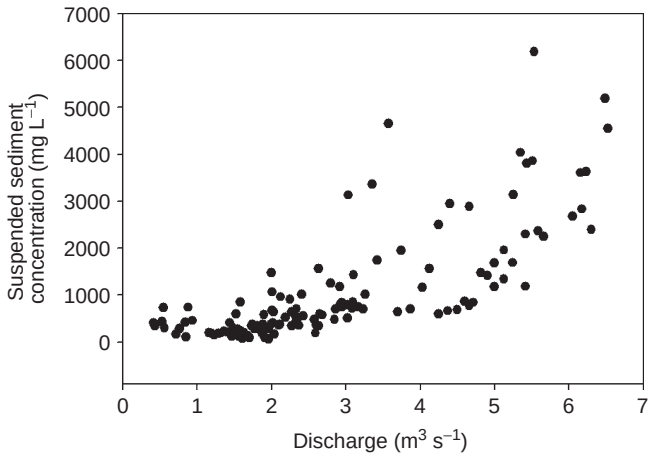

Figure 4 Scatterplot of suspended sediment concentration versus discharge for Haut Glacier d'Arolla. Data are for 1989

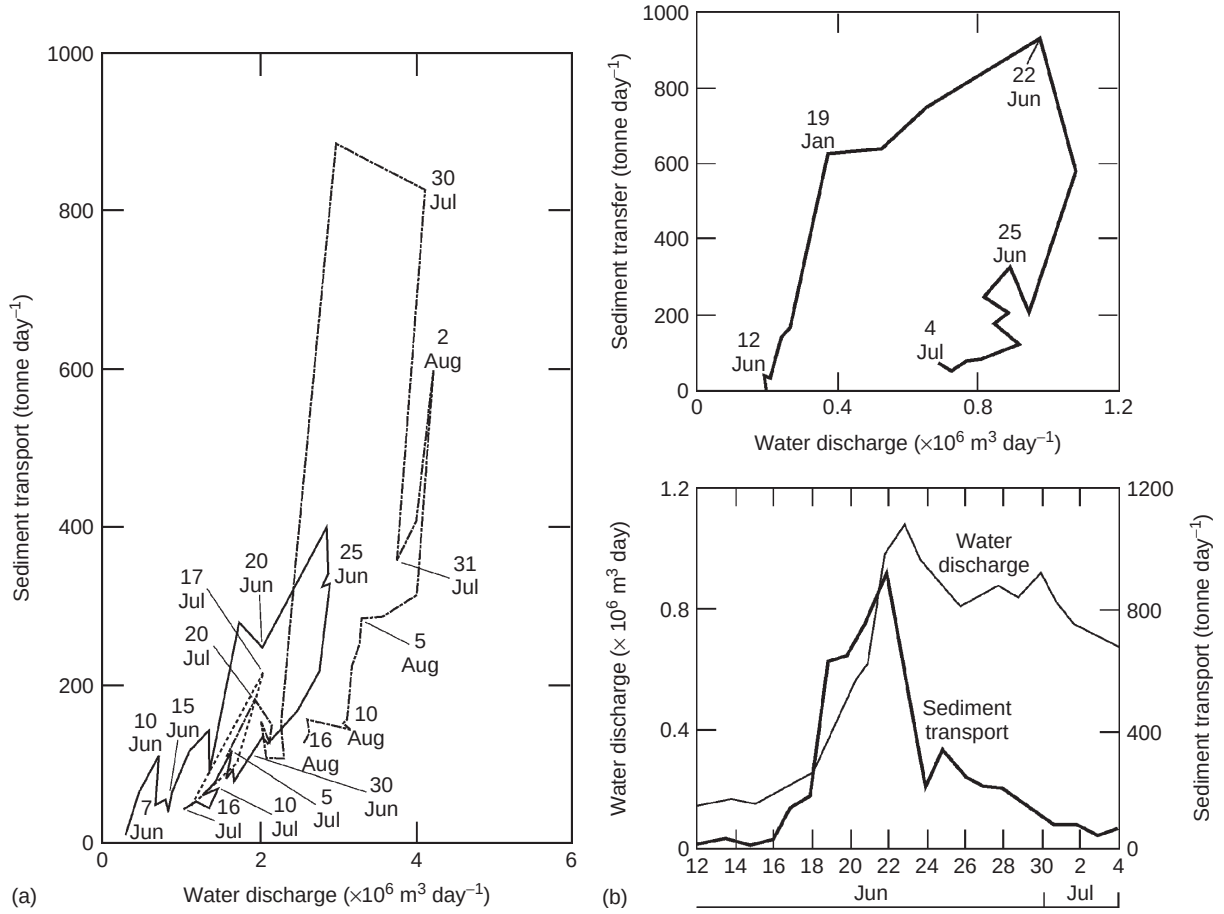

Figure 5 Hysteresis in time series of suspended sediment concentrations versus discharge. (a) Nigardsbreen, Norway, in 1993 (after Lawson, 1993). (b) Erdalsbreen, Norway in flood during 1969 (after Lawson, 1993)

to that in suspension. Bed load fluxes are greater than those in suspension at Nigardsbreen, Norway, during glacial advance (Figure 6), although the reasons for this are not clear-cut. Presumably, it is a consequence of the physical disruption of subglacial and proglacial sediments as ice thicknesses and velocities in the vicinity of the glacier margin increase.

Sediment fluxes from glaciated catchments can be obtained by a variety of means. Direct measurements usually concentrate on suspended sediment concentrations, largely ignoring bed load (Hallet *et al.*, 1996). The frequency of sampling is on timescales ranging from hours to days. Estimates of suspended sediment concentrations can also be made more frequently from continuous measurements of turbidity, although frequent calibration of the turbidity probes is necessary (Gurnell, 1987). These latter studies obtain estimates of suspended sediment concentrations with a resolution similar to that of discharge, but most studies use rating curves, which establish an association between variations in suspended sediment concentration and discharge for specific intervals of time. This approach gives rise to estimates of annual sediment yield that are of order of magnitude accuracy (Lawson, 1993). Longer-term sediment fluxes may be calculated from sedimentation rates in ice-proximal environments, such as fjords and lakes. The shortcomings with these estimates include the difficulty of defining sediment sources with certainty and problems of associated with cyclical erosion and deposition of sediment (Hallet *et al.*, 1996).

There is a positive association between the specific sediment yield and basin area in glaciated terrain (Figure 3). The largest basins are in Alaska, while those of intermediate and smallest size are from New Zealand, Asia, Iceland, Norway, Svalbard, and the Swiss Alps. There is some scatter in the data, but the data for each region show a positive linear trend, and data from different regions overlap. The overall association is that, to a first approximation, the specific sediment yield increases by approximately one order of magnitude for each order of magnitude increase in basin area. This remarkable association is believed to be the consequence of greater ice thicknesses and fluxes through the equilibrium line in larger basins, which in turn impacts on

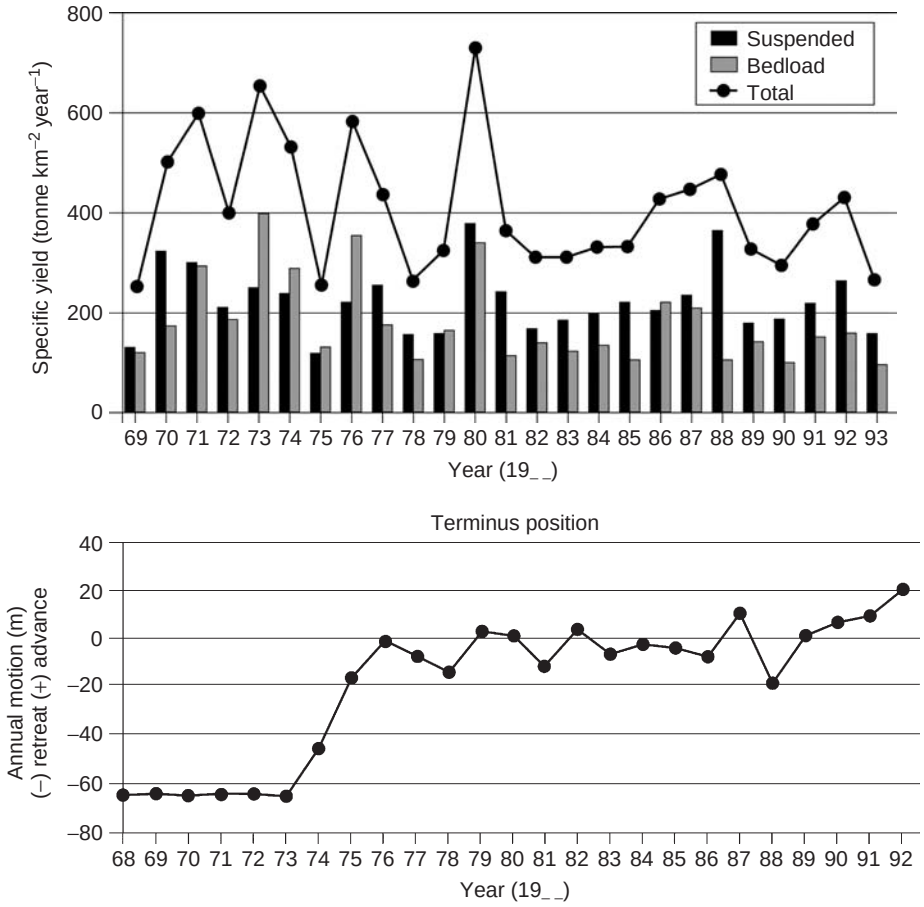

Figure 6 Suspended and bed load sediment yield for Nigardsbreen, Norway, in relation to the advance of the terminus (after Lawson, 1993)

the potential physical erosion that the glacier can undertake (Hallet *et al.*, 1996). Basins with >30% glacial cover have sediment yields that are an order of magnitude greater than those of proximal unglaciated basins (Hallet *et al.*, 1996).

It follows that current estimates of effective erosion rates (mm year^{-1}) vary by several orders of magnitude (Figure 3). Closer examination of effective rates reveals the influence of factors such as the type of glacier, the bedrock lithology, the climate, and the tectonic setting (Hallet *et al.*, 1996). The lowest effective erosion rates are for cold-based (i.e. frozen to the bed) polar glaciers and for those glaciers eroding crystalline bedrock of glaciers, and are comparable to those of the continental average (Table 2). By contrast, the highest rates are three or four orders of magnitude higher, occurring in SE Alaska, where the temperate valley glaciers are large, fast moving, and occupy tectonically active mountain ranges.

Glacial erosion rates do not stay constant during a glacial cycle, since the rate of sediment production and transport are not directly linked (Hallet *et al.*, 1996). Effective erosion increases during glacial advance, as sediment is mobilized from the proglacial zone and rates of subglacial erosion increase as a consequence of increasing ice thicknesses and fluxes. Effective erosion remains at relatively high values during the early stages of retreat, as sediment sources are plentiful and specific runoff is high. The relaxation time to background effective erosion rates following glaciation can be on the order of 10^3–10^5 years (Church and Slaymaker, 1989).

Table 2 Effective erosion in different glaciated regions (Hallet *et al.*, 1996)

Region	Effective erosion (mm a^{-1})
Svalbard	0.27–1.0
Norway	0.08–0.96
European Alps	0.41–1.7
SE Alaska	5.2–60
Canada	0.03–0.86
Central Asia	0.24–5.0
Greenland	0.01–0.04
Continental average	0.008[a]

CHEMICAL CONCENTRATIONS, SUBGLACIAL CHEMICAL WEATHERING AND CHEMICAL WEATHERING FLUXES

The major ions in glacial runoff are Ca^{2+}, HCO_3^-, and SO_4^{2-} (Table 3). The dominant non-seasalt cation is Ca^{2+}, irrespective of bedrock lithology (Raiswell, 1984), and HCO_3^- and SO_4^{2-} are the dominant non-seasalt anions because glaciers preferentially dissolve carbonates and sulfides. Glaciers are effective at promoting the solubilization of trace reactive components in the bedrock, which include carbonates, sulfides, and fluid inclusions. Laboratory experiments and direct sampling of waters from the glacier bed (Tranter *et al.*, 1997, 2002b) show that the initial reactions to occur when dilute snow and ice-melt first access glacial flour are carbonate and silicate hydrolysis (equations 1 and 2; Figure 7). These reactions raise the pH to high values (>9), lower the PCO_2 (to $\sim 10^{-6}$ atms), and maximize the potential of the water to adsorb CO_2. Carbonate hydrolysis produces a solution with a Ca^{2+} concentration of $\sim 200\,\mu eq\,L^{-1}$, with HCO_3^- the dominant anion.

$$\underset{\text{calcite}}{Ca_{1-x}(Mg_x)CO_3}\ (s) + H_2O(l) \leftrightarrow (1-x)Ca^{2+}(aq) + x\ Mg^{2+}(aq) + HCO_3^-(aq) + OH^-(aq) \quad (1)$$

$$\underset{\text{K-feldspar}}{KAlSi_3O_8(s)} + H_2O(l) \leftrightarrow \underset{\text{weathered feldspar surface}}{HAlSi_3O_8} + K^+(aq) + OH^-(aq) \quad (2)$$

Relatively dilute meltwater in contact with fine-grained glacial flour promotes the exchange of divalent ions from solution for monovalent ions on surface exchange sites. Hence, some of the Ca^{2+} and Mg^{2+} released from carbonate

Table 3 The concentration of major ions in glacial runoff from different regions of the world (after Brown, 2002). Concentrations are reported in $\mu eq\,L^{-1}$

Region	Ca^{2+}	HCO_3^-	SO_4^{2-}
Greenland	130–170	220–340	90–200
Antarctica	72–1300	91–1600	34–1200
Iceland	110–350	190–570	26–130
Alaska	550	430	260
Canadian High Arctic	260–2600	210–690	59–3900
Canadian Rockies	960–1100	890–920	380–520
Cascades	35–80	83–100	7.9–29
European Alps	20–640	11–400	10–240
Himalayas	75–590	200–730	160–410
Norway	8.8–620	1.4–680	7–140
Svalbard	120–1000	110–940	96–760
Global mean runoff	670	850	170

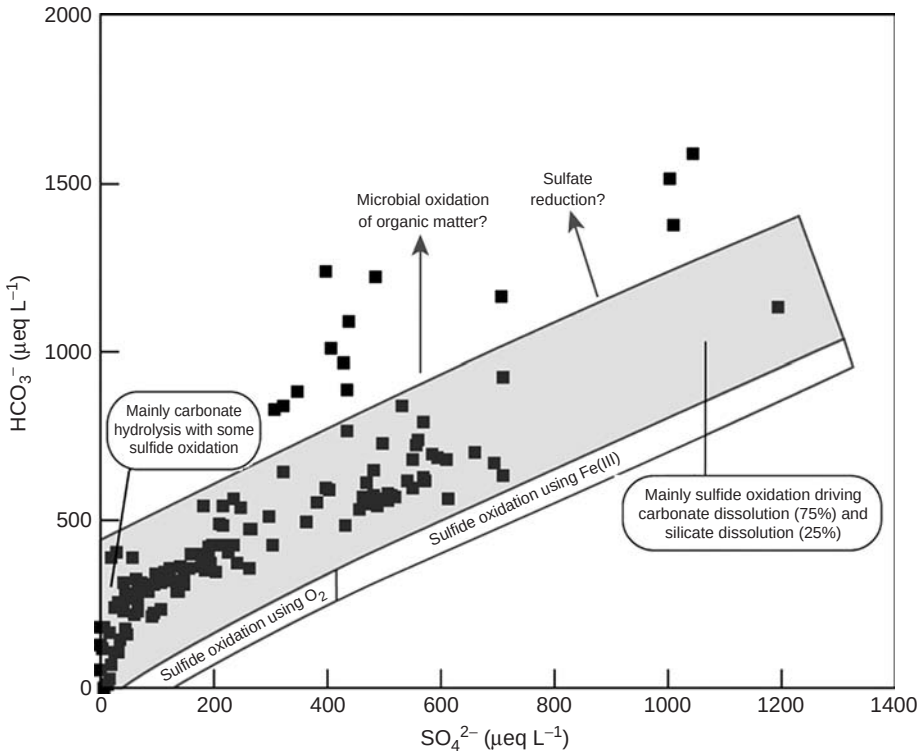

Figure 7 Scatterplot of HCO_3^- versus SO_4^{2-} for waters sampled from the bed of Haut Glacier d'Arolla (after Tranter *et al.*, 2002b). Microbial oxidation of organic matter and sulfate reduction in water-filled subglacial environments effect drive water compositions toward relatively high HCO_3^- concentrations with respect to SO_4^{2-}

and silicate hydrolysis is exchanged for Na^+ and K^+ (Figure 8).

$$\text{glacial flour} - Na_{(2-z)}, K_z(s) + (1-x)Ca^{2+}(aq) + xMg^{2+}(aq) \leftrightarrow \text{glacial flour} - Ca_{(1-x)}, Mg_x(s) + (2-z)Na^+(aq) + zK^+(aq) \quad (3)$$

The high pH derived from hydrolysis enhances the dissolution of aluminosilicate lattices, since Al and Si become more soluble at pH > 9 (Wollast, 1967). Hydrolysis of carbonates results in a solution that is near saturation with calcite. It is only in these types of waters that aluminosilicate dissolution is greater than carbonate dissolution. The influx of gases (including CO_2 and O_2), either from the atmosphere or from basal ice, and CO_2 produced by microbial respiration (see the following text) both lowers the pH and the saturation with respect to carbonates. In addition, sulfide oxidation produces acidity (see the following text). Hence, almost all subglacial meltwaters are undersaturated with respect to calcite. The rapid dissolution kinetics of carbonates with respect to silicates means that carbonate dissolution continues to have a large impact on meltwater chemistry despite carbonates being present often in only trace concentrations in the bedrock. For example, Haut Glacier d'Arolla has a bedrock that is composed of metamorphic silicate rocks. Carbonates and sulfides are present in trace quantities in bedrock samples (0.00–0.58% and <0.005–0.71% respectively). There are also occasional carbonate veins present in the schistose granite. Despite the bedrock being dominated by silicates, sulfide oxidation in subglacial environments dissolves carbonate to silicate in a ratio of ~5:1 (Tranter *et al.*, 2002b), compared to the global average of ~1.3:1 (Holland, 1978).

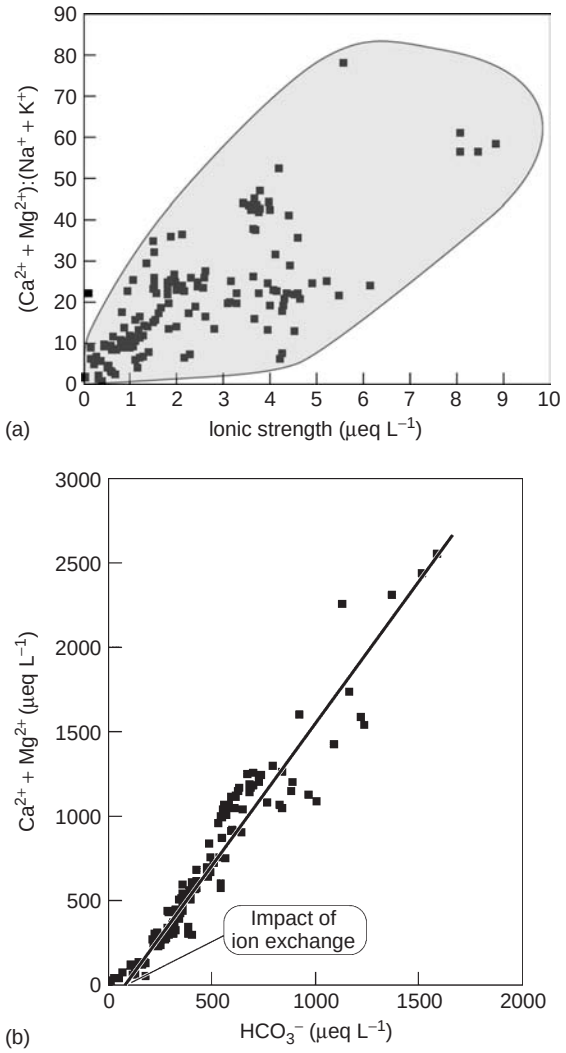

Figure 8 (a) Scatterplot of the ratio of divalent:monovalent base cations versus ionic strength for waters sampled from the bed of Haut Glacier d'Arolla (after Tranter *et al.*, 2002b) (b) Scatterplot of divalent base cations versus HCO_3^- for waters sampled from the bed of Haut Glacier d'Arolla (after Tranter *et al.*, 2002b)

The acid hydrolysis of silicates and carbonates (equations 4 and 5) that arises from the dissociation of CO_2 in solution is known as *carbonation*. Carbonation occurs in a restricted number of subglacial environments because ingress of atmospheric gases to these water-filled environments is restricted. It largely occurs in the major arterial channels at low flow, particularly near the terminus, and at the bottom of crevasses and moulins that reach the bed. Fine-grained sediment is flushed rapidly from these environments, and there is little time for the formation of secondary weathering products, such as clays. Hence, silicates dissolve incongruently (Figure 9), as crudely represented by equation 4.

$$\underset{\text{anorthite}}{CaAl_2Si_2O_8(s)} + 2CO_2(aq) + 2H_2O(l) \leftrightarrow Ca^{2+}(aq) + 2HCO_3^-(aq) + \underset{\text{weathered feldspar surfaces}}{H_2Al_2Si_2O_8(s)} \quad (4)$$

$$\underset{\text{calcite}}{Ca_{1-x}(Mg_x)CO_3(s)} + CO_2(aq) + H_2O(l) \leftrightarrow (1-x)Ca^{2+}(aq) + xMg^{2+}(aq) + 2HCO_3(aq) \quad (5)$$

There is a limited body of evidence that suggests that microbial oxidation of bedrock kerogen occurs (Wadham *et al.*, 2004), and if this is the case, carbonation as a consequence of microbial respiration may occur in debris-rich environments, such as in the distributed drainage system and the channel marginal zone.

$$C_{org}(s) + O_2(aq) + H_2O(l) \leftrightarrow CO_2(aq) + H_2O(l) \leftrightarrow H^+(aq) + HCO_3^-(aq) \quad (6)$$

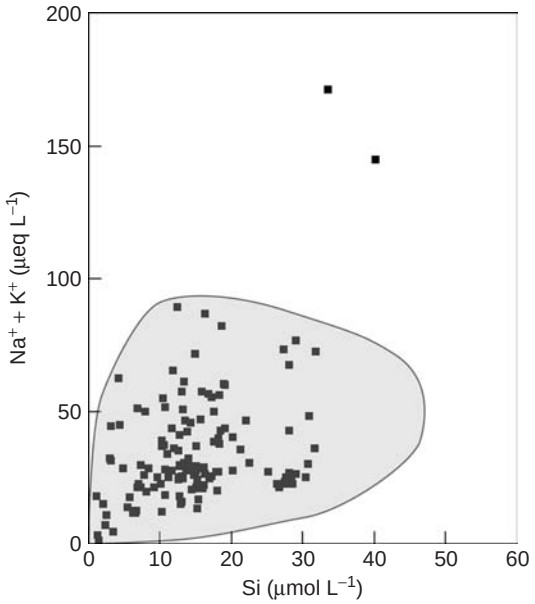

Figure 9 Scatterplot of monovalent base cations versus dissolved Si for waters sampled from the bed of Haut Glacier d'Arolla (after Tranter *et al.*, 2002b)

The dominant reaction in subglacial environments is sulfide oxidation, since, following hydrolysis, this is the major reaction that provides protons to solution thereby lowering the pH, decreasing the saturation index of carbonates, and allowing more carbonate dissolution (equation 7; Figure 7). Sulfide oxidation occurs predominantly in debris-rich environments where comminuted bedrock is first in contact with water. It is microbially mediated, occurring several orders of magnitude faster than in sterile systems (Sharp *et al.*, 1999). It consumes oxygen, driving down the PO_2 of the water.

$$\underset{\text{pyrite}}{4FeS_2(s)} + 16Ca_{1-x}(Mg_x)CO_3(s) + 15O_2(aq) + 14H_2O(l) \longleftrightarrow 16(1-x)Ca^{2+}(aq) + 16xMg^{2+}(aq) + 16HCO_3^-(aq) + 8SO_4^{2-}(aq) + \underset{\text{ferric oxyhydroxides}}{4Fe(OH)_3(s)} \quad (7)$$

Earlier studies suggested that the limit on sulfide oxidation was the oxygen content of supraglacial melt, since subglacial supplies of oxygen are limited to that released from bubbles in the ice during regelation, the process of basal ice-melting and refreezing as it flows around bedrock obstacles. However, studies of water samples from boreholes drilled to the glacier bed show that the SO_4^{2-} concentrations may be two or three times that allowed by the oxygen content of supraglacial meltwaters (Tranter *et al.*, 2002b). This suggests that oxidizing agents other than oxygen are present at the glacier bed. It seems very likely that microbially mediated sulfide oxidation drives certain sectors of the bed toward anoxia, and that in these anoxic conditions, Fe(III), rather than O_2, is used as an oxidizing agent (equation 8; Figure 7). Sources of Fe(III) include the products of the oxidation of pyrite and other Fe(II) silicates in a previous oxic environment, as well as that found in magnetite and hematite.

$$FeS_2(s) + 14Fe^{3+}(aq) + 8H_2O(l) \leftrightarrow 15Fe^{2+}(aq) + 2SO_4^{2-}(aq) + 16H^+(aq) \quad (8)$$

Support for anoxia within subglacial environments comes from the $\delta^{18}O\text{-}SO_4$, which is enriched in ^{16}O when sulfide is oxidized in the absence of oxygen (Bottrell and Tranter, 2002).

The predominance of carbonate hydrolysis, carbonation, and sulfide oxidation in subglacial weathering reactions on aluminosilicate/silicate bedrock is also found on carbonate bedrock. However, the balance between carbonate dissolution and sulfide oxidation depends on the spatial distribution of sulfides in the bedrock and basal debris (Fairchild *et al.*, 1999). Noncongruent dissolution of Sr and Mg from carbonate is also observed in high rock–water weathering environments, such as the distributed drainage system, in which water flow is also low (Fairchild *et al.*, 1999).

To date, there are few studies of glacial chemical weathering on bedrock with a significant evaporitic content. Work at John Evans Glacier in the Canadian High Arctic has shown that gypsum is dissolved in some areas of the bed, and that mixing of relatively concentrated Ca^{2+}–SO_4^{2-} waters with more dilute Ca^{2+}–HCO_3^-–SO_4^{2-} waters results in $CaCO_3$ precipitation due to the common ion effect (Skidmore, personal communication). Kennicott Glacier, Alaska, is underlain by a sabkha facies limestone, which contains trace quantities of halite. Waters accessing sites of active erosion readily acquire Na^+ and Cl^- (Anderson *et al.*, in press).

A key feature of the above chemical weathering scenarios is that relatively little atmospheric or biogenic CO_2 is involved. Hence, whereas ~23% and ~77% of solutes, excluding recycled sea salt, found in global mean river water is derived from the atmosphere and rock respectively (Holland, 1978), atmospheric sources account for a maximum of 3–11% of solute in glacial runoff (after Hodson *et al.*, 2000).

Typically, glacial runoff contains a few tens to a few hundreds of $\mu eq\,L^{-1}$ of positive charge. Higher concentrations may be found in the concentrated runoff that occurs at low discharge (Figure 1), but the discharge-weighted concentration is always much lower. Hence, glacial runoff is usually more dilute than global mean river water. The major ions are often 2–10 times higher in global mean riverine runoff than in glacial runoff (Table 3). Glacial runoff usually contains proportionally higher concentrations of K^+

and SO_4^{2-}, and lower concentrations of Si (Anderson *et al.*, 1997; Tranter, 2003).

Holland (1978) showed that specific annual discharge is the most significant control upon chemical erosion in temperate catchments. The same is true in glacierized basins. The lithology of the catchment is an important secondary control (Figure 10), with carbonate-rich and basaltic lithologies exhibiting the highest cationic denudation rates (Anderson *et al.*, 1997; Hodson *et al.*, 2000). Chemical erosion rates in glaciated catchments are usually near to or greater than the continental average (see Table 4) because glaciated catchments usually have high specific runoff. The rapid flow of water over fine-grained, recently crushed, reactive mineral surfaces maximizes both the potential rates of chemical weathering and chemical erosion.

Two studies have attempted to measure the enhancement of chemical erosion by reactions within the proglacial zone (Anderson *et al.*, 2000; Wadham *et al.*, 2001). Both studies noted an enhancement of chemical weathering rate in the proglacial zone relative to that of the glacier by a factor of 3–4. Colonization of the proglacial zone by plants is likely to further increase the rate of chemical weathering of silicates (Anderson *et al.*, 2000). However, the flux of water through sediments within the proglacial zone relative to the water flux from glaciers is small, and hence the net impact on solute export from glacial basins is likely to be of the order of 10%.

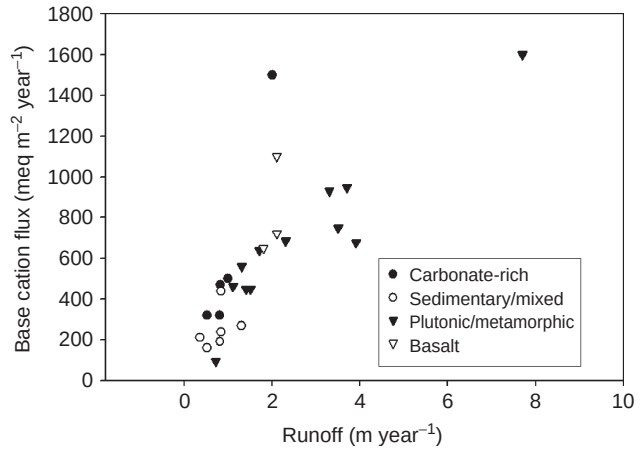

Figure 10 Scatter plot of base cation yield versus specific runoff for worldwide glacier basins of differing lithology (data from Hodson *et al.*, 2000)

Table 4 Specific runoff and cationic denudation rates for glaciers in different regions (after Hodson *et al.*, 2000)

Region	Specific runoff ($m\,a^{-1}$)	Cationic denudation rate ($\Sigma meq^{+}\,m^{-2}\,a^{-1}$)
Svalbard	0.35–1.5	190–560
European Alps	1.4–2.3	450–690
North America	0.7–7.7	94–1600
Iceland	1.8–2.1	650–1100
Asia	1.1–3.5	460–1600
Continental average	0.31	390

SIGNIFICANCE OF GLACIAL FLUXES OF SEDIMENT AND SOLUTE IN GLOBAL WATER, SEDIMENT, AND GEOCHEMICAL CYCLES

Approximately 10% ($\sim 15.9 \times 10^6\,km^2$; Knight, 1999) of the earth's surface is presently covered by glaciers, with most being concentrated in Antarctica and Greenland. Estimates of the current annual runoff from ice sheets range from $0.3–1 \times 10^{12}\,m^3\,year^{-1}$ (Jones *et al.*, 2002). Some $0.3 \times 10^{12}\,m^3\,year^{-1}$ is from Greenland (Oerlemans, 1993) and $0.4–50 \times 10^9\,m^3\,year^{-1}$ is from Antarctica (Jacobs *et al.*, 1992). The amount of runoff from smaller terrestrial ice masses is not well known. However, the potential water flux may be significant. A crude potential value can be obtained from the average residence time of ice in the smaller ice masses. Table 1 shows that the current volume of terrestrial ice that exists in locations other than the Antarctic and Greenland ice sheets is of the order of $0.2 \times 10^{15}\,m^3$. If the runoff from these glaciers comes from ice that has a volume-weighted glacier residence time of the order of $10^2–10^4$ years (Warrick and Oerlemans, 1990), then runoff from these smaller ice masses is of the order of $0.02–2.0 \times 10^{12}$. Hence, glaciers may currently contribute ~0.7–7% to current global annual runoff ($\sim 46 \times 10^{12}\,m^3\,year^{-1}$; Holland, 1978).

The volume of terrestrial ice approximately trebled at the LGM, when some ~22–29% of the present-day land surface was covered by glaciers. Table 1 shows that much of the additional ice volume was in the two great ice sheets of the northern hemisphere, the Laurentide Ice Sheet that grew over North America, and the Scandinavian Ice Sheet that grew over Europe. The average runoff from ice sheets during the last 100 kyr was $1.3 \times 10^{12}\,m^3\,year^{-1}$, approximately three times the current ice sheet runoff (Tranter *et al.*, 2002b). Average global glacial runoff might be double this value, dependent on the volume-weighted average residence time of ice in smaller ice masses. There were several occasions between 80–10 kyr BP when ice sheet runoff approached 20–30% of current global annual runoff to the oceans, but the most sustained period of relatively high ice sheet runoff was between 15–5 kyr BP, when ice sheet runoff was of the order of $2–10 \times 10^{12}\,m^3\,year^{-1}$. The impact of runoff from smaller ice masses has not been documented.

To date, modeling that attempts to determine the impact of physical and chemical erosion on atmospheric CO_2 concentrations is still at an early stage of development. Significant perturbations have not yet been found (Ludwig *et al.*, 1998; Jones *et al.*, 2002; Tranter *et al.*, 2002b).

Models of water fluxes from glaciers over cycles of advance and retreat have focused on ice sheet runoff. There is the potential for significant underestimation of total global glacial runoff if the volume-weighted runoff from smaller ice masses is calculated assuming that the mean residence time of ice in these smaller masses is the order of 10^3 years. The impact of glacial solute fluxes on ocean chemistry may become more significant as a consequence. Some 25% of all suspended sediment from rivers has been trapped in fjords over the last 100 kyr (Syvitski *et al.*, 1987), testimony to the direct and indirect impact that glaciers have had on marine sedimentation. As yet, the global impact of glacio-marine sedimentation on organic carbon burial has not been fully documented.

SIGNIFICANCE OF GLACIAL WEATHERING AND EROSION TO SUBGLACIAL ECOSYSTEMS

The realization that there is microbial mediation of certain chemical weathering reactions in subglacial environments (Sharp *et al.*, 1999; Skidmore *et al.*, 2000; Bottrell and Tranter, 2002) has resulted in a paradigm shift, since the types of reactions that may occur in anoxic sectors of the bed include the common redox reactions that occur, for instance, in lake or marine sediments (Drever, 1988). A key difference in glacial systems is that the supply of new or recent organic matter is limited to that in-washed from the glacier surface, such as algae, insects, and animal feces, or overridden soils during glacier advance. By contrast, the supply of old organic matter from comminuted rocks is plentiful. Given the thermodynamic instability of organic matter in the presence of O_2 or SO_4^{2-}, it seems likely that microbes will have evolved to colonize subglacial environments and utilize kerogen as an energy source. The first data to support this assertion is stable isotope analysis from Finsterwalderbreen, a small polythermal-based glacier on Svalbard, which has shale as a significant component of its bedrock (Wadham *et al.*, 2004). The δ^{18}O-SO_4 of waters upwelling from subglacial sediments are very enriched in ^{18}O, and the δ^{34}S is enriched in ^{34}S, which suggests that cyclical sulfate reduction and oxidation has been occurring. The δ^{13}C of DIC (dissolved inorganic carbon) is highly negative, consistent with the assertion that organic matter has been oxidized. Mass balance calculations suggest that a possible source of organic matter is kerogen, but the necromass of dead bacteria cannot be discounted. Whatever is the source of organic matter, sectors of the bed at Finsterwalderbreen are so anoxic that sulfate reduction is occurring (equation 9).

$$\underset{\text{organic carbon}}{2CH_2O(s)} + SO_4^{2-}(aq) \leftrightarrow 2HCO_3^{-}(aq) + H_2S(aq) \quad (9)$$

It is possible that methanogenesis occurs under certain ice masses, since methanogens have been isolated from subglacial debris (Skidmore *et al.*, 2000). The low δ^{13}C-CH_4 and high concentration of methane found in gas bubbles within the basal ice of the Greenland Ice Sheet are consistent with there being methanogenesis within the basal organic-rich paleosols.

The colonization of subglacial environments by microbes suggests that both energy and nutrient sources are readily available. Energy sources, such as sulfides and kerogen, have been discussed previously. Comminuted bedrock may also provide a source of nutrient. Average crustal rock contains 1050 ppm of P. Typically, this is contained in sparingly soluble minerals such as apatite, and calcium, aluminum, and ferrous phosphates (O'Neill, 1985). Comminuted bedrock and basal debris provides a renewable source of P on mineral surfaces, and it is likely that uptake of P by microbes maximizes the extraction of P from these activated surfaces. Hodson *et al.* (in press) suggest that $1-23\ \mu gP\,g^{-1}$ is present as readily extractable P on the surface of glacial flour. Sources of N may also be derived from comminuted rock (Holloway and Dahlgren, 2002). The N content of rocks is typically 20 ppm (Krauskopf, 1967), but may exceed 1000 ppm in some sedimentary and metasedimentary rock (Holloway and Dahlgren, 2002). For example, bedrock has been shown to be a source of NH_4^+ from schists in the Sierra Nevadas, California (Holloway *et al.*, 1998), and there may be appreciable concentrations of NH_4^+, which substitutes for K^+, in biotite, muscovite, K-feldspar, and pagioclase (Mingram and Brauer, 2001). It follows that glacial comminution of bedrock and basal debris maximizes the likelihood that N-producing surfaces are exposed to meltwaters and microbes, and given that bedrock in the Sierra Nevadas can act as an N source, it is likely that comminuted glacial debris is also a potential source of N.

CONCLUSIONS

This review has attempted to quantify the typical concentrations of suspended sediment and solute in glacial meltwaters, and shown that sediment and solute yield scale with basin area and specific runoff respectively. Globally significant quantities of sediment are transported by glacial runoff to the oceans, but significant quantities of the major ions are only transported during deglaciation, when large quantities of dilute meltwater are discharged into the oceans. That glaciers comminute bedrock and allow the transit of water at their beds provides a set of physical and chemical conditions that allow glacier beds to act as refugia for microbial life. Comminuted subglacial flour appears to contain sufficient energy sources and nutrient to sustain a range of microbes that inhabit oxic

through anoxic environments. Hence, even waters draining glaciers and ice sheets, in common with waters in other rivers at the earth surface, contain fingerprints of biological activity.

170: Modeling Glacier Hydrology

REGINE HOCK AND PETER JANSSON

Department of Physical Geography and Quaternary Geology, Stockholm University, Stockholm, Sweden

Modeling glacier hydrology is essential for many aspects of glacier research and water resources planning. Model complexity has developed in parallel with our increasing understanding of the glacier system. Different models can be used depending on the purpose of the modeled results. Stochastic models constitute the first attempts to model glacier discharge. Use of such models has declined because they require extensive site-specific calibrations and lack a conceptual basis, which makes them cumbersome to use. Conceptual models are the most widely used models for estimating discharge from glacierized basins. Commonly, the concept of linear reservoirs is applied to route melt and rain water through the glacier. Despite the wide variety of models of differing complexity, common to most conceptual models is that they omit many of the physical processes. Therefore attempts have been made to build physically based models that account for all processes in the glacier hydrological system. Because of the complexity of the modeled system and the wide variety of conditions on, in and under glaciers, the first models are relatively site-specific. However, despite the inherent difficulties, they still yield good results. Physically based models will likely play an increasingly important role in glaciohydrological research while the conceptual models will continue to dominate the monitoring and forecasting modeling in applied hydrology because of their modest data requirements and ease of use.

INTRODUCTION

Modeling glacier hydrology is of great scientific and practical interest. Modeling efforts have contributed substantially to our understanding of the processes and mechanisms of glacier hydrology. Increasing human use of areas influenced by glacier runoff has nourished the development of models to predict glacier runoff. Such models are widely used for all aspects of watershed management, including optimization of hydroelectric power schemes, reservoir operation, water supply, and flood forecasting, but also for assessing the contribution of glaciers to sea-level change. The need for modeling is particularly emphasized in the face of global warming and expected enhanced glacier retreat (IPCC, 2001). In the longer term, continued glacier mass loss will invoke a risk of low flow in for example, semiarid areas since water amounts currently delivered by glacier melt will diminish as glaciers become smaller. On the other hand, short-term effects of enhanced glacier melt will lead to an increased risk for floods in the vicinity of glaciers, as peak flows increase dramatically, mostly due to faster runoff generation when snow and firn cover vanish (Braun *et al.*, 2000; Hock *et al.*, 2005).

From a hydrological perspective, glaciers represent important water resources contributing substantial quantities of water to streamflow in many areas of the world, even in lowlands beyond the source areas in mountain ranges. Glacier hydrology differs from conventional hydrology since glaciers significantly modify streamflow in quantity, timing, and variability by temporarily storing water as snow and ice on many different timescales (Jansson *et al.*, 2003). Dominant characteristics of glacier discharge include pronounced melt-induced diurnal cyclicity and a concentration of annual runoff during the melt season (Escher-Vetter and Reinwarth, 1994). Many areas benefit from this specific seasonal runoff variation characteristic for glaciers in mid- and high-latitudes since ice meltwater is typically released during periods of otherwise low flow conditions. Total annual runoff is enhanced or decreased in years of negative or positive mass balances, respectively. In addition, glaciers tend to act as streamflow regulators reducing year-to-year variability to a minimum at moderate fractions

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

(often 10–40%) of catchment glacierization (Röthlisberger and Lang, 1987).

The seasonal change in glacier discharge hydrographs reflects fluctuations in meltwater inputs but also an increase in efficiency of the glacier drainage system as it evolves during the melt season. Hence, modeling glacier hydrology consists of two principal steps: (i) estimation of water input to the glacier, (ii) discharge routing through the glacier, that is, the transformation of rain- and meltwater into a runoff hydrograph. Melt modeling is relatively advanced with a hierarchy of ice and snow melt models ranging from simple *temperature index models*, which relate melt in empirical expressions to one or more variables including air temperature (Hock, 2003) to more physically based *energy balance models*, which compute melt from an assessment of the energy fluxes to and from the surface (*see* **Chapter 165, Mass and Energy Balances of Glaciers and Ice Sheets, Volume 4**). The processes of water movement in and under a glacier, however, are intrinsically complex and far less understood. Temperate glaciers consist of spatially zoned aquifers with distinctly different hydraulic properties. Water movement through firn and snow occurs by slow percolation (Schneider, 2000), whereas the bulk of water in and under the ice body generally travels along a well-defined passage system with considerably larger travel velocities. A variety of models of subglacial drainage have been invoked, including channels incised into ice or underlying bedrock, sheet flow, linked-cavity system (tortuous system of cavities connected by small channels or orifices), flow through subglacial unconsolidated sediments and "canals" in deformable beds (see reviews in e.g. Hubbard and Nienow, 1997; Fountain and Walder, 1998; *see also* **Chapter 167, Subglacial Drainage, Volume 4**). Channels are subject to change from both creep processes and phase changes (Röthlisberger, 1972; Hooke, 1984). Various modes of flow have been shown to coexist but switch locally from one to another during the melt season and between years (Nienow *et al.*, 1998). The shape of discharge hydrographs changes over the season owing to increased efficiency of the glacier drainage system as the winter snow cover melts away and the internal system develops. The continuous process of snow metamorphism, the high deformability of ice under pressure and phase transformations, since the aquifer consists of a mixture of water in its liquid and solid phase, contribute to the complexity of glacial drainage processes. The system is hence dynamic at all timescales from minutes to years, rendering modeling inherently difficult.

While models of internal glacier drainage are dealt with extensively by **Chapter 166, Surface and Englacial Drainage of Glaciers and Ice Sheets, Volume 4** and **Chapter 167, Subglacial Drainage, Volume 4**, this review focuses on modeling of glacier hydrology from a water resources perspective, hence on models predicting glacier runoff, and representation of internal flow routing in such models. Such work has to date focused on predominantly temperate glaciers. Very few operational models have been developed exclusively for glacier melt-runoff estimation (Fountain and Tangborn, 1985; Singh, 1995). Mostly, snowmelt runoff routines in existing runoff models are used or adjusted for glacier-runoff modeling. Generally, models fall into three categories: stochastic, conceptual, and physically based models.

STOCHASTIC MODELS

Stochastic models relate glacier runoff directly to meteorological variables using multiple regression techniques (Lang, 1968; Jensen and Lang, 1973; Østrem, 1973). Such models were widely developed in the 1960s and 1970s prompted by a need for seasonal and short-term runoff forecasts in dimensioning and efficient operation of hydroelectric facilities. These models are typically adjusted and calibrated to specific glacier basins. Results have often shown that meteorological variables like air temperature, wind speed, and vapor pressure contribute significantly to the overall correlation, while the contribution of radiative fluxes is surprisingly small, despite their general dominance in the heat budget (Østrem, 1973).

Through stepwise multiple regression of up to 10 observed variables in various Norwegian glacierized catchments, Østrem (1973) found that discharge could be well explained by only two to three meteorological variables, usually air temperature, precipitation, and wind speed. Inclusion of additional variables did not enhance correlation. Best results were often obtained when products of meteorological variables, instead of single variables, were used as independent variables. In addition models including the meteorological averages for the preceding two days were established to account for any time lag between meteorological variables and runoff. Lang (1968) and Jensen and Lang (1973) developed sets of multiple regression equations for daily and hourly discharge for several glaciers in the Swiss Alps to serve primarily for operational purposes. Forecasts were based on air temperature, precipitation, global radiation, and vapor pressure and included data from up to five preceding days. In addition, antecedent discharge turned out to be a powerful predictor. In contrast to Østrem (1973), the effect of wind speed appeared negligible, while vapor pressure was an important variable. To accommodate the glacier drainage system evolution, the melt season was subdivided into three intervals based on observed runoff characteristics employing different sets of equations for each interval.

In spite of accurate forecasts in practical operational hydrology, stochastic models lack a conceptual basis and general applicability since they require detailed regression analysis and calibration of coefficients at each site. Their

calibration is based on observational records, and they thus fail to provide reliable results in assessing the response of glacier discharge to future climate changes.

CONCEPTUAL MODELS

Conceptual models are most widely used for both practical and scientific studies of glacier hydrology. They generally consist of series of numerical steps representing the known physical processes in a simplified manner (Kachroo, 1992). Owing to generally limited knowledge of the large heterogeneity of physical processes in a glacier basin, some spatial variability of the input data is ignored by replacing spatially variable functions by their areal means (lumping). Nevertheless, the strength of conceptual models is moderate data requirements, and hence widespread applicability in hydrological modeling.

Linear Reservoir Models

In models considering internal flow routing, the most widely adopted concept to route water through glaciers is the concept of *linear reservoirs* (Chow *et al.*, 1988). A linear reservoir can be visualized as a water-filled container with a tap at the bottom, where outflow, $Q_{(t)}$, is proportional to the stored water volume, $V_{(t)}$. The factor of proportionality is the *storage constant*, k, with units of time, representing the time shift between the centroid of the inflow and that of the outflow. The use of linear reservoirs thus accommodates the storage effect and resulting delay of water in the glacier hydrological system. Storage and continuity equations for the reservoir are

$$V_{(t)} = kQ_{(t)} \tag{1}$$

and

$$\frac{\mathrm{d}V}{\mathrm{d}t} = I_{(t)} - Q_{(t)} \tag{2}$$

where $I_{(t)}$ is the inflow, here the sum of melt- and rainwater. In the case of constant $Q = I$, k corresponds to the time required for water entering the reservoir to flow out at the bottom, and thus to the residence time of the water in the reservoir. Combining both equations gives

$$k\frac{\mathrm{d}Q}{\mathrm{d}t} = I_{(t)} - Q_{(t)} \tag{3}$$

Integrating equation (3) yields

$$Q_{(t)} = Q(t_0)e^{-(t-t_0)/k} + I_{(t)}\left[1 - e^{-(t-t_0)/k}\right] \tag{4}$$

where t_0 is the time step preceding t.

The glacier is usually subdivided into one or several linear reservoirs with different storage constants (Figure 1): one reservoir (NAM-model: Gottlieb, 1980; HYMET model: Tangborn, 1984; Moore, 1993), two reservoirs (UBC model: Quick and Pipes, 1977; Van de Wal and Russell, 1994; Hannah and Gurnell, 2001) or three reservoirs (Baker *et al.*, 1982; Hock and Noetzli, 1997; Escher-Vetter, 2000). The reservoirs are coupled either in series with outflow of one reservoir providing the inflow to another reservoir (e.g. Van de Wal and Russell, 1994), or in parallel, whereby outflow of each individual reservoir is summed up for each time step to yield total glacier runoff (e.g. Baker *et al.*, 1982). Escher-Vetter (2000) used three linear reservoirs but added a constant groundwater flow which is equivalent to a fourth linear reservoir with an infinite storage constant. By assigning different storage constants to different reservoirs, this model formulation accommodates the markedly different through-flow velocities characteristic of the different reservoirs of a glacier.

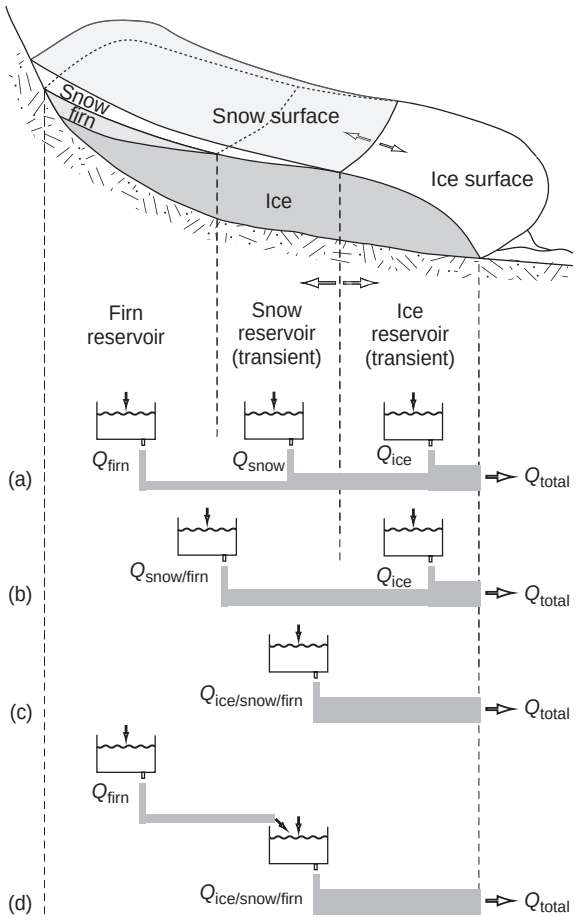

Figure 1 Concept of linear reservoirs as applied to glaciers using one to three (c–a) different linear reservoirs. Reservoirs are coupled in parallel in (a–b), and in series in (d). Exact delineation of reservoirs varies between studies. Q is outflow from the reservoirs

For example, Hock and Noetzli (1997) elaborate the work of Baker *et al.* (1982) by subdividing the glacier into three reservoirs discriminated by their surface characteristics: a firn reservoir defined by the area above the previous year's equilibrium line; a seasonally variable snow reservoir defined as the snow-covered area outside the firn reservoir; and an ice reservoir, defined as the area of exposed ice (Figure 1a). A large and small storage constant are assigned to the firn and ice reservoir, respectively, with an intermediate value for the snow reservoir, thus accounting for the different hydraulic properties of these media with respect to water transit times. Since the area of exposed ice grows at the expense of the snow-covered area as the melt season proceeds, increasing portions of water are routed through the "faster" ice reservoir, generating more peaked hydrographs (Figure 2). In this way, seasonal changes resulting from areal increases and decreases in firn, snow, and ice reservoirs are accounted for. However, most studies assume time-invariant storage constants, thus ignoring any temporal changes within each reservoir, such as enhanced drainage efficiency of the subglacial channel system or thinning of the snowpack during the course of the melt season.

Moore (1993) applied a single glacier reservoir and allowed the storage coefficient to vary on a daily basis according to an Antecedent Flow Index (AFI), which is computed as a function of the inflow to the reservoir for the current day. Although in his study the model performed better compared to employment of a constant storage coefficient, the approach does not account for the influence of any other factors on the evolution of the drainage system and also fails to capture any subdaily variations. Generally, storage constants are obtained either by tuning, that is, by maximizing the agreement between modeled and observed glacier discharge (e.g. Hock and Noetzli, 1997; Klok *et al.*, 2001), or by recession analysis (e.g. Gurnell, 1993) discussed below. Values used in some melt-runoff modeling studies are summarized in Table 1.

Models are validated primarily by comparing modeled and observed hydrographs and usually expressing agreement by the efficiency criterion R^2 ($-\infty$ to 1; Nash and Sutcliffe, 1970). Despite their simplicity, conceptual models are known to be robust and powerful tools for daily and hourly glacier melt-runoff modeling, often yielding $R^2 > 0.8$. Disagreement between simulations and observations often occurs at the onset and end of the ablation season and during peak (flood) flows (e.g. Moore, 1993; Hock and Noetzli, 1997; Escher-Vetter, 2000). The former is partly attributed to difficulties in modeling whether precipitation falls as rain or snow, while the latter can result from uncertainties in precipitation data, unreliable discharge measurements under floodlike conditions or neglect of variability of

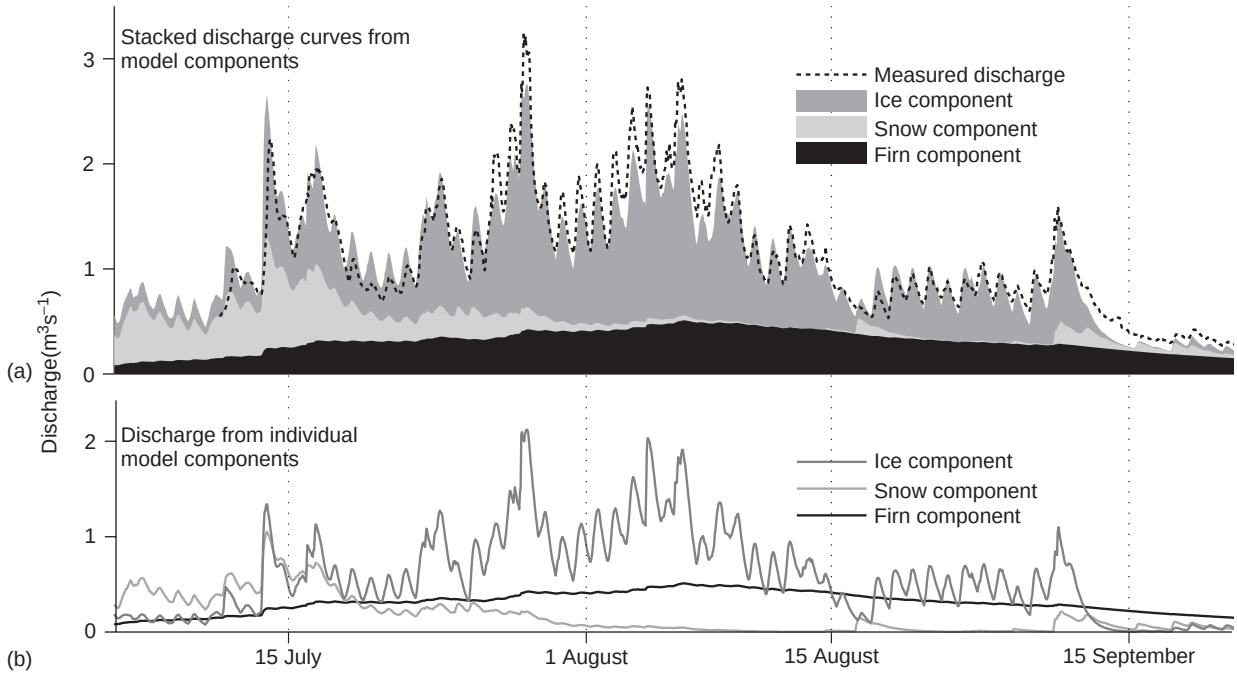

Figure 2 (a) Simulated and measured hourly discharge at Storglaciären 1994 applying three parallel linear reservoirs with storage constants $k_{firn} = 350$ h, $k_{snow} = 30$ h, $k_{ice} = 16$ h. The shaded areas denote the stacked contributions of the firn, snow, and ice reservoirs to total discharge. Contributions from the snow reservoir decline as the snowline retreats. Melt is computed from a distributed energy balance model. (b) Simulated ice, firn, and snow reservoir discharges (Reprinted from Jansson *et al.*, 2003, The concept of glacier storage: a review, *Journal of Hydrology* **282**:116–129. © 2003, with permission from Elsevier)

Table 1 Storage constants used in various melt-runoff modeling studies on glaciers, applying the concept of three parallel linear reservoirs for water routing through the glacier. Storage constants, k, are given in hours (h) for the firn reservoir (slow), snow (intermediate) and ice reservoir (fast)

Site (basin size, glacierization)	k_{firn} (h)	k_{snow} (h)	k_{ice} (h)	Source	Reference
Storglaciären[a] (4.4 km[b], 70%)	350	30	16	Tuning	Hock and Noetzli (1997)
Vernagtferner[b] (11.1 km[b], 81%)	430	30	4	Recession analysis	Baker *et al.* (1982)
Vernagtferner[b] (11.1 km[b], 81%)	430	40–80	6	Tuning	Escher-Vetter (2000)
Rhoneglacier at Gletsch[a] (38.9 km[b], 48%)	350	120	45	Tuning	Klok *et al.* (2001)

[b]The firn reservoir is defined as the uppermost ca. 10% of the firn area. The remaining firn area is classified as snow reservoir.

the internal drainage system in model formulation. Despite good model performance regarding discharge, good fits can be achieved for the wrong physical reasons, leading to false impressions of model accuracy (Burlando *et al.*, 2002). An underestimation of snow precipitation can be compensated for by excess ice melt and vice versa (Braun and Aellen, 1990). Hence, models are preferably tested against additional data, such as glacier mass balance or snow line retreat, the latter greatly facilitated by advances in remote sensing techniques (e.g. Turpin *et al.*, 1997). Willis *et al.* (2002) test performance of their distributed glacier hydrology model against hourly point measurements of ablation and supraglacial discharge measurements. Internal model validation of intermediate results will gain importance as melt-runoff models are used for simulation of variables other than total streamflow.

Recession Analysis

Recession analysis is based on hydrograph-recession curves allowing storage constants, k, to be estimated from the slope of a semilogarithmic plot of discharge versus time (Figure 3). Recessions from a linear reservoir will conform as straight lines since outflow Q_t at time t during periods of no recharge is given by

$$Q_t = Q_0 e^{-(t-t_0)/k} \quad (5)$$

where Q_0 is preceding recession flow at time t_0. Identification of more than one linear component is interpreted as recessions from different reservoirs, thus allowing the number of reservoirs that are operating to be determined, although such interpretation is questionable if reservoirs are partly or entirely linked in series (Gurnell, 1993).

Analyzing recession limbs at Haut Glacier d'Arolla (glacier area 6.3 km^2), Gurnell (1993) identified four reservoirs, but recession coefficients varied as a function of discharge and time of the season. For the same glacier, Richards *et al.* (1996) inferred three reservoirs with approximate average reservoir constants of 12, 27, and 72 h, but emphasized nonlinear behavior of the reservoirs. Hannah and Gurnell (2001) identified two linear reservoirs for a small cirque glacier in the Pyrénées (glacier area 0.2 km^2).

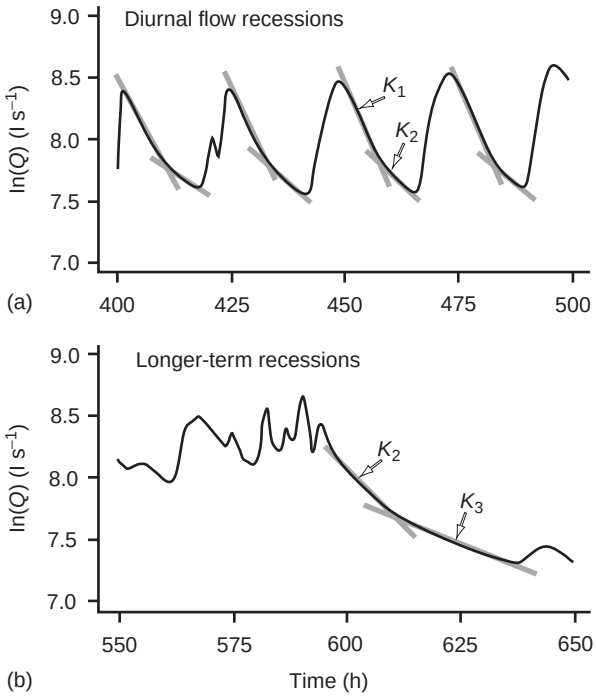

Figure 3 Semilogarithmic recession curves for diurnal and longer term discharge variations (Q), illustrating the separation of flow components from different reservoirs (modified after Gurnell, 1993) (Reproduced with modifications from Gurnell, 1993, by permission of the International Glaciological Society)

Storage coefficients from the "fast" reservoir declined from ~13 to 5 h and for the "slow" reservoir from ~45 to 19 h over the melt season. Later in the season, the drainage system was best represented as a single reservoir. Although recession analysis assuming linear reservoirs is recognized as useful to provide insight into glacier hydrological processes (Nilsson and Sundblad, 1975; Hannah and Gurnell, 2001), Gurnell (1993) suggests that use of a single but nonlinear reservoir might be more adequate for operational modeling purposes.

It is obvious that much uncertainty remains as to the use of recession analysis to provide input to conceptual glacier-runoff modeling. Despite drawbacks of linear

reservoir models to account for observed nonlinearity of storage coefficients, linear reservoir models have generally performed well (Figure 2). This might suggest that such models are sufficiently robust while accurate estimation of melt water input, including modeling the aggregational state of precipitation are more important for hydrograph modeling than deficiencies arising from the assumption of linear reservoirs in subsequent water routing. The differences in hydraulic properties between the "faster" ice reservoir and the "slower" snow/firn reservoirs are probably sufficiently pronounced that effects from seasonal evolution of drainage efficiency are subdued.

PHYSICALLY BASED MODELS

Modeling the physics of glacier hydrology is complex since it involves the liquid phase, namely water, moving through the solid phase, namely ice, at the melting temperature. Furthermore, ice is deformable under relatively low stresses, which allows channels and conduits in glaciers to change size and shape much more rapidly than channels eroded in rock or sediment. The glacier system is thus transient on all timescales and over all spatial scales.

The first physically based models in glaciology were made to reproduce simple observable phenomena in glacier hydrology. Röthlisberger (1972) and Shreve (1972) presented simple numerical models (Röthlisberger: conduit flow; Shreve: potential flow) for water flow in glaciers. The assumptions made were that the rate of melt-enlargement is balanced by creep closure (Röthlisberger) and that water pressure was in balance with ice pressure (Shreve). Nye (1976) and Spring and Hutter (1981) presented a physically based theory of unsteady flow through intraglacial channels. Hooke (1984) investigated the effects of nonsteady conditions, in particular, open channel flow, on the Röthlisberger system. This was elaborated by Kohler (1995) who investigated the ratio of open-to-filled channel flow in a subglacial system. Most models have assumed circular cross-section pipe flow. However, discrepancies between measurements and model calculations led Hooke *et al.* (1990) to propose low broad tunnels in place of the semicircular types in order to be able to apply Glen's flow law deformation with reasonable viscosity parameter values. Conduit flow was found not to reproduce water pressure and fluxes observed during the surge of Variegated Glacier. This prompted Kamb (1987) to propose the linked-cavity system which combined large cross section with small flow velocities. Walder and Fowler (1994) extended Röthlisberger's model to include "canals" cut into deformable till.

A first approach to produce a complete physically based model for a glacier was reported in Arnold *et al.* (1998; henceforth referred to as the Arnold model). Their model contains three components. A surface energy balance model calculates distributed glacier surface melt water production. A routing model takes rain- and meltwater and either delivers it to *a priori* prescribed moulins, where it enters the glacier interior, or supraglacially to the ice margin. The third and final component is a subglacial model which involves a conduit system. The englacial drainage is treated as part of the subglacial conduit system and simulated analogous to a sewage pipe system. Subglacial conduits are fed by a network of "drains", which represent moulins where water can enter or overflow from the system. Subglacial conduits can enlarge and contract in response to changes in the rates of wall melting and creep closure associated to changes in water inputs. In addition, the configuration of the system can change between a distributed system and a channelized system represented by different predefined number and geometries of conduits. "Distributed" links were changed to "channelized" flowpaths as the modeled snowline passed each moulin. From this perspective, the subglacial model is rigid since switching between both systems does not permit smooth transitions with the bed being partially drained by each system. The model was applied to Haut Glacier d'Arolla, Switzerland, and performed well in comparison with proglacial stream discharge, but limitations are indicated by discrepancies between model outputs and field observations of subglacial water pressure and water velocities, although the substantial features of these records could be reproduced.

Flowers and Clarke (2002a; 2002b; henceforth referred to as the Flowers model) developed a different approach to a complete physically based model. The model comprises coupled surface runoff, englacial, subglacial, and groundwater systems. Each of the four components is represented as a two-dimensional, vertically integrated layer that communicates with its neighbors through water exchange (Figure 4). Melt is computed by a distributed temperature

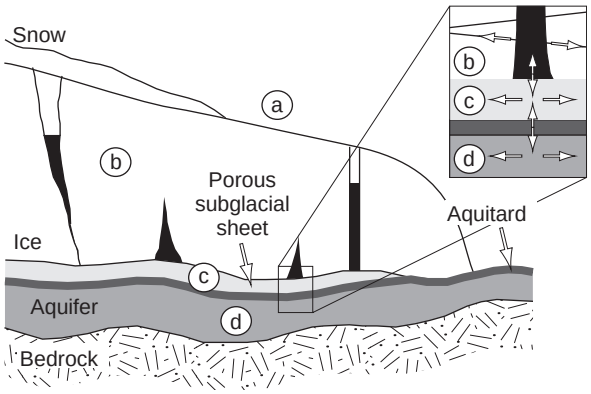

Figure 4 Schematic presentation of the glacier hydrology components in the Flowers model. Circled letters refer to (a) surface ablation and runoff, (b) englacial storage and transport, (c) flow in a porous subglacial layer and (d) subsurface groundwater flow (Reproduced with modifications from Flowers and Clarke, 2002a, by permission of the American Geophysical Union)

index model. Englacial hydrology is represented by describing a variety of bulk storage elements and allowing water transport between them in a system of cracks. Hence, the englacial system is treated as fracture-connected crevasses and pipes. The Flowers model was built to model conditions at Trapridge Glacier in Canada which is underlain by thick porous sediments. Their subglacial model therefore comprises flow through macroporous glacier sediments at the ice-bed interface and subsurface aquifers of buried sediment layers not directly exposed to the base of the glacier. Hence there are no explicit tunnels as in the Arnold model. The model reproduced well diurnal cycles of subglacial water pressure as measured in boreholes.

The present state of physically based models is still crude, in that these models have been tailored to specific glaciers or glacier-types and are not necessarily easily and generally transferable. Melt water production is handled comparatively well; it is probably also the simplest part to model since the entire system is easily observable. Surface energy balance models and temperature index melt models are readily available and have proven to perform very well, even at relatively uncomplicated levels (Hock, 2005; *see also* **Chapter 165, Mass and Energy Balances of Glaciers and Ice Sheets, Volume 4**). The internal and subglacial system is more complicated, characterized by large variability in possible drainage system configurations. Much uncertainty yet remains as to the exact geometry of drainage systems and how these systems can coexist or switch from one state to the other, thus hampering physically based modeling. A crevasselike englacial network, as adopted in the Flowers model, has been observed on Storglaciären, Sweden (Fountain *et al.*, 2005), countering previous notions of englacial water flow through few melt-enlarged conduits. If subglacial sediments are present, groundwater flow may be a significant part of the system, as in the Flowers model, or flow may occur in channels eroded into the subglacial sediments. On harder beds or beds of less permeable sediments such as tills, water flow may occur in conduit systems melted into the ice or in linked-cavity systems. Hence, a general physically based model would have to accommodate all these possibilities and even coupled different types of systems beneath different parts of a glacier. Such a model would be inherently complex.

Another issue which is not satisfactorily met is the time-transgressive development of subglacial systems. In the Flowers model, this is not necessary since flow through porous sediments does not involve significant time-dependent changes, except possible changes such as development of piping or siltation of the porous media from fines produced through sediment deformation. In the case of the Arnold model, it is widely reported (e.g. Nienow *et al.*, 1998) that the subglacial drainage system changes both in sizes of conduits and in complexity of the network of channels through the course of a season. The subglacial system is very dynamic and it seems as if a complete and accurate model description of this system may be distant. However, most changes in such a system occur in response to rapid changes, both increases or decreases in water inputs, so a first-order approximation may be to switch between a series of systems prompted by key events in the forcing.

CONCLUDING REMARKS

An increasing practical and scientific need to model glacier water resources in light of globally increasing freshwater demand and potential impacts of climate change has fostered a large variety of glacier hydrology models varying greatly in scope and sophistication. A fundamental question concerns the level of complexity which models should employ. Stochastic models, simple but of limited value if transferred to different areas or climate conditions, have often been replaced by more process-orientated models following considerable advancements in computer power and process-understanding over the last few decades. Sophisticated physically based models including surficial, englacial, and subglacial components and their variability in space and time are hampered by complexity and large variability of the drainage system. Such models most accurately describe the processes involved, but limits are set by availability, accuracy, and representativeness of input data and also by spatial variability of processes. Although latest attempts are tailored to specific sites (Arnold *et al.*, 1998; Flowers and Clarke, 2002), and thus may lack direct transferability to other glaciers, physically based models are important research tools for process studies and should contribute to advancing simpler conceptual models.

Lumped conceptual models will most certainly retain their prominent position in operational glacier-runoff modeling. Commonly, the concept of linear reservoirs is invoked to route water through the glacier. Despite moderate data requirements and simplification of processes involved, such as neglect of nonlinearity of storage coefficients, such models have proven to provide robust tools for predictive purposes. Many widely used runoff models (Singh, 1995) include some kind of glacier melt routine, but neglect explicit consideration of the presence of glaciers in runoff-routing. Considering the large effect of glaciers on basin hydrology even at glacierization levels of only a few percent due to the specific characteristics of glacier drainage (Hock *et al.*, 2005), glacier-runoff models need to include specific routines for internal glacier drainage. This is necessary in particular if long- and short-term effects of climate change on glacier hydrology are to be assessed since partitioning of "slow" and "fast" flow components will change in response to changes in snow and firn cover (Braun *et al.*, 2000). Much effort has been devoted to glacier melt modeling, while relatively little development of conceptual models of internal flow routing has occurred. Further

research should explore possibilities to consider nonlinear reservoirs for flow routing, while retaining low data input requirements.

Generally speaking, both stochastic and conceptual models have been used widely in operational forecasting of glacier runoff, while physically based models are yet sparse and have generally been tailored to scientific interests and specific glaciers. Merging both strategies – aiming at robust and easy-to-operate conceptual models while enhancing their physical base to better represent the large spatial and temporal variability in glacier hydrology – provides the challenge for future model developments and quantitative assessment of possible future evolution of glacial water resources.

171: River-Ice Hydrology

TERRY D PROWSE

Department of Geography, National Water Research Institute of Environment Canada, University of Victoria, Victoria, BC, Canada

The hydrology of almost 60% of rivers in the Northern Hemisphere is affected by ice for at least a portion of the winter. At the higher latitudes, river ice is the major controller of most fluvial processes. Although traditionally the pursuit of hydraulic engineers, hydrologic studies of river ice have broadened greatly over the last decade. Initially, this was driven by recognition that many hydrologic extremes produced by river ice, such as floods and low flows, exceed those of the more intensively studied, open-water period. Added recognition that river ice strongly influenced other fluvial disciplines, such as geomorphology and aquatic ecology, increased its scientific visibility. This manuscript reviews the basic physics of river ice; evaluates its effect on various hydrologic processes and events from freeze-up to breakup; and discusses its extended role in affecting sediment transport/erosion, river morphology and a number of key ecological processes including geochemical mixing and habitat modification. Arguments are made for increased focus on river-ice hydrology given its significance to physical and ecological processes, and the growing need to understand the effects of climate change and flow regulation on cold regions rivers.

INTRODUCTION

Ice is a dominant feature of the hydrologic cycle in the near-polar latitudes and at higher elevations. For example, almost 25% of the land-mass or 29% of the total river length in the Northern Hemisphere are found north of the mean-annual 0 °C isotherm (Bennett and Prowse, 2004) and thus experience significant ice effects. Notably, this area includes the downstream reaches of four of the world's 15 largest rivers (by discharge or drainage area), including the Lena, Hob, Mackenzie, and Yenisei. For almost half the year, the hydrologic conditions in rivers of this immense area are influenced by the formation, growth and breakup of freshwater ice. Considering the total hydrologic zone experiencing even transient ice effects (i.e. climates where the mean January air temperature is <0 °C), the land-mass and river-length percentages of the Northern Hemisphere rise to 53 and 57, respectively. Moreover, this zone extends as far south as 33 °N in North America and 26 °N in Eurasia, and encompasses all of the above four large Arctic rivers and increases the listing from the top 15 rivers to include the Mississippi, Yangtze, and even the Ganges, which have cold regions headwaters.

Traditionally, the study of river ice has been the domain of hydraulic engineers focused largely on finding solutions to localized river-development problems. Over the last two decades, however, the subfield of river-ice hydrology has emerged (Beltaos, 2000; Morse and Hicks, 2004). To a large part, this has been driven by the recognition that in-channel ice effects are frequently more important than landscape processes, or even open-water flow, in producing hydrologic extremes such as low flows and floods (e.g. Gerard, 1990; Prowse, 1994; Prowse and Beltaos, 2002) and related, costly infrastructure damage (e.g. Gerard and Davar, 1995). Given the importance of river ice to water levels and discharge, there has been further recognition that river ice controls many related fluvial processes, such as sediment transport/deposition, bio-chemical exchanges and aquatic productivity/diversity (e.g. Prowse, 2001a,b).

Achieving an understanding of river-ice hydrology requires some additional scientific fundamentals that are not normally a part of hydrologic studies of open-water conditions, such as mechanics and thermodynamics. To provide an introduction to the field, the next section of this chapter reviews basic river-ice physics, explaining how ice forms, grows, decays, and breaks up in fluvial systems.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

For additional background about river-ice hydraulics and physics, interested readers are referred to other texts, such as Ashton (1986), Beltaos (1995) and Davar *et al.* (1996; which includes worked examples) and Gray and Prowse (1993; which focuses on hydrologic issues and discusses problems of ice-affected hydrometric measurements). The next section considers the major stage, storage, and flow extremes that are produced by river ice from first freeze-over in the autumn to final ice clearance in the spring. Additional subsections review the effects of river ice on fluvial geomorphology and aquatic ecology.

RIVER-ICE PROCESSES

Autumn Cooling

Unlike on lakes, flowing water in rivers is constantly mixed and, in the absence of thermal stratification, the entire water column cools during the autumn months at approximately the same rate. Changes in water temperature are controlled by the net heat flux to the water column (Φ_*), which comprises a number of heat fluxes that occur at the water surface and riverbed, and within the water column:

$$\phi_* = \phi_S + \phi_L + \phi_H + \phi_E + \phi_P + \phi_G + \phi_B + \phi_F \quad (1)$$

where Φ_S and Φ_L are the net fluxes of short- and long-wave radiation; Φ_H, $\Phi_{E,}$ and Φ_P are the sensible, latent, and precipitation heat fluxes from the overlying atmosphere; Φ_G and Φ_B are the groundwater and bed (geothermal and sediment) heat fluxes, and Φ_F is the heat flux to the water from flow friction (positive values representing a heat flux to the water). Under open-water conditions, the last two terms are relatively minor, although heat supplied from the bed can become important once an ice cover eliminates direct water column-atmosphere heat exchanges. The magnitude of Φ_B declines as the heat stored in the bed during the warmer months is gradually conducted to the river. The significance of Φ_G as a major heat source depends on the temperature of the groundwater and its flow rate relative to the river discharge. Groundwater is sometimes the major source of baseflow and can be responsible for keeping river reaches open throughout the winter, even at high northern latitudes (e.g. Prowse, 2001b).

Shortwave radiation supplies most heat prior to freeze-over, although much of it can be reflected away by surface fog that frequently forms when air temperatures are significantly below those of the water. Most cooling of the water column results from negative values of Φ_L (negative long-wave radiation budget), Φ_H (convection of heat upwards to the atmosphere) and Φ_E (evaporation) – the strength of all three controlled by the water–air temperature difference and, for the latter two, windspeed.

The temperature of the precipitation relative to that of the river water and whether it is in liquid or solid form determine the magnitude and direction of Φ_P. Snow is most effective in cooling river water because of the heat required to raise its temperature and, more importantly, the large amounts of latent heat required to melt it.

Efficiency of river cooling depends on surface area to volume ratios. Thus, for similar discharge and meteorological conditions, wide shallow rivers cool most rapidly and deep narrow ones relatively slowly. Small tributary streams also cool more quickly than larger rivers carrying greater flow. Assuming that cooling is sufficient for the water column to reach 0 °C and permit subsequent ice formation, the same sequence among rivers of varying geometry and size characterizes the freeze-up pattern. Such contrasts can cause, for example, freeze-up delays of up to a month or more between small and large rivers in the same climatic region.

Ice Production

Once water temperatures reach 0 °C, a river is capable of producing a variety of ice forms. As on lakes, the first ice to form is usually "border ice" along the banks and around islands or other material (e.g. large boulders) protruding above the water level. Ice develops here because the bank material is usually colder than the main river flow and effectively chills water in close contact with it. The lateral growth of border ice, however, depends on flow turbulence and the rate of cooling at the growing edge. In pool sections, for example, quiescent flow conditions combined with a high rate of cooling can permit border ice to cover the entire river width. Under similar conditions, large moving ice sheets can develop from vertical ice growth without attachment to the border ice, such as on the St. Lawrence River where sheets several hundred meters across have been observed (e.g. Marcotte, 1984).

Quite a different type of river ice is formed within the more turbulent portions of a river, and is generally referred to as "frazil ice", a word derived from the old French word "fraisil" meaning an accumulation of cinders (Michel, 1981) – a suitably descriptive term for the initial stages of frazil generation. Frazil ice particles nucleate when the water experiences a slight degree of supercooling (typically < -0.05 °C) and can cause further rapid multiplication of additional frazil particles with concentrations reaching as high as 10^6 m^{-3} (Gilfilian *et al.*, 1972). Although having an initial discoid shape, they become more angular as their size increases to typical diameters of 0.1 to 5 mm. Under intense water-to-air heat loss, frazil may be generated during the daytime but, because of warming from solar radiation, it often follows a diurnal cycle characterized by rapid growth at night and cessation during the day.

While frazil particles remain supercooled, they may adhere to and coat other objects within the flow (e.g.

trash racks at hydroelectric plants) or on the riverbed (e.g. macrophytes, rocks, and boulders). Rarely do they coat fine-grained material because they are too easily buoyed by even small amounts of ice and/or because the stronger bed heat flow to such fine-grained smooth surfaces prevents a strong ice-bed bond. In very turbulent conditions, even supercooled water can be carried to the bed, where it nucleates and adheres to the bed. Both of these bed-ice forms are termed "anchor ice", the nucleation-anchor ice having the smoother surface of the two (Tsang, 1982). Where flow and cold conditions permit continued anchor-ice growth, substantial accumulations can develop. These will either ablate during warming periods or release, either when they are sufficient to buoy the bed material or when they suddenly lose their bond during a period of rapid warming. Marcotte (1984), for example, reports large blocks 6 m in length being released from a 20-km^2 zone of the St. Lawrence River, where anchor ice grows up to 1.5 m thick.

Frazil crystals that remain within the main flow gradually grow and agglomerate into small clusters and larger flocs (5–100 mm). Eventually, they reach sufficient size and buoyancy that they periodically float to the surface where they are exposed to direct surface cooling, begin to grow and become even more buoyant. Accumulation of large amounts of frazil flocs at the surface is referred to as "frazil slush". Such material also tends to adhere to border ice, successive "buttering" of the edges producing bands that demark cycles in frazil-ice production. Eventually, interstitial spaces in the frazil slush become sufficiently frozen that they take on a more rigid surface form called "frazil pans".

Swept around by surface currents and ground against one another, the frazil pans gradually take on a circular form and are referred to as "pancake ice" (Figure 1a). As these frazil products become more congested and in contact with one another for long enough periods, they freeze-bond into large frazil floes. Although the above has described frazil evolution from initial crystal to large floe, all forms can be present within a reach at the same time.

Highly turbulent sections, such as rapids, can generate tremendous amounts of frazil ice; much more than would be produced if the section developed an *in situ* ice cover. An estimate of the total potential ice production in an open reach can be obtained by simply integrating the water surface to atmosphere heat loss over time (when the water temperature = 0 °C):

$$V_i = \frac{1}{\rho_i \lambda_i} \int_{t_2}^{t_1} A_o \phi_* \, dt \qquad (2)$$

where V_i is the volumetric production of ice (m^3 s^{-1}), ρ_i is the density of ice ($\sim$920 kg m^{-3}), λ_i is the latent heat of fusion for ice (3.34×10^5 J kg^{-1}), A_o is the area of the open-water reach that may also change with time from ice accumulation and border-ice growth (m^2), and t is time (s). This equation assumes that all ice is produced under open-water conditions, such as the typical case for frazil production. It does not account for ice growth at the base of an *in situ* ice cover, which can be much slower because of the insulation to air temperatures created by the overlying ice and snow.

Freeze-up

Eventually, enough ice is produced and transported along a river that floes become sufficiently large and congested to bridge across the river and obstruct the downstream passage of other upstream ice (Figure 1b; see, e.g. Shen (2000) for a review of ice transport theories). Bridging locations are difficult to predict but reach geometry and flow characteristics that favor congestion, such as a narrowing reach or a concentration of bridge piers, are particularly susceptible. Whether additional upstream ice will accumulate behind, or pass beneath the arched floes depends primarily on ice thickness, flow depth, and river velocity. Flow velocities greater than $2\,\mathrm{m\,s^{-1}}$, for example, are required to submerge and entrain large ice pans (Michel, 1971), whereas much lower velocities are sufficient to transport less-developed frazil forms.

Travelling beneath an ice cover, transported ice will melt, reemerge at a downstream open-water section, or deposit underneath where local flow conditions reduce transport capacity. Large accumulations of such deposited ice are referred to as hanging dams. Common locations for their formation include deep pools adjoining upstream rapids and confluences of rivers and lakes. Some massive hanging dams have been reported. On the La Grande River in Canada, for example, one was reported to contain $56 \times 10^6\,\mathrm{m^3}$ of ice over a 16-km long reach (Tsang, 1982). Such large obstructions in the channel cross-section can concentrate flow and cause localized bed erosion. During periods of rising discharge, particularly during the spring, they can also create serious backwater flooding problems before being flushed downstream or thermally eroded.

Winter Ice Growth

Initially, the surface layer of river ice will comprise a myriad of accumulating and/or compressed frazil forms. Subsequent growth results from vertical downward freezing of the underlying water column and the incorporation of any frazil ice deposited along the ice bottom. In the absence of frazil, the ice cover can be highly transparent, similar to the "black" ice (or blue ice having a large-grained columnar structure, often transparent) that is typical of lake ice (Adams, 1981; Prowse, 1995). The rate of growth depends on heat exchanges at both the ice-atmosphere and ice-water boundaries:

$$\frac{\mathrm{d}h_\mathrm{i}}{\mathrm{d}t}\rho_\mathrm{i}\lambda_\mathrm{i} = \frac{(T_\mathrm{b} - T_\mathrm{a})}{(t_\mathrm{i}/k_\mathrm{i}) + (t_\mathrm{s}/K_\mathrm{s})(1/C_\mathrm{a})} - C_\mathrm{w}(T_\mathrm{w} - T_\mathrm{b}) \quad (3)$$

where t_i and t_s are ice and snow thicknesses (m), k_i and k_s are the thermal conductivities of ice ($2.2\,\mathrm{W\,m^{-1}/°C}$) and snow (0.1 to $0.5\,\mathrm{W\,m^{-1}/°C}$ for snow densities of 150 to $500\,\mathrm{kg\,m^{-3}}$); T_a, T_b and T_w are the air, basal ice and water temperatures (°C); and, C_a and C_w are the heat transfer coefficients from ice to air and water to ice ($\mathrm{W\,m^{-2}/°C}$). The latter two coefficients are highly variable primarily depending on ice roughness and wind and current velocity. See Ashton (1986) and Prowse (1995) for further explanation.

When the ice cover is rapidly growing in near 0 °C-water, the right-hand term in equation (3) – the water-ice heat transfer is often considered to be relatively insignificant. With other relatively minor simplifications (see Prowse, 1995), it is possible to predict ice growth using the Stefan formula that uses a degree-day index for the major heat fluxes:

$$t_\mathrm{i} = \kappa(D_\mathrm{f})^{1/2} \quad (4)$$

where D_f is accumulated freezing degree-days below 0 °C and κ is a coefficient (which has a theoretical maximum of $[2k_\mathrm{i}/\rho_\mathrm{i}\lambda_\mathrm{i}]^{1/2}$ or $0.035\,\mathrm{m/°C^{1/2}\ d^{1/2}}$) that accounts for differing surface insulation as supplied by overlying snow and varying degrees of exposure to atmospheric heat fluxes. Although equation (4) tends to overpredict growth during the initial stages, it gives reasonably reliable results once the cover is greater than approximately 0.1 m. Typical values of κ for a river with snow are $0.014–0.017\,\mathrm{m/°C^{1/2}\ d^{1/2}}$. Insulation provided by snow can dramatically slow ice growth. For relatively thick ice covers, a snow depth equal to approximately half the ice thickness will effectively halt further ice growth (Michel, 1971).

When significant accumulations of snow load an ice cover, it can depress the ice below the hydrostatic water level such that water rises into the overlying snow, "slushes" it and, following a subsequent refreezing of this snow-water mixture, leaves a surface stratum of "white-ice" (or snow-ice having a typical small-grain polycrystalline structure, generally translucent; e.g. Adams, 1981; Prowse, 1995). The small-grain physical structure of this ice is not too dissimilar from many frazil-ice forms. Such ice growth occurs at an accelerated rate since the freezing occurs in more direct contact with the cold atmosphere. Thick layers of frazil deposited at the base of an ice cover can also accelerate total growth since the downward freezing will occur much more rapidly into an ice-water mixture than into water alone (Calkins, 1979; Timco and Goodrich, 1988).

Icings, aufeis, or naleds are another form of river ice but are most typical of the colder subarctic and arctic climates. Somewhat similar to the formation of snow-ice, icings are surficial accumulations formed by the flow of water onto the surface of an ice cover, usually the result of some localized flow resistance in a channel that forces water to the surface or, in the case of smaller streams, from groundwater seepage (e.g. Carey, 1973; Kane, 1981; van Everdingen, 1990). They can accumulate as a widespread sheet of ice or as a localized mound depending on the rate of flow versus surface freezing. In cases where the process continues throughout the winter and where an icing deposit

may be fed by a number of seepage points, entire channels and even floodplains can be coated to thicknesses several times the open-water channel depth or the ice thickness that would occur from normal freezing of the underlying flow. So large are some accumulations that they control the routing of flow during spring melt and sustain flow during the warmer summer months (e.g. Shumskii, 1964; Gray and MacKay, 1979). Icings can create a flood risk where they plug culverts and, by their mass, decrease the flow required to overtop banks.

Ice Breakup

Breakup of a river-ice cover can occur at anytime during the ice-covered season. Within the more temperate climates, the winter period may actually comprise a series of freeze-up/breakup cycles, whereas in colder climates, breakup is typically a spring event. In either case, breakup is initiated when the forces driving breakup, primarily resulting from the spring flood wave produced by snowmelt and sometimes assisted by rainfall, exceed the resisting forces or those operating to keep the ice cover intact, such as ice thickness, internal mechanical strength, and bonds to the bank and bed.

During the prebreakup period, as the snowcover on the landscape begins to ripen and melt, so does the river-ice cover both at the surface and at the bottom. The ice bottom melts when the water-ice heat transfer exceeds the rate at which heat can be conducted upward into the ice sheet – most rapid melt typically occurring after the ice sheet has warmed to a 0 °C isothermal state. Although the temperature of the river water may only be a fraction of a degree above freezing, even moderate flow velocities can cause a large and rapid heat transfer to the ice bottom (Marsh and Prowse, 1987). The rate is also influenced by the bottom-ice roughness, which tends to increase during the prebreakup period from the formation of ice ripples. Heat transfer greater than 50 to 60% has been reported for rippled compared to smooth ice bottoms (Ashton and Kennedy, 1972; Gilpin *et al.*, 1980).

Obtaining relevant data to calculate the combined surface and bottom ablation of a river-ice cover is extremely difficult but moderate success has been achieved by relating total thinning with accumulated melting degree-days (Bilello, 1980):

$$t_i = t_o - \varepsilon\beta_m \tag{5}$$

where t_o is the maximum ice thickness prior to decay (m), β_m is accumulated melting degree-days (–5 °C base temperature for river locations) and ε is a site dependent, empirical constant (for values typical of specific regions see Bilello, 1980; Beltaos, 2005).

Melt at the snow and ice surface is driven by a combination of sensible, latent and radiative heat transfers but it is only shortwave radiation that produces major changes to the mechanical strength of an ice cover. Once the highly reflective surface-ice forms such as surface frazil and snow-ice are ablated, significant amounts of radiation can penetrate the ice sheet where it is attenuated at ice-crystal boundaries producing localized melt (Ashton, 1985; Prowse *et al.*, 1990). As this process continues, the structural integrity of the ice sheet reduces and poses an ever-decreasing resistance to the forces impinging on it by the rising flow.

As flows and stage increase, the ice cover eventually fractures in patterns determined by its spatial heterogeneity in thickness, strength, and bond to the bed and banks. In particular, upward loading by the rising water causes cracks to develop parallel to and in close proximity to the banks (Beltaos, 1997). Eventually, the main ice sheet will detach from the banks completely and an open-water shore lead will exist. With such detachment and a wider channel produced by the rising stage, the ice cover is able to shift within its channel, eventually leading to the formation of transverse cracks (Shulyakovskii, 1972; Beltaos, 1997). These are commonly found at acute changes in channel geometry such as at meander bends (Beltaos, 1984a).

Hydrometeorological conditions leading to the final breakup are typically defined into two general states: over-mature and premature. In the first case, which resembles ice breakup conditions on lakes, the ice cover continues to be thermally and mechanically weakened while river runoff remains relatively small. The low discharge is usually because of a small winter snowpack and/or slow protracted snowmelt. The ice cover is eventually so weakened that it offers minimal resistance to even low flow and is easily swept downstream. This type of event is usually referred to as a "thermal" breakup. For the premature case, conditions are reversed to include a large flood wave being driven into a mechanically strong, largely competent ice cover.

Eventually, the rising discharge becomes sufficient to dislodge, further fracture, and drive the ice cover downstream. This is usually referred to as a "dynamic" or "mechanical" breakup.

Breakup timing at a site is a complex process dependent on a suite of variables including, cover thickness (ice and snow), ice strength and structural variability, river geometry, flow velocity, and stage. The simplest approach used in predicting breakup timing has relied on a single heat index such as accumulated degree-days. Only limited success has been achieved with this approach because it does not treat separately changes in the components that comprise the driving and resisting forces. Another simplified approach has focused on the rise in stage relative to the freeze-up level and the peak ice thickness. It assumes that breakup should not occur until the stage has surpassed the original freeze-up level, at which time the ice cover has been freed from most bed and bank constraints. The stage

at which breakup occurs is then measured relative to the ice thickness. A rise in level equivalent of two to four times the ice thickness is a typical value (e.g. Beltaos, 1984b, 1990; Donchenko, 1975), although this relates to a fairly broad range in water levels and rises in stage are also difficult to predict. A refinement of this approach (Shulyakovskii, 1966; Beltaos, 1990) also considers the decreases in ice thickness and strength that occur during the prebreakup period by including an accumulated heat flux term, usually calculated from local climate-station data. A premature (mature) breakup, for example, would be one with small (large) amounts of prebreakup warming but large (small) rises in the stage. Beltaos (1997) reviews more physically based equations for predicting the initiation of mechanical breakups using variables such as river surface width, channel curvature, freeze-up stage, and ice competence.

ICE EFFECTS ON WATER LEVELS AND DISCHARGE

Ice-covered conditions on rivers create water level and flow conditions quite dissimilar from those for the open-water period. Such conditions begin with the first formation of an ice cover and its elevation of water levels. For steady flow in a wide rectangular channel the water depth, H (m), is given as

$$H = 1.32\left[\frac{Qn_c}{B\sqrt{S}}\right]^{3/5} + \frac{\rho_i t_i}{\rho_w} \tag{6}$$

where Q is discharge ($m^3\ s^{-1}$); B is the cover accumulation width (m); S is water surface slope; and n_c is the composite Manning roughness coefficient. The depth of flow beneath the ice, as derived from the uniform-flow resistance equation, is represented by the first term on the right-hand side of equation (6). The second term represents the submerged portion of the ice cover, assuming free floatation without snow loading. The composite Manning roughness coefficient is given by (e.g. Ashton, 1986)

$$n_c = \left[\frac{n_b^{3/2} + n_i^{3/2}}{2}\right]^{2/3} \tag{7}$$

where n_b and n_i are the hydraulic roughness coefficients for the riverbed and ice bottom respectively. For typical values see Ashton (1986) and Gray and Prowse (1993). Much of the increase in stage under ice conditions results from the increase in wetted perimeter produced by the ice cover. Ice roughness plays an additional role depending on whether it is rougher or smoother than that of the bed. The ratio of ice to open-water depth for varying ice roughnesses can be obtained from the simplification of Beltaos (1982):

$$\frac{H_i}{H_o} = \left[1 + \left(\frac{n_i}{n_b}\right)^{3/2}\right]^{2/5} + 0.92\frac{t_i}{H_o} \tag{8}$$

where H_i and H_o are the water depth (m) for ice and open-water conditions, respectively.

Freeze-up Levels

As frazil pans and floes begin to accumulate in a river reach, it is their thickness and sub-surface roughness that cause a rise of the water level above the open-water value. Even when the ice thickness is relatively small, their roughness alone can cause an appreciable increase in stage. For example, when n_i is equal to n_b (equation 8), the flow depth will be approximately one-third greater than that for equivalent discharge under open-water conditions. Much larger backwater effects can be created when the ice cover thickens or collapses to form a relatively rough, freeze-up ice jam.

The initial thickness of an accumulating freeze-up cover depends on flow depth and velocity, and ice floe characteristics such as porosity (e.g. see reviews by Beltaos, 1995; Gray and Prowse, 1993). This type of cover development assumes that the internal strength of the accumulation can withstand the increases in forces created by its own gravitational-weight component and fluid shear stress at its base, as it grows upstream. For wide river channels, however, such "deposition" covers lack the initial strength to resist these forces and tend to collapse and telescope down into a thickness with sufficient internal resistance. These thicker and usually rougher accumulations create substantially more backwater and in extreme cases can pose a significant flood hazard. For example, with $n_i = 3n_b$ and a jam thickness approximately equal to the open-water depth, water depth would approximately triple. Over time, however, the roughness of such accumulations tends to reduce, either from thermal smoothing of the ice bottom or from additional infilling of ice from frazil deposition in concave portions (Ashton and Zufelt, 1991). As this occurs, the backwater decreases. Large additions of frazil, however, could also increase roughness and raise water levels.

Flow Storage and Low Flows

As a freeze-up cover develops, it can also affect discharge through the storage of river water either in the form of ice or in hydraulic storage. The first process most strongly affects shallow low-velocity streams, and is most pronounced during the initial rapid stage of ice formation, but continues throughout the winter as the ice cover continues to grow. Its total effect on flow is relatively minor. A much larger effect on discharge is created by the hydraulic storage of

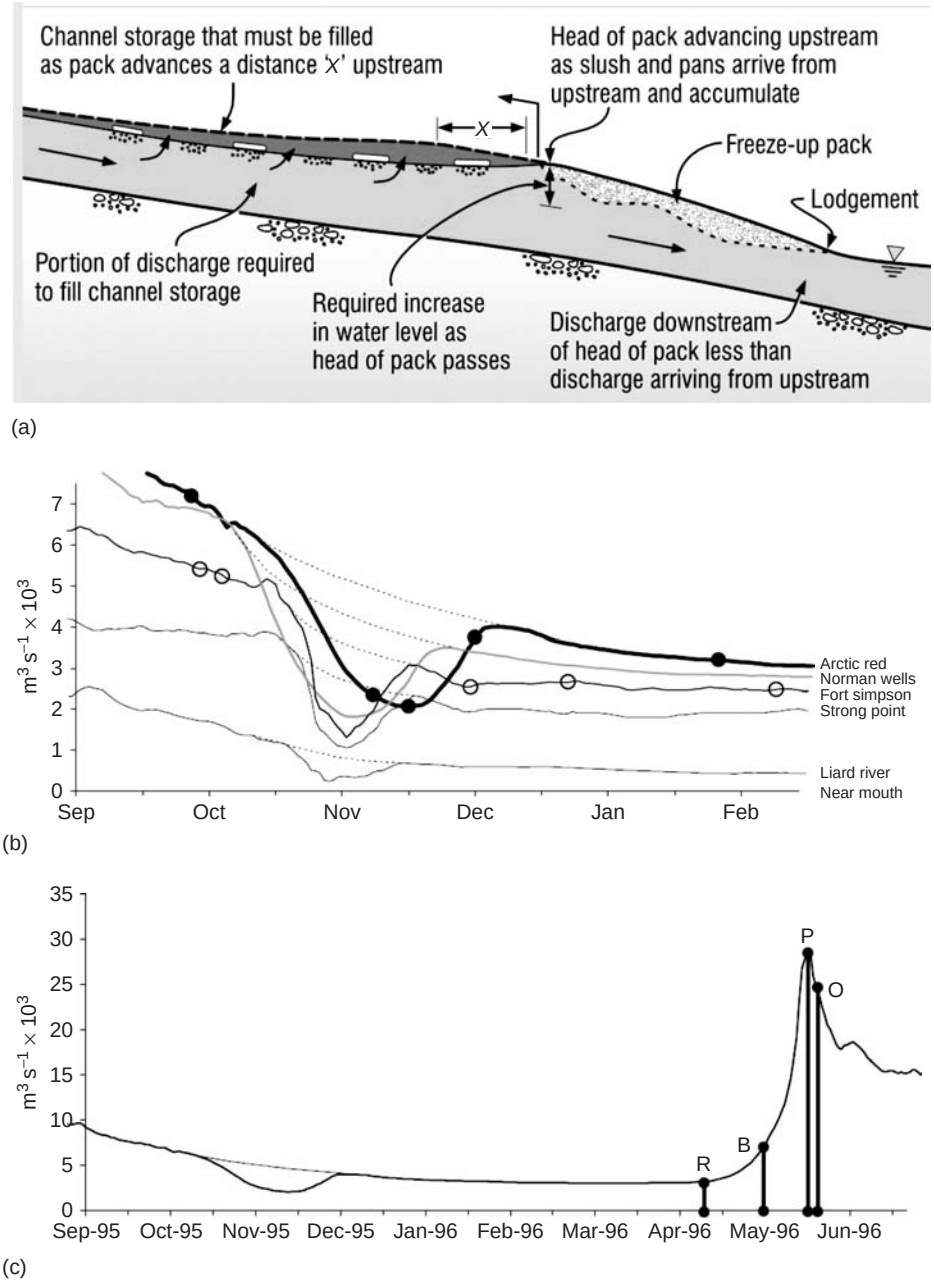

Figure 2 (a) Loss of storage to advancing freeze-up front (after Gerard, 1990); (b) Depressions in fall discharge on various sections of the Mackenzie River, Canada, 1995. Circles indicate field hydrometric measurements. (c) Same depression is evident in the seasonal hydrograph, which contrasts the size of the spring freshet. Most of the freeze-up storage is released between interval labeled ''R'' and ''O'' ((b) and (c) Reproduced from Prowse and Carter, 2002 by permission of John Wiley & Sons Ltd.). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

river water as it is abstracted to satisfy the stage increase at freeze-up (Figure 2a). The amount required depends on equation (8) and the upstream geometry of the channel. Huge storage requirements exist, for example, in cases where a lake or wide-channel system exist upstream of an ice-jam location. During the time that water is being removed from the flow, a period of reduced discharge exists downstream. As shown in Figure 2(a), the low flow at the trough of the discharge depression can be less than half that which would occur without ice effects (i.e. dashed line). Moreover, it is lower than that occurring in late winter when runoff from the snow-covered landscape is at a minimum. Flow abstraction ceases when the ice cover stops advancing upstream. Although this effect has been documented on a

variety of systems ranging from small temperate streams to large subarctic rivers (e.g. Conly and Prowse, 1997; Gerard, 1981; Gerard, 1990; Gray and Prowse, 1993; Hamilton and Moore, 1996; Moore *et al.*, 2002; Prowse and Carter, 2002), it is most pronounced and long-lasting on large rivers, with extensive upstream storage requirements. On the lower portions of the Mackenzie River, for example, Prowse and Carter (2002) found the period of freeze-up flow abstraction to last 60 days and to account for approximately 27% of the total expected flow during this period (Figure 2b).

Flow Augmentation

All the water abstracted from flow by river ice, either through hydraulic or frozen storage, is eventually released back into the flow. One of the more significant flow additions occurs when water in hydraulic storage is "discharged" at breakup. Even prior to this, however, volumes of water can be released as the ice-cover roughness changes. Thermal smoothing of initially rough freeze-up ice covers, for example, will lead to a release of some stored water although additional water can be placed back into storage as the bottom roughness increases due to thermal roughening (development of waves or ripples in the ice bottom) in early spring. Final release of this stored water only occurs at breakup when the ice cover is removed and the flow resistance of the ice cover eliminated. Studies of the Mackenzie River have shown that such seasonal transfer of water (from freeze-up to breakup) *via* hydraulic storage effects is rarely considered in flow calculations and can lead to an overestimate of the size of the spring snowmelt runoff (Figure 2c; Prowse and Carter, 2002).

Accompanying the release of hydraulically stored water at breakup is the melt of the accumulated winter ice cover. Depending on the intensity of the spring heating from atmospheric and hydrothermal sources, ice melt can be very protracted or produce a rapid addition of water to river flow. The localized addition of flow can be especially pronounced where breakup has led to a large thick accumulation of ice. Prowse (1990), for example, showed that the intense ablation of an ice jam produced a flow addition of approximately $100\,m^3\,s^{-1}$ over a three-day period on a large northern river, a value roughly equal to that contributed by spring melt from major tributary streams. Significant additions to flow from melting of in-channel ice also occur on systems characterized by large and/or numerous icings. These can be quite extensive on some northern rivers and produce a significant effect on the magnitude of flow on downstream larger-order rivers (e.g. Gerard, 1981). Of particular importance are contributions to summer flow on high-latitude continental rivers, which are typically low because of small summer precipitation and runoff (van Everdingen, 1987; Prowse, 1994).

Floating ice covers on lakes can assist in augmenting flow to downstream rivers at various times throughout the ice-covered season. This is particularly the case in regions or seasons characterized by significant winter snowfall. Loading of an ice sheet by a snowpack depresses it into the water column and displaces the related volume of water into the downstream flow system. Over 10% of the total winter flow in areas of northern Quebec, Canada, has been attributed to snow loading effects (Jones, 1969). Moreover, a snow load of only 50 mm (water equivalent) has been calculated to produce a 20% increase in discharge from some Finnish lakes (Kuusisto, 1984). Such flow additions are important modifiers of the winter flow regime, particularly in areas of low winter discharge. Periodic snowfall events are reflected as flow pulses in river hydrographs.

Breakup Ice Jams, Flooding and Surges

The progression of river-ice breakup is not continuous and is frequently interrupted by the formation of ice jams, the initiation of which is the focus of considerable current research (e.g. Beltaos, 1995; Hicks *et al.*, 1997; White, 2003). Although ice jams may develop at almost any location, especially when initially developed from the final runout of a breakup surge (Figure 3a), sites of regular major ice-jam formation are those where ice conveyance is significantly reduced. Channel constrictions, sharp bends, island complexes, bridge piers (Figure 3b), and reaches with significant decreases in river slope and/or widening of the channel, such as rivers entering larger rivers or lakes, are sites especially prone to ice-jam development. Unfortunately, an ability to forecast whether and where a jam will develop remains elusive (Beltaos, 2000).

A shoving and thickening of fragmented floes into a thickness with sufficient internal strength to resist the downstream forces exerted on it usually forms major breakup ice jams. At the downstream end or "toe", ice thickness is greatest and can even extend to the bed, thereby greatly increasing the flow resistance and strength of the accumulation. Water levels increase rapidly through the toe, typically creating a hydraulic slope greater than anything possible under normal open-water conditions. Assuming that the ice jam is of sufficient length, the central portion is occupied by an equilibrium reach characterized by maximum water levels (for this jam at this site) as well as uniform ice thickness and flow conditions (Beltaos, 1983, 1995). Further upstream within the ice jam head, the ice thicknesses gradually decrease into the upstream open-water zone. Backwater effects, however, can be experienced significant distances upstream beyond the ice-covered zone. On large northern rivers, they can easily extend 20 or more river widths upstream. The distance depends on the magnitude of the ice-jam water-level increase and the slope of the upstream channel.

Depression of intact ice cover by advancing front has produced temporary surface ponding of water (Photograph: T.D. Prowse). (b) Ice jam formed against road bridge and supporting piers, St. John River, Canada (Photograph: S. Beltaos). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Ice jams exceeding 5 to 10 m in thickness are common on large northern rivers and the n_i created by the rough ice in such accumulations can be 0.05 to 0.10 (Gray and Prowse, 1993; Beltaos, 2001). Given such high thicknesses and that roughness values are several times those for even gravel or cobble bed rivers (e.g. 0.02–0.03; Shen and Julien, 1993), it is evident from equation (8) that the largest backwater levels are possible under ice-jam conditions.

Maximum water levels from an ice jam exist within the equilibrium reach but not all ice jams reach an equilibrium state. Regardless, however, the water levels that they create still exceed those under open-water conditions at equivalent discharge. It is the equilibrium condition that is typically used to assess maximum flood risk from ice jams (Watt, 1989). As for open-water conditions, higher discharge equates to increased equilibrium ice-jam water levels. Figure 4(a) illustrates a case for a large northern river including a theoretical maximum ice-jam curve, records of observed ice-jam water levels, and a rating curve derived for open-water conditions. Notably, in this case, many of the jam-induced water levels exceed those produced by the highest open-water flood ever recorded on the river. Moreover, most were produced at discharges only one–third to one–fourth as great even without reaching an equilibrium state.

Despite the strong effect that ice has on water levels, probability/recurrence interval analyses of ice-induced flooding are relatively rare (e.g. Gerard and Karpuk, 1979; Gerard and Calkins, 1984; Watt, 1989; Grover *et al.*, 1999). This is more surprising from a flood-damage reduction perspective since data (e.g. Beltaos, 1982; Beltaos and Burrell, 2000a; Gerard and Karpuk, 1979) suggest that the larger floods have lower recurrence intervals under breakup than open-water conditions (e.g. Figure 4b).

Even when ice jams do not form in a particular reach, the large roughness associated with the rubbled ice in the advancing breakup front can produce dramatic increases in stage. Some of the largest and most rapid increases can be produced by surges associated with the upstream release of an ice jam (e.g. Beltaos and Krishnappan, 1982; Henderson and Gerard, 1981; Blackburn and Hicks, 2003). Breaking fronts associated with such surges have been documented to travel at over $5\,\mathrm{m\,s^{-1}}$ over long distances (e.g. Jasek, 1999, 2003). Rapid releases from flow-control structures have produced similar responses and offer opportunities for operational control of breakup conditions (Ferrick and Mulherin, 1989).

Sediment Transport and River Morphology

River ice is an important agent of geomorphological change because of its effects on erosional and depositional processes. The additional resistance to flow created by an ice cover leads to an increase in flow depth and a decrease in average flow velocity. A slower rate of energy dissipation is therefore required because the channel is conveying a deeper, slower flow. In general, therefore, the overall capacity of the channel to transport sediment and channel shaping is reduced. This can, for example, trigger changes to thalweg alignment and/or concentration. In the case of sinuous braided channels, for example, ice-induced reductions in the energy gradient can cause flow to concentrate in a single thalweg of greater sinuosity than the open-water thalweg (Ettema, 2002).

Variations in an ice cover can also lead to the redistribution of flow and changes in the position and/or depth of the thalweg (e.g. Hicks, 1993; Ettema and Zabilansky, 2004). In the special case of hanging ice dams, for example, their

large thickness can cause a concentration of flow and a pronounced local scour of the riverbed (e.g. Sui *et al.*, 2000).

Many morphological features of an ice-covered river have developed over multiple years, although ice is also capable of producing some very dramatic changes within a single season. The most dramatic of these occur during the dynamic periods of freeze-up and particularly breakup. In contrast to the general reduction in sediment transport capacity that occurs during the stable ice period, breakup can produce dramatic increases in suspended sediment concentration, largely as a result of the intense ice scour of the bed and banks (Figure 5a and b). Field studies of two quite different Canadian rivers found that although sediment concentrations were quite low during the late-winter prebreakup period ($<10\,\mathrm{mg\,L^{-1}}$), they gradually increased by an order of magnitude or more just prior to breakup, and then peaked at over $1000\,\mathrm{mg\,L^{-1}}$ during active breakup (Prowse, 1993; Beltaos *et al.*, 1994; Beltaos and Burrell, 2000b; Milburn and Prowse, 1996, 2002). Peak concentrations can be several times that which would occur under open-water conditions for equivalent discharge (Prowse, 1993), pointing to the weakness of using any open-water derived sediment rating curves during these dynamic periods (Milburn and Prowse, 1996).

For many northern rivers, breakup can also be the period of maximum annual sediment transport. Walker (1969), for example, found that 75% of the annual sediment load was transported on a large Alaskan River during the three to four weeks period accompanying and immediately following breakup (also associated with 50% of the annual runoff). Flow surges during breakup are also believed to be effective transporters of bed-load material. Beltaos (1993), for example, estimated that a $5\text{-m\,s}^{-1}$ breakup surge would produce sufficient shear to move bed material as large as 0.2 m in diameter.

Although ice can accelerate erosion of soft-rock material, such as shale and limestone (Dionne, 1974; Danilov, 1972), ice-scour effects are most pronounced in alluvial rivers. Examples of erosional features include high-level benches (Smith, 1980) and undercut banks (e.g. Marusenko, 1956); the oversteepening of the latter being a major contributing factor in the initiation of landslides (Code, 1973). Slope failures can also result from sudden changes in effective (inter-granular) pressure and shearing resistance of the bank material produced by rapid fluctuations in water level produced by dynamic ice events. Over the long term, breakup has been proposed as being a significant factor in overall channel enlargement (Smith, 1980; Martinson, 1980). This issue remains unresolved (e.g. Kellerhals and Church, 1980; Church and Miles, 1982; Koutaniemi, 1984) and some evidence exists to suggest that overbank losses of flow due to ice jams may even promote channel narrowing (Ettema, 2002).

In regions dominated by permafrost or well-frozen near-surface material, the effects of ice scour are usually limited to the initial layer of unfrozen bank material (e.g. Eardley, 1938; Gill, 1972; Outhet, 1974), although near the ice-water-bank interface, thermo-erosional niches can be common (e.g. Lawson, 1983). Where such ice and water action exposes ice-rich permafrost, major bank destabilization can occur (Newbury and McCullough, 1983; Scott, 1978; Walker and Arnborg, 1966; Walker, 1969).

Ice-induced erosion can be especially effective in modifying channel morphology at river bends and meanders (e.g. Martinson, 1980). Under open-water conditions, the

outside of meander bends is normally a site of sediment erosion and the inside, sediment deposition. Under ice-jam conditions, however, the congestion of ice in the main channel often leads to a diversion of flow across a meander bend (e.g. Mackay *et al.*, 1974). If severe enough and/or if a meander-loop neck is relatively short, flow can be redirected into ancillary channels or a new dominant channel can develop through the neck thereby reducing local channel sinuosity (Williams and MacKay, 1973; MacKay *et al.*, 1974). Redirection of flow is common in river deltas, where ice-induced flooding frequently causes the shifting of distributaries through channel avulsion.

Although most ice-induced erosional features have been observed above the ice-water level, breakup ice scour is also known to affect the channel bed (e.g. Collinson, 1971; Danilov, 1972; King and Martini, 1984). Similarly, high-water velocities produced by ice-jam surges and found beneath ice jams can produce significant local bed erosion (e.g. Mercer and Cooper, 1977; Wuebben, 1988).

In addition to erosional features, river ice also leaves some unique depositional features varying from thick layers of sediment to localized boulder accumulations. In the meander case note above, for example, where a meander-loop neck is too wide and/or not easily eroded, overbank deposition of large amounts of sediment can raise the bank height and reinforce the meander loop (Ettema, 2002). For river regimes characterized by a decline in discharge following breakup, thick coats of sediment often blanket the low-velocity portions of the channel bed. Similar coatings can be found on the bank and floodplains, their depth being exceptionally large where breakup flow velocities, and hence sediment transport capacity, are dramatically reduced compared to those experienced in the main channel. Alluvium depths from a single event of up to 1 m, for example, have been reported on the Yukon River where successive accumulation are believed to have raised portions of the floodplain by as much as 6 m (Eardley, 1938). Sediment accumulation on the floodplain combined with low-level ice scour can accentuate the form of the above-noted high-level benches. The term "bechevniks" (portion of a bank suitable for rope towing of river craft) has been used to describe some of these ridge or bench features on Russian rivers, especially those repetitively worked by ice push (Hamelin, 1979). Sediment deposited by backwater flooding from ice jams in river deltas has also been noted to assist in the development of levees (Henoch, 1960) and the buildup of land between channels (King and Martini, 1984; Ritchie and Walker, 1974).

Direct ice-shove can also produce some localized large-scale depositional features, especially at outside bends, upstream ends of islands and banks opposite major tributaries. Although layers of light alluvium are often bulldozed into ramparts at such locations, they are usually washed away by subsequent surface runoff and high channel discharge (e.g. Bird, 1974). Where heavier till exists, the regular bulldozing of material and the subsequent washing away of finer materials can lead to the formation of more stable features such as boulder buttresses, barricades, ridges, and pavements (e.g. Mackay and MacKay, 1977; Rosen, 1979; Barnes, 1982). The first three are relatively localized features (Figure 6a) but wide stretches of the latter (Figure 6b) can be found covering hundreds of kilometers of river bank on large northern rivers (Kindle, 1918; Wentworth, 1932).

River Ecology

Dissolved Oxygen and Mixing Processes

Hydrologic processes affect numerous bio-geochemical systems in rivers. Over the winter months, isolation of the water column from direct atmospheric exchanges through

(a)

(b)

the development of an ice cover produces some dramatic changes in stream-water chemistry. A change in dissolved oxygen (DO) levels is one of the most significant and has the largest potential to affect the entire river ecology.

As water temperatures decline during the autumn, rivers typically experience a rise in DO, often reaching a peak just prior to freeze-up, largely because of the increasing solubility of oxygen with decreasing water temperatures. Following complete freeze-over, however, DO can drop dramatically (e.g. within days; Whitfield and McNaughton, 1986). The rate of decline is largely dependent on the oxygen demand of the water column and channel bed (i.e. from respiration and decomposition), and the background DO level of the waters comprising the late-autumn discharge. With the elimination of direct water–air reaeration, DO decline can be quite precipitous for rivers where poorly oxygenated groundwater is the major, autumn flow component. Subsequent reductions tend to be much more gradual, reflecting the increasing proportion of poorly oxygenated groundwater in the flow (e.g. Schreier *et al.*, 1980), such as that originating from extensive wetlands, peatlands, bogs and/or fens. The oxidation of organic carbon flowing from such environments can further reduce DO levels. Similar DO depression can result from the input of oxygen-consuming material such as from industrial and municipal sources (e.g. Chambers *et al.*, 1997). In all these cases, it is important to remember that the presence of an ice cover effectively increases the residence time of the flow (by increasing stage and slowing velocity) exposed to various oxygen exchange processes (Ferrick and Calkins, 1996). Furthermore, since cold water temperatures slow decomposition and winter low flows reduce dilution, biological oxygen demand (BOD) can also be the highest during the ice-covered period (Hou and Li, 1987).

Although many rivers exhibit a gradual downstream decline in DO, this effect is not universal (Chambers *et al.*, 1997). Downstream gradients in DO are rarely simple and reflect a complex mixture of climatic, hydrologic, hydraulic, geochemical, and anthropogenic chemical conditions. Often, severe depletion can be eliminated by reaeration from a reach of open-water rapids or from highly oxygenated flow introduced from a lake-fed tributary. Moreover, although ice-covered conditions favor low DO, even larger depressions can occur under summer conditions with higher water temperatures and greater inputs of organic material.

Similar to the controlling conditions in lakes (e.g. Prowse and Stephenson, 1986), DO in rivers can rise in the spring because of the seasonal increase in available radiation, a decline in reflective losses as the snow is ablated exposing lower-albedo ice surfaces, and the resultant increase in photosynthetic activity (Whitfield and McNaughton, 1986; Cheng *et al.*, 1993). Over much of the winter, reflective losses are controlled by the overlying snowcover, which can have an albedo as high as 0.95 but decreases to the 0.4–0.6 range as the snow ages and ripens (e.g. Gray and Prowse, 1993). Much lower albedos characterize the various underlying white and black ice forms produced under varying combinations of precipitation input, thermal conditions, energy gradients and flow turbulence. Most bare river-ice surfaces are typically formed of white ice with albedos in the 0.3–0.4 range, although some black ice can develop, such as in calm windblown reaches. Highly transparent black ice can have an albedo similar to that for open water, although such conditions are more typical on lakes.

Conditions conducive to increasing the prebreakup photosynthetic production of oxygen are poorest on deep northern rivers characterized by thick ice covers and minimal under-ice flora and greatest on shallower, temperate rivers with thinner ice covers and larger plant biomass. Once the turbulent phase of breakup commences, direct reaeration resumes and DO levels can rapidly increase (e.g. Tilsworth and Bateman, 1982), even to the point of brief supersaturation (Milburn and Prowse, 2000). By contrast, breakup can also promote dramatic spring declines in DO. This can occur when significant amounts of organic material are resuspended by ice-induced breakup turbulence and scour and/or collected into the main flow by backwater floods sweeping organically rich riparian zones (Hynes, 1970; Hou and Li, 1987). High water temperatures that often immediately follow ice clearance (e.g. Prowse, 1990; Prowse and Marsh, 1989) can cause a rapid metabolism of such material and produce a marked reduction in DO.

Reductions in flow velocity and shear-stress parameters by an ice cover also directly affect a number of river-mixing parameters such as vertical diffusivity, transverse mixing and longitudinal dispersion. Vertical spreading of dissolved and suspended particles is largely controlled by the degree of turbulence in the flow. Although some questions remain about the vertical distributions of ice-affected flow velocities, it can be generally expected that an ice cover reduces vertical diffusive capacity (Beltaos, 1993). Similarly, although ice is known to change radial velocities (e.g. Zufelt, 1988; Urroz and Ettema, 1992), its effect on transverse mixing remains poorly defined. Most data, however, indicate that similar values of the dimensionless mixing coefficient (relative to total flow depth, not hydraulic radius) can be used for ice and open-water conditions (e.g. see Lau, 1985). Similarly, knowledge is relatively meager about ice effects on longitudinal dispersion, but the downstream spread of materials is expected to be smaller primarily because flow velocities are lower under ice than open-water conditions at equivalent flow depths (e.g. Beltaos, 1993).

Habitat Modification and Disturbance

Ice is capable of creating and destroying the quantity and quality of freshwater habitat on river systems. This

occurs throughout the entire winter season from initial ice growth to final breakup, and the effects are quite different from those normally associated with open-water hydrologic processes.

With the initial formation of border ice, new low-velocity zones protected from terrestrial predators are created along the channel margins (e.g. Power *et al.*, 1993; Maciolek and Needham, 1952). By contrast, the frazil-ice generation that accompanies freeze-up can cause some fish species to avoid main flow sections (e.g. Armstrong, 1986). Such avoidance is probably related to negative effects of frazil on gills and associated breathing (e.g. Brown *et al.*, 1994, 1999; Tack, 1938).

Deposition of frazil ice on the bed and the formation of anchor ice can also cause significant mortality of benthic fauna, ranging from invertebrates to fish embryo and even parr (e.g. McNeil, 1966; Reiser and Wesche, 1979; Calkins and Brockett, 1988; Walsh and Calkins, 1986). Impermeable coats of anchor ice severely restrict the flow of oxygenated water to substrate habitat and prevent the removal of waste products, thereby significantly decreasing the quality of substrate habitat (Figure 7a and b; e.g. Power *et al.*, 1993).

Frazil ice that accumulates on the bottom of an ice cover can, when in large quantities, significantly decrease the amount of available underwater fisheries habitat. Moreover, most deposition occurs in low-velocity zones and pools, the preferred winter habitat for fish to minimize energy expenditure (Brown and Mackay, 1995; Cunjak and Caissie, 1994). As a result of changing winter ice conditions, fish can be forced to emigrate into less-desirable winter habitat. Some fish species, however, depend on frazil masses as an incubating medium, such as the Atlantic tomcod (Fortin *et al.*, 1992; Power *et al.*, 1993). Prowse (2001b) reviews other effects of frazil and anchor ice on winter habitat.

Once a surface ice cover is established, increases in river-water stage and groundwater levels (created either by backwater staging or from direct increases associated with anchor ice buildup) can effectively recharge aquatic habitat in riparian zones that become dewatered by the autumn–winter decline in discharge (e.g. Burn, 1993; Paschke and Coleman, 1986). Many such side-channels and ponds even become preferred winter habitat for some fish species. Decreases in flow resulting from freeze-up staging, however, can also temporarily dewater downstream zones of shallow habitat.

Gradual declines in winter discharge on most ice-covered rivers can also create some unique near-bank habitat. As water levels decline, the original ice cover hinged along the banks drops to lower levels leaving open spaces beneath. These are known to provide access for aquatic mammals that forage bank vegetation and aquatic biota (Calkins, 1993). A similar under-ice habitat can be created in the middle portions of streams where the ice cover

Figure 7 (a) Frazil and anchor ice beneath a floating ice cover, Dutch Creek, Alberta, Canada (Photograph: R.S. Brown); (b) Schematic of frazil production beneath an ice cover, hanging dam formation and coating of gravel bed. Anchor ice makes the gravel bed relatively impermeable to flow and DO, thereby being detrimental to fish egg survival (from Prowse, 2000). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

becomes suspended on high-elevation points of the bed as flows decline (e.g. Calkins and Brockett, 1988; Power *et al.*, 1993).

As ice continues to grow over the winter period, it can freeze directly to the substrate, usually along the banks and in shallow zones. This can produce mortality of benthic organisms depending on their ability to withstand freezing effects and cold temperatures (e.g. Olsson, 1981; Oswood *et al.*, 1991). Extensive reaches of some shallow streams and larger rivers at high latitudes can freeze completely to the bed leaving only isolated pools for overwintering habitat. These are often sustained by groundwater flow and, for some arctic coastal rivers devoid of other unfrozen freshwater habitat (e.g. deep lakes), provide critical overwintering

and/or spawning sites for fish (Craig, 1989; Craig and Poulin, 1975; West and Smith, 1992).

Extreme hydrologic events create a large disturbance to the ecological form and function of freshwater ecosystems. Only of late has the role of river-ice hydrology, and specifically breakup, been identified as a neglected factor in ecological theory of rivers, particularly as it affects disturbances that control biological productivity and diversity (Prowse and Culp, 2003). One of the most obvious effects of the disturbance created by breakup is the gradient in riparian vegetation, whose floristic composition varies by exposure to ice action (e.g. Uunila, 1997). Where relatively frequent dynamic breakups occur, there typically exists a down-bank transition from upper woody species to lower herbaceous plants. Scour from moving or shoved ice usually determines the lower limit of tree growth. Lower sections become denuded of vegetation by breakup action but are usually rapidly recolonized by fast-growing, highly productive pioneer species, usually with root structures that permit a resumption of growth after breakup (e.g. willows (*Salix* spp.)). Banks lacking such vegetation gradients and species diversity are usually indicative of a system dominated by thermal breakups with correspondingly minimal ice scour. Ice scars on trees provide an excellent source of dendrochronological information for examining historical trends in breakup flooding (e.g. Gerard, 1981; Smith and Reynolds, 1983).

Although field observations are relatively scarce, breakup is also believed to be a major modifier of aquatic systems below the water line. Submerged macrophytes, for example, are believed to experience a similar fate to lower-elevation bank vegetation (e.g. Nichols *et al.*, 1989). Breakup intensity has also been suggested to affect the timing of peak algal biomass, species abundance, and community composition (e.g. Scrimgeour *et al.*, 1994). Moreover, since breakup floodwaters reach the elevations of organically rich riparian zones more often than open-water floods, they are likely to be the major supplier of allocthonous organic material and associated nutrients to the river channel and ultimately downstream lakes, deltas and estuaries (Lesack *et al.*, 1991; Scrimgeour *et al.*, 1994). This is especially important in high-latitude cold regions rivers, where biological productivity is commonly limited by nutrient supply (Peterson *et al.*, 1993). Breakup flooding has also been noted as being an essential water-balance component for maintaining water within the myriad of "perched" basins (elevated above the main flow network) that typify northern river deltas (e.g. Marsh and Lesack, 1996; Peters *et al.*, 2004). Drying because of the lack of breakup flooding has been noted to lead to major habitat modification and affect populations of, for example, waterfowl, aquatic mammals, and even large terrestrial mammals (PADIC, 1987; Prowse and Conly, 2001).

Although breakup has been shown to cause major disturbance to macroinvertebrates, their communities seem to recolonize quickly afterward and remain relatively stable from year to year. Interestingly, however, some invertebrate and fish species also exhibit specific behavioral responses, usually involving some type of shelter seeking, to avoid the effects of breakup and ice scour (Brown *et al.*, 2000; Olsson and Söderström, 1978; Prowse and Culp, 2003). In severe breakup that scours large portions of the channel, however, it may not be possible to avoid negative effects. Cunjak *et al.* (1998), for example, found that a major breakup event led to significant declines in the survival of various life stages of Atlantic salmon, especially those in the immobile egg stage at the time of the disturbance. Importantly, this event occurred in the midwinter when some biota tend to be less mobile and more susceptible to impact. Midwinter breakups, often initiated by sudden warming and/or rain-on snow events (e.g. Lawford *et al.*, 1995; Beltaos, 2002) are most characteristic of the climatic margins of the cold regions (Prowse and Bonsal, 2004), the ones most difficult to predict, and with the greatest potential to cause extensive damage to natural and built environments.

SUMMARY

Although past water resource studies of river ice have been limited primarily to site-specific hydraulic issues, the last decade has seen a rapidly growing recognition that river ice can affect a much broader realm of hydrologic processes. Moreover, its effects on basic hydrologic variables can be quite broad in time and space, varying from the short-term generation of localized floods to seasonal redistribution of discharge in major northern basins. Because of its often-dominant role in controlling discharge, velocity and water levels as well as energy and mass exchanges between the atmosphere and water column, it is also a major controller of other geomorphologic and ecologic processes. Despite its recent recognition as an important subfield of hydrology, the study of river ice remains a nascent and slow-growing science. This can partly be explained by (i) a reluctance by many researchers to shift energies away from the more readily studied open-water period, (ii) the greater practical difficulties of conducting field research into river ice as compared to, for example, cold regions landscape processes, and (iii) the broad scientific background required to tackle many river-ice hydrologic problems, such as ice mechanics, hydraulics and thermodynamics. However, considering that the major northward flowing rivers in the cold regions of the Northern Hemisphere are least affected by flow regulation and that they also offer some of the greatest potential for future development (e.g. Dynesius and Nilsson, 1994), it would seem scientifically prudent to focus more attention on advancing our understanding of river-ice hydrology. Further justification is provided by

the fact that ice-covered rivers at high latitudes and the cold regions/temperate margins are the ones expected to be most significantly affected by future climate change (Anisimov *et al.*, 2001; Gitay *et al.*, 2001; Prowse *et al.*, 2002a; Wrona *et al.*, 2004).

Acknowledgments

The author is indebted to S. Beltaos, M. Lacroix, M. Sharp, L. de Rham, D.L. Peters, and the anonymous reviewers for comments on earlier drafts of this manuscript. 172: Permafrost Hydrology

LARRY D HINZMAN[1], DOUGLAS L KANE[1] AND MING-KO WOO[2]

[1]Water and Environmental Research Center, Institute of Northern Engineering, University of Alaska, Fairbanks, AK, US
[2]School of Geography and Geology, McMaster University, Hamilton, Canada

Permafrost is earth material that has temperature at or below 0°C for at least two consecutive summers. Above the permafrost is the active layer, a zone that freezes in winter and thaws in summer. Even though the principles governing water movement in permafrost areas are the same as those in more temperate regions, interactions of extremes in climate and the land surface characteristics render permafrost hydrology different from the hydrology of temperate latitudes. Ice-rich permafrost prevents infiltration of rainfall or snowmelt water, often maintaining a moist to saturated active layer where the permafrost table is shallow. Most hydrologic activities are confined above ground or in the thin active layer, which supplies summer moisture to plants and for evaporative flux. Limited storage capacity of the thawed zone does not support extended baseflow in a stream, though the proportion of baseflow increases as the percentage of permafrost extent decreases. In areas where permafrost is discontinuous or where it has thawed substantially near the surface, local hydrology may display a marked different character as there are stronger exchanges between the surface water and the ground water system, or water may drain laterally resulting in drier surface conditions. Runoff paths range from interhummock cracks, soil pipes, water tracks to distinct channels; and permafrost affects the ground water and contaminant migration pathways. Understanding the interdependence of permafrost, hydrology, and ecosystems is critically important to enable accurate projections of future conditions in the high latitudes.

INTRODUCTION

Hydrology in high latitudes and elevations is uniquely dominated by snow, ice, and frozen ground. Permafrost establishes a unique discipline of hydrologic science where the hydrologic regime is intimately coupled with the thermal regime to the extent that one may not be completely understood without correct characterization of the other. In permafrost regions, material properties may change drastically on a scale of centimeters to meters, particularly in the vertical dimension due to distinct changes in soil and thermal characteristics. Properties may vary just as dramatically in the horizontal dimension across the boundary of discontinuous permafrost. The active layer, the thin layer of soil (on the order of cm to m) above the permafrost, thaws and freezes annually, creating a system of constantly changing storage capacity and thermal and hydraulic properties. Although the spatial extent of permafrost changes on relatively slow timescales in response to disturbance or a changing climate, this too introduces an added level of complexity, as some watershed characteristics may not be considered constant on short or long timescales. Permafrost may nearly eliminate the interactions between near-surface and subpermafrost aquifers, which in essence defines the hydrologic response of every watershed that is directly influenced by permafrost. This text will explore the dynamic control that permafrost exerts upon hydrological processes including distribution, movement, and storage of water that is directly or indirectly influenced by permafrost.

PERMAFROST EXTENT AND CHARACTERISTICS

Permafrost, or perennially frozen ground (*see* **Chapter 71, Freezing and Thawing Phenomena in Soils, Volume 2**), is common throughout the high latitudes and is estimated

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

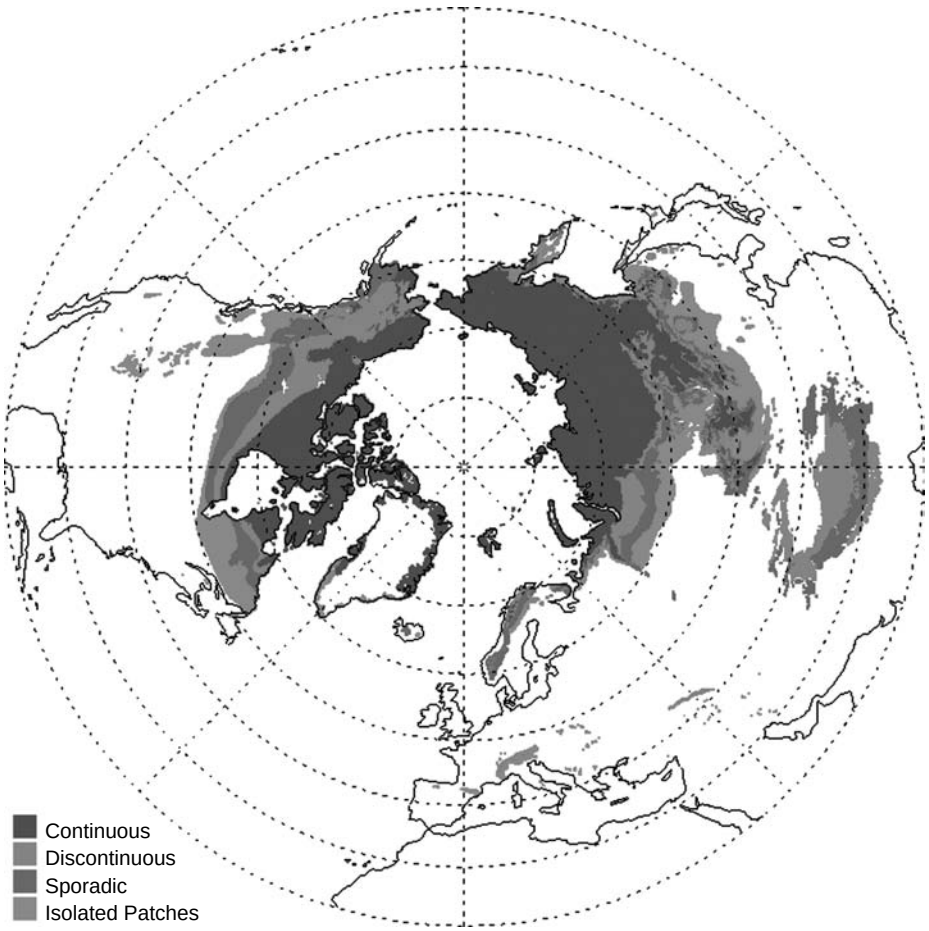

Figure 1 North Polar projection of permafrost distribution in the NorthernHemisphere (Zhang *et al.,* 1999). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

to underlie about 18–24% of the terrestrial surface of the Northern Hemisphere (Brown, 1970; Brown *et al.*, 1998; Zhang *et al.*, 2001) (Figure 1) and exerts tremendous influences upon the ecological, climatological, and hydrological processes occurring in those areas. Permafrost is not defined by geology or region, but is characterized only by a description of the thermal regime. If the ground temperature (be it ice, peat, mineral soil, or rock) remains below 0 °C for two or more consecutive years, it is considered permafrost.

Permafrost may be continuous, discontinuous, or sporadic under the ground surface (Figure 2), as controlled by the surface energy balance, soil thermal and hydraulic properties, terrain, and snow cover. Permafrost is generally continuous in the more northerly reaches of North America and Eastern Russia, but discontinuous permafrost does extend as far south as 50° north latitude in Canada and Russia (Brown, 1970; Romanovskii, 1985, *see* **Chapter 25, Global Energy and Water Balances, Volume 1**). Discontinuous permafrost is also extensive in the Tibetan Plateau due to the high elevations (Wang and French, 1995; Jin *et al.*, 2000). Alpine permafrost exists in high mountainous regions throughout the world, even in the tropical latitudes (Paepe and Van Overloop, 2001). Permafrost is also common in the Southern Hemisphere in the nonglaciated areas of Antarctic and in the high elevations of the South American Andes (Trombotto *et al.*, 1997). In the nonglaciated regions of Russia, permafrost may penetrate as deep as 1500 m (Grigoriev and Sokolov, 1994), while the thickest permafrost in northern Alaska is estimated at about 600 m (Osterkamp *et al.*, 1985) and 1000 m in northern Canada (Brown, 1978). Even within these bounds, small areas of unfrozen ground, called *taliks,* exist beneath large lakes and rivers or near springs (Permafrost Subcommittee, 1988). Permafrost boundaries in the discontinuous regions are primarily controlled by physiographic factors such as slope, aspect, and elevation; however, anthropogenic and natural disturbances such as wildfires can have substantial effects on the permafrost thermal status and extent (Yoshikawa *et al.*, 2002). The predominant control of permafrost on hydrology is most apparent when comparisons are made across a permafrost boundary where regional differences in climate may be eliminated. Although we

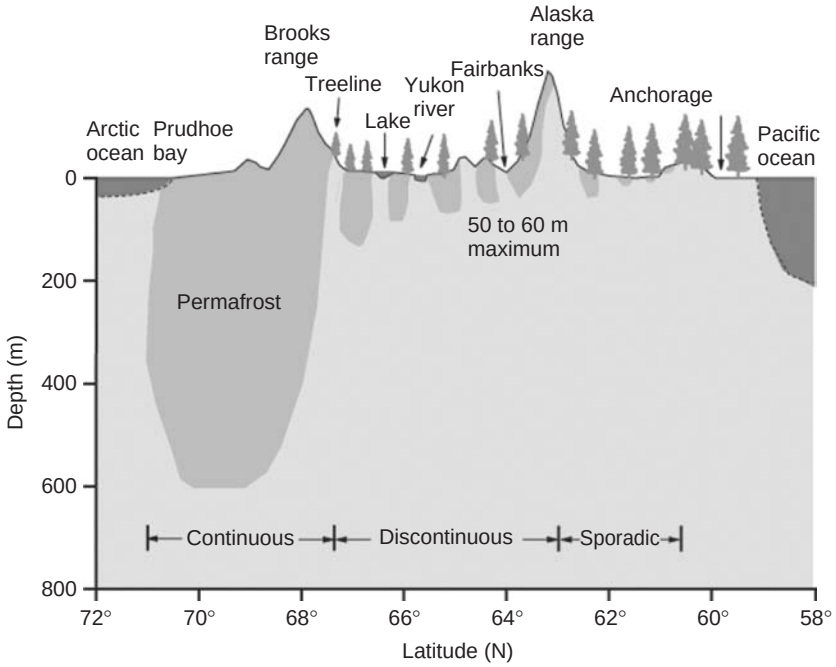

Figure 2 In Alaska, permafrost is generally continuous and quite thick north of the Brooks Range. It is discontinuous between the Brooks Range and Alaska Range and becomes sporadic south of the Alaska Range. The extent and thickness of the permafrost strongly influences the surface and subsurface hydrologic processes (taken from Kane and Boike, 2002). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

often observe changes in vegetation and other ecosystem processes occurring there as well (*see* **Chapter 101, Ecosystem Processes, Volume 3**), such indirect impacts of permafrost also influence the hydrology.

The characteristics of hydrology in permafrost regions vary greatly with region, being strongly influenced by regional climate, topography, and geology (Prowse, 1990; Kane and Yang, 2004). In general, evapotranspiration rates decrease with increasing latitude. The ratios of runoff to precipitation (R/P) tends to increase with increasing latitude; this is probably related to lower losses to evaporation and more limited storage in the thinner active layers of the higher latitude watersheds. However, in regional and local perspectives, hydrological processes are greatly influenced by permafrost characteristics that may be unique to a particular area. For example, hydrology in the Low Arctic of Alaska and Canada is strongly influenced by the thick organic soils (Dingman, 1973; Quinton and Gray, 2003) that have accumulated in some cases since the Pleistocene (Mann *et al.*, 2002). The polar deserts of the Canadian High Arctic and Antarctica yield markedly different hydrologic responses due to the thinner active layers, more undeveloped soils, and shorter thaw seasons (Edlund *et al.*, 1990; Woo and Young, 2003; Lyons *et al.*, 1997).

There are also several important characteristics shared by watersheds influenced by permafrost. Snowmelt is typically the dominant annual hydrologic event (*see* **Chapter 114, Snowmelt Runoff Generation, Volume 3**) usually yielding both the peak runoff magnitude and much of the annual runoff volume (Woo, 1986; Marsh, 1990; Ishii *et al.*, 2001). However, for small watersheds ($< \sim 1000\,\text{km}^2$) the floods of record are rainfall generated (Kane *et al.*, 2003). The low permeability zone created by permafrost functions as an aquiclude that effectively divides the ground water system into sub- and suprapermafrost components (Woo, 1990). In the zone of continuous permafrost, the predominance of hydrologic processes occurs in the seasonally frozen and thawed zone above the permafrost table, and processes associated with deep ground water are usually absent (Woo, 1990). Typically, during the winter season, the only active hydrologic processes are freezing of soil moisture in the active layer, redistribution of snow by wind and, in some locations, development of icings (also called *aufeis*) on the surface (Washburn, 1979; Kane, 1981; Grigoriev and Sokolov, 1994). There is a close association between energy and water fluxes and freeze-thaw events in water storage and redistribution as snow and ice melt. There is also a threshold change in hydrologic processes.

Perhaps the most important characteristic of permafrost is the ice content, impacting surface terrain, the geotechnical properties, and hydrologic properties and processes. Permafrost may be ice rich or lack significant amounts of ice, and the hydraulic properties can vary dramatically depending upon the ice-filled pore volume. Kane (1980)

and Kane and Stein (1983a) looked at infiltration rates into ice-rich frozen soils and demonstrated that no significant ground water recharge occurs in areas with shallow permafrost due to reduced permeability of the frozen soils where pores are completely blocked with ice. Kane and Stein (1983b) found that the hydraulic conductivity of ice-rich frozen soil can be several orders of magnitude less than its unfrozen counterpart and that permafrost acts as a relatively impermeable confining layer (*see* **Chapter 74, Soil Hydraulic Properties, Volume 2**). Woo (1986), investigating hydrologically similar areas in Canada, stated that hydraulic activity occurs almost exclusively in the taliks and the active layer. Percolation of soil water to permafrost can effectively eliminate flow to subpermafrost aquifers as the percolated water freezes to seal the soil pore space.

The amount of ice contained within the permafrost is an important condition and influences hydrological processes in several ways. Ground ice ranges in size from the microscopic pore ice (Williams and Smith, 1989) to large ice wedges (Brown, 1967) and on to the massive ice-rich yedoma complexes (Popov, 1983). Segregated ice forms as water migrates across a thermal gradient to form ice lenses within the active layer (Guymon *et al.*, 1984). These ice lenses form parallel to the freezing front, which is, in general, parallel to the ground surface but not necessarily horizontal. Ice wedges are larger ice structures (Figure 3a), which initiate within the active layer but may penetrate tens of meters into the permafrost. These form over many years as soil contracts during cold winters, causing cracks to form within existing ice wedges. As the snow melts during the following spring, water percolates and refreezes in the crack, expanding and pushing the adjacent soil apart (Harry, 1988). Networks of ice wedges are commonly found in marshy floodplains, dry surfaces of alluvial, aeolian, and glaciofluvial sands, or on peat bogs (Romanovskii, 1985) and in fact are found throughout the arctic landscape, on plateaus and hillslopes as well as the low plains. These networks of ice wedges create the characteristic low- or high-centered polygons common throughout the Arctic and occasionally found in the Subarctic. Polygonal networks with the ridges raised relative to the polygon center (low-centered polygons) indicate recently active ice wedges as the soil expands during the summer and experiences upward displacement adjacent to the ice wedge. Polygonal networks where ice wedges have begun to degrade due to disturbance or climate warming will display polygon centers markedly higher than the edges (high-centered polygons). In many low-gradient areas, the microtopography of the polygonal network controls the surface hydrological regime, typically remaining wet to saturated immediately above the ice wedge and in the middle of the low-centered polygons. The polygon rims and middle of high-centered polygons may become quite dry during extended periods of no precipitation.

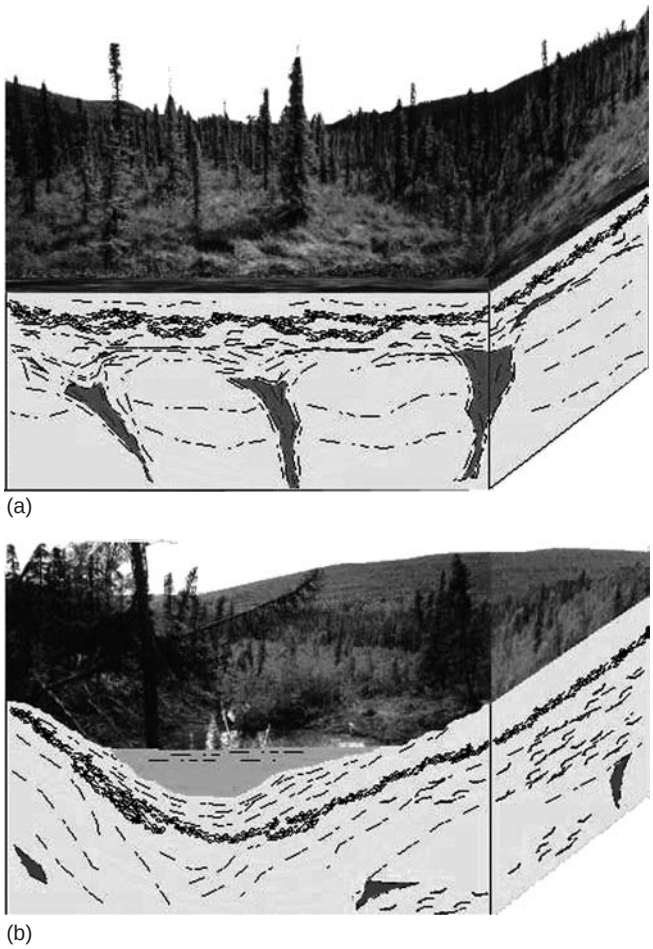

Figure 3 (a,b.) Thermokarst topography forms as ice-rich permafrost thaws, either naturally or anthropogenically, and the ground surface subsides into the resulting voids. The important and dynamic processes involved in thermokarsting include thaw, ponding, surface and subsurface drainage, surface subsidence, and related erosion. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Substantial subsidence of the surface or thermokarst may occur following disturbance of the surface if buried ice is exposed to warmer air temperatures or running water (Figure 3b). Thermokarst lakes are a common feature throughout the Arctic, often forming in response to some disturbance at the surface, such as a change in the surface drainage, removal of vegetation, wildfire, or warming climate. Many of these lakes exist because the talik, common below lakes, does not completely penetrate the permafrost, preventing the lakes from draining vertically. However, if the talik does thaw to the extent that infiltration to the subpermafrost ground water does occur, then the water balance of the lake may change, perhaps shrinking the pond surface area or drying completely (Yoshikawa and Hinzman, 2003) or conversely permitting lake recharge from ground

water (Kane and Slaughter, 1973). Thermokarst can also impact surface hydrological processes even if the talik does not completely penetrate the permafrost. Thermokarsts also improve surface drainage, creating drier conditions at least adjacent to the disturbance, promoting introduction of invasive species (Lloyd *et al.*, 2003) and enabling establishment of different community types according to tolerance of soil saturation (Drury, 1956).

ACTIVE LAYER HYDROLOGY

The soil, peat, or rock above the permafrost that experiences freeze and thaw annually is called the *active* layer (*see* **Chapter 71, Freezing and Thawing Phenomena in Soils, Volume 2**). Almost all of the biological and hydrological processes occur within this thin layer of soil, which ranges from centimeters to a few meters in thickness depending upon local conditions. Throughout the summer and early winter, the active layer progresses from frozen to thawed states or vice versa; consequently the soil volume available for liquid moisture storage is continuously changing. This is an important consideration as one attempts to calculate water balance of permafrost-dominated watersheds. It is sometimes feasible to conduct comparative water balance studies over time periods where the active layer is completely saturated, allowing the soil moisture storage term to be eliminated from the water balance equation (Kane *et al.*, 2000). However, it has been demonstrated that the short-term storage of the active layer can vary if autumn rains do not replenish the deficit that develops because of evapotranspiration through the summer (Woo *et al.*, 1983).

The active layer begins to thaw during the spring snowmelt event and continues to thicken until reaching maximum thickness in about late August or September (Figure 4). In much of the Low Arctic of Alaska and Canada, depending upon local physiography, a porous organic soil overlies a less porous mineral soil. Over the Canadian Shield, this organic layer may be quite thin or absent on the uplands, giving way to bedrock, except for the soil-filled valleys (Spence and Woo, 2002). In many parts of the High Arctic of Canada or Russia, the organic layer may not have developed due to low rates

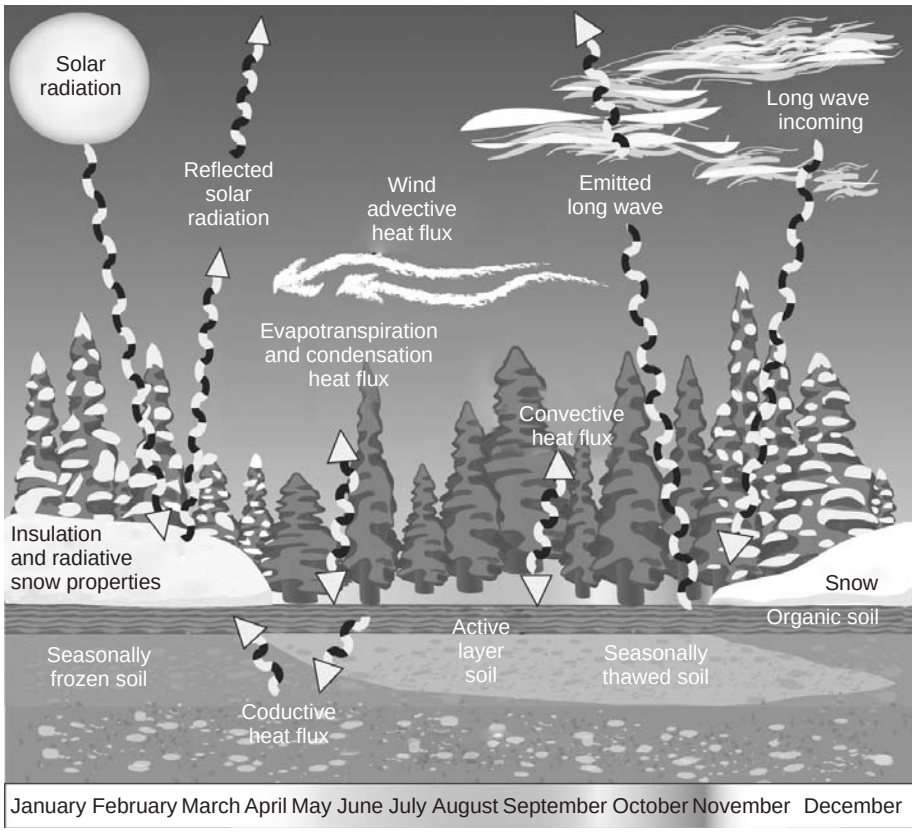

Figure 4 In regions of continuous permafrost, all hydrological processes occur in the active layer, the thin layer of soil above the permafrost that thaws during the summer months. The rate of thawing and refreezing is controlled by the surface energy balance and the thermal properties of the soil and the overlying snow. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

of vegetative growth or frequent wildfire occurrence. In the vast peat lands of central Siberia, Subarctic Canada, and Alaska, the organic layers may be several meters thick (Racine and Walters, 1991; Gibson *et al.*, 1993; Smith *et al.*, 2000). The low thermal conductivity and relatively high hydraulic conductivity of the near-surface organic soils (as compared to the underlying mineral soils) exerts a controlling influence upon the thermal and hydrologic regime of the active layer (Hinzman *et al.*, 1991). Spring thawing of the surficial organic layer is initially quite rapid, due primarily to the open pores caused by desiccation of ice during the previous winter. The rate of thawing generally follows a curve that may be approximated by a square root of time (Terzaghi, 1952). Soil freezing primarily occurs from the surface downward, but can also freeze from the permafrost upwards, giving rise to two-sided freezing (Mackay, 1983). Clear, segregated ice lenses may form within the active layer as water migrates to meet the advancing freezing front (Ad Hoc Study Group on Ice Segregation and Frost Heaving, 1984). Likewise, water migration towards the permafrost table during the summer months maintains an ice-rich layer of very low permeability. In the sandy soils of southern Siberia, the active layer can reach several meters in thickness, permitting good lateral drainage in spite of underlying permafrost.

The surface organic layer exerts a strong influence upon hillslope hydrology in the continuous permafrost regions of the low Arctic and the Subarctic. During spring runoff events, when the active layer is still very thin, the rapid component of hillslope runoff occurs either as overland flow, inter-tussock flow, or as pipeflow and matrix flow in the highly organic near-surface soil (Carey and Woo, 2000). Runoff occurring during this period is quite flashy, typically with fast responses and recessions following rain and snowmelt events (Kane *et al.*, 1991). As the active layer thaws throughout the summer, a slower component of subsurface flow occurs in the mineral soil above the ice-rich permafrost table (Hinzman and Kane, 1991). The characteristic hydrographs of streams in permafrost areas display a rapid rise to peak and rapid fall from the peak as near-surface runoff occurs through highly porous organic layers, followed by a more prolonged recession of flow through the deeper layers (Dingman, 1973; McNamara *et al.*, 1998). In regions of continuous permafrost, although an extensive subpermafrost aquifer does exist (Deming *et al.*, 1992), most ground water activity occurs above the permafrost in the suprapermafrost zone. As the active layer continues to develop throughout the summer season, greater volumes of liquid soil water may be temporarily held in storage; as a result, flashy responses are slightly less, peak flows may decrease somewhat, and hydrograph recessions become slightly longer (McNamara *et al.*, 1998; Bolton *et al.*, 2000).

It is difficult to generalize the role of hydrological processes in the dynamics of the thermal regime because of the regional variations in geology, vegetation, and permafrost and because of the low density of stations collecting the extensive data required to complete an energy balance. Ablation is usually the most important hydrologic event annually in permafrost regions, but it is also a threshold event for the surface energy balance (Boike *et al.*, 2003). Dramatic changes occur as the albedo decreases from about 0.8 for the snowpack to 0.2 for the snow-free surface. The active layer begins to thaw immediately after snowmelt (Boike *et al.*, 1998). The surface soil moisture content is a very important parameter controlling many of the processes associated with the surface energy balance. Unfortunately, this is not an easy variable to quantify in the spatial and temporal scales needed to accurately characterize thermal and hydrological interactions over large areas. Surface soil moistures will affect albedo, long-wave emissivity, evapotranspiration, and subsurface heat conduction.

The surface energy balance may be written as

$$Q_h + Q_e + Q_{net} + Q_c + Q_a + Q_m = 0 \qquad (1)$$

where Q_h is sensible heat flux between the surface and the air associated with convection, Q_e is latent heat flux associated with evaporation (sublimation or condensation) (*see* **Chapter 45, Actual Evaporation, Volume 1**), Q_{net} is energy transferred at the surface by net radiation (*see* **Chapter 39, Surface Radiation Balance, Volume 1**), Q_c is energy flux via conduction between the soil surface and the subsurface, Q_a is the energy convected in running water or rainfall, and Q_m is energy utilized for melting of the snowpack (*see* **Chapter 160, Energy Balance and Thermophysical Processes in Snowpacks, Volume 4**). Heat transfer within ice-rich permafrost masses is almost completely due to conduction, as liquid water and vapor fluxes are generally limited (Romanovsky and Osterkamp, 2000). However, vapor flux from near-surface soil throughout the winter can leave the surface layer quite desiccated (Woo, 1982), and liquid water migration across thermal gradients can create ice lenses within permafrost (Perfect and Williams, 1980). In cases where liquid moisture movement can occur (such as springs, or cracks with flowing water), advective heat transfer will usually dominate (Kane *et al.*, 2001) and can initiate severe permafrost degradation and erosion (Brown and Grave, 1979).

SURFACE WATER HYDROLOGY IN PERMAFROST REGIONS

The connection between surface water and deeper ground water is perhaps the primary distinction between watershed

processes in continuous and discontinuous or permafrost-free regions (Hinzman *et al.*, 2003). The proportion of baseflow in a stream increases as the percentage of permafrost extent decreases (Bolton *et al.*, 2000). Watersheds with larger proportions of permafrost tend to display flashier responses to precipitation events, rising quickly to higher specific discharge peaks and falling rapidly after reaching the peak. Basins with less permafrost allow a greater percentage of precipitation to infiltrate to deeper ground water reservoirs, thus providing a more stable base streamflow between precipitation events or during winter. Additionally, streams in basins with larger proportions of permafrost tend to have greater contributing areas (i.e. areas near the stream contributing water directly to streamflow during storms) as compared to watersheds with smaller amounts of permafrost (Petrone *et al.*, 2000). Although occasionally relatively warm springs do penetrate thick layers of permafrost (Williams and van Everdingen, 1973), the ice-rich permafrost typically isolates surface water from deeper ground water. Consequently, in areas of continuous permafrost, river base flow is extremely limited and small streams often cease flow completely during prolonged periods of low rainfall. Of those rivers with watersheds completely in regions of continuous permafrost, all but the largest typically have zero or very limited discharge during the late winter months. Several of the major north flowing rivers in the Russian Arctic (Ob, Lena, etc.) and the Mackenzie in the Canadian Arctic have their headwaters in permafrost-free areas, providing a stable source of baseflow and thus allowing year round river flow. The smaller coastal rivers in the Alaskan, Canadian, and much of the Siberian Arctic originate within the zone of continuous permafrost, and although several are fed by subpermafrost springs, discharge is quite low during the winter.

Thaw lakes are an important characteristic of surficial hydrology in some areas underlain by continuous permafrost (Carson, 2001). These lakes occupy up to 25% of the Arctic coastal plain of Alaska (Sellmann *et al.*, 1975) and are also common in coastal plain and the silty-clay flat lowlands in the northern territories of Canada. Thaw lakes initially form in thermokarsts when subsidence at the surface creates depressions where water can become ponded (Hopkins, 1949). These ponds absorb more solar radiation and may accumulate heat through advective heat transfer, accelerating the thawing of permafrost and further subsidence. Additionally, the ponds may be enlarged by wave action, which prompts thawing and caving or erosion along the margins. As the lakes grow in size, they occasionally coalesce as lakes intersect each other. Thaw lakes seldom become filled by sediment, but often drain catastrophically when an ice wedge becomes exposed to running water and rapidly melts. In areas where the thaw lake cycle is very active, the age of the lakes is usually less than several thousand years (Sellmann *et al.*, 1975). These lakes may be called *oriented* lakes if the primary axis of the lake length is nearly normal to the dominant wind direction forming a characteristic pattern in response to thermal and mechanical erosion along the edges of the longer ends (Black and Barksdale, 1949). Typically, the lakes are quite shallow, usually less than 2 m and most freeze completely to the bottom (Jeffries *et al.*, 1996) each winter. As the active layer and lakes freeze during the winter, solute exclusion causes the liquid water below the ice to become increasingly brackish and unpotable (Hinzman *et al.*, 1998).

The storage capacity of these lakes plays an important role in summer hydrology of permafrost regions. Pond levels typically drop throughout the summer as evaporation usually exceeds precipitation, although late summer storms occasionally replenish water levels to some degree. In low-gradient watersheds, lateral flows essentially cease when water levels drop below lake outlets (Bowling *et al.*, 2003). Rivers such as those completely within the Arctic Coastal Plain of Alaska transmit little, if any, discharge after snowmelt is complete, as surface outflow from the lakes diminishes because ice-rich permafrost restricts subsurface drainage to rivers. These lakes are replenished annually during spring melt when much of the Coastal Plain is inundated. Thaw ponds of the Mackenzie Delta are similarly replenished during spring melt when the river level rises above the banks and floods the adjacent delta lakes (Marsh, 1986).

Typically in areas of thick, relatively impermeable permafrost, the surface water is effectively isolated from subpermafrost ground water processes. However, in some isolated locations, springs extend through the permafrost to release ground water at the surface (Nelson and Munter, 1990; van Everdingen, 1990). Ground water springs may penetrate thick permafrost; the limiting factors of permafrost thickness and ground temperature must be offset by spring flow rate and water temperature (Liestøl, 1977; Yoshikawa, 1998). In zones of thinner permafrost (tens to hundreds of meters) taliks may extend completely through permafrost allowing ground water recharge or discharge. These taliks allow connection of deeper subpermafrost ground water with surficial water bodies. In some cases (depending upon the thickness of the permafrost), they allow ground water recharge as the water from rivers and lakes infiltrates to the subpermafrost aquifer (Yoshikawa and Hinzman, 2003) or in reverse as ground water discharge (Jorgenson *et al.*, 2001).

GROUND WATER HYDROLOGY IN CONTINUOUS AND DISCONTINUOUS PERMAFROST

Permafrost is the primary factor influencing ground water supply, availability, quality, and distribution (Prowse, 1990; *see* also **Chapter 145, Groundwater as an Element in**

the Hydrological Cycle, Volume 4). Ground water flow in arctic and subarctic regions is usually classified as suprapermafrost or subpermafrost depending upon whether it is flow above or below permafrost (van Everdingen, 1990; *see* also **Chapter 149, Hydrodynamics of Groundwater, Volume 4**). The suprapermafrost ground water is usually quite limited in volume and often subject to surface contamination from anthropogenic compounds or naturally occurring organics. In areas where permafrost is very thick, this source of water can be quite important. Suprapermafrost ground water is responsible for sustaining wetlands and may supply lakes at certain times of the year. A dynamic equilibrium of suprapermafrost ground water exists between wetlands and lakes in the Arctic, sustaining life in both ecosystems (Rovansek *et al.*, 1996; *see* also **Chapter 108, Lake Ecosystems (Stratification and Seasonal Mixing Processes, Pelagic and Benthic Coupling), Volume 3**). Taliks are zones of unfrozen ground that forms below lakes and rivers. These unfrozen islands in permafrost can become water sources for the growth of pingos and are critical for supporting fish habitat in deep pools that do not freeze solid (Nelson and Munter, 1990). These unfrozen zones may extend completely through permafrost under very large lakes. A talik has been used for water supply after it was enlarged by stripping vegetation and creating an impoundment (Feulner and Williams, 1967). If a talik in direct contact with a deep pool that supports fish is used for water supply, it may result in death of the fish unless the water is replenished by flowing water.

Subpermafrost ground water is generally not present in large quantities in the areas in the Arctic where the soils are alluvium (Nelson and Munter, 1990). However, in permafrost areas underlain by carbonate rocks, extensive ground water flow can occur through springs (Sloan and van Everdingen, 1988). Significant springs exist on many of the major river systems in the Alaskan, Canadian, and Russian Arctic. The quality of subpermafrost ground water ranges from relatively fresh ($400\,\mu S\,cm^{-1}$) (Childers *et al.*, 1977) to brine. The temperatures range from hot to cold (Sloan and van Everdingen, 1988). Nelson and Munter state that our knowledge of subpermafrost ground water is poor because: "(1) the population density in the Arctic and Subarctic is relatively low; (2) the expense of drilling through thick permafrost is high; (3) the thickness of permafrost is poorly known in many areas; and (4) nonpotable water occurs at depth in some places."

In the Northern Hemisphere, as one travels south of the zone of continuous permafrost, the permafrost becomes thinner and discontinuous below the ground surface, occurring primarily on north-facing slopes and in valley bottoms. The dominating influence of permafrost on hydrological processes is particularly evident in the zone of discontinuous permafrost. If the active layer is less than approximately one meter, then ice-rich permafrost can maintain wet soils in the rooting zone by limiting vertical percolation. In the discontinuous permafrost zone of Interior Alaska and Canada, distinct differences in ecology and hydrology are often apparent as one crosses a permafrost boundary (Brown, 1969; Viereck *et al.*, 1992; *see* also **Chapter 103, Terrestrial Ecosystems, Volume 3**). Although the rainfall rates are low, ice-rich permafrost maintains moist to saturated conditions in near-surface soils. The organic layer is typically thicker as low temperatures and anaerobic conditions slow decomposition rates. In valley bottoms, typical vegetation includes thick moss mats and other hydrophilic vegetation. On hillslopes underlain by shallow permafrost, thick organic layers with stunted black spruce indicate moist soils. Permafrost-free hillslopes often support deciduous vegetation with only a thin duff layer 10–20 cm in thickness, overlying a mineral soil. The runoff patterns from these contrasting slopes are markedly different (Slaughter and Kane, 1979), and consequently reflect strongly contrasting water chemistry signatures (Figure 5, Petrone *et al.*, 2000; *see* also **Chapter 91, Water Quality, Volume 3**). Soil water that migrates to a stream above a permafrost table is usually enriched in dissolved organic carbon (DOC) and nitrogen (DON). Soil water percolating into permafrost-free slopes infiltrates into a deeper ground water system, where organic carbon, and nitrogen are often sequestered and water becomes enriched with inorganic forms of carbon (DIC) and nitrogen (DIN).

Permafrost not only controls the pathways of ground water flow, but also dictates the zones of recharge. In areas of shallow, discontinuous permafrost, surface water will infiltrate to the permafrost table at which point it will flow along the top of the permafrost until it reaches a permafrost-free area (Hinzman *et al.*, 2000). The ground water recharge occurs in these permafrost-free zones. It is also possible that velocities in these zones may be higher. An understanding of where ground water recharge occurs is perhaps more important than the rate of recharge to successfully quantify ground water flow in discontinuous permafrost regions. Snowmelt is the primary source of ground water recharge in Subarctic Alaska as summer rainfalls typically only meet evapotranspiration losses (Kane and Stein, 1983a; Gieck and Kane, 1986).

Water that is able to infiltrate to deeper ground water in the permafrost-free hillslopes is often older and considerably more mineralized (i.e. higher electrical conductivity) when it enters the stream, as compared to the water following shorter and quicker flowpaths over permafrost or through surface organic layers. The ground water below the permafrost may have increased mineralization due to longer residence times; however, water quality is often greatly influenced by local conditions and it is difficult to generalize (Williams and van Everdingen, 1973). Water below very thick permafrost is usually of lower quality compared to shallow ground water. Ground water pumped

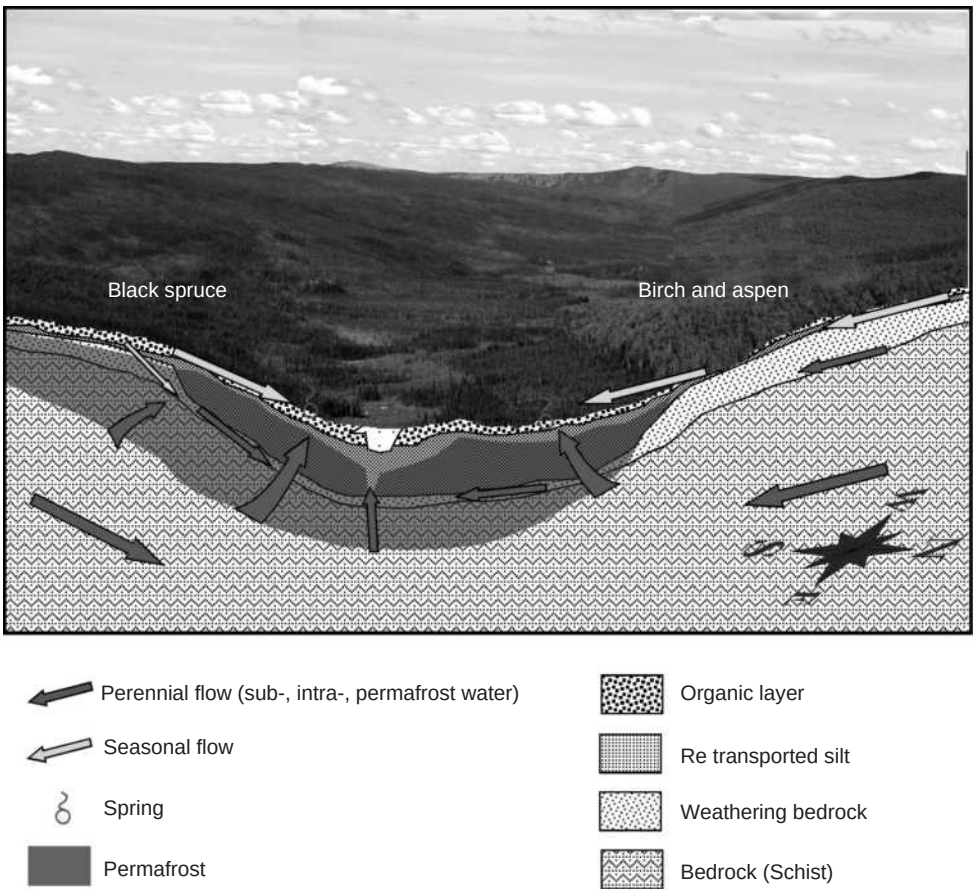

Figure 5 The various pathways of surface and subsurface flow in regions of discontinuous permafrost will create distinctly different water chemistry signatures as influenced by the flow media (*see* **Chapter 91, Water Quality, Volume 3**). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

from alluvium often contains high concentrations of iron and manganese, high organic content (with brownish color and objectionable odor) often with excess hardness. Permafrost may serve to shield ground water in coastal areas from excess salinity and hardness. Wells in regions of continuous permafrost are usually located in the talik of larger rivers, although surface water from lakes, rivers, or streams is usually the predominant source of water for most communities in these areas. In most cases where ground water is extracted from a talik or thaw bulb under a river, the availability may be of limited extent (Isaacs, 2000). In large floodplains, wells may be drilled to a depth below the permafrost with some success (Trimble *et al.*, 1983). Recently, some Alaskan villages along the major river systems are utilizing the relatively new technology of directional drilling to establish wells directly beneath a river ensuring ample supply of good quality water.

Ground water springs are frequently found near the upslope boundary of discontinuous permafrost where it interrupts the subsurface flow paths (Sloan *et al.*, 1975). Ground water may also be forced to the surface when the seasonally frozen layer freezes down to depths where it meets the permafrost, again blocking subsurface flow paths (van Everdingen, 1988). In both situations, large icings (also called *aufeis* or *naleds*) can form during the winter (Washburn, 1979; Kane, 1981). These icings may become a significant source of flow augmentation during the summer and may provide stable base flow in some basins (Reedyk *et al.*, 1995). Their locations are controlled by local geology, terrain, and thermal characteristics of discharge water. In some cases, aufeis deposits source from near-surface water supplies (such as in a talik above permafrost) or form at the permafrost boundary. In other cases, these aufeis fields develop from springs that perforate the permafrost. These subterranean channels remain open (unfrozen) only because of the combination of adequate flow rates and warm temperature. The areal extent of the aufeis is directly related to the ground water discharge rates (Hall and Roswell, 1981).

Extensive layers of permafrost in valleys can act as confining layers for ground water aquifers occasionally creating artesian conditions (Figure 6). Although this is true for continuous and discontinuous permafrost regions, it is more problematic in the warmer discontinuous permafrost of the

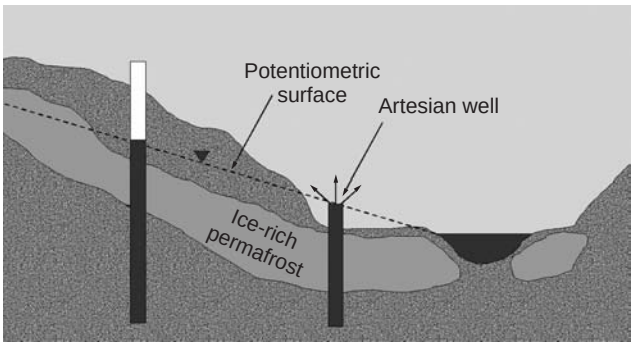

Figure 6 Permafrost often acts as an impermeable or confining layer that may induce natural spring formation. Wells drilled through substantial permafrost in valley bottoms frequently encounter artesian conditions. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Subarctic. This is partially due to the fact that few ground water wells penetrate the continuous permafrost but also because ground water in the discontinuous permafrost zone experiences far greater recharge. Soil moisture may readily percolate through the permafrost-free south-facing slopes to encounter a confining layer along north-facing slopes (White *et al.*, 2002). Wells penetrating the permafrost in such valley bottoms may encounter substantial positive water pressures. A well drilled in a valley near Fairbanks, Alaska yielded artesian pressures 8.45 m above the ground surface (Linell, 1973). Lakes and large streams lower in the valley enabled development of taliks that penetrated the permafrost and allowed natural discharge of ground water to the surface (Kane and Slaughter, 1973).

Movement of water within permafrost masses is restricted to very thin films along soil grains, even at temperatures well below freezing, the amount being a function of soil type and temperature (Anderson and Morgenstern, 1973). Although this water movement can, over long time periods, be important in its effect upon roads or houses, from a watershed water balance viewpoint, ice-rich permafrost is usually considered impermeable to water. Dry permafrost does exist and may be very permeable to contaminants such as hydrocarbons or other chemicals.

PERMAFROST CONTROL ON WATERSHED MORPHOLOGY

Permafrost exerts a dominant control over the physical character of arctic watersheds by greatly restricting fluvial erosion. The drainage networks of some basins in the Alaskan Arctic tend to be less developed as compared to those in more temperate regions (McNamara *et al.*, 1999). Watersheds in temperate regions tend to evolve towards a dendritic drainage pattern; however, headwater watersheds in regions of continuous permafrost seem to be locked in a less-developed state. Small drainage features called *water tracks* form on hillsides to rapidly transport water straight down the hillside directly to the stream (Hastings *et al.*, 1989). These water tracks may be quite subtle in their general morphology, often being distinguishable only by slight changes in dominant vegetation type. Numerous water tracks are generally parallel to each other, perpendicular to the stream channel, and spaced on the order of tens of meters apart (Hinzman *et al.*, 1993). The channel network may more closely resemble a comb, as opposed to the treelike networks typically encountered. Interhummock flow (Quinton and Marsh, 1998, 1999), often observed in areas of tussock tundra, behaves in a similar manner yielding large drainage densities and surface storage, but less runoff efficiency and longer recession periods following rain events. Pipeflow, or runoff within small tunnels between the surface organic soil and underlying mineral soils, has been observed in highly organic soils of Subarctic Canada (Carey and Woo, 2000). This runoff mechanism is highly efficient, but ephemeral, as this flow only occurs when the water table is above the level of the pipes. As the soils are usually frozen during the annual peak flow events (spring melt), and the high density of channels prevents large runoff volumes from causing significant erosion, these channels may not develop incised channels nor yield significant sediment if not disturbed. Conversely, if the permafrost on hillsides or stream banks is disturbed and experiences additional thawing, then thermal and mechanical erosion may be rapid and substantial (Viereck, 1982; Gautier *et al.*, 2003). Other features of channelized water conveyance, including gullies, rills, the patterned ground called *stripes* (Hall, 1994), slump scars, and thermokarst subsidence conduits are observed throughout the Arctic, particularly in areas without a vegetation cover. These drainage features form in response to erosional processes similar to those that occur in nonpermafrost areas, but thermal processes also play a role in controlling mechanical properties. Running water can accelerate thermal and mechanical erosion of frozen soils, rapidly accelerating sediment transport and substantial morphological changes (Gautier *et al.*, 2003). It has also been noted that permafrost-dominated areas may be particularly prone to increased sedimentation following wildfire or under a warmer climate (Huscroft *et al.*, 2004).

Headwater streams in the low Arctic regions over continuous permafrost typically freeze solidly to the bottom each winter. This bedfast ice offers rigid protection from the spring melt flood event; however, some rafting of cobbles and pebbles can occur as the ice breaks free of the bed. As one moves out of the headwaters to channels that drain a larger watershed area, eventually channels become deep enough to not completely freeze during the winter. These channels are particularly susceptible to erosive forces and mechanical damage of large ice floes during the spring melt

event (McNamara, 2000; Prowse and Ferrick, 2002). Additionally, the lack of complete freezing in the river (or lakes) maintains taliks above the permafrost (Arcone, 1998). In the high Arctic though, with the exception of larger rivers, most arctic streams do not have any ice in the channels because the limited drainage from the thin active layer and the absence of baseflow leaves channels dry in autumn. Most arctic streams would be snow-filled, often with snow dams, and their breakup follows the fashion described in Woo and Sauriol (1980, 1981).

CONTAMINANT TRANSPORT

Permafrost, particularly discontinuous permafrost, makes hydrologic analyses of contaminant transport challenging (*see* **Chapter 91, Water Quality, Volume 3**), both in field studies and in computer model simulations. Permafrost was shown to clearly affect the water and contaminant migration pathways in a study of contaminant transport in a region of discontinuous permafrost near Fairbanks, Alaska (Hinzman *et al.*, 2000; *see* also **Chapter 153, Groundwater Pollution and Remediation, Volume 4**). Thawed channels within permafrost fields existed due to the presence of a talik that was formed under an ancient river slough. The down-gradient concentration of contaminants is not necessarily diminished by the permafrost masses, but rather is more channelized. This is important in field investigations with a limited number of wells. If the permafrost configuration is not understood, the contaminant plumes may be missed because of being channeled in directions different from those indicated by area-wide hydraulic gradients. Numeric simulations of contaminant transport modeling in areas of discontinuous permafrost can lead to model instabilities due to the drastic changes in hydraulic properties over short distances (Johnson *et al.*, 1996). Ice-rich permafrost may protect subpermafrost aquifers from contamination at the point of impact (*see* **Chapter 91, Water Quality, Volume 3**) (Collins *et al.*, 1994); however, downslope migration of fuel spills may allow such contamination if the spill is not effectively contained. Soil structure and soil moisture content greatly influence contaminant infiltration into frozen ground (White and Williams, 1999). Dry permafrost may not act as a barrier to infiltration or migration by contaminants such as fuels with low freezing points.

CONCLUSIONS

Permafrost exerts a dominant influence on hydrologic processes in arctic, subarctic, and high alpine regions. The predominant role of permafrost is acting as a relatively impermeable layer; in some cases, enhancing near-surface soil moisture, sometimes creating perched lakes, frequently confining deeper ground water aquifers that discharge through taliks developed under lakes and rivers. In continuous permafrost regions, hillside hydrology is dominated by the properties of the shallow active layer, generally characterized by limited storage that increases as it thaws throughout the summer. River discharges in the continuous permafrost regions are generally flashy with rapid rise and falls from peak flows and long recessions to limited or no base flow. Snowmelt typically produces the dominant runoff event each year. Winter discharge in rivers that source completely within continuous permafrost is almost zero. The influence of permafrost is perhaps most apparent in the discontinuous zones due to the sharp contrasts between permafrost-free areas and those underlain with shallow permafrost. These differences become less distinct as the active layer becomes thicker, particularly when a talik or unfrozen layer is maintained above the permafrost throughout the winter. This unfrozen layer permits subsurface drainage throughout the year and initiates drier conditions at the surface. River discharges in the discontinuous permafrost regions are generally characterized by considerable baseflow, typically flowing throughout the winter.

Permafrost binds fine-grained soils together, particularly where organic matter is incorporated into the frozen ground, lowering the erodibility of fine-grained soils. Sediment transport in permafrost regions depends on the type of soil and the interaction among ground ice, soil materials, and thermoerosional processes, in some cases limiting bank erosion and channel network development. Running water can accelerate thermal and mechanical erosion of frozen soils, rapidly accelerating sediment transport and substantial morphological changes.

In the Subarctic to low Arctic, the cold, moist conditions maintained by permafrost often creates conditions unfavorable to aerobic decomposition resulting in accumulation of organic matter ranging in thickness from centimeters to meters. This organic layer acts as an insulative mat, thermally protecting the underlying permafrost and maintaining many of the unique characteristics of permafrost hydrology. The hydraulic conductivity of the unfrozen porous organic soils often contrast markedly with the underlying mineral soils, which, when unfrozen, also differ greatly in properties from permafrost. These sharp distinctions in properties shape much of the hydrologic response of basins influenced by permafrost. In the high Arctic and Antarctic, growing seasons are more limited and development of organic soils is greatly diminished. There, hillslope hydrology during the thaw season is strongly influenced by limited storage and melting of active layer ice.

Water cycle is the never-ending movement of water on Earth. Water continuously cycles through various reservoirs in the ocean, sky, and soil. A variety of measurement systems are necessary to quantify the fluxes between reservoirs, ranging from simple buckets to measure rainfall to sophisticated satellites orbiting the Earth. The hydrologic cycle is mainly characterized by its variability in space and time. The Earth contains an incredible diversity in climates, including rainforests, parched deserts and frozen tundra. Water cycle at any given location changes both rapidly and slowly, with the passing of flash floods to the decadal shifts in ocean patterns. Anticipated impacts of human-induced climate change on the hydrologic cycle are as yet unknown, but the consequences are potentially severe. Nonetheless, humans have a long history of altering the hydrologic cycle including the diversion and impoundment of streamflow, pumping of groundwater, irrigation of fields and management of forests. While the water cycle has been recognized for ages, many interesting fundamental research questions remain.

INTRODUCTION

Water is critical to the habitability of our environment and planet as a whole. It is both a subtle agent and a powerful geologic force, shaping landscapes and influencing climate. On a wide range of time scales, water is in eternal movement, cycling through various reservoirs in the ocean, sky, and soil. This unending circulation of the Earth's moisture is called the water cycle or hydrologic cycle.

As with all cycles, the hydrologic cycle is ongoing and continuous, with no specific start or end point; however, by far, the greatest reservoir of water is the ocean, covering about three fourth of the Earth's surface. Water from the oceans evaporate into the atmosphere. The atmosphere then releases this water vapor primarily as precipitation in the form of rain, snow, sleet, or hail. During precipitation, some of the moisture evaporates back to the atmosphere before reaching the ground, some water is intercepted by vegetation, a portion infiltrates the ground, and the remainder flows off the land into lakes, rivers, or back to the ocean. The moisture on and beneath the Earth's surface is of particular importance to humans and society. Water cycle is also intricately intertwined with many other environmental cycles, such as the transportation of energy, chemicals, and sediments.

About half a million km^3 of water evaporate from the ocean's surface each year. Approximately the same amount falls back as precipitation across the globe, only one fifth of which falls on land. The water falling on land would equal a depth of more than 300 m over an area of the size of Germany.

Hydrologic cycle is mainly characterized by its variability in space and time. For example, water continuously evaporates from the surfaces of water bodies (such as oceans, lakes, and rivers). Similarly, precipitation that is intercepted by plants and other surfaces often evaporates in a matter of hours. Once evaporated, it takes an average of about ten days for a parcel of water to cycle through the atmosphere again. If the precipitation infiltrates into the water table, or falls on a perennial glacier, it may reside there for hundreds of years before moving on to the next step in the hydrologic cycle. In addition to variable residence times, the processes associated with the hydrologic cycle are not evenly distributed over the globe; and

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

vary by climatic regions. For example, evapotranspiration occurs readily in semiarid regions, but subsequent precipitation may not occur within the same basin or region. The dramatic differences in the revolutions of water are especially evident when one evaluates the hydrologic cycle at the catchment scale.

Water in the hydrologic cycle can be both a benefit as well as a hazard, with its extreme variations being particularly dangerous. Societies can thrive in otherwise hostile climates by drawing supplemental water from the ground or diverting it from rivers, but rapid and intense precipitation or snowmelt can also cause devastating floods and contribute to soil erosion. However, more detrimental are the extended periods without precipitation causing severe droughts. Such droughts cause hardships today, but have contributed to the collapse of civilizations in the past.

Additional, varying and detailed discussions of the water cycle may be found in Freeze and Cherry (1979), Driscoll (1986), Chahine (1992), Maidment (1993), Horden (1998), and Bonan (2002). Shiklomanov (1997, 1999) is an excellent source of quantitative data about the availability of global freshwater resources.

RESERVOIRS AND FLUXES OF THE WATER CYCLE

The fluxes and reservoirs of the hydrologic cycle are depicted graphically, schematically, and conceptually in Figures 1–3. The relative size and importance of the different components ultimately depend on the scale of interest. However, on a global level, the major reservoirs for water are the ocean, atmosphere, cryosphere (snow and ice), lithosphere (surface and groundwater), and biosphere (Table 1). Water is transferred between reservoirs primarily via four fluxes: precipitation, evapotranspiration, sublimation, and runoff (Table 2). Additionally, there are fluxes that transfer water within a reservoir, such as advection of moisture in the air, percolation in soils, and the so-called Thermohaline Circulation, which conveys water to and from the ocean's surface and its depth.

Reservoirs

As mentioned earlier, oceans are the largest reservoirs of moisture on Earth, containing approximately 96.5% of the total available water. The oceans store and circulate an enormous amount of water and energy. Varying patterns of ocean surface temperatures can exert strong influence on circulation patterns in the atmosphere. The most well known of such a pattern is El Niño, characterized by unseasonably warm or cool surface temperatures in the equatorial Pacific Ocean. On average, water resides in the ocean for about 4000 years before evaporating. This residence time varies with ocean depth, with waters of ancient time residing at the bottom of the ocean.

Although the volume of water contained in the atmosphere is small (only 0.001% of the Earth's total reserves), it is a very quickly cycling reservoir. On average, water resides in the atmosphere eight to ten days before falling back to Earth. Water is stored in the atmosphere in liquid and solid forms in clouds or as water vapor. While the oceans circulate both water and energy, water regulates the radiation budget of the atmosphere. Water absorbs and reflects incoming short-wave solar radiation and absorbs long-wave radiation emitted from the Earth's surface. Atmospheric water is the most significant contributor to the natural greenhouse effect; without it, the Earth would be on average about 30 °C colder than it is today.

The *cryosphere* includes all portions of the climatic system, consisting of the world's ice masses and snow

deposits. This comprises the ice sheets, ice shelves, ice caps and glaciers, sea ice, seasonal snow cover, lake and river ice, seasonally frozen ground, and permafrost. In many mid-latitude regions, winter precipitation falls as snow and remains on the ground for months. During spring and summer, melting snow sustains river flow during much of the period of greatest human demand. Nature's mountain snow is a water storage facility greater than any storage ever

made or conceived by man. While representing only 1.7% of the Earth's total water supply, the cryosphere comprises almost 67% of the Earth's freshwater reserves.

The cryosphere further has a powerful impact on the Earth's energy cycle, due to the high albedo (reflective ability) of ice and snow. Dark, snow-free surfaces absorb more solar radiation, which in turn increases the surface air temperature, leading again to more warming and less snow due to the positive feedback. At the opposite extreme, it has been hypothesized that, if the polar icecaps grow beyond approximately 30° latitude, a "runaway ice-albedo" effect would result in the Earth being entirely covered in ice.

The low thermal inertia of high latitude and high altitude regions also makes these reservoirs particularly vulnerable to changes in climate.

Rain that reaches the soil surface is wholly or partially absorbed by the soil in the process of infiltration. Water can be conveyed across or stored on the land surface by lakes, wetlands, rivers, surface soil moisture, and in biota. Like the atmosphere, the content of water in this reservoir is relatively small, but its fluxes are very rapid. The relevance of surface water to human activities is paramount. Society has a long history of altering the surface component of the hydrologic cycle by building aqueducts, digging irrigation canals, and diverting and damming rivers. The character of vegetation on the land's surface influences both its hydrologic and thermal properties. Barren soils or grasslands have dramatically different evapotranspiration and radiation regimes than tropical or boreal forests.

Water beneath the land surface, or groundwater, can be classified in a variety of ways. Typically, above a zone of saturation is a zone of aeration, which itself can be divided into a region of near-surface soil moisture, an intermediate zone, and a capillary fringe. The boundary between the saturated and unsaturated parts of the soil is called the water table. While the near-surface soil moisture is important for vegetation and agriculture, the saturated zone or "aquifer" supplies water for wells and baseflow for streams and springs. The movement of water within the groundwater system is typically very slow, with some reservoirs effectively considered ancient and nonrenewable. On a global scale, groundwater contains a small percentage of the world's total water, yet it accounts for 30% of the Earth's freshwater reserves.

The issue of scale is important when considering the various reservoirs of the hydrologic cycle. If all the water on Earth were to fit proportionately within a 55-gallon drum, groundwater and water in the cryosphere would fill less than one gallon each. Water reserves in lakes, including the Great Lakes, would fill less than two tablespoons. The water in the atmosphere would amount to three drops, and all of the Earth's rivers; from the Nile to the Amazon, the Yangtze, and the Mississippi, would fit into the eye of a needle.

Fluxes

Precipitation is the process by which water, in the form of rain, snow, sleet, and hail, falls from the atmosphere to the Earth's surface. The occurrence of precipitation over land is typically cited as the driving force of the hydrologic cycle, because it triggers the commencement of other fluxes (evapotranspiration, runoff, infiltration) by providing a new source of moisture to the system. There are three general storm types that bring about precipitation: cyclonic, convectional, and orographic. *Cyclonic storms* are generally widespread in nature and form at the boundaries between cold polar air masses and warm tropical air. These storms are in contrast to the small *convective storms* that result from uneven heating of the Earth's surface. Unstable air rises, forming towering cloud masses that deliver brief but intense rainfall. Finally, when warm moist air masses interact with topography such as mountains, the air is lifted and cooled, causing the air parcels to saturate and precipitate moisture via *orographic lifting*. Of course, individual storms such as thunderstorms that cluster around mountains, can display more than one characteristic of the three general storm types. Evaporation is the return of water from bare soil or open bodies of water (mainly the ocean surface) to the atmosphere. Transpiration is the transfer of water to the atmosphere through the stomata of vegetation. Except on the ocean surface, it is difficult to distinguish evaporation and transpiration, and the two terms are often combined into *evapotranspiration* when vegetation is present. Evaporation rates are determined by the availability of energy, primarily solar radiation, and the capacity of air to carry away moisture. Strong warm, dry winds are very efficient at wicking water into the atmosphere. Soil conditions and characteristics also influence evaporation rates. Potential evaporation is the rate at which water could be evaporated, were it available, such as from a completely saturated surface. Actual evaporation is limited by the rate at which unsaturated surfaces can supply available moisture to the atmosphere. Actual evaporation is the minimum of atmospheric demand and land-surface supply. If the soil surface is free of plants and covered with a thick insulating layer of litter, evaporation will be much less than if the soil is bare. Agriculturists combat soil-moisture loss by laying protective mulches on the soil.

During photosynthesis, plants absorb CO_2 from the atmosphere through stomata or tiny holes. When these stomata are open, moisture escapes to the atmosphere. This moisture is often drawn up through the roots of plants and to the leaves, desiccating soils in the process. Many of the same factors that influence evaporation such as radiation and dry winds, also influence transpiration. However, the type, condition, and quantity of vegetation are also important. Generally, agricultural crops have greater transpiration rates than natural vegetation under equivalent conditions. When plants are dormant, transpiration rates are low. Plants transpire until the soil-moisture level falls to the wilting point, at which the plant cannot extract moisture from the soils. A variety of sophisticated methods for calculating evapotranspiration exist.

Similar to evaporation, *sublimation* is the loss of snow or ice on the land surface to vapor in the atmosphere. Warm, dry winds favor sublimation. The transformation of solid water directly to water vapor requires over eight times the energy required for evaporation. While sublimation in nature is not well understood or measured, it can be of serious importance to water managers. During a 5-day period in April 2003 in northcentral Utah, a warm air

mass with sustained $50-100\,\mathrm{km\,h^{-1}}$ winds sublimated an estimated 7.5 cm of snow water equivalent. This disappearance of 30% of the existing mountain snowpack rapidly darkened the water supply outlook for this region. This exceptional event had sublimation rates much higher than typical values.

While snow can sublimate from the land surface, it can also be lost while resting on vegetation. Interception of precipitation by vegetation and throughfall to the surface is a small but important component of the hydrologic cycle. Leaves can typically store 1.3 mm of liquid water, but forests can store 3.8 mm of water in snow. Water leaves the plant surface by evaporation, by throughfall when incoming precipitation exceeds leaf storage ability, or by mechanical removal when trees sway in the wind.

As water is intercepted by vegetation, it also falls on other permeable and impermeable surfaces. This water can gather into small rivulets that carry this overland flow into small channels, then onto larger channels, and finally as streamflow in rivers.

Of the water that permeates into the land surface, subsurface flow is the runoff that travels through the upper soil layers laterally toward streams. A part of the subsurface flow may enter the stream quickly, while the remaining part may take a long time before becoming streamflow. *Hortonian overland flow* occurs when rainfall intensity exceeds the rate at which the soils can absorb the water. In contrast, *saturation excess flow* results when new precipitation is added to already saturated soils. The final source of runoff is water that travels to the deep soils, joins the groundwater and contributes to baseflow. The entry of water into soils is called infiltration, and the movement of water underneath the land surface is called percolation or subflow.

Many factors contribute to the character and variability of runoff. The most influential factors are, of course, precipitation and evaporation, specifically their amount, seasonality, intensity, and sequencing. Land-surface characteristics, as well as basin geology and geography, also play an important role. Soil compaction, trampling, intense forest fires, and urbanization can reduce infiltration rates, which increase overland flow and decrease recharge. Soil porosity and soil type influence the landscape's water transmission and water-holding capacity.

Vegetation and forests have a complex relationship with runoff. The effect of ground litter and vegetation on soil structure generally helps infiltration. Vegetation transpires, and canopies can both inhibit and foster sublimation. In the past, land managers have viewed deforestation and removal of riparian vegetation as a way to increase water yields. However, these increases generally do not offset the costs of mechanical removal or the secondary consequences of erosion or increased runoff "flashiness".

DATA AND THE HYDROLOGIC CYCLE

Timely and accurate hydrologic data are critical for human activities ranging from irrigation water management and reservoir control to developing and improving fundamental understanding of the Earth's system and its reactions to past and future forces of climatic change. There are many ways to measure different aspects of the hydrologic cycle and, because these approaches are always changing, only a limited subset of the major techniques will be addressed in this section.

Precipitation is measured primarily by gauges, radar, and satellites. In the United States, precipitation has been measured on the ground at over 18 000 locations. Typically, rainfall is funneled into a small-diameter measuring tube, where its depth is amplified so that hundredths of an inch can be measured accurately by the human eye. Many automatic systems also exist, such as those that funnel the rainfall into a bucket that is weighed, or a small "tipping bucket" of a known volume that empties when filled (precipitation rate is measured by the frequency of tipping). In cold regions where precipitation often falls as snow, the gauge can be charged with antifreeze and capped with an oil film to minimize evaporation.

Although ground-based gauge measurements are accurate, they lack the complete spatial coverage and continuous measuring capability of the radar. An antenna transmits radiation of a specific frequency at defined intervals and listens for an echo. Heavier rain reflects more energy back to the radar than lighter rain. However, rain that is more distant also gives a weaker, delayed signal. After accounting for the time between sending the transmission and receiving the echo, and the intensity of the echo, one can measure precipitation rate relatively accurately. This system is particularly useful because it also provides information about storm direction, speed, and whether the precipitation is falling as liquid or solid.

Because radar cannot travel through the Earth's surface, there can be gaps in coverage where the radar beam is blocked by mountains. Satellites provide a "bird's-eye" view of the surface. Tall clouds are often associated with vigorous precipitation; satellites measure cloud-top temperatures to infer precipitation rates. Hybrid systems exist, taking advantage of the strengths of multiple sources of information. Precipitation Estimation from Remotely Sensed Information using Artificial Neural Networks (PERSIANN), (Sorooshian *et al.*, 2000) specifically uses cloud top-temperature and texture from geosynchronous satellite images to estimate surface rainfall rates. The parameters of the model are updated using gauge and radar data. Several other similar satellite precipitation estimation systems exist, as described by Kuligowski (2002), Ba and Gruber (2001) and Scofield (1987).

Snow depth can be sampled using a measuring stick or a permanently mounted stake. Newer automatic measurements echo ultrasonic waves off the snow surface. However, as snow density can vary widely, snow water equivalent measurements are more accurate indications of total water supply. At one time, snow water equivalent measurements involved extracting a core from the snowpack, originally using a stovepipe, and melting it in the field to its liquid form. After the turn of the century, metal snow samplers were developed so that one only needed to obtain a core and weigh the entire apparatus. In the 1970s, over 1500 locations (snow courses) were being routinely measured near the first of each month throughout the western United States to support seasonal water supply forecast activities. Shortly after, many of these sites were converted to Snow Telemetry (SNOTEL) sites that measure snowpacks by the pressure they exert on a large liquid-filled bladder resting on the ground. State-of-the-art satellites also measure snow-covered area with reasonable accuracy.

Atmospheric humidity is measured by a variety of methods, including the sling psychrometer. Two thermometers, one of which is wrapped in damp gauze, are attached to a sling and swung in a circle. This motion causes the moisture in the gauze to evaporate, releasing latent energy, and thereby lowering the temperature of the thermometer. The final difference in the temperatures is proportional to the absolute humidity. Chilling a mirror until dew condenses on its surface and using the data so obtained works on a similar principle. Many measurements are taken by electronic means, such as how humidity changes the capacitance of a thin gold-plated plastic film transducer. Sensors are routinely attached to balloons, and the humidity is measured at several layers of the atmosphere. The atmospheric advection component of a local water budget is sometimes calculated using a battery of such radiosondes launched in unison around the perimeter of a region. Satellite measurements of humidity exist, yet the capacity of satellite-based sensors to probe beneath cloud levels remains an issue.

Aside from groundwater recharge, the most uncertain component of the water budget is evaporation. Stainless steel pans are filled with water, and the lowering of water level, minus precipitation, is proportional to potential evaporation. This method does not give an estimate of the actual evaporation, because it does not account for unsaturated soils and vegetation. Often, all other components of the water budget are measured, and evaporation is "measured" by calculating the residual of the other terms.

Streamflow in rivers is measured in two steps. First, a current meter is dropped into the stream at fixed spatial intervals. The earlier current meters involved rotating cups that spun as water passed through the meter, measuring water velocity in much the same way that wind speed is measured. Newer technologies involve sonic sensors. Measurements are taken at fixed depths and intervals from one riverbed to the other. The velocity of the river multiplied by the area equals the total flow. Because the depth of a river is proportional to its flow, routine, automatic measurements typically measure only the river depth, which is later converted to flow by an equation specific to the river and location being measured. Depth is measured by observing the water level in a stilling well. If possible, a controlled structure such as a weir or a flume can be placed in the streambed and the flow calculated directly by measuring the water depth in the structure.

MODELING OF THE WATER CYCLE

Mathematical Water Balance

The most simplistic formulation of a water balance is denoted by the elementary continuity equation (1) that conveys the notion that "input to a hydrologic system equals the output from the system, plus or minus any changes in storage":

$$I = O \pm \Delta S \tag{1}$$

where, for a given domain, I is the total inflow, O is the outflow, and ΔS is the change in storage. Figure 4 shows a conceptual model of a water balance at a watershed scale. Note that the figure does not represent changes in storage caused by anthropogenic activities such as groundwater pumping, artificial recharge, and other modifications.

In a parcel of the atmosphere, for example, the inputs would be evapotranspiration from below and advection of moisture from nearby parts of the atmosphere. Outputs would be precipitation as well as advection out of the parcel. The change in storage is the change in the specific humidity.

The water balance beneath the soil surface is the mirror image of the atmosphere. Precipitation (infiltration) is now an input, evapotranspiration is an output, along with runoff. Lateral groundwater flow and subsurface flow is the equivalent of atmospheric advection. The change in storage is measured by the change in near-surface soil moisture and water content of the aquifer.

On a global basis, the Earth is effectively a closed system, and the amount of water present remains relatively constant (i.e., $\Delta S \cong 0$). However, input and output rates of the hydrologic cycle vary regionally and on a wide range of time scales (see Figure 5). Describing, quantifying, and predicting these variations are, in essence, major tasks in contemporary hydrology.

Climate and Hydrology Models

To describe and predict variations within the hydrologic cycle, considerable effort has been invested in developing computer-based numerical models of hydrology and climate. Every component of the climate system has its own models (from groundwater to oceanography and the

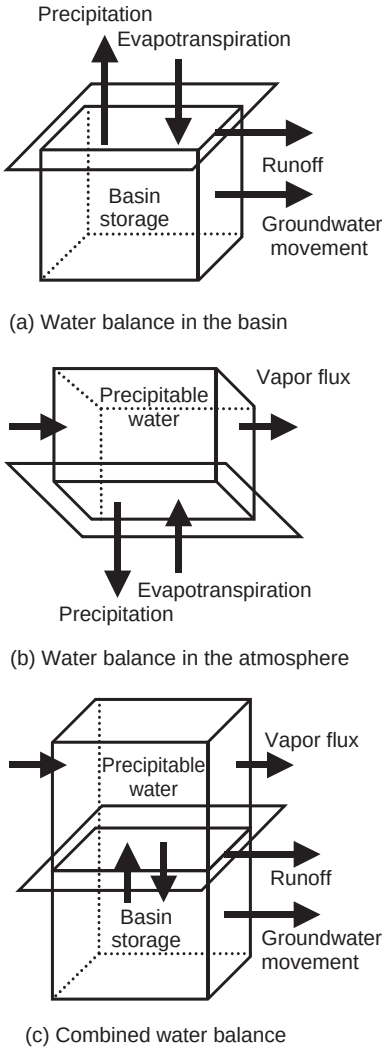

Figure 4 Mathematical schematic diagram of water balance for (a) the atmosphere (b) the land surface, and (c) the atmosphere and land surface combined (Reproduced from Oki, 1999 with permission of Cambridge University Press)

atmosphere to the land surface) and, within disciplines, there are too many different models to be completely described here.

Simple surface hydrologic models are often statistically based or regression models. For example, operational hydrologists within the United States commonly use the principal components-based multiple linear regression procedure developed by Garen (1992). At lead times of several months, precipitation, snowpack, and antecedent streamflow data are used to predict the total amount of flow that will occur over a season. Other simple models include the Natural Resources Conservation Service Curve Number, Rational Method, or the Antecedent Precipitation Index.

In a coarse sense, simple conceptual hydrologic models describe the land surface like a leaky bucket of water. A very wet watershed releases water to the streams at a much greater rate than a parched watershed would, much like how a full bucket leaks water faster than a bucket that is half full. Similarly, when a watershed is completely saturated, all additional moisture will go directly to the streams, like a bucket overtopping when it is completely full.

More complex hydrologic models, such as the Sacramento Soil Moisture Accounting Model and the Precipitation-Runoff Modeling System, often comprises a series of interlinked leaky buckets. Various buckets represent various parts of the soil profile, from the near-surface soil moisture to the deep water contributing to baseflow. Each model has a number of parameters to describe the size of each bucket and the rate at which water travels between reservoirs. These parameters are often related to physical characteristics of the watershed, such as soil types, vegetation cover, geology, basin size, and so on. Some models may treat an entire basin as a single bucket; increasingly complex models have high spatial resolution and describe the movement of water between grid cells across the landscape.

The spatial and temporal scales of their applications vary from model to model, but range from tens to thousands of km^2 and from minutes and hours to days and years (Sorooshian *et al.*, 1997 and Singh, 1995). The structure of a model also reflects its intended purpose. Some models have the ability to describe the coupling of hydrology with other natural cycles (e.g., erosion or water quality).

The most complex models available describe nearly all of the major natural cycles in concert. These General Circulation Models (GCMs) have full global representations of the ocean, atmosphere, cryosphere, and land surface. Most of the early work on GCMs related to refining the treatment of the ocean-atmosphere interface. Recently, more emphasis has been put upon accurately describing the land surface-atmosphere interface. Such land surface models include the Biosphere Atmosphere Transfer Scheme and the Simple Biosphere Model. Lau *et al.* (1995) compared the ability of 29 GCMs in simulating various aspects of regional hydrologic processes and found them insufficient for use in climate studies related to continental scale water balance. One of the primary impediments is the fine scale of hydrologic processes and the coarse resolution of climate models. Regardless, this is an area of very active research and, as computing power increases rapidly in the near future, one can expect these models to improve.

HUMANS AND THE HYDROLOGIC CYCLE

Climate Change

The primary motivation for improving the representation of land-surface processes in GCMs is to gain a better understanding of the anticipated impacts of climate change

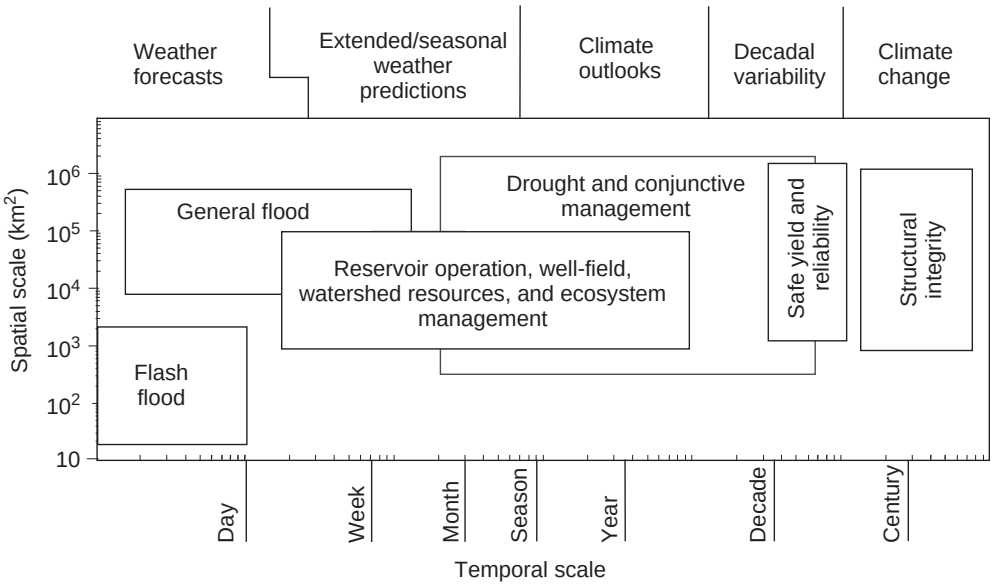

Figure 5 Space time issues in hydrology

on the hydrologic cycle. Humans are currently engaged in what has been described as a grand irreversible and uncontrolled experiment, the environmental consequences of which could be second only to global nuclear war. Since World War II, the emission of CO_2 into the atmosphere has increased almost sevenfold due to the burning of fossil fuels. This rate could increase dramatically during the impending modernization and industrialization of developing nations. Carbon dioxide in the atmosphere contributes to the "greenhouse effect" which could raise the Earth's temperature at an unprecedented rate. The resulting changes on the remainder of the climate system are yet unknown (see Table 3). Table 4 shows some of the trends in hydrology observed in the recent past.

While there is some uncertainty and debate concerning climate change and global warming, the theory as to why the hydrologic cycle may change is relatively straightforward. Greenhouse gases in the atmosphere reflect and reradiate outbound long-wave radiation back to the Earth's surface, increasing the surface temperature. Carbon dioxide is one such gas, while methane and nitrous oxide are among some of the others. As mentioned previously, atmospheric water vapor is the most significant contributor to the natural greenhouse effect.

Coincident variations in greenhouse gases and air temperatures have been thoroughly documented on geologic time scales. For example, during the last glacial period when atmospheric CO_2 concentrations were closer to 200 parts per million by volume (ppmv), the Earth was 6–8 °C cooler than during preindustrial conditions of 280 ppmv. The current concentration as of 2005 is approximately 380 ppmv, and the predictions of future concentrations range from 540

Table 3 Best estimates of climate change projections over the next 50–100 years (from Schneider *et al.* (1992) and S. Schneider (personal communication, July 27, 2000))

		Distribution of changes				Confidence of projection	
Indicators	Annual average change	Regional average	Change in seasonality	Interannual variability	Significant transients	Global average	Regional average
Temperature	+1 to +3.5 °C	−3 to +10 °C	Yes	Down?	Yes	High	Medium
Sea level	+15 to +95 cm	–	No	?	Unlikely	High	Medium

to 970 ppmv by the year 2100. The anticipated increase in global surface temperatures over this period is expected to be between 1.4 and 5.8 °C.

If the amount of long-wave radiation reflected back to the Earth's surface is increased, the potential evaporation from the ocean and the land surface may also increase. The amount of water required to saturate a parcel of air increases exponentially in direct proportion to its temperature; because warmer air can potentially hold more water, humidity may increase. If the increase in water vapor storage does not balance the increased evaporation, then precipitation rates, on average, could increase.

Beyond these first few concepts, the vision of the future of the hydrologic cycle becomes murky. The Earth's climate contains many complex feedbacks, some of which are self-regulating and others reinforcing. For example, a more vigorous atmospheric water cycle may involve increased low clouds that might reduce the amount of incoming solar radiation, leading to a negative feedback and cooling. An increase in high clouds, which are efficient at reflecting long-wave radiation back to the Earth's surface while letting short-wave radiation pass through would reinforce positive feedback with further warming.

The most difficult issue concerning global warming is translating changes in climate to impacts on societies. Humans are most sensitive to extremes in hydrologic variations, and the sequences of events it causes. Such questions as, "How will climate change affect the occurrence of drought in a particular region?" remain open to debate. However, considerable effort has been devoted to researching these questions through analyses of historical records and computer simulations of the future (National Assessment Synthesis Team, 2001).

It is possible that the clearest changes associated with global warming could be in the occurrences of catastrophic events such as heavy floods, extended droughts, and hurricanes. If a climatological variable has a Normal (bell-shaped) distribution, changes in the mean will bring proportionally greater shifts in intensity and frequency at the tails of the distribution (Trenberth, 1999; *see also* Easterling *et al.*, 2000 for an excellent discussion of the observed and anticipated changes in extreme events induced by climate change). Unfortunately, because of its rarity, it is very difficult to estimate the change in frequency of extreme events. The climate may change irreversibly by the time that undeniable evidence of change accumulates.

The atmosphere is not the only component of the hydrologic cycle that may be affected by climate change; the ocean and cryosphere may be impacted as well. Computer simulations of climate change predict that the greatest warming will occur at high latitudes and altitudes. Locally, this poses a threat to regions with permafrost, where melting can cause land-surface subsidence and damage to structures. For the first time in its 30-year

history, the start of the 2003 Iditarod sled dog race had to be moved north because of exceptionally warm weather and a lack of snowpack in Alaska. From October to April 2003, warm temperatures, heavy rains, and the lack of a winter freeze caused a near-complete reversal of the seasonal cycle for the Kenai River at Cooper Landing in Alaska. Although record-high streamflows occurred during the normally frozen winter, sparse snowpack remained to carry the flow through the summer when the surge of melt usually occurs. There is concern that a similar change in the seasons may occur in the mountainous western United States, particularly the Cascades and Sierra Nevada mountain ranges.

If temperatures increase sufficiently, glacial melt and thermal expansion of the oceans may also cause sea-level changes over the next 100 years. A 1% decrease in glacial water content translates to a 30-cm rise in sea level. A 2-meter rise in sea level could inundate the Republic of the Maldives, making an entire nation a casualty of climatic change. Changes in surface albedo associated with the change from surface-ice to bare ground or open ocean is a positive feedback, and associated with increased absorption, higher temperatures, and possibly increased melting. The latest projection for global mean sea-level rise between 1990 and 2100 is between 9 and 88 cm, with significant regional variations (IPCC, 2001). Such a change could have dire consequences for coastal ecosystems.

Not all of the changes in the hydrologic cycle may be gradual or linear. Warm temperatures at high latitudes, increased precipitation, and glacial melt may alter the vertical density profile of the North Atlantic Ocean. Warm and relatively freshwater in the North Atlantic could slow or halt the sinking of colder, saltier water to the bottom of the ocean. A disruption in this cycle would greatly impact the climate of Europe, as was seen during the "Younger Dryas" period 13 000 years ago, when temperatures plunged several degrees Celsius in the course of a few decades. Model simulations to study the effects of doubling CO_2 concentrations in the atmosphere predict a disruption in the Northern Atlantic circulation with eventual recovery. Quadrupling concentrations lead to a nearly irreversible collapse of the circulation. These simulations are highly model-dependent, but they do suggest the presence of "thresholds" and "triggers" within the climate system.

Land-use and Hydrology Changes

By far, global climate change associated with fossil fuel burning will not be the first interaction humans have had with the hydrologic cycle. Most of history is linked to redirecting and damming rivers, cultivating land, moving mountains, and pushing the bounds of habitability on Earth (Figure 6). Construction of water supply systems, drainage systems, and irrigation canals extend back to ancient civilizations. In several basins across the globe, surface-water resources have been so extensively developed that major rivers (e.g., the Colorado River in the United States and the Yellow River in China) periodically cease flowing into the ocean.

Water is both a necessity and a resource for financial gain. However, while it is beneficial, it can also turn into a hazard. On average, over $8 billion (£5 billion) worth of damages have resulted annually from flooding and hurricanes in the United States alone (Kunkel *et al.*, 1999). Often, such damages arise partly from unwise human choices. The above figure does not include the damages caused by pandemic health hazards created by poor water quality.

The most pervasive change to the hydrologic cycle due to human activities is caused by land-use change. According to van Dam (1999, pp. xiii), "The effects of climate variability and change on the hydrological cycle will be coincident with those of changes in land use, which could be of the same order of magnitude." The various types of land-use changes range from deforestation, agricultural use, and urbanization to draining of swamplands for various purposes. The impact of these land uses on streamflow is presented in Table 5. The impacts arise from changes in surface albedo, surface roughness, surface permeability (the ability of water to pass through a surface, such as concrete), and the ability of the surface to intercept and evaporate moisture.

These impacts are inherently scale-dependent, and most local land-use change will not have a major impact on the continental and global hydrologic cycle. However, the extent of land-use change in total is considerable; Flohn (1973) suggested that, over the last 8000 years, approximately 11% of the land surface has already been converted to arable land, and 31% of forests have been modified from their original condition. Additionally, certain regions are poised to have a disproportionately strong impact on global circulation. For example, there is debate as to whether Amazon deforestation will have a remote impact on tropical and extratropical climate. Although this is being actively researched, the expected impacts from Amazon deforestation outside the region remain unclear (Gash and Nobre, 1996).

While global fluxes or distributions of water may not be influenced by water quality, there is significant impact of humans on water quality at every step of the hydrologic cycle. Since the 1970s, the primary atmospheric water quality concern has been acid rain. Acid rain damages trees at high elevations and contributes to the acidification of lakes and streams. Regions already affected include North America and northern Europe.

Contamination of water at and below the land surface poses a significant threat to potable water supplies (*see* Fetter, 1998; Bedient *et al.*, 1999 for further reading on groundwater contamination). Water quality can be affected

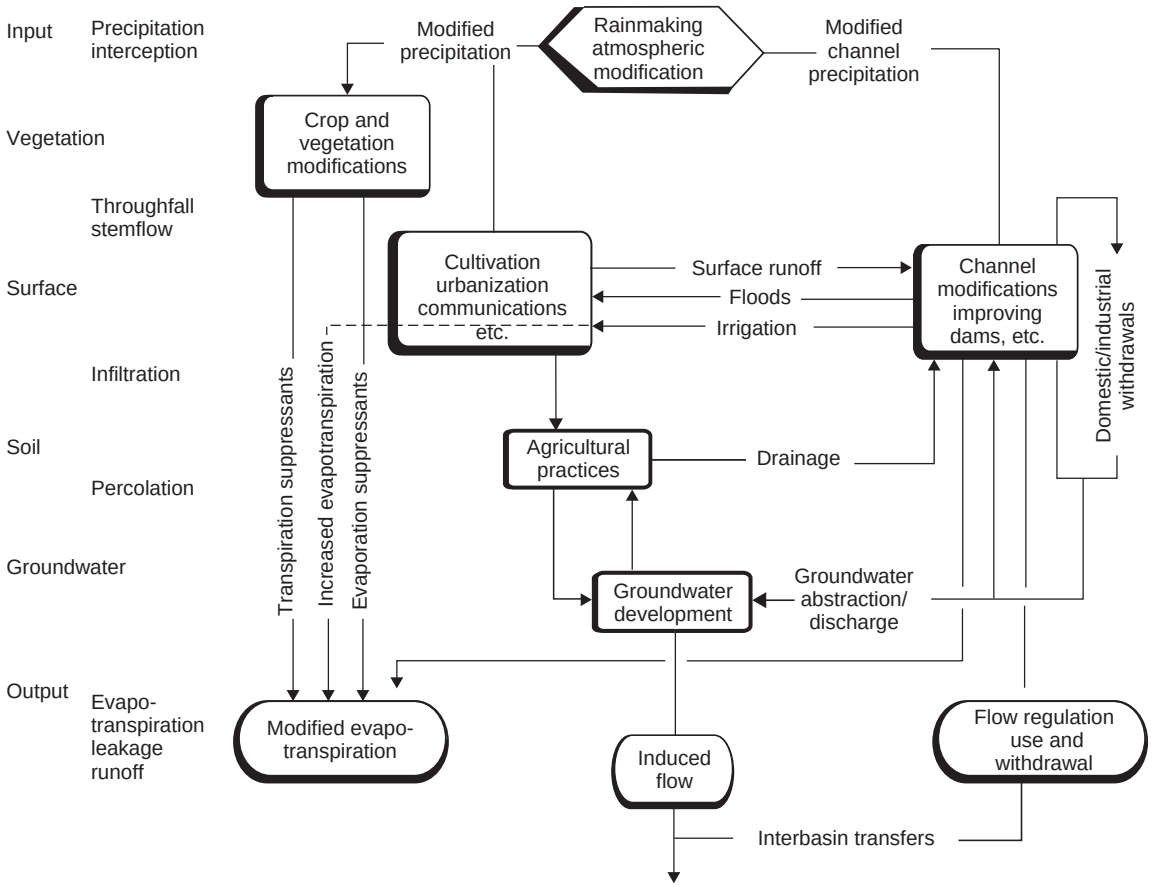

Figure 6 Systems diagram of the impacts of human activities on streamflow (From Ward, 1990 reproduced with kind permission of the Open University/McGraw-Hill Publishing Company)

by human activities in a multitude of ways, including release of effluents, leeching from landfills, industrial and mining activities, and runoffs from fertilizers and pesticides used in agriculture among others. In particular, the long-term isolation of hazardous radiological byproducts from water supplies poses a special challenge.

TOWARD IMPROVED UNDERSTANDING OF THE HYDROLOGIC CYCLE

Although the hydrologic cycle has been studied for well over a century, with considerable work being done in recent decades, many unresolved questions in the expanding frontiers of research into the water cycle remain. In particular, understanding the impacts of human activities on the hydrologic cycle is an area of active research. Considerable effort is also being devoted to understanding the linkages between the ocean and atmosphere in the tropics (such as El Niño), as well as at mid-latitudes and on longer time scales. Increased attention has been devoted to land-surface and hydrologic representation in large-scale computer models, the intent of which is to improve predictions of variations in the hydrologic cycle on interannual and decadal horizons. Medium-range weather predictions can also improve by having a better understanding and model representation of soil-moisture processes (Chahine, 1992). Finally, groundwater and surface interactions, ranging from the amount of water recharged into an aquifer from snowmelt to the hydrology of natural springs, are some of the less understood components of basin-scale water balances.

Improved understanding of the hydrologic cycle is not limited to the understanding contained within the scientific research community. It is also that of the operational water management community, the public, and other stakeholders of water resources. Concepts such as climate stationarity (the belief that the statistics of the climate of a particular region are constant in time) are key assumptions for most design and planning of water management, although the research community has long recognized the flaws in this assumption. For example, for structural design purposes, relatively brief historical records are used to estimate the magnitude of the flood that would happen once in a 100 years. If the historical period being considered contains

Table 5 Summary of impacts of land-use changes. Table modified from Calder (1993) with additional data from Urbonas and Roesner (1993)

Land-use change	Component affected	Principal hydrologic process involved	Geographic scale and likely magnitude of effect
Afforestation (deforestation has converse effect, except where disturbance caused by forest clearance may be of overriding importance)	Annual flow	Increased interception in wet periods. Increased transpiration in dry periods through increased water availability to deep root systems	Basin scale; magnitude proportional to forest cover. World average is 34 mm $year^{-1}$ reduction for 10% increase in forest cover
	Seasonal flow	Increased interception and increased dry period transpiration will increase soil-moisture deficits and reduce dry season flow	Basin scale; can be of sufficient magnitude to stop dry season flows
		Drainage activities associated with planting may increase dry season flows through initial dewatering and also through long-term effects of the drainage system	Basin scale; drainage activities will increase dry season flows
		Cloud water (mist or fog) deposition will augment dry season flows	High-altitude basins only; increased cloud water deposition may have a significant effect on dry season flows
	Climate	Increased evaporation and reduced sensible heat fluxes from forests affect climate	Micro, meso, and global scale; forests generally cool and humidify the atmosphere
Agricultural intensification	Water quantity	Altering of transpiration rates affect runoff	Basin scale; effect is marginal
		Timing of storm runoff altered through land drainage	Basin scale; significant effect
Draining wetlands	Annual flow	Initial dewatering following drainage will increase annual flow	Basin scale; effect may last from 1 to 2 years to decades
		Afforestation following drainage will reduce annual flow	Basin scale; effects as for afforestation
	Seasonal flow	Upland peat bogs, groundwater fends, and African dambos have little effect in maintaining dry season flows	Basin scale: drainage or removal of wetland will not reduce and may increase dry season flows
		Lowering of the water table may induce soil-moisture stress, reduce transpiration, and increase dry season flows	Basin scale; a reduction of water-table depth to a minimum of 30 cm below surface is required
		Initial dewatering following drainage will increase dry season flows	Basin scale; effect may last from 1–2 years to decades
		The deeper flow outlet of the drainage system will lead to increased dry season flows	Basin scale; effects will be long-term
Urbanization	Runoff volume	Impervious surfaces such as paved roads, roofs, and parking lots increase surface runoff during storm events and decrease groundwater recharge	Basin scale; magnitude of effect depends on extent of urbanization

unusually wet or dry spells, this approach will not give a representative estimate of what may occur in the future. Many reservoirs are operated based on expected inflow resulting from snowmelt runoff. If temperatures warm to the point where more winter precipitation falls as rain than snow, then the reservoir operator and water users will come up short in late summer months. Likewise, most regions lack legal recognition of the connection between the groundwater and surface-water components of the hydrologic cycle. The impacts of excessive groundwater withdrawals on streamflow have been fairly well understood and developed within the scientific research community, although few, if any, regions have laws that reflect this understanding.

There are several major research programs designed to develop an increasingly more sophisticated understanding of the hydrologic cycle. One such program, the Global Energy and Water cycle EXperiment (GEWEX), was initiated in 1988 by the World Climate Research Programme (WCRP) 1990; (Chahine, 1992). Part of GEWEX is designed to observe and model the hydrologic cycle, with the ultimate goal of predicting global and regional climate change. The program includes large-scale field activities, intensive measurements as well as modeling and research. GEWEX has contributed to the development of improved numerical models and the creation of state-of-the-art climate data sets, and it is helping to achieve its goals of improving resource management through scientific outreach to the engineering as well as other user communities.

Acknowledgments

We gratefully acknowledge the support provided by SAHRA ("Sustainability of Semiarid Hydrology and Riparian Areas"), an National Science Foundation (NSF) Science and Technology Center at the University of Arizona, as well as the Global Energy and Water cycle EXperiment (GEWEX). Our sincere gratitude is also extended to Terri Hogue, Martha Whitaker, and Corrie Thies for their thoughtful comments and editing of this document in its various stages of completion.

174: Global Water Budgets – Fundamental Theory and Mechanisms

C ADAM SCHLOSSER

Joint Program on the Science and Policy of Global Change Massachusetts Institute of Technology, Cambridge, MA, US

The global water cycle represents the transport and transformation of water within the Earth system, and, in doing so, distributes freshwater over the Earth's surface. The cycling of water in the Earth's system employs water in all three of its phases: solid, liquid, and gaseous. In its coarsest and most conventional depiction, the Earth system's cycling of water is viewed as the continual displacement of water taken from the ocean, transported through the atmosphere, deposited over land, and ultimately fed back to the ocean. However, many processes and pathways are responsible for this global transit and cycling. Therefore, to monitor the global water cycle in the context of all of these key interactions with the global environment requires a comprehensive representation of the budgets and cycling of all phases of water storage. An analytic discussion is provided to elucidate the various mechanisms that contribute to the global transport of water within and between the Earth's atmosphere, land, and ocean systems.

INTRODUCTION

The global water cycle (Figure 1) represents the transport and transformation of water within the Earth system, and, in doing so, distributes freshwater over the Earth's surface. The cycling of water in the Earth's system employs water in all three of its phases: solid, liquid, and gaseous. The global water cycle operates on a continuum of time and spatial scales and exchanges large amounts of energy as water undergoes phase changes and is moved from one part of the Earth system to another. In its coarsest and most conventional depiction, the Earth system's cycling of water is viewed as the continual displacement of water taken from the ocean, transported through the atmosphere, deposited over land, and ultimately fed back to the ocean. However, many processes and pathways are responsible for this global transit and cycling (as depicted in Figure 1). Water is, indeed, abundant in our environment, but it is unevenly distributed in its forms that are amenable for sustaining life on our planet. Therefore, to monitor the global water cycle in the context of all of these key interactions with the global environment requires a comprehensive representation of the budgets and cycling of all phases of water storage.

WATER BUDGETS

Global Budget

Two conventional perspectives are typically used in global water budget analyses to analytically represent the global transport and storage of water: from the atmosphere or from the surface of the earth. From an atmospheric perspective, the *global* water budget can be described as

$$\frac{\mathrm{d}Q}{\mathrm{d}t} = E - P \tag{1}$$

where Q is the *total* (i.e. vapor, liquid, and solid) amount of water stored by the *entire* atmosphere and P and E are the corresponding global fluxes of precipitation and evapotranspiration respectively. Note that, implicit in this and all equations that follow, all storage terms are in units of mass and fluxes are mass per unit time, but these equations can also be viewed as volumetric budgets. Strictly speaking, the expression given by equation (1) ignores any loss (e.g. molecular diffusion) or gain (e.g. comet material) of water to/from outer space. These source and sink terms are typically regarded as insignificant when compared with the magnitude of the variation of global Q (on the order

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

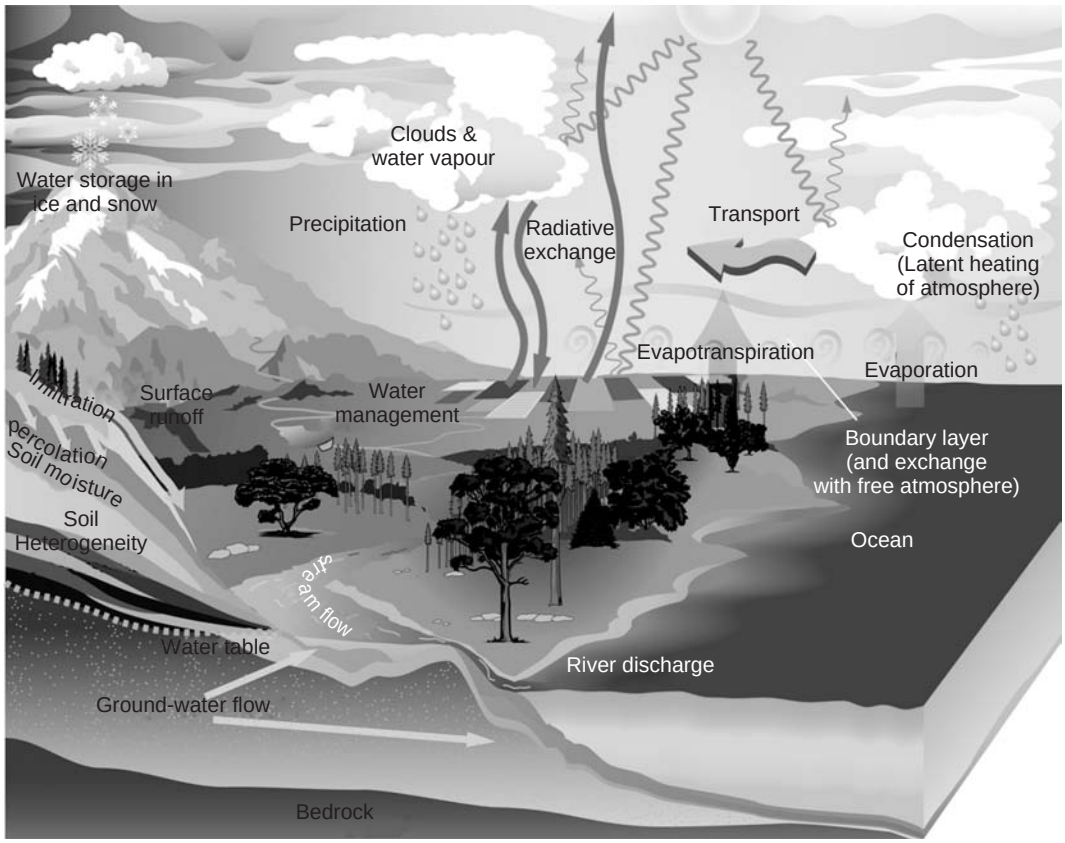

Figure 1 Conceptualization of the global water cycle. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

of 10^{14} kg of water, (c.f. Peixoto and Oort, 1992). When viewed from the perspective over the entire Earth's surface (i.e. ocean and land), the water budget can also be expressed as

$$\frac{\mathrm{d}W}{\mathrm{d}t} = P - E \tag{2}$$

where W is the *total* (i.e. vapor, liquid, and solid) change of storage of water over and within the Earth's continents and oceans (surface and subsurface). By combining the two equations above, the expression

$$\frac{\mathrm{d}Q}{\mathrm{d}t} = -\frac{\mathrm{d}W}{\mathrm{d}t} \tag{3}$$

states simply that for the globe, over any time interval, a loss in total water storage in either the atmosphere or over the Earth's surface must be balanced by a gain in the other. The expression given by equation (3) is quite impractical in terms of gaining any salient scientific applications or insights into the processes and/or mechanisms that are embedded within the global water cycle – which can vary in strength quite substantially in space and time. As a result, more descriptive and comprehensive versions of equations (1) and/or (2) must be used to depict the processes and mechanisms that comprise the global water cycle.

Atmosphere

When considering the atmospheric column and taking equation (1) over a unit area (or any subdomain of the globe), the water budget must take into account the net horizontal transport of water into and out of the domain's horizontal boundaries. By assuming that diffusive processes of water transport are negligible, and using Gauss' theorem (otherwise known as the *divergence theorem*), the atmospheric water budget is expanded to (c.f. Peixoto and Oort, 1992)

$$\frac{\partial Q}{\partial t} = E - P - \frac{\oint (A_{\mathrm{Q}} \cdot n)\,\mathrm{d}s}{D} \tag{4}$$

in which the rightmost term represents the net total-column (i.e. vertically integrated) horizontal flux of atmospheric water, A_{Q}, around the domain of area D (note that for the unit area this becomes = 1). The unit vector n points outward and normal to the domain boundaries. The horizontal flux term, A_{Q}, is a vector quantity:

$$A_{\mathrm{Q}} = \int_0^{z_{\mathrm{top}}} q\vec{\mathbf{V}}\,\mathrm{d}z \tag{5}$$

where q is the vertical profile of *total* atmospheric water storage (vapor, solid, and liquid) surrounding the given domain. However, for most practices, the solid and liquid components of A_Q are usually ignored (e.g. Peixoto and Oort, 1992). Nevertheless, the dot product will result in an integration of the advective flux that is everywhere normal around the horizontal boundaries. Note also that the time derivative on the left-hand side of equation (4) now reflects the local (i.e. Eulerian) change in atmospheric water storage.

In practice, the expression given by equation (4) is widely used as the basis to calculate regional or zonal accountings of atmospheric water budgets. The flux term in equation (4) is viewed as the analytic aggregation of all the mechanisms that contribute to the "transport" (depicted in Figure 1) of water. The interpretation as to what particular atmospheric processes and/or systems comprise the flux term will depend largely on a few factors that include spatial characteristics of the chosen domain (i.e. size, location, orientation, etc.) and temporal resolution of calculation (length, time of year, etc.).

For the purposes of studying convection and cloud processes (both major facets of the global water cycle, i.e. Figure 1), the vertical transport of water within the atmospheric column and additional (microphysical) processes must be considered, such as phase changes of water and entrainment and detrainment. In such a cloud or convective system, discrete vertical layers of the atmosphere (or horizontal "slices"), and the transport between these layers, are necessarily considered. Therefore equation (4) is further expanded to represent storage changes within a given atmospheric layer, a, in order to comprehensively include vertical transport processes (Emanuel, 1994):

$$\frac{\partial Q_a}{\partial t} = E_a - \left.\frac{\partial (wQ)}{\partial z}\right|_a - P_a - \frac{\oint_a (A_Q \cdot n)\,\mathrm{d}s}{D} \qquad (6)$$

The first two terms on the right-hand side of equation (6) collectively represent the transport of water via turbulent fluxes (i.e. evapotranspiration from the surface), convective processes, and larger-scale motions (i.e. synoptic weather systems). The subscript, a, is applied to E and P to denote the *net effect* of these terms to water storage in the layer. E_a will only be nonzero when the bottom of the atmospheric layer considered is bounded by the Earth's surface and P_a will be nonzero when precipitation forms *within* the layer or the process of collision-coalescence increases the size of precipitation droplets falling through the layer. The subscript a in the rightmost term denotes that the vertical integration (equation 5) is applied only through the thickness of the atmospheric layer considered. The vertical flux divergence, $\left.\frac{\partial (wQ)}{\partial z}\right|_a$, is usually determined via a discrete method, which calculates the difference between the value of wQ at the top and bottom of the layer, normalized by the thickness of the layer. As shown, the water budget implicitly includes evapotranspiration, convection, precipitation, and advection of all phases of water storage. Nevertheless, the form of equation (6) represents the fundamental mechanisms of the atmosphere for the large-scale water transport: precipitation, horizontal transport, convection, and large-scale vertical transport.

Land

For the entire Earth's surface, the cycling of water could be more explicitly expressed as

$$\frac{\mathrm{d}W_\mathrm{l}}{\mathrm{d}t} + \frac{\mathrm{d}W_\mathrm{o}}{\mathrm{d}t} = P_\mathrm{l} + P_\mathrm{o} - E_\mathrm{l} - E_\mathrm{o} \qquad (7)$$

where the l and o subscripts refer to the land and ocean components respectively. Typically, this budget is treated separately for the land and ocean components. When considering only land surfaces, the loss of water storage to the ocean due to runoff (ultimately river discharge) must then be taken into account. Therefore, after pooling all land terms in equation (7) and dropping the subscripts for clarity, the land portion of the equation becomes

$$\frac{\mathrm{d}W}{\mathrm{d}t} = P - E - R \qquad (8)$$

For all global land surfaces, the total runoff term, R, represents the *total* (i.e. surface and subsurface) lateral flow of water that reaches the oceans, and this is primarily in the form of global river discharge. However, when considering a water budget over smaller horizontal domains (i.e. river basins, catchments, etc.), both surface (i.e. stream/river flow and/or surface) and subsurface lateral flow (i.e. groundwater and aquifer flow) would contribute more equally to the runoff term. Surface runoff, which ultimately results as river/stream flow, is caused by a few possible conditions: extreme precipitation events in which the rate of precipitation falling is much faster than the ground can absorb, and precipitation falling atop a saturated and/or impermeable ground surface. Lateral subsurface runoff primarily results from groundwater and/or aquifer flow. In addition, evapotranspiration is the aggregate of two distinct biogeophysical subprocesses: *transpiration* – defined as the water transport and ultimately water vapor loss through the root/stem/leaf/stomata system of the canopy as a result of plant photosynthesis; and *evaporation* – this includes vaporization/sublimation of liquid/frozen water from the soil and snow surface as well as from the vegetation canopy surface (i.e. standing liquid/frozen water that vaporizes/sublimates directly from leaves, branches, etc.). Moreover, for high latitude regions, the storage of frozen water (i.e. snow and ice) and phase changes between

solid and liquid water storage are considerable and represent a considerable water resource as well as influence of climate variations. Thus, in considering all these issues above, the global land water budget equation (8) may then be more comprehensively written as two budget equations:

$$\frac{dL}{dt} = R + C - E^{i} - E^{t} - E^{s} - R^{s} - R^{u} \quad (9)$$

$$\frac{dF}{dt} = S - E_{f} - C \quad (10)$$

where the superscripts i, t, and s refer to the canopy evaporation, transpiration, and soil-surface evaporation respectively. The terms L and F refer to the liquid and frozen storages and fluxes of water respectively. Rainfall and snowfall rates are given by R and S respectively. For the case of frozen water budget, the term E_f then represents the process of sublimation. The superscripts s and u refer to the surface and subsurface (i.e. underground) fluxes. Note that equations (9) and (10) can be applied to either subsurface or surface (i.e. snow and/or canopy) water budgets, noting that for the case of the latter, E^t is zero (i.e. transpiration from the canopy root-system extracts water from the soil subsurface) and C represents the phase change between solid and liquid storage (i.e. melting/freezing). The budgets as given by equations (9) and (10) omit any explicit consideration of water vapor storage within the soil/canopy column. Although the total storage of water vapor is typically considered small compared to the liquid and solid counterparts, the *transport* of water vapor within the soil column can be, at times, important and the process is primarily controlled by diffusion (e.g. Hillel, 1982).

Similar to the case for the atmosphere, the vertical transport (and resulting profile) of water storage is an important issue for land–atmosphere interactions as well as deep-soil hydrologic variations. To represent the relevant processes, a vertical discretization is taken (as done for the atmosphere), in which changes of soil-water storage are considered within a soil layer $-$ l. In this case, vertical water flux, H, must be considered and is typically described by the effects of gravity and mass (i.e. hydraulic) flow (e.g. Hillel, 1982). Thus, changes of soil-water storage within l are given by

$$\frac{dL_l}{dt} = R - E^{i} - \eta_l E^{t} - E^{s} - R^{s} - R^{u} + \left.\frac{\partial H}{\partial z}\right|_l + C_l \quad (11)$$

$$\frac{dF_l}{dt} = S - E_f - C_l \quad (12)$$

Similar to the atmospheric layer water budget, the precipitation (R and S), evaporation (E^i and E^s) terms, and surface runoff terms are nonzero only for a soil layer whose top is at the surface (and thus the soil layer feels the impact of these surface fluxes). The transpiration term, E^t, is nonzero when the soil layer contains roots, and water is thus extracted by plant-system demand. The amount of water extracted by roots within a given soil layer will be a fraction (depicted by η_l in equation 11) of the total transpiration rate, and is controlled by a complex combination of factors that primarily include the thickness of the soil layer considered, the root density in the soil layer, the amount of liquid water storage in the layer, soil type, and plant type. The divergence of vertical water flux, $\left.\frac{\partial H}{\partial z}\right|_l$, is largely the *net* effect of gravitational drainage and diffusive transport of water through the soil layer. The frozen water budget as given by equation (12) crudely captures the fundamental governing mechanisms over the land (i.e. sublimation, phase changes, and frozen precipitation) by treating frozen soil water and snow pack as a single lumped storage. In nature, however, these storages have a complicated vertical and horizontal structure, and, thus, to accurately track the changes of these storages in time, the frozen soil water and snow processes must be accounted in substantially greater detail.

Ocean

Perhaps ironically for the oceans, the change in storage of (fresh) water becomes a rather impractical and untenable variable to diagnose. Therefore, tracking the variations in sea-surface salinity is commonly used as the surrogate to an explicit water budget, and subsequently underscores an important linkage between the global water cycle and Earth's climate system. Given that the input (i.e. precipitation) and release (i.e. evaporation) of freshwater from the ocean, as well as the influx of freshwater from the land's river basins will have a substantial impact on the salinity, S, of ocean water. The expression

$$h\frac{\partial S}{\partial t} = S[E_o - P_o - R] - \upsilon_H \left.\frac{\partial S}{\partial z}\right|_h \quad (13)$$

describes analytically the major processes influencing the (Eulerian) evolution of ocean salinity for a well-defined, homogeneous mixed layer (e.g. Haidvogel and Bryan, 1986) that is free of sea ice. In order to highlight the water cycle processes that play a controlling role in equation (13), the depth of the mixed layer, h, is assumed time invariant (and thus changes in the mixed layer depth are ignored), and υ_H is the turbulent viscosity coefficient. When considering subglobal domains (i.e. ocean or sea basins), R will only be nonzero when the domain is bounded by a land region, and would then be equal to the sum of all river-basin discharge across the land/ocean border. The critical link shown in equation (13) is the vertical and lateral fluxes of (fresh) water directly contributing to change in S, and, in turn, variations in salinity controlling many of the ocean's

major overturning currents/circulations (e.g. thermohaline circulation and bottom-water development). As such, it becomes quite salient that the global water cycle and ocean circulation operate in close harmony, and therefore changes in one system will potentially solicit a response in the other.

In addition to salinity, an equally important form of "storage" of ocean water is sea ice, W_i, as it plays an important role in modulating climate variations and changes. Taking the ocean components of equation (7), and noting that the relevant vertical fluxes would be incident frozen precipitation, P_i, and sublimation, E_i, over sea ice, the budget for sea-ice systems can be given simply as

$$\frac{dW_i}{dt} = P_i - E_i - M + G \tag{14}$$

The form of equation (14) as given, while analytically accurate, masks a number of important, but very complex, processes that necessarily govern sea-ice evolution. For example, the melting term, M_i, would be influenced by such processes as ablation via incident rainfall, radiant energy, and/or heat-flux from the surrounding/underlying ocean or overlying atmosphere, and would also be dependent on salinity. Similarly, the rate of sea-ice growth, G, that is independent of incident precipitation would be a function of the environment and its ability to freeze saline ocean water. Moreover, the budget given by equation (12) omits any consideration of the geometry and spatial distribution of the sea ice, and treats the frozen storage of water as one lumped store.

175: Observations of the Global Water Cycle – Global Monitoring Networks

DENNIS P LETTENMAIER

Department of Civil and Environmental Engineering, University of Washington, Seattle, WA, US

Until the last few decades, in situ networks were the primary source of information for the estimation of the global water cycle. Such networks provide reasonably good climatological estimates of the major terms in the water cycle over the industrialized parts of the world, but are much less adequate in the lesser-developed countries and in sparsely populated areas. Furthermore, in situ networks have been in the decline over the last several decades. An ongoing trend is toward greater reliance on satellite remote sensing. In some cases (e.g. soil moisture), satellite estimates have characteristics that cannot reasonably be matched by in situ networks. In others, it is less likely that the needs for global observations can be met from remote sensing. Furthermore, there will remain a need for high quality in situ data for algorithm testing and evaluation, and for evaluation of differences between historic in situ-based, and satellite-based, observations. The characteristics of in situ and satellite-based estimates of the dominant fluxes and storages in the land surface and atmospheric branches of the global water cycle are reviewed.

BACKGROUND

"Earth is the water planet." So begins a recent report of the US Global Change Research Program (Hornberger *et al.*, 2001). To be convinced of this, one only needs to look at a globe or any image of Earth from space. Given that over 70% of the Earth's surface is ocean, it is no surprise that the oceans dominate this first impression. Yet, to humans, the ocean arguably is less important a component of the global water cycle than those fluxes – like precipitation and streamflow – and stores of water (like lakes, reservoirs, and groundwater) over land that provide most of the water required for human existence.

While hydrology is an ancient field, dating at least to the first civilizations in the Middle East that developed methods to divert water for irrigation and potable supplies, hydrologists have tended to have a local focus. Recently, however, there has evolved a growing attention to the water cycle as a global system. While it is straightforward to write water balance equations for the land surface, the atmosphere, and the oceans, estimating the terms remains difficult. Legates and Mather (1992) summarize seven previous estimates of global and continental water balances. The range in estimates of the various water balance terms from these studies can be considered to give an indication of the lower bound of the actual errors (because many of the studies used variations of the same data, the estimates cannot be considered independent, and in any event, biases, such as those due to precipitation undercatch errors, are not accounted for). In any event, the normalized midrange of the values from the different studies is about 8% for precipitation, 14% for evapotranspiration, and 16% for runoff. For the individual continents, the errors are considerably larger. This suggests that even for long-term averages over global land areas, most terms are probably not known to an accuracy greater than about $\pm 10\%$ (and errors are most likely larger over the oceans). The reasons for these relatively large uncertainties are twofold. First, over the oceans, measurements of fluxes like precipitation and evaporation are difficult, and the available observations using *in situ* platforms like ships and buoys are sparse. Second, over land, measurement networks, as well as instrumentation, vary across political boundaries, and network density is usually affected by political instability, and national wealth, as well as population density. For the most part, observation densities for key terms in the water

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

budget over land are greatest in the industrialized countries of the Northern Hemisphere.

SCOPE

The water balance equations relevant to this article are:

Land surface (over a river basin):

$$\overline{P} - \overline{E} = Q_s + Q_g + \frac{d\overline{S}}{dt} \quad (1)$$

where $\overline{E}, \overline{P}$ are basin-averaged evapotranspiration and precipitation, Q_s is river discharge, Q_g is groundwater discharge across the basin boundary, total surface and subsurface storage is $S = S_{sm} + S_{sn} + S_{lw} + S_v + S_g + S_{gi}$, with S_{sm} = soil moisture, S_{sn} = snow water content, S_{lw} = lakes and wetlands storage, S_v = vegetation water content, S_g = groundwater storage, S_{gi} = storage in glaciers and ice sheets.

Atmosphere (over an arbitrary land area):

$$\overline{E} - \overline{P} = \overline{\nabla \cdot \vec{Q}} + \frac{\partial \overline{(W + W_c)}}{\partial t} \quad (2)$$

where W is the vertically averaged water vapor and W_c the vertically averaged cloud (liquid) water content.

The oceanic freshwater balance is not treated here in detail. However, it should be noted that the key terms in the global ocean balance are precipitation and evaporation over the ocean surface and river and groundwater flux from the continents. The latter two terms appear also in the land surface water balance (equation 2) and are discussed in Sections "Scope" and "*In situ* methods". Some brief comments are made in the Section "Satellite methods" about the estimation of precipitation and evaporation over the oceans.

Clearly, equations (1) and (2) reflect different perspectives. For the land surface, the implied control volume is from the land surface to an indefinite depth. For the atmosphere, the control volume is from the top of the atmosphere to the land surface. For the oceans, the control volume is from the ocean surface to the ocean bottom. However, as noted earlier, this article considers only the fluxes across the ocean–atmosphere surface and from the land to the ocean. Changes in storage of freshwater and ocean fluxes are not treated – not because they are not important but because the topic and issues are so broad that they cannot reasonably be covered in an article of this length.

Given the topic of the article, we assume that the objective of the networks discussed is to estimate the terms in the various water balance equations at the global scale, or, over land, at the scale of the continents or major divisions thereof, like major continental river basins. This in turn implies timescales of the order of monthly to seasonal, notwithstanding that considerably shorter observation or accumulation intervals might be required to provide accurate estimates at the monthly to seasonal timescale.

IN SITU METHODS

Precipitation

Most nations have precipitation gage networks intended for a variety of purposes. Often there are two classes of networks with some overlap. Real-time observations are made for weather-related purposes like flood forecasting. Some of these observations are archived and are used for climate-related purposes (like estimation of agricultural water requirements). Climate networks, which do not require real-time information, may include more stations that do not report in real time. This is the case in the United States where there are about 5000 operationally reporting precipitation gauges of which about 3500 report through the Global Telecommunications System (GTS) and are archived at the National Climatic Data Center (NCDC) in real time. A much denser observation network of precipitation from accumulation gauges (often daily) operated by unpaid cooperative observers produces data that are also archived (with a delay of several weeks to months or more) at NCDC. In the United States, the primary reporting method for cooperative observer stations is via mailing of summary forms to NCDC once per month, where they are keypunched and archived. NCDC is currently in the process of a modernization program that is upgrading some cooperative observer stations to have a capability for real-time data transmission and archiving.

NCDC also operates the World Data Center for Meteorology (WDCM) that archives precipitation (among other variables) in near real time. Because these data are acquired in near real time, they generally do not meet the quality required for climate and water balance studies. The Global Precipitation Climatology Center (GPCC) archives precipitation data for the land areas of the globe on a delayed basis. The data archived by GPCC come from a variety of sources, including the GTS (in this sense the real-time data should be similar to those received by WDMC), but also receives climate network data from many countries, in some cases with delays (relative to real time) of several years or more. Figure 1 indicates a key problem with gage-based estimates of precipitation over land – the spatial coverage is highly nonuniform. The densities shown in Figure 1 reflect maxima in the industrialized parts of Europe and North America and correspond to about one station per 400 km^2.

Evapotranspiration

Measurement of actual evaporation is difficult, particularly over large areas. Historically, attention has been

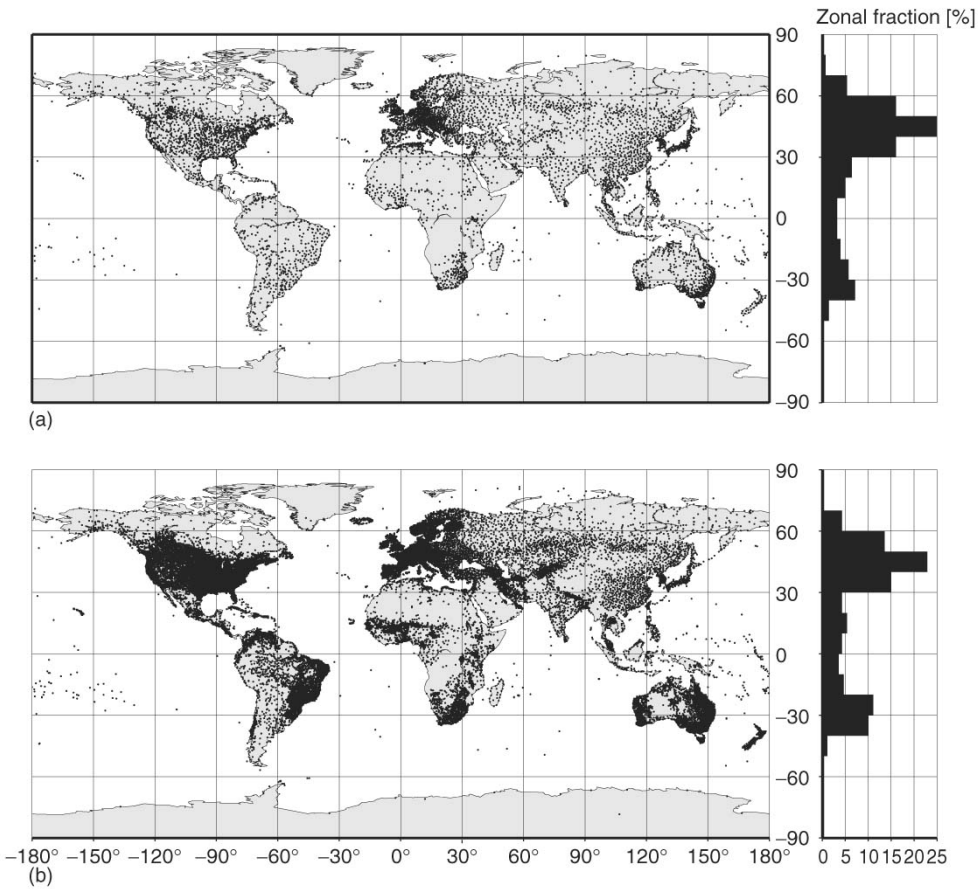

Figure 1 Archived precipitation stations reporting to the Global Precipitation Climatology Centre. (a) shows stations reporting in real time (total approximately 7000); (b) shows climate stations with delayed reporting (total approximately 40 000) (Reproduced from Rudolf, B. and F. Rubel (2005) Global Precipitation. Chapter 11 of Hantel, M. (Ed.). Observed Global Climate. Landolt-Börnstein by permission of Springer)
