In this article, we focus on the processes and the resulting climate of the ABL over land. Figure 1 (after Ek and Holtslag, 2004) gives a schematic illustration of the relevant processes and interactions in an ABL over land during daytime conditions. In such conditions, the sensible heat arising from the surface supports a growing boundary layer with a rising temperature. This may be amplified by the mixing of warmer air from above the boundary layer, known as "entrainment". Given a certain value of specific humidity in the ABL, a rising temperature in the ABL implicates a lower value for the relative humidity (*RH*). This normally implies a higher evaporation or transpiration (latent heat flux) from the surface given that sufficient soil moisture is available. However, the energy for sensible and latent heat at the surface is limited by the available net radiation and soil heat flux. These variables depend in turn on the characteristics of the

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

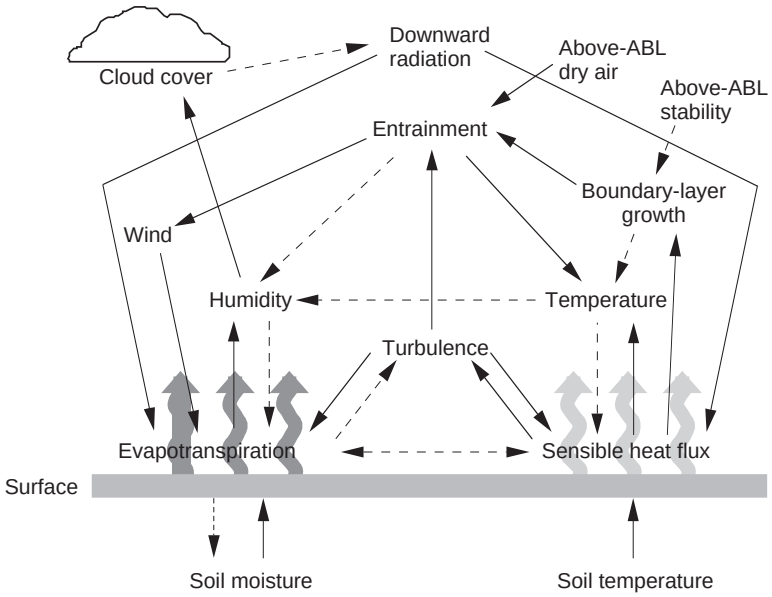

Figure 1 Schematic showing important interactions between the land surface and atmospheric boundary layer for conditions of daytime surface heating (Ek and Holtslag, (2004). © 2004 American Meteorological Society). Full lines indicate the direction of feedbacks, which are normally positive (leading to an increase of the recipient variable), while dashed lines indicate negative feedbacks. Two consecutive negative feedbacks make a positive one. Note the many positive and negative feedback loops, which may lead to increased or decreased humidity and cloud cover

surface and the temperature and moisture conditions in the soil.

The preceding text illustrates that the coupling of the ABL to the land surface is rather complex and depends on many variables. More background on this is given by Betts (2000), Margulis and Entekhabi (2001), Bonan (2002), Findell and Eltahir (2003), and Kabat *et al.* (2004), among many others studies. Ek and Holtslag (2004) quantified the different factors influencing cloud initiation in the ABL, with an analytical development. The findings of the latter study are summarized below (Section 6).

The purpose of this article is to provide an overview of the relevant processes and interactions in the ABL over land as well as the modeling of these. For readers not familiar with atmospheric turbulence and meteorological definitions, some background is given in Section 2. Subsequently, Section 3 provides an overview of the boundary-layer characteristics over land, and Section 4 summarizes the modeling principles for the ABL. Then, Section 5 deals with the surface fluxes and Section 6 with the interactions between the ABL and the land surface, in particular, the role of soil moisture on boundary-layer cloud initiation.

BACKGROUND

There is an enormous range of scales in atmospheric motion, with length scales from millimeters to the atmospheric motion on global scales (e.g. Stull, 1988; Garratt, 1992; Holtslag, 2002). As such, there is a need to separate the relatively small scales of atmospheric turbulence (length scales up to orders of kilometers) from the larger-scale motions. Let C denote an atmospheric variable, such as specific humidity. Then, $\overline{C}$ represents a mean or "smoothed" value of C, typically taken on a horizontal scale of order 10 (or more) kilometers and a corresponding timescale on the order of 10 min to 1 h. A local or instantaneous value of C would differ from $\overline{C}$. Thus, we have

$$C = \overline{C} + c \tag{1}$$

Here c represents the smaller-scale fluctuations (note that we use lower case for the latter). In principle, the fluctuations around the mean motion also reflect gravity waves and other smaller-scale motions, in addition to turbulence. Gravity waves often coexist with turbulence or are generated by turbulence. If the wind at the same time is weak, there may be no turbulence at all. Anyhow, if turbulence exists, it is usually more important for most atmospheric applications, because it mixes more efficiently than the other small-scale motions.

To make the mathematical handling of c tractable, it must satisfy the so-called Reynolds postulates. These require, for example, that $\overline{c} = 0$ and that small- and larger-scale values must not be correlated. After a quantity has been averaged to create a larger-scale quantity, further averaging should produce no further changes, in order for this postulate to apply. The mean of the summation of two variables A

and C will produce $\overline{A \pm C} = \overline{A} \pm \overline{C}$. A further condition is that a mean variable $\overline{C}$ must be differentiable, since differentials show up in the atmospheric equations (see below). In practice, not all these conditions are rigorously satisfied. If the Reynolds postulates are fulfilled, then the averaging for the product of two variables provides

$$\overline{AC} = \overline{A}\,\overline{C} + \overline{ac} \tag{2}$$

The second term at the right-hand side of equation (2) is known as the *turbulent covariance*. Similarly, the turbulent variance of a quantity is given by $\overline{C^2} - (\overline{C})^2$ (which is the square of the standard deviation).

If, in equation (2), the variable A represents one of the velocity components (U,V,W in the x,y,z direction, respectively), then $\overline{AC}$ is the total flux of C and the second term at the right-hand side of equation (2) represents a turbulent flux of C. For instance, $\overline{uc}$ and $\overline{wc}$ are the horizontal and vertical turbulent fluxes of the variable C, respectively. Here u and w are the turbulent fluctuations of the horizontal and vertical velocities. Near the surface, the mean vertical wind $\overline{W}$ is usually small, and thus the total vertical fluxes are normally dominated by the turbulent contributions. However, important exceptions occur over heterogeneous and sloping terrain.

Turbulent fluxes and related variables are directly influenced by the vertical variation of temperature, humidity, and wind (see below). Here the variation of temperature in the atmospheric boundary layer plays an important role in particular. Since pressure decreases with altitude, air parcels, which are forced to rise (sink), do expand (compress). According to the first law of thermodynamics, a rising (sinking) parcel will cool (warm) if there is no additional energy source such as condensation of water vapor. Then, this is called a *dry adiabatic process*.

It can be shown that in the atmospheric boundary layer, the temperature (T) variation with height for a dry adiabatic process is $\mathrm{d}T/\mathrm{d}z = -g/C_\mathrm{p}$ (where g is the gravity constant and C_p is the specific heat for air at constant pressure). The value for g/C_p is approximately 1 K per 100 m. An atmospheric layer that has such a temperature variation with height is called *neutral for dry air* (at least when there is no convection arising from other levels). In that case, $\Theta = T + (g/C_\mathrm{p})z$ is constant, where Θ is called the *potential temperature* (note that the previous definition for potential temperature is not accurate above the boundary layer). Since air normally contains water vapor and because moist air is lighter than dry air, we have to correct for the influence of this on vertical motions. Consequently, a virtual potential temperature is defined as $\Theta_v = \Theta\,(1 + 0.61q)$, where q is the specific humidity (defined as the mass of water vapor per unit mass of moist air).

In a neutral layer with constant Θ_v, vertical motions of moist (not saturated) air can maintain themselves. If the virtual potential temperature of the atmospheric layer increases with height, vertical displacements are suppressed. This is called a *stable condition* (or "inversion"). On the other hand, when the virtual potential temperature decreases with height, vertical fluctuations may be accelerated. Consequently, this is called an *unstable condition*. Thus, in considerations with turbulent fluctuations and atmospheric stability, we have to deal with the (virtual) potential temperature and not with the actual temperature.

THE ATMOSPHERIC BOUNDARY LAYER OVER LAND

The mean structure of the ABL over land depends strongly on the surface fluxes on scales of 5 km or larger. Figure 2 (after Stull, 1988), provides the typical, idealized, mean vertical profiles for temperature T, potential temperature Θ, specific humidity q, in addition to the horizontal wind M (defined by $M^2 = U^2 + V^2$). These profiles apply for an atmospheric boundary layer over land in clear-sky conditions in the afternoon and around midnight, respectively.

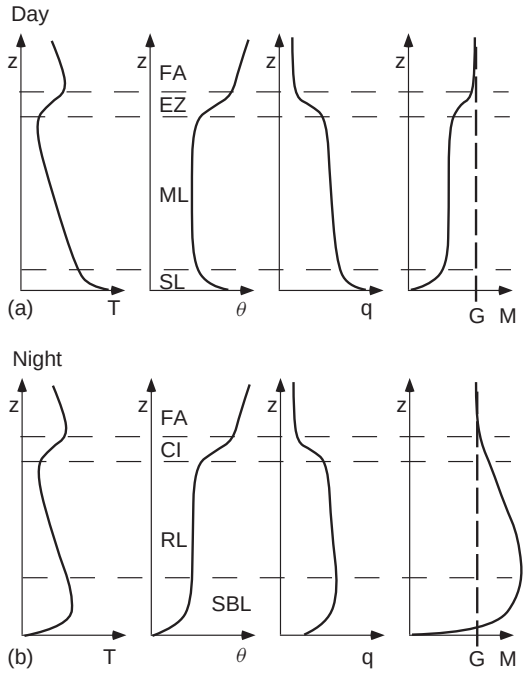

Figure 2 Idealized vertical profiles of mean variables in the atmospheric boundary layer (ABL) over land in fair weather (Stull, 1988, with kind permission of Springer Science & Business Media). In (a), SL refers to the surface layer (lowest 10% of the ABL), ML is the mixed layer, EZ is the entrainment zone, FA is the free atmosphere. In (b), SBL is stable boundary layer, RL is residual layer, CI is the capping inversion. For further explanation, see text and Figure 3

Note that in the free atmosphere the horizontal wind is mostly a result of the acting of the larger-scale pressure differences and the Coriolis force due to the rotation of the earth (but other effects may play a role as well). The resulting wind is known as the *Geostrophic* wind, and is indicated with G in Figure 2 (dashed line). In the daytime boundary layer, the actual wind is smaller due to surface friction, while at clear nights the actual wind away from the surface may be substantially stronger than G due to inertial effects (resulting in the so-called low level jet).

An idealized "clear-sky" picture for the temporal variation of the boundary layer over land is given in Figure 3 (after Stull, 1988). Here the arrows with local time indications refer to the day and nighttime cases of Figure 2. The depth of the dry ABL can vary over land between tens of meters during night up to kilometers during daytime in clear-sky conditions. Over sea, the depth is often only a few hundred meters and rather constant on the timescale of a day. In overcast situations, and in cases with relatively high wind speeds (say over $6\,m\,s^{-1}$ at the 10-m level), the diurnal cycle in the ABL over land is relatively small (as over sea). So, realize that Figures 2 and 3 are not generally valid and that reality is more complex and less ideal!

In any case, the temporal variation of the boundary layer and its characteristics over land is, in particular, substantial in cases with strong diurnal variation of solar incoming radiation (as in spring and summer time) and in cases with nighttime cooling at the land surface (when clear skies and low winds prevail). During daytime, the turbulent boundary layer grows into the nonturbulent "free atmosphere" (indicted as FA in Figure 1). At night, the turbulent part of the stable boundary layer (SBL) may only extend up to a few hundred meters or less (the lowest dashed line in the lower figure).

Figure 2 indicates that the ideal boundary layer during daytime shows a three-layer structure: an unstable "surface layer (SL)", a "well-mixed layer (ML)", and the "entrainment zone (EZ)". The surface layer refers to the lowest 10% of the ABL, in which the turbulent fluxes are rather constant with height but in which the mean profiles normally show the strongest variation with height due to the presence of the surface. In contrast, in the "well-mixed layer (ML)" the (virtual) potential temperature and wind profiles are rather uniform with height due to the strong turbulent mixing, although other variables may still show significant structure. The latter is influenced by the exchange processes in the entrainment zone (EZ), in which turbulence acts to exchange heat, momentum, water vapor, and trace gasses between the boundary layer and the free atmosphere in dependence on the mean values inside and above the boundary layer. The mean values above the boundary layer may vary strongly in time and space depending on the actual larger-scale weather patterns.

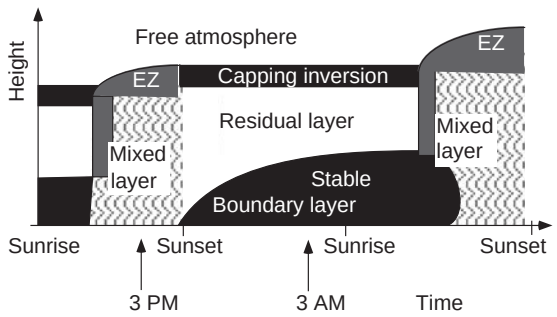

Figure 3 Idealized diurnal evolution of the atmospheric boundary layer over land in fair weather (Stull, 1988, with kind permission of Springer Science & Business Media). The different layers are also indicated in Figure 2

During nighttime, often, the vertical structure of the previous day persists above the SBL. As such, a "residual layer (RL)" with sporadic turbulence (remaining from the previous day) can be identified as well as a "capping inversion (CI)". Also, a surface layer can still be identified as the lowest 10% of the SBL, but then the surface layer is rather shallow in terms of actual height for the ideal case (therefore not shown in the Figures 2 and 3).

Overall turbulence in the ABL is mainly due to the mechanical turbulence by vertical wind shear and convection. Most of the atmosphere above the ABL is not turbulent, although turbulence can occur throughout the whole atmosphere. For instance, cumulus-type clouds, which may grow into thunderstorms, are always turbulent through convection produced by the heat released due to the condensation of water vapor. Turbulence can also occur in clear air above the ABL; most of this is produced in layers of strong vertical wind shear at the boundary between air masses (so-called Clear-Air Turbulence).

Because of the mixing capacity of turbulence, modeling the ABL is also relevant for many practical applications. For instance, chimney plumes are diluted and spread over larger volumes than they would be without turbulence. Turbulent fluctuations in the horizontal motions during severe storms can be fatal to tall buildings or bridges, particularly if resonance (e.g. forcing of a system at its natural frequency) occurs.

ATMOSPHERIC BOUNDARY-LAYER MODELING

The challenge of modeling the atmospheric boundary layer is the prediction of the temporal variation of the vertical and horizontal structures in response to the influence of the major processes acting in the atmosphere and at the earth's surface. As such, the governing equations have to be integrated. In practice, the variables are split into "mean" larger-scale motions and smaller-scale fluctuations as in

equation (1). Inserting this into the basic equations and after averaging this provides a set of equations for the behavior of the larger-scale (mean) variables. The larger-scale variables are then used explicitly in atmospheric models. This can be demonstrated as given below (after the treatments in text books as Stull, 1988; Garratt, 1992).

The general character of any of the budget equations dealing with atmospheric motions is

$$\frac{DC}{Dt} = S_i \tag{3a}$$

Here S_i represents the subsequent sources and sinks for the variable C (such as radiation or chemistry effects). The notation DC/Dt represents the total rate of change for the variable C by local changes ($\partial/\partial t$), and changes transported with the fluid motion in the three directions. As such, we have

$$\frac{\partial C}{\partial t} + U\frac{\partial C}{\partial x} + V\frac{\partial C}{\partial y} + W\frac{\partial C}{\partial z} = S_i \tag{3b}$$

(Recall that U,V,W are the wind speed components in the three directions x,y,z respectively).

If in the atmospheric motion, each variable is split into a mean component and a fluctuation, then equation (3b) provides after Reynolds-averaging, some algebraic manipulations and simplifying assumptions, a budget equation for the mean variable $\overline{C}$. This reads as

$$\begin{aligned}\frac{D\overline{C}}{Dt} &= \frac{\partial \overline{C}}{\partial t} + \overline{U}\frac{\partial \overline{C}}{\partial x} + \overline{V}\frac{\partial \overline{C}}{\partial y} + \overline{W}\frac{\partial \overline{C}}{\partial z} \\ &= \overline{S_i} - \frac{\partial \overline{uc}}{\partial x} - \frac{\partial \overline{vc}}{\partial y} - \frac{\partial \overline{wc}}{\partial z}\end{aligned} \tag{4}$$

We may note that in the derivation of equation (4), single terms representing fluctuations have disappeared (as above in equation 2). However, terms involving the product of two fluctuations remain.

Thus, because the basic equations are nonlinear, the budget equations for the mean variables contain terms involving smaller-scale motions. The latter terms are of the form of a divergence of fluxes produced by such motions in the three directions and appear as the last three terms in equation (4). These motions are said to be subgrid and, consequently, closure formulations or parameterizations are needed to introduce mixing by the smaller-scale (subgrid) motions into the equations for the larger-scale motions (as resolved by the model). Note that additional terms may also appear in equation (4) when the source or sink term S_i incorporates nonlinear effects (such as in the case of clouds and chemistry). These additional factors are not considered here for simplicity.

A special and simple form of equation (4) arises for horizontally homogeneous conditions. In such cases, the terms including horizontal derivatives are negligible. If in addition the mean vertical wind is small and if there are no other sources and sinks, then equation (4) provides

$$\frac{\partial \overline{C}}{\partial t} = -\frac{\partial \overline{wc}}{\partial z} \tag{5}$$

This equation is known as the one-dimensional, vertical "diffusion" equation. It shows that the local time rate of change for the mean of a variable (such as temperature or wind) at a certain height is only given by the divergence of the turbulent (e.g. corresponding heat or momentum) flux in the vertical direction at that height. As such, information on the turbulent flux may produce a local forecast of the variation of a mean variable (but only under the simplifications mentioned). Often, this equation is used for illustrative purposes in comparison with observations on so-called Golden days. However, normally, the other terms in equation (4) are also relevant, in particular, the terms with mean wind speed (the so-called advection terms). This means that in general the budget equations for momentum, heat, and the various scalars are closely coupled in any atmospheric model.

To solve the budget equation (4) for all the mean atmospheric variables involved, the terms involving turbulent fluxes need to be provided or "parameterized". As mentioned before, this means that the fluxes need to be expressed in terms of available mean model quantities, both in the atmosphere and at the surface. Note that the surface fluxes enter as boundary conditions when solving the budget equations for all the relevant mean variables. The atmospheric model equations are integrated starting with proper initial values (taken from observations). New values are then calculated for the following time step and so on.

The most frequently used parameterization for environmental and atmospheric models is known as first-order closure, often also called *K-theory*. In this theory, it is assumed that the flux $\overline{wc}$ of a variable C in the vertical direction z is down the vertical gradient of the mean concentration of C per unit mass. Thus,

$$\overline{wc} = -K_c\frac{\partial \overline{C}}{\partial z} \tag{6}$$

Here, K_c is known as the *eddy-diffusivity* or mixing coefficient for the variable C. Similarly, the horizontal fluxes can be represented in terms of horizontal gradients. Note that the corresponding eddy-diffusivities typically are not constant, but that they generally depend on properties of the flow and the variable of interest. This also means that normally no analytic solutions are possible and numerical methods must be used.

In atmospheric boundary layers with strong atmospheric convection, the turbulent flux of a conserved quantity is

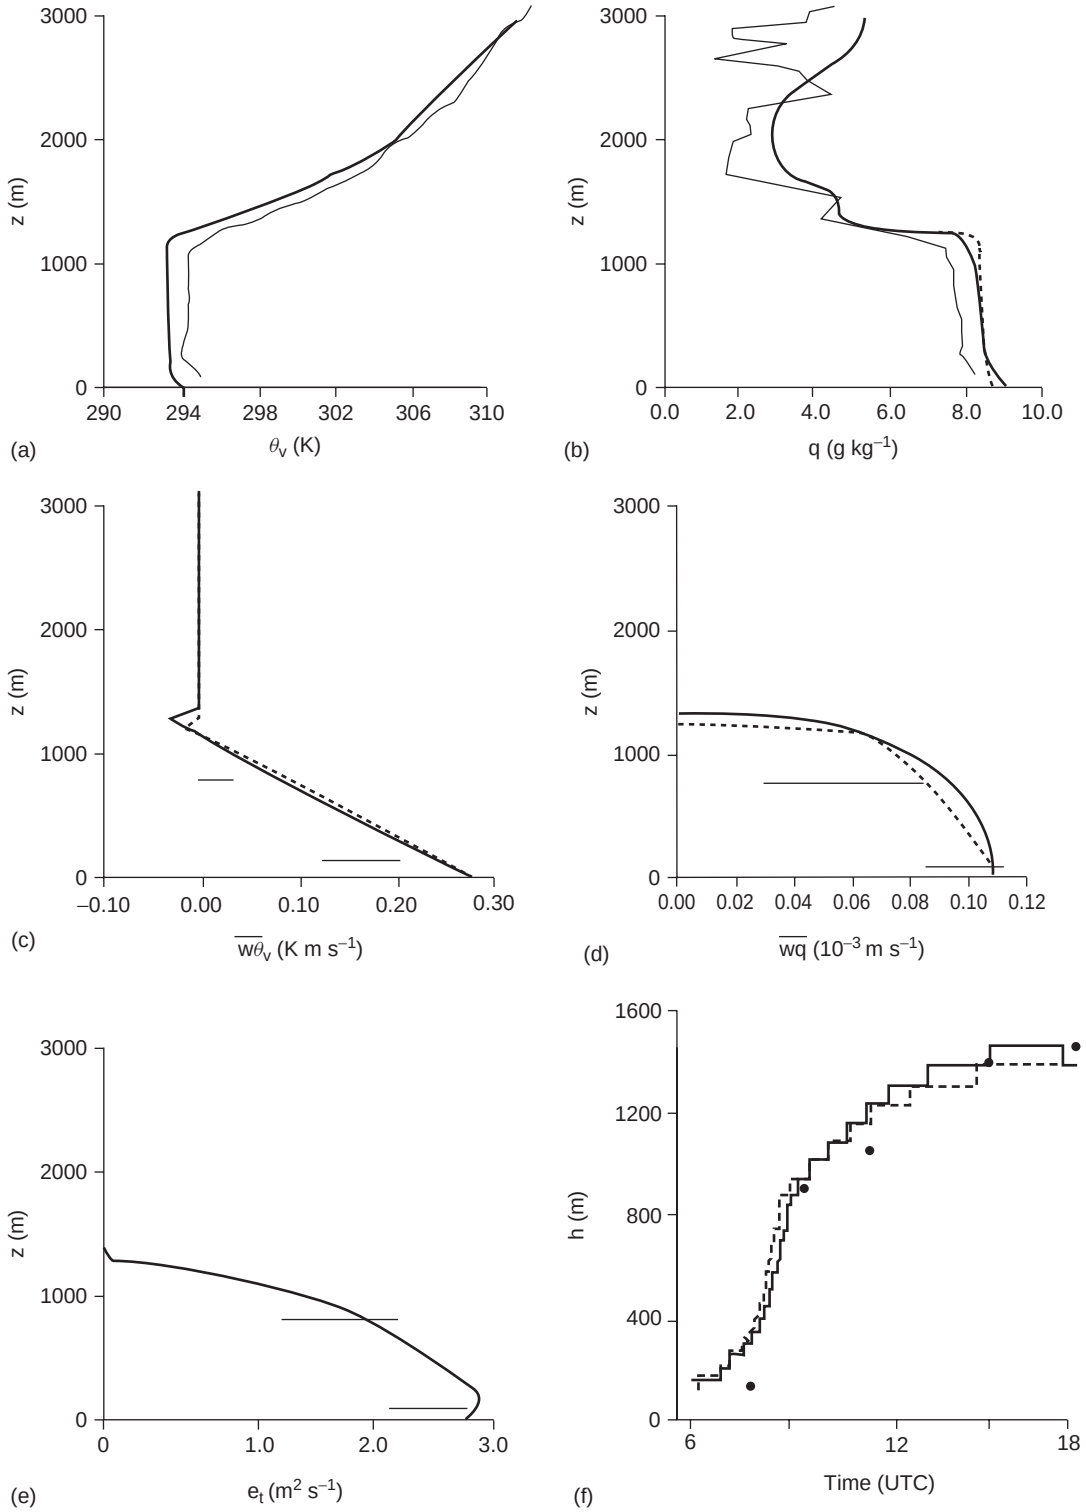

Figure 4 A comparison of observations made on 8 July 1986, in the ''HAPEX-MOBILHY'' field experiment (thin lines) with model outputs for the atmospheric boundary layer in fair weather using two different turbulence parameterizations (Cuxart *et al.*, 1994, with kind permission of Springer Science & Business Media). The models are based on a ''1.5 order closure'' (thick lines) and a ''transilient turbulence closure'' (dashed lines). The results are for mean virtual potential temperature (a), specific humidity (b), the vertical virtual potential heat flux (c), the vertical specific humidity flux (d), the turbulent kinetic energy (e), and the thickness of the turbulent boundary layer (f), The horizontal thin lines in (c), (d), and (e) indicate the range of the corresponding observations, and the dots in (f) refer to observations for the boundary-layer depth

typically not proportional to the local gradient alone as predicted by equation (6). In fact, in a large part of the ABL, the mean gradients are small in conditions with dry convection, in particular, for potential temperature (see Figure 2). Then, the fluxes depend mostly on the mixing characteristics of the larger turbulent motions ("eddies") across the depth of the ABL. Theories are available (see e.g. Stull, 1988; Garratt, 1992, or Holtslag, 2002 for overviews), which have modified K-theory to allow for the influence of convection. To reproduce larger eddy mixing, additional terms on the right-hand side of equation (6) can be incorporated. This has important impacts on reproducing the global land surface climate (e.g. Holtslag and Boville, 1993).

Figure 4 gives an example of a short-range forecast produced by an atmospheric boundary-layer model in comparison with observations (after Cuxart *et al.*, 1994). Here the observations are taken from the "HAPEX-MOBILHY" experiment for July 8, 1986, in France. In this case, a composite of observations for the surface fluxes was used to act as surface boundary conditions for the solving of the budget equations (4) for temperature and humidity, and the initial profiles and advection terms were taken from a meso-scale analysis (see Cuxart *et al.*, 1994). The model outputs for the atmospheric boundary layer apply for fair weather using two different turbulence parameterizations. The models are based on two alternative parameterizations, namely, a so-called 1.5 order closure (e.g. Garratt, 1992) (thick lines) and a so-called transilient turbulence closure (e.g. Stull, 1988) (dashed lines). The results are for the mean variables, the vertical fluxes, the turbulent kinetic energy (defined by $e_t = (\overline{u^2} + \overline{v^2} + \overline{w^2})/2$), and the depth of the turbulent boundary layer. It is seen that overall the agreement with observations is rather good in this case, in particular, because of the details known in the atmospheric forcing conditions and because the surface fluxes were prescribed. However, in general, the agreement may be much less due to lack of proper representation of atmospheric and land surface factors and for long integration times (see below).

The atmospheric model equations can also be applied on much smaller spatial and temporal scales than discussed here, for instance, by using vertical and horizontal grid elements of 10 to 100 m, and time steps of seconds only. It is important to realize that in such cases a significant part of the turbulent fluctuations are resolved by the model equations. This type of modeling is nowadays known as "Large-Eddy Simulation (LES)". This has become a powerful and popular tool in the last decade to study turbulence in clear and cloudy boundary layers under well-defined conditions (e.g. Wyngaard, 1997). It is important to realize that in the case of LES the simplifying assumptions leading to equation (2) are normally not valid.

SURFACE FLUXES OVER LAND

Near the surface, the turbulent fluxes for sensible and latent heat are given by $H = \rho C_p \overline{w\theta_0}$ and $LE = \rho L \overline{wq}_0$. These fluxes (or more specifically flux densities) represent the energy per time and unit area of the involved variables at the surface. Here ρ is the density of the air (in $\mathrm{kg\,m^{-3}}$), C_p is the specific heat at constant pressure (in $\mathrm{J\,K^{-1}}$ kg), L is latent heat of vaporization (in $\mathrm{J\,kg^{-1}}$), and the subscript (o) indicates a surface value (note that here specific humidity q should be given in $\mathrm{kg\,kg^{-1}}$) (*see* **Chapter 201, Land-Atmosphere Models for Water and Energy Cycle Studies, Volume 5**).

Over land, the surface heat fluxes are related through the available energy at the surface

$$H + LE = Q_* - G \tag{7}$$

where Q_* is the surface net radiation and G is the soil heat flux (all in $\mathrm{W\,m^{-2}}$). Here the net radiation is given by the sum of downward ($K^{\downarrow}$) and reflected ($K^{\uparrow}$) short wave, and downward ($L^{\downarrow}$) and emitted ($L^{\uparrow}$) long-wave radiation components at the surface (*see* **Chapter 39, Surface Radiation Balance, Volume 1**). This reads as

$$Q_* = K^{\downarrow} - K^{\uparrow} + L^{\downarrow} - L^{\uparrow} \tag{8}$$

As an example, Figures 5 and 6 give observations and model results of the diurnal variation for the surface fluxes and the related radiation and atmospheric variables over land. The findings apply for the "Golden day" of May 31, 1978, during daytime over a grass-covered surface at Cabauw, The Netherlands (after Ek and Holtslag, 2004). In fact, the observations in Figure 5 are fairly typical for a grass-covered surface in mid-latitude summertime conditions with sufficient soil moisture. In such cases, most of the available net radiation is distributed to the latent heat flux. Consequently, the Bowen ratio *H/LE* is about 35% and the evaporative fraction $LE/(H + LE)$ is about 70%. The soil heat flux is typically small for this type of vegetated surfaces during daytime (order 10% of net radiation Q_*). However, these ratios may be significantly different for other values of soil moisture and for other surface conditions such as in the case of tall plants, forests, and urban landscapes (e.g. Bonan, 2002; Kabat *et al.*, 2004). For instance, in a desert, the latent heat flux (or evaporative fraction) is typically small and the soil heat flux is relatively large (e.g. Heusinkveld *et al.*, 2004).

In Figure 5, also several model results are indicated of a land surface (LS) scheme. The simplest case is given by a LS scheme in stand-alone mode. In such a case, the observations of atmospheric temperature, specific humidity, wind speed, the (incoming and reflected) solar radiation as well as the downward long-wave radiation of Figure 6 were

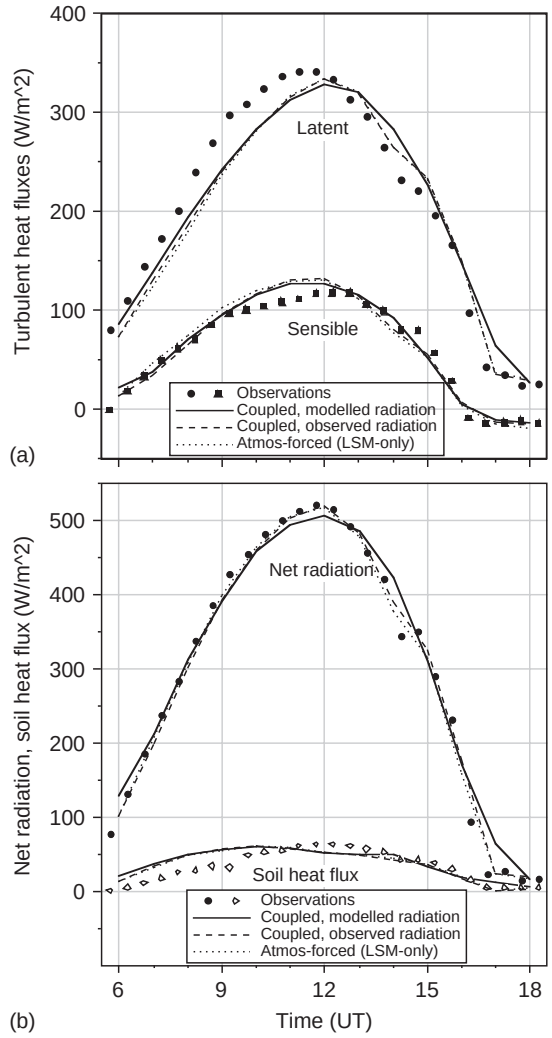

Figure 5 The diurnal variation of the energy balance components for May 31, 1978, at Cabauw, NL (Ek and Holtslag (2004). © 2004 American Meteorological Society)

used as input to calculate the surface fluxes. Consequently, the case is referred as the "atmospheric forcing" case. To calculate the surface fluxes, equations (7) and (8) are utilized in combination with the usual soil diffusion equation, and a "transfer equation" for the surface fluxes.

The transfer equation reads similar as equation (6), but rather than the atmospheric gradient the difference of atmospheric and surface properties is used for the quantity of interest. For heat this reads as (e.g. Beljaars and Holtslag, 1991)

$$\overline{w\theta_0} = \beta_t u_{*0}(\Theta_0 - \Theta_a) \tag{9}$$

Here Θ_0 and Θ_a are the values of the (potential) temperature at the surface and in the air, respectively; β_t is a transfer parameter and u_{*0} is the well-known surface friction velocity. The latter is directly related to the surface momentum fluxes (or stresses), as defined by

$$u_{*0}^4 = ((-\overline{uw_0})^2 + (-\overline{vw_0})^2) \tag{10}$$

It is important to realize that near the surface the average wind must vanish because the mean wind is zero at the earth's surface. On the other hand, we know from observations that the fluxes of heat, momentum, and trace gasses are nonzero. Consequently, equation (9) represents the "effective" surface flux of sensible heat $\overline{w\theta_0}$ due to the combined effect of molecular diffusion and turbulence at the surface. As such, β_t depends on surface characteristics and the atmospheric state near the surface. Similar relations apply for the latent heat flux and other surface fluxes. In any case, the surface value for the involved quantity needs special consideration as well as the formulation of the transfer parameter β_t. The latter is normally part of the land surface scheme (e.g. Beljaars and Holtslag, 1991; Holtslag and Ek, 1996; Bonan, 2002).

Figure 5 shows that the surface fluxes can be realistically modeled in the "off-line" case. The next step is to couple the land surface scheme to the ABL model. Here the ABL model of Troen and Mahrt (1986) and Holtslag and Boville (1993) is used (see Ek and Holtslag, 2004 for a list of recent updates). It is seen that the coupled model results are very similar to the "off-line" results for this case, indicating realistic behavior of both the land surface and boundary-layer scheme for the present "ideal" case Figure 6. Using a sophisticated land surface scheme allows the land–atmosphere system the freedom to respond interactively with the ABL where many processes and important feedback mechanisms are represented (Figure 1). However, in general, the correct modeling is not at all trivial, certainly not for the more complex situations that occur in reality (see Bonan, 2002 for more information on this issue).

In any case, to understand and to correctly model boundary-layer climates as well as the feedbacks in the coupled land–atmospheric system, a realistic model of both the atmospheric boundary-layer (ABL) and the land surface (LS) is needed.

LAND SURFACE AND BOUNDARY-LAYER INTERACTIONS

On the basis of the coupled land surface – atmospheric boundary-layer model set up as discussed above – we can explore the interaction of the land surface with the ABL and the effect on boundary-layer cloud development. We focus on the role of soil moisture and, consequently, we make a series of model runs (a "reference" set) where we change the soil moisture from dry to wet conditions with initial conditions and forcing the same as in the coupled model

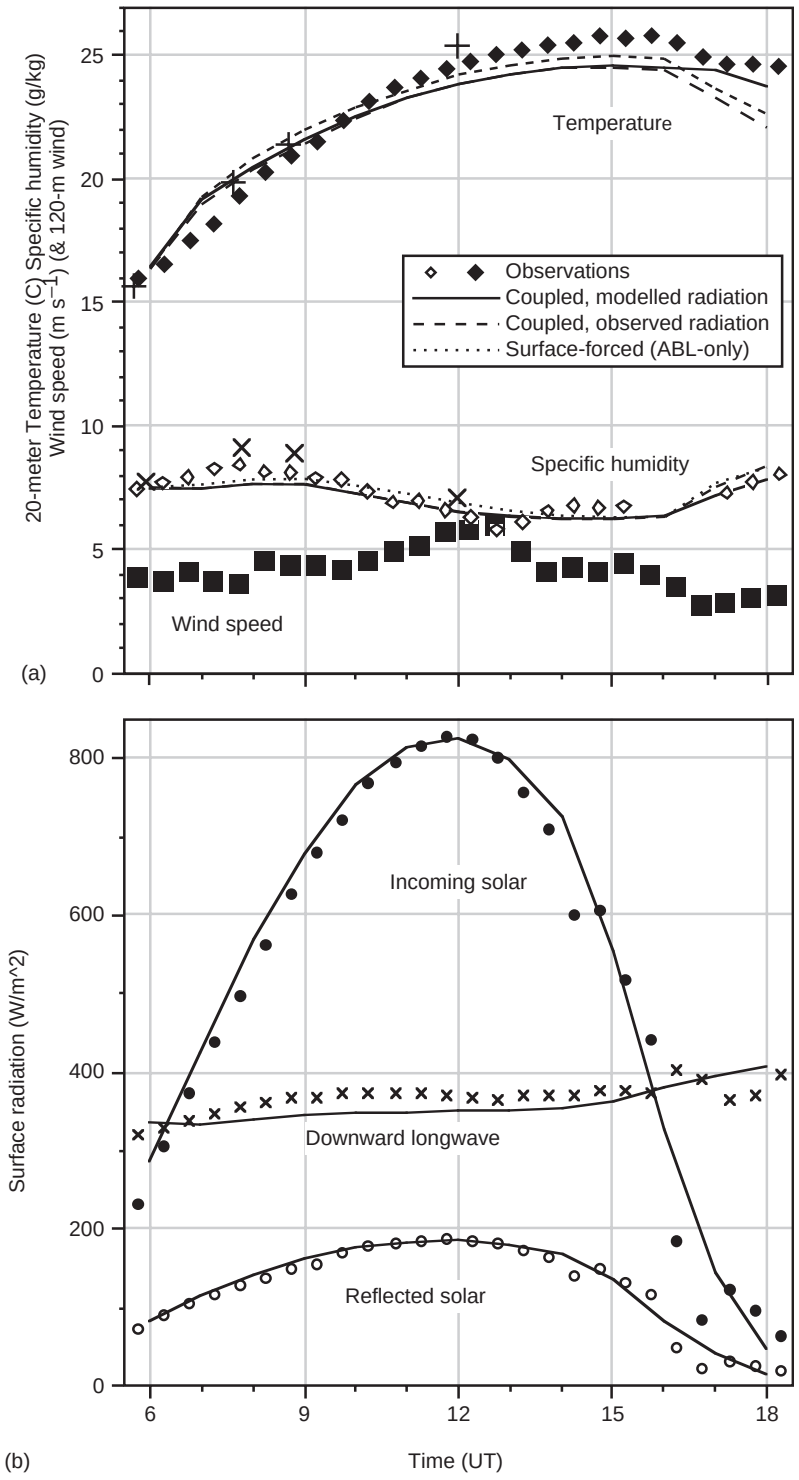

Figure 6 The diurnal variation of the radiation components and atmospheric variables (T, q, U) for May 31, 1978, at Cabauw, NL (Ek and Holtslag (2004). © 2004 American Meteorological Society)

runs (as above). As such, we vary soil moisture from below the wilting point (quite dry) to near saturation (quite wet).

When the initial soil moisture is decreased from intermediate soil moisture values (close to the Cabauw observations with volumetric soil moisture ≈0.43) to below the wilting point, the ABL cloud cover decreases to zero (Figure 7). This confirms intuition. However, as we increase the initial soil moisture from intermediate soil moisture values to near

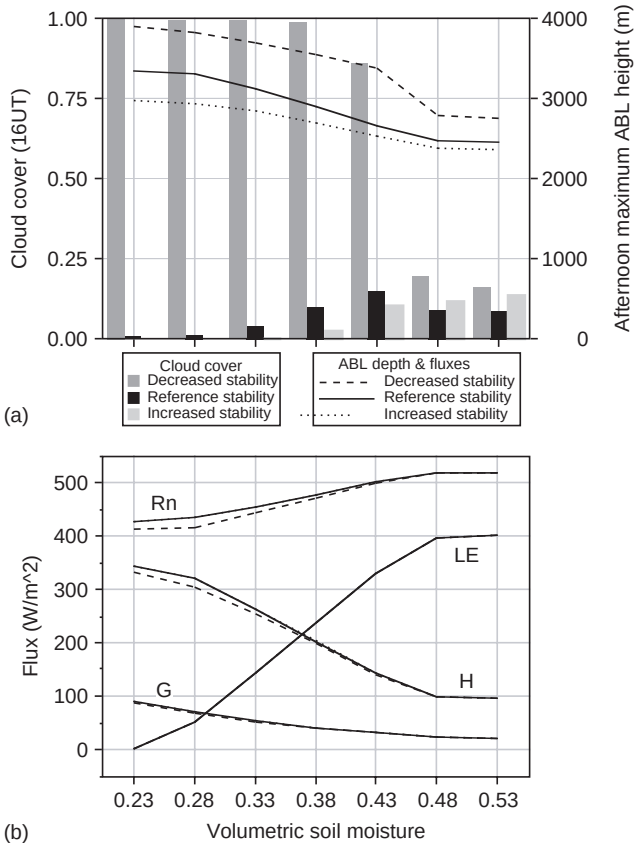

Figure 7 The impact of variation in volumetric soil moisture on the ABL depth and cloud cover (a), and components of the surface energy budget (b) for May 31, 1978, at Cabauw, NL (Ek and Holtslag (2004). © 2004 American Meteorological Society). The different sets of model runs refer to a reference case, and cases with increased and decreased stability above the ABL (see text for full explanation)

saturation, ABL cloud cover decreases slightly, a somewhat counterintuitive result. Certainly, there are a number of processes that account for this behavior, that is, interactions between the land surface, atmospheric boundary layer (including ABL clouds), free atmosphere, and initial ABL conditions (Figure 1).

Before attempting an explanation of this response, we also examine the role of atmospheric stability (that is the strength of the capping inversion) above the ABL. Note that the atmospheric stability above the ABL, in general, has a strong influence on the boundary-layer depth and on its temporal variation (see Garratt, 1992; Stull, 1988 for more background on this). To illustrate this effect, we make two additional sets of model runs as above, namely, a run in which we prescribe an increased atmospheric stability above the afternoon boundary-layer top and another run with decreased atmospheric stability. We then examine the resulting afternoon ABL depth and fractional cloud cover and the mid-day surface energy budget as it changes with changing prescribed initial soil moisture (see Figure 7).

The set of model runs with stronger atmospheric stability have a shallower ABL depth than the reference set and less cloud cover for drier soils, with increasing cloud cover for model runs with increased soil moisture (Figure 7). However, in great contrast, the set of model runs with weaker atmospheric stability above the ABL have a deeper ABL depth (as one would expect) and yet a much greater cloud cover for drier soils, with decreasing cloud cover for increasing soil moisture. These effects are not easily expected beforehand.

To further understand the role of soil moisture and other factors on ABL cloud development, Ek and Holtslag (2004) examine a useful new equation for relative humidity (*RH*) tendency at the ABL top:

$$\frac{\partial RH}{\partial t} = \frac{(Q_* - G)}{\rho L h q_s}[ef + ne(1 - ef)] \qquad (11)$$

Here $Q_* - G$ is the available energy at the surface, h is ABL depth, and q_s is saturation-specific humidity just below the ABL top (again ρ is air density and L is latent heat of vaporization). The surface evaporative fraction (the surface energy available for evaporation), *ef*, is already defined above. Furthermore, *ne* reflects the direct effects of nonevaporative processes on relative humidity tendency (see Ek and Holtslag, 2004). Basically, *ne* consists of three factors: ABL-top dry-air entrainment (a negative contribution to the tendency of relative humidity at the ABL top), the boundary-layer growth (a positive contribution), and boundary-layer heating through surface warming and ABL-top warm-air entrainment (a negative contribution).

From equation (11), we see that the relative humidity tendency is proportional to available energy and inversely proportional to ABL depth and temperature (via saturation-specific humidity), while the sign of the relative humidity tendency is determined by the sign of $ef + ne\ (1 - ef)$. On examining equation 11, it is apparent that the direct role of *ef* is to increase the ABL-top relative humidity, while the indirect role of surface evaporation (via reduced surface heating, and diminished ABL growth and entrainment) is found in the expression $ne\ (1 - ef)$. Figure 8 shows how $ef + ne\ (1 - ef)$ depends on *ef* versus *ne*, where $ef + ne\ (1 - ef)$ is simply the relative humidity tendency, $\partial RH/\partial t$, normalized by the available energy term $(Q_* - G)/\rho L h q_s$. In Figure 7 also, some data points are given for the Cabauw case (labeled with their time of occurrence).

For the case where $ne < 1$, $\partial RH/\partial t$ increases as the evaporative fraction (ef) increases, confirming intuition. (For the range $0 < ne < 1$, $\partial RH/\partial t > 0$ and increases with increasing *ef*, while for $ne < 0$, $\partial RH/\partial t > 0$ only when *ef* exceeds some threshold value that increases for increasingly negative values of *ne*). Here soil moisture acts to increase ABL-top relative humidity tendency and thus increases the

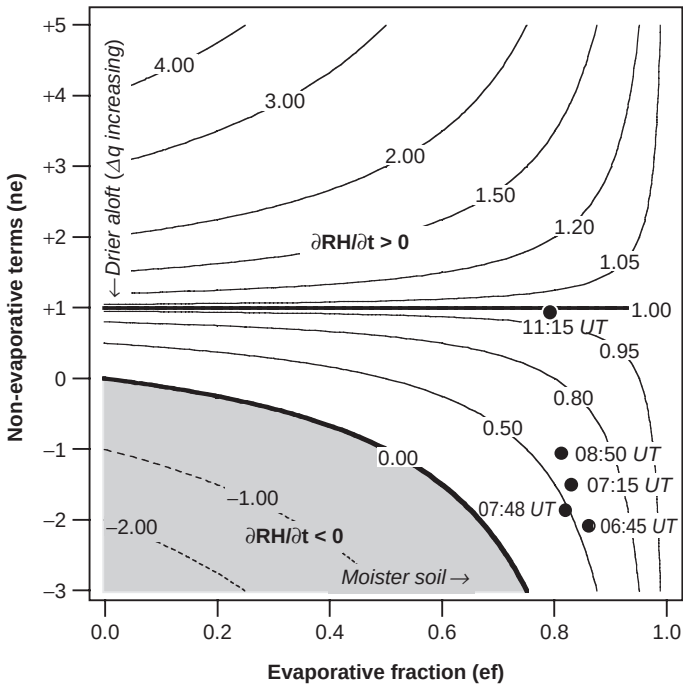

Figure 8 Relative humidity tendency (normalized by the available energy term), with dependence on evaporative fraction versus nonevaporative terms (Ek and Holtslag (2004). © 2004 American Meteorological Society). See text for full description

probability of ABL cloud initiation, given a sufficient initial ABL relative humidity. This is the case when the soil is sufficiently moist for unrestricted surface evaporation, and the environment above the ABL is not too dry and atmospheric stability is not too weak.

For the case where $ne > 1$, $\partial RH/\partial t$ increases as ef decreases (which is somewhat counterintuitive) so that here soil moisture acts to limit the increase of ABL-top relative humidity and thus decreases the probability of ABL cloud initiation. This is the case when the environment above the ABL is again not too dry but atmospheric stability is rather weak, so for drier soils, surface evaporation is lower with boundary-layer growth less restricted than with moister soils. Note that the largest values of $\partial RH/\partial t$ are achieved for $ne > 1$, suggesting that the greatest potential for ABL cloud initiation is not over moist soils, but rather over dry soils with weak stability (and air not too dry above the ABL).

We may note that the outcome of equation 11 (as presented in Figure 8) agrees well with the output of the coupled model (confirmed by more than a thousand model runs), as long as the ABL is sufficiently well mixed (as reflected by rather uniform potential temperature and large heat fluxes). For the set of model runs with increased (stronger) atmospheric stability, ABL depth is shallower (as one would expect), and since $ne < 1$, there is a decrease in relative humidity tendency at the ABL-top. This implies less cloud cover for drier soils (Figure 8), with increasing cloud cover for increasing soil moisture ($ne \approx 0$). In contrast, for the set of model runs with decreased (weaker) atmospheric stability, ABL depth is deeper (as one would expect), and yet since $ne > 1$ there is an increase in ABL-top relative humidity tendency. This implies more cloud cover for drier soils, with decreasing cloud cover for increasing soil moisture ($ne \gg 1$), as was suggested in the relative humidity tendency development described above.

The indicated findings are qualitatively consistent with Ek and Mahrt (1994) for HAPEX-MOBILHY data (summer 1986, Southwest France), which found that a day with strong atmospheric stability above the ABL and a large observed evaporative fraction (via higher soil moisture) gave a similar mid-day relative humidity at the ABL-top as a case nine days later, with weaker atmospheric stability and soil moisture that had decreased by 20%.

SUMMARY

In this article, we have focused on atmospheric boundary-layer climates over land. Special emphasis was given to the basic characteristics and approaches in use for modeling and parameterization of the ABL in relation with the land surface. Examples are given for "Golden days" in the "HAPEX-MOBILHY" experiment in France (after Cuxart *et al.*, 1994), and at Cabauw, The Netherlands (after Ek and Holtslag, 2004). It is shown that both the ABL and

the coupled soil-vegetation-atmosphere system can be well represented in the well-defined cases examined. At the same time, it is realized that reality is often much more complex (e.g. Bonan, 2002; Kabat *et al.*, 2004).

The role of soil moisture in the development of ABL clouds is explored via model runs and an analytical development. This is done in terms of tendency equation of relative humidity (*RH*) at the ABL-top, which involves a number of land-atmosphere interactions (Ek and Holtslag, 2004). It is shown that the effect of soil moisture is to increase ABL-top *RH* tendency and thus potential for ABL cloud formation (confirming intuition), but only if the stability above the ABL is not too weak (and given sufficient initial *RH* in the ABL and air above the ABL that is not too dry). Alternately, for weak stability above the ABL, drier soils yield a greater ABL-top *RH* tendency and thus potential for ABL cloud formation (somewhat counter-intuitive), where in this case soil moisture acts to limit the increase of relative humidity at ABL-top. Then, the largest values of ABL-top *RH* tendency are predicted over dry soils. The new relative humidity tendency equation presented (after Ek and Holtslag, 2004) may provide a useful quantitative framework for hydrometeorological studies involving land surface interaction with the atmospheric boundary layer.

30: Topographic Effects on Precipitation

GEOFFREY L AUSTIN[1] AND KIM N DIRKS[2]

[1] *Department of Physics, The University of Auckland, Auckland, New Zealand*
[2] *Department of Physiology, The University of Auckland, Auckland, New Zealand*

Topography and orography can drastically alter the wind patterns in the atmosphere that in turn can have a major effect on the geographical distribution of precipitation. The processes involved include the upslope enhancement of existing rainfall or the triggering of new rainfall in mountainous regions, and the effect of temperature or humidity contrasts between boundary layer air masses over land and oceanic areas. These processes can result in rainfall patterns ranging from a single triggered thunderstorm to widespread torrential rainfall, as occur when tropical cyclone air masses are pushed up steep coastal mountain ranges. Since the magnitude and distribution of the resulting precipitation pattern can depend critically on the wind speed and direction, as well as the terrain itself, the topographical precipitation processes often determine not only the climatic rainfall patterns of a region but also the interannual variability of this distribution.

INTRODUCTION

Topography leads to a diverse range of modifications to the wind patterns of the Earth's atmosphere. These modifications, in the form of topographically induced circulations, can modify cloud and precipitation-producing processes. The net effect of the topography and orography can be to redistribute and modify the amount of precipitation that would have occurred in the absence of complex terrain and, in some cases, to produce precipitation that would otherwise not have occurred at all.

Processes that modify the airflow can be due to the movement of moist air over or around hills or mountain ranges. In such situations, a variety of circulations and precipitation patterns are possible depending on the stability and humidity of the air and the height and horizontal extent of the topographical barrier. Clearly, if the atmosphere is unstable, the topography may induce convective overturning, whereas if the air mass is stable, then the flow may exhibit lee waves.

The modification of airflows can also be caused by thermal gradients due to changes in the nature of the Earth's surface. Sea-breeze circulations and monsoons are examples of such phenomena. Both of these can also result in triggered convection (convection resulting from potentially unstable air being lifted as a result of topography). A particularly well-studied example of smaller-scale sea-breeze circulations is the development of thunderstorms over Florida (Pielke, 1974; Nicholls *et al.*, 1991), where the sea breeze may provide enough lifting for thunderstorms to develop. An example of a much larger system is the Asian monsoon where large contrasts in temperature develop between the Indian Ocean and the continent, leading to substantial amounts of rainfall (Huang-Hsiung and Liu, 2003).

Probably the most useful accounts of mesoscale circulations, both from observational and theoretical points of view, are contained in Atkinson (1989) and Ray (1986) to which the reader is referred. With the exception of monsoon circulations, all of the thermally and orographically induced circulations described below fit into the category of mesoscale circulations. The development of radar and satellite remote-sensing systems have allowed better depictions of these circulations by viewing cloud and precipitation patterns that were too small for global networks to reveal. These technologies have been supplemented in projects around the world with high spatial-resolution networks of rain gauges and meteorological towers. In situations of complex terrain, such networks often provide the most accurate measures of the spatial distribution of rainfall.

Over the years, a number of experimental programmes have been undertaken in various parts of the world to

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

investigate the effects of mountainous topography on precipitation patterns, following the pioneering work in the United Kingdom South of Wales Experiment (Browning, 1980). Of particular note are the recent GAME project of the Asian Monsoon (**http://www.hyarc.nagoya-u.ac.jp/game/**), investigations into the effect of the Rocky Mountains on rainfall in the Northwestern United States (Klimowski *et al.*, 1998), the effect of the European Alps (Frei and Schär, 1998), and rainfall patterns resulting from the Southern Alps in the South Island of New Zealand (Wratt *et al.*, 1996). It is apparent from these studies that where the scale of the mountains or the stability or wind speed differ, the precipitation-forming mechanisms can be quite different from one another. For example, for South Wales with relatively modest mountains and high humidity, the presence of snow aloft frequently induces large rainfalls by the seeder-feeder process (see later), whereas for other locations this process may be unimportant.

In this chapter, we attempt to describe some of the basic aspects of topographically and orographically induced flows and their impact on precipitation patterns. Some of the experimental programmes carried out to investigate these mechanisms are also described.

TOPOGRAPHICALLY INDUCED FLOW

Land–Sea Breezes

One of the most studied mesoscale circulations is the land–sea breeze system. Land and sea breezes result from thermal discontinuities at the interface between the sea and land and dominate the flow during calm, clear conditions in coastal environments. In the morning, solar radiation heats the land more quickly than the sea, causing the air above it to expand. This results in a slope in the isobars from land to sea, leading to a light flow of air towards the land at the ground surface and seaward flow aloft, along with rising air above the land with subsiding air above the sea, as shown in Figure 1. At night, the reverse flow occurs, though it is generally weaker than during the day, and the vertical extent of the circulation is generally reduced. Sea breezes are strongest under calm wind conditions, clear skies and when the difference between the temperature of the sea surface and the land is at its maximum. For a narrow isthmus of land in the ocean, a convergence zone may develop at the boundary between two opposing sea breezes, resulting in the potential for triggered convection along the convergence zone.

A particularly striking example of such a sea-breeze circulation is that which frequently develops over Florida during the wet summer season. The convergence of moist winds from both the Atlantic Ocean and the Gulf of Mexico results in convection and clouds, often with cloud-free air over the water. If the atmosphere is conditionally

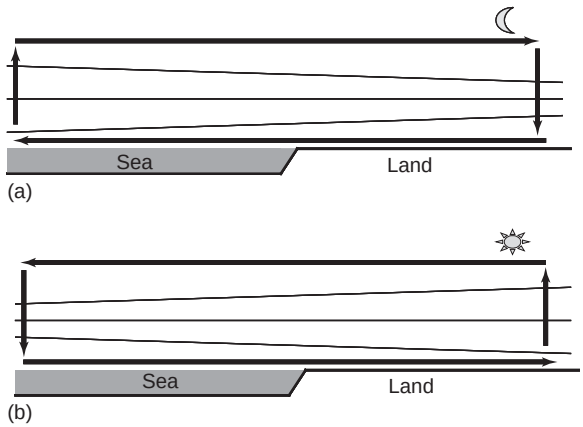

Figure 1 The land-sea breeze circulation. The differential heating of the land and sea results in offshore winds near the surface at night (a) and onshore winds near the surface during the day (b). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

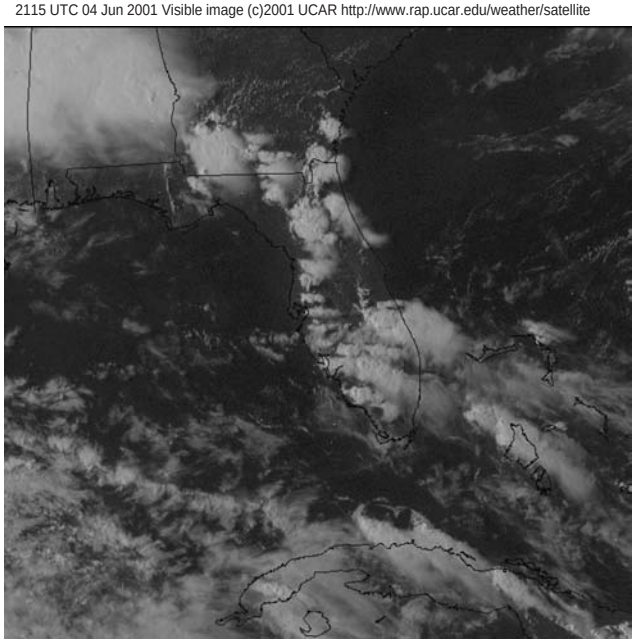

Figure 2 Satellite imagery of thunderstorm development over Florida (The source of this material is the University Corporation for Atmospheric Research (UCAR). © 2002 All Rights Reserved)

unstable, then thunderstorms may be formed by the sea breeze convergence, as originally suggested by Byers and Rodebush (1948). More clear evidence of the development of thunderstorms as a result of the sea breezes over Florida can be seen from satellite imagery, as shown in Figure 2.

Monsoon Circulations

Monsoon circulations are large-scale shifts in seasonal wind patterns caused by differential heating between continents

and the oceans which reverse between summer and winter. In some ways, monsoon circulations are similar to large-scale sea-land breezes that occur on a yearly cycle rather than a daily cycle. The Asian monsoon, the Singapore monsoon, the West African monsoon, and the Arizona monsoon are examples of monsoon systems found around the world. In the case of the Asian monsoon, during the winter, the air mass over South Asia becomes much cooler than the air mass over the Indian Ocean. This results in the development of a large high-pressure system over land, and a clockwise circulation of air that flows out over the Indian Ocean, as shown in Figure 3. The northeasterly winds over southern and eastern Asia generally bring dry air and clear skies. In contrast, during the summer, the air mass over South Asia becomes much warmer than the air mass over the Indian Ocean so a low-pressure system tends to develop over land, leading to moist southwesterly winds from the ocean. The lifting of these air masses as a result of the topography leads to heavy rain and thunderstorms at this time of the year.

The Asian monsoon is the most intense and the most complicated of the monsoons because of the existence of the Himalaya–Tibetan plateau (Chou, 2003). Many studies carried out over the past 30 years have shown the importance of the Tibetan plateau as an elevated heat source (Hahn and Manabe, 1975; He *et al.*, 1987) and the impact this has on the precipitation patterns resulting from thermal triggering. The livelihood of nearly a billion people is dependent on the arrival of monsoon rains, while at the same time the monsoon can result in devastating floods.

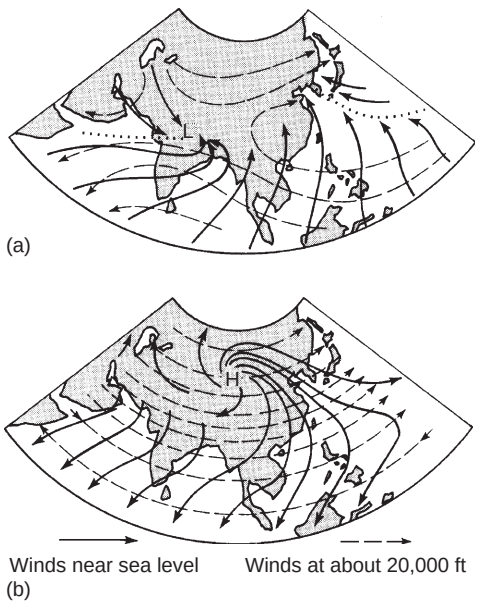

Figure 3 The Asian monsoon circulation (a) during the summer and (b) during the winter (Reproduced from Petterssen, 1969 with premission of the McGraw Hill Companies)

OROGRAPHIC AIRFLOWS

Updrafts can be significantly increased when wind flows are lifted over mountain barriers. In the case of preexisting rainfall, this can result in increased rainfall and the possibility of convective rainfall. The effects of this rainfall-generating process over mountain barriers can be readily recognized in the geographical distribution of rainfall in the form of enhancements on the upwind side of ranges facing moist prevailing winds. An example of this is the enhanced rainfall on the windward side of the Southern Alps of New Zealand often observed under moist northwesterly wind conditions.

Whether or not an air mass is raining before it arrives at a mountain, it will cool as a result of the uplift, and, on reaching saturation, produce an orographic cloud and/or become unstable and trigger convection. In the case of a stable airmass, the orographic cloud will eventually produce precipitation as the cloud droplets combine to give precipitation-sized particles. Early observations and theoretical calculations of this process suggest that it may take as long as 20 min to produce rain in this way. Findeisen (1939) carried out some of the first calculations of the growth of cloud droplets by coalescence while Langmuir (1948) refined the calculations and discussed the role of drop breakup in generating fragments suitable for further growth. Langmuir's calculations were later confirmed by Bowen (1950) using radar observations. If the rain barrier is of modest horizontal extent (less than about 50 km or so), this 20 min or so required for rain-sized drops to be produced from an orographic cloud may be insufficient to generate rain at the surface of the orographic barrier. Microphysical enhancement processes which allow these clouds to rain are discussed below in the section on cloud microphysical processes.

For hills or mountains of modest horizontal extent, several different mechanisms may lead to a modest enhancement or redistribution of preexisting precipitation or the development of precipitation from moist air. However, for the case where a strongly developing tropical cyclone is incident on a similar orographic barrier, the large volumes of warm saturated air that are lifted over the barrier can lead to torrential rainfall.

Houze (1993) describes seven basic types of orographic mechanisms depicted in Figure 4. They are: "(a) The seeder-feeder mechanism of Bergeron (1950, 1968) in which low orographic clouds provide liquid water 'food' to enhance the growth of precipitation particles falling from mid-level clouds; (b) condensation by forced upslope flow; (c) upslope triggering of convection; (d) upstream cloud formation resulting from orographic flow-blocking or vertically propagating gravity waves; (e) thermal triggering by an elevated heat source; (f) lee-side convergence owing to flow around a 3D obstacle; and (g) lee-side enhancement

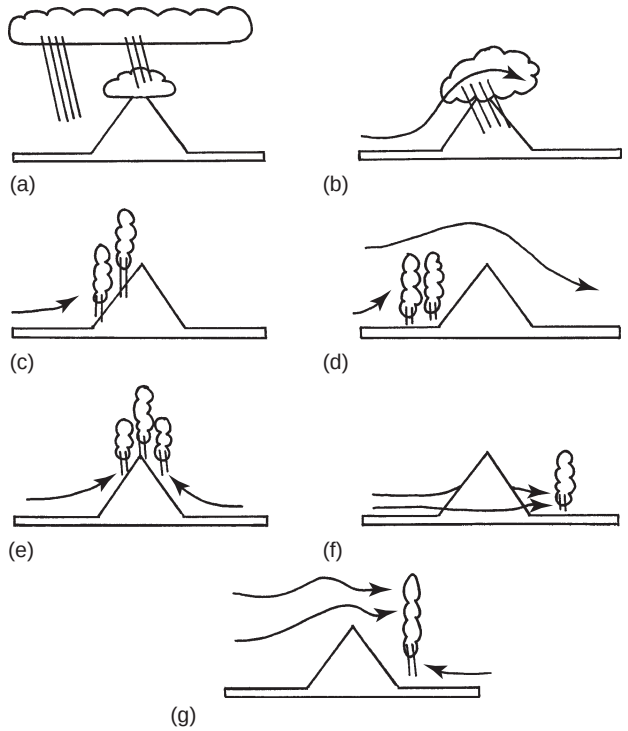

Figure 4 Mountain airflows leading to precipitation and/or precipitation enhancement by (a) the seeder-feeder mechanism, (b) condensation by forced upslope flow, (c) upslope triggering of convection, (d) upstream cloud formation resulting from orographic flow-blocking or vertically propagating gravity waves, (e) thermal triggering by an elevated heat source, (f) lee-side convergence owing to flow around a 3D obstacle, and (g) lee-side enhancement of precipitation by mountain-induced gravity waves upslope convection (Reprint from Houze, 1993 with permission from Elsevier)

of precipitation by mountain-induced gravity waves. In addition to these mechanisms, there is the important effect of concentration of the windward flow into valleys. These convergent flows produce extreme climatological maxima, ... and concentrate the precipitation and runoff to produce extreme flooding events".

In some situations of low hills of 300 m or so, it has been observed that there is a deficit in precipitation upwind of the peak and a relative excess downwind, inconsistent with the predictions of the above-mentioned mechanisms. In this case, it may be that there has not been any enhancement in precipitation as such, and that the observed spatial variability is simply a redistribution of precipitation as a result of a perturbation in the trajectories of raindrops due to a distortion in wind flow. This rainfall redistribution mechanism is discussed in more detail below.

Of particular interest in the area of predictive meteorology is the role of orographic barriers in the formation of cyclones on their lee side and the subsequent precipitation that may result. Petterssen (1956) and Pierrehumbert (1986) have shown this to occur in the lee of the Rocky Mountains and the European Alps, respectively. There appears to be no completely satisfactory theory on the mechanism of lee cyclogenesis, although it clearly involves the modification of a barotropic instability by the flow over the mountain. The reader is referred to Pierrehumbert (1986) for further discussion on this topic.

CLOUD MICROPHYSICAL PROCESSES

As suggested by Houze (1993) "A common feature of these orographic precipitation mechanisms is the sensitive interdependence of orographically-induced flow dynamics (channeling, blocking and gravity-wave responses) and cloud microphysics. The microphysical effects are profound in regions of complex terrain. Heavy orographic precipitation often involves the growth and fallout of ice particles, which exhibit a wide range of fall velocities. Vapor-grown crystals and aggregates of ice crystals fall at speeds of 0.3–1.5 m/s. The more the particles grow by riming of supercooled water, the more dense they are and the faster they fall. Heavily rimed particles (graupel) fall at speeds of 1–3 m/s, while hail falls at 1–50 m/s. These fall speeds become crucial to determining precipitation patterns in complex terrain. Since cloud ice and snow particles are so readily carried by the horizontal wind, slight differences in the fallspeeds of ice particles determine which side of the mountain or in which valley (i.e. hydrological basin) precipitation ultimately reaches the ground."

Seeder-feeder Mechanism

The seeder-feeder mechanism was first proposed by Bergeron (1950, 1965) to explain orographic enhancements of up to a factor of 0.5 over small hills. Conventional microphysical analysis would suggest that the air traversing small terrain features of a few hundreds of meters or so is much too quick for the formation of raindrops from clouds produced by the hills themselves. The mechanism has two basic requirements: the presence of an upper-level seeder cloud and the existence of a lower-level feeder cloud. The feeder cloud is produced as a result of a low-level near-saturated air mass being forced to rise as it meets an orographic barrier. The water vapor in the air condenses, forming a cloud on the windward side of the hill. A stratiform seeder cloud provides precipitation particles to seed the lower-level feeder cloud and results in the removal of many cloud droplets of the feeder cloud that would otherwise be carried over the mountain. There must be a high liquid water content in the feeder cloud for the seeder-feeder mechanism to be effective, and there must also be a strong low-level flow in order to replenish the moisture lost due to the wash-out of the feeder cloud. This effect is found to be more significant when the "seeder" cloud is in the form

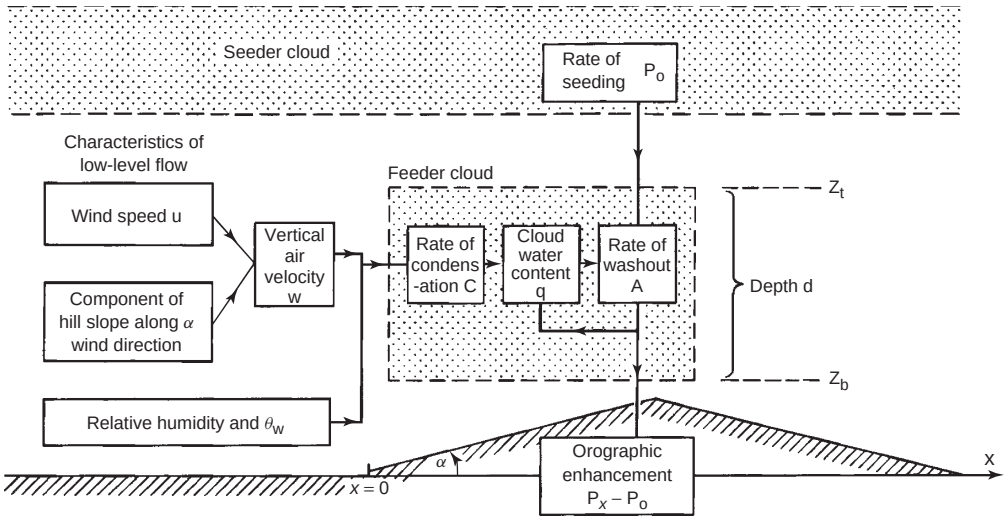

Figure 5 Schematic diagram illustrating the seeder-feeder mechanism (From Browning, 1980)

of snow (Choularton and Perry, 1986). Figure 5 illustrates the principle of the seeder-feeder mechanism as depicted by Browning (1980).

In situations of small hills, such as in South Wales, precipitation enhancements tend to coincide with areas where there is preexisting rain. The seeder-feeder effect plays a much lesser role in the scale of terrain features found on the west coast of the United States. In this situation, the majority of the orographic rainfall is the result of convection embedded in rainbands where a significant amount of orographic precipitation can fall without the presence of any preexisting rainfall.

During 1994–1996, observational field campaigns were undertaken over the Southern Alps of New Zealand as part of the Southern Alps Experiment (SALPEX) programme. The main aim of the programme was to develop a better understanding of the processes leading to enhancements of up to a factor of four observed on the windward side of the mountain range (Henderson, 1993), and the factors influencing the amount of spillover to the lee side of the mountains. (The mountain range regularly exceeds 2 km in altitude and is approximately 800 km in length.) Annual accumulations of rainfall on the windward western slopes often exceed 10 m, with rainfall accumulations on the lee side averaging at about 2 m.

Purdy *et al.*, (in press) present the results of a study showing radar evidence of orographic enhancement due to the seeder-feeder mechanism. SALPEX provided data from a vertically pointing radar (shown in Figure 6) showing clear evidence of the seeder-feeder mechanism at work. In this case, shallow rainfall at a height of approximately 2500 m has been enhanced by snowfall from above. However, it was found that the majority of the precipitation was due to the existence of drizzle drops of about 40 μm in diameter in the saturated airmass which approached the mountains. Thus the rain could form very quickly because the initial part of the 20 min buildup time had already occurred.

Rainfall Redistribution

An mentioned previously, in some regions with low hills it is observed that there is a deficit in rainfall upwind of the peak and a relative excess downwind, inconsistent with the predictions of most common rainfall production processes. In these cases, it may be that there has not been any enhancement in rainfall as such, and that the observed spatial variability is simply a redistribution of rainfall from a perturbation in the raindrop trajectories, due to the distortion of wind flow, as they pass over the hill. Such rainfall patterns were observed in a study on Norfolk Island in the South Pacific where a high-density rain-gauge network was installed in order to investigate high-resolution rainfall patterns (Stow and Dirks, 1998). The network consisted of 13 rain gauges distributed over the 8 km by 5 km island dominated by a 300 m high hill. In this study, Bradley *et al.*, (1998) suggested that the rainfall patterns were simply a result of a redistribution of raindrops due to perturbations of wind flows over the hill, as shown in Figure 7. In this figure, the bold line represents a transect of the topography of the island, while the other lines running left to right represent the wind streamlines. The deflection of the wind flow results in a deflection of raindrop trajectories (illustrated by the lines running from the top left to the bottom right of the diagram). Areas where there is a large spacing between the trajectories as the drops hit the ground represent deficits in rainfall, whereas small spacings between trajectories represent increases. These rainfall patterns were modeled using the analytic solutions for potential flow over a cylinder to find streamlines similar to the topographical transects through the hill and aligned with the wind direction. The results indicate that rainfall

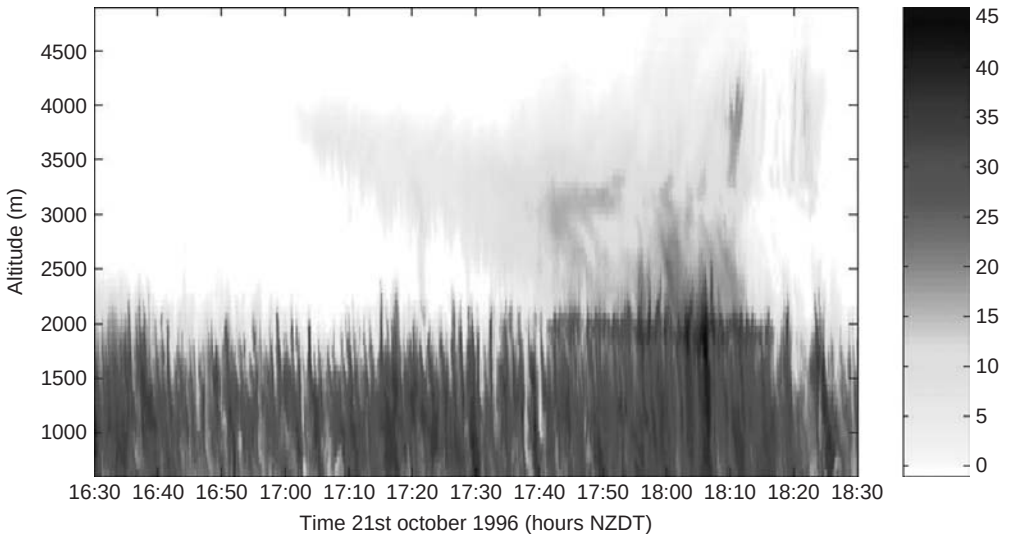

Figure 6 Evidence of the seeder-feeder mechanism at work from radar observations (with permission of Joanne Purdy). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

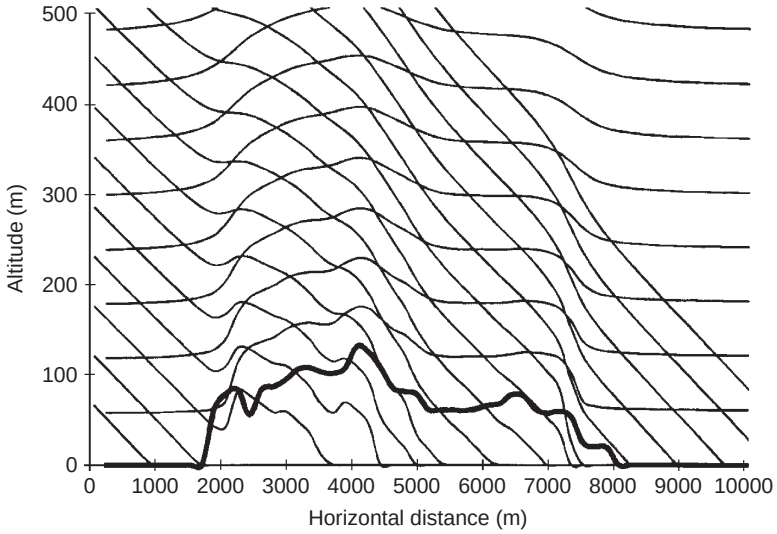

Figure 7 Predictions from the general three-dimensional potential flow model for a ratio of drop fall speed to wind speed equal to 0.075. The topography is shown as an overlay together with streamlines (running from left to right) and drop trajectories (running from upper left to lower right) (From Bradley *et al.,* 1998)

redistribution is a plausible mechanism for the observed rainfall patterns for small hills in the absence of low-level moisture.

CONCLUSIONS AND FURTHER DIRECTIONS

The effects of topography and orography on precipitation are largely dictated by the effects of the terrain on wind flows. In the simplest case, the modified low-level flow causes the precipitation to be redistributed. In more fundamental cases, the topography may result in mesoscale circulations due to the modified thermal properties or the slope of the boundary layer. These mesoscale air circulations can result in triggered convection, upslope rainfall, or completely new mesoscale systems, such as lee depressions. In the more stratiform cases, the long times required for precipitation development from the newly formed clouds may not always minimize the effects of topography. In South Wales, upper level snowfall often scavenges rain from the lower orographically induced cloud, and in the New Zealand Southern Alps, often the inflowing air mass has

large drizzle drops already formed before orographic lifting occurs.

The complex and important effects of topography on precipitation will continue to be studied because they are a dominant process in determining the geographical distribution of rainfall worldwide. Moreover, they are the origin of several hazardous conditions, including thunderstorms running up valleys or canyons in mountainous regions, and the landfall of both tropical and subtropical cyclones over coastal mountain ranges which can lift very moist precipitating air, leading to a potential for disastrous flooding.

31: Models of Clouds, Precipitation and Storms

ANDREA I FLOSSMANN

Laboratoire de Météorologie Physique/OPGC, Université Blaise Pascal/CNRS, Aubière Cedex, France

Clouds play an important role for life on earth. Apart from influencing, for example, the radiative balance of the atmosphere and the lifetime of atmospheric trace constituents, they are the essential element in the hydrological cycle. Clouds transport the evaporated water of the oceans to the continents where the precipitation releases the water load. This release of water can be more or less vigorous depending on the energy stored in the cloud in the form of condensed hydrometeors (liquid or solid). This energy depends on the amount of available moisture and the way the vertical lifting necessary for cloud formation proceeds. We distinguish here mainly two different forms with varying extensions on the horizontal scale: the gentle uplift associated to the large-scale lifting, for example at a frontal zone, and the vigorous small-scale ascent associated with convection, knowing that also mixed forms of the lifting occur.

This article provides an introduction to the complex subject of modeling clouds, the production of precipitation, and the development of cloud and storm systems. The elements intervening in cloud modeling are exposed, starting from a description of the physical phenomena. On the basis of the occurring scale problem, a number of approaches for simplification are presented. These simplifications concern the dynamics as well as the microphysics. Bulk and bin modeling approaches are explained, as well as cumulus parameterizations. Some numerical problems are discussed. This approach gives an insight into current state-of-the-art cloud modeling and the necessary balance between the degree of parameterization, the number of physical and chemical processes relevant to a particular problem, and the available computing resources.

INTRODUCTION

Clouds play an important role for life on earth. Apart from influencing, for example, the radiative balance of the atmosphere and the lifetime of atmospheric trace constituents, they are *the* essential element in the hydrological cycle (*see* **Chapter 25, Global Energy and Water Balances, Volume 1**). Clouds transport the evaporated water of the oceans to the continents where the precipitation releases the water load. This release of water can be more or less vigorous depending on the energy stored in the cloud in the form of condensed hydrometeors (liquid or solid). This energy depends on the amount of available moisture and the way the vertical lifting necessary for cloud formation proceeds. We distinguish here mainly two different forms with varying extensions on the horizontal scale: the gentle uplift associated to the large-scale lifting, for example, at a frontal zone, and the vigorous small-scale ascent associated with convection, knowing that also mixed forms of the lifting occur.

Consequently, when deciding to model clouds, precipitation, and storms, we immediately encounter a problem of scale: in order to model correctly the large-scale dynamics, we need to consider a horizontal domain of several thousand kilometers. And in order to consider correctly the form and the size of the condensed hydrometeors, we need also to take into account processes that take place on the micrometer scale.

Below, we quickly review the type and scale of microphysical processes that need to be considered (Flossmann and Laj, 1998) before presenting the different types of approaches used in cloud modeling in order to account for the scale problem.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

MICROPHYSICAL PROCESSES

For a complete description see, for example, Pruppacher and Klett (1997), Rogers and Yau (1989), Cotton and Anthes (1989), and Houze (1993) (*see* **Chapter 28, Clouds and Precipitation, Volume 1**).

Nucleation of Drops

Our atmosphere does not allow the formation of drops by agglomerating water vapor molecules (homogeneous nucleation) alone. In order to form a tiny drop of $2 \times 10^{-3}\,\mu$m radius, assembled of 800 molecules, it would require a relative humidity of 200%. Consequently, in the atmosphere droplets form on already existing nuclei (heterogeneous nucleation). A subset of the aerosol particles present in every air mass provides these necessary nuclei.

Aerosol particles typically encountered in the atmosphere have a size range between 10^{-3} and 10 μm. Their total number concentration varies between 100 and 1 00 000 cm^{-3} and their mass can reach up to several hundreds of $\mu\mathrm{g\,m}^{-3}$. It has been proposed to distinguish three different size ranges for the particles corresponding to different formation and destruction mechanisms:

Table 1 points out that Aitken and large aerosol particles are formed by condensation processes from the gas phase and aggregation. The gases can be of natural or anthropogenic origin. However, giant aerosol particles have a mechanical origin, which is mostly natural.

Depending on their size, chemical composition and the ambient relative humidity aerosol particles take up a certain amount of water (Köhler curve, see Pruppacher and Klett, 1997). So even in the absence of a cloud, the atmosphere is full of tiny droplets representing swollen aerosol particles, which can become visible, for example, in an atmospheric haze.

At a given size, particles carrying more hygroscopic material can take up more water before achieving a critical size at a critical relative humidity (supersaturation below 5%). When a given aerosol particle has passed its critical size, we call it activated. It serves as a cloud condensation nucleus (CCN). Then, it does not require a further increase in relative humidity to make it grow and it is considered a cloud droplet as long as supersaturation prevails. At a given ambient supersaturation, all aerosol particles whose critical supersaturation is below the ambient one will be activated and transformed into drops.

Condensation and Evaporation

Once moist aerosol particles have been activated to form drops, they grow according to the droplet growth equation

$$\frac{\mathrm{d}m_{\mathrm{con/eva}}}{\mathrm{d}t} = \frac{\left(\mathrm{s_{vw}} - \dfrac{2M_{\mathrm{w}}\sigma_{\mathrm{s,a}}}{RT\rho_{\mathrm{w}}r} - \dfrac{\upsilon\phi_{\mathrm{s}}\varepsilon_{\mathrm{v}}M_{\mathrm{w}}\rho_{\mathrm{s}}r_{\mathrm{N}}^3}{M_{\mathrm{s}}\rho_{\mathrm{w}}(r^3 - r_{\mathrm{N}}^3)}\right) f_{\mathrm{v}}}{\dfrac{\rho_{\mathrm{w}}RT}{e_{\mathrm{sat,w}}D_{\mathrm{v}}'M_{\mathrm{w}}} + \dfrac{l_{\mathrm{vw}}\rho_{\mathrm{w}}}{K'T}\left(\dfrac{l_{\mathrm{vw}}M_{\mathrm{w}}}{RT} - 1\right)} \tag{1}$$

Equation (1) describes the change of the drop mass m (radius r) as a function of the supersaturation $s_{\mathrm{vw}} = e_{\mathrm{a}}/e_{\mathrm{sat,w}}$ (ratio of the vapor pressure and the saturation vapor pressure). Herein, T: temperature, l_{vw}: latent heat of evaporation, D_{v}': modified diffusion coefficient, K': modified thermal conductivity, $\sigma_{\mathrm{s,a}}$: surface tension of the solution droplet, ρ_{w}, ρ_{s}: density of water and salt respectively, M_{w}, M_{s} molecular weight of water and salt, υ: number of ions, ϕ_{s}: osmotic coefficient, R: universal gas constant, ε_{v}: mass fraction of soluble material, r_{N}: radius of the insoluble aerosol nucleus, f_{v}: is the ventilation coefficient which is due to the falling motion of drops in the atmosphere (for more information see Pruppacher and Klett, 1997).

The growth rates given by this formula are rapid for small droplets. However, they decrease with increasing radius and become quite small for drops larger than 10 μm radius (see Pruppacher and Klett, 1997). Consequently, the larger the drop, the longer it will take for it to grow further, leading to a halt in growth by condensation at around 30 μm in radius. Consequently, in order to form precipitation-sized drops other growth mechanisms interfere as detailed below.

Fall Speed of Drops

The terminal velocity of a drop is determined by a balance between buoyancy-corrected gravitation and the drag force

Table 1 Classification of aerosols after Junge and Whitby and the different formation and removal processes most important for the various size classes of aerosol particles

Size classes (μ m)	Junge (1963)	Whitby (1978)	Formation	Removal
$r < 0.1$	Aitken particles	Nuclei or transient mode	Condensation from the gas phase	Aggregation
$0.1 < r < 1$	Large particles	Accumulation mode	Condensation, aggregation	Washout and rainout
$r > 1$	Giant particles	Coarse mode	Sea spray, wind- blown dust, volcanoes, plant debris, diesel engines	Sedimentation

Table 2 Approximate fall velocities of water drops for the conditions at the surface (1013 hPa, 20 °C)

Radius (r) in μm	50	100	200	500	1000	2000
Terminal velocity (V_∞) in ms^{-1}	~0.25	~0.8	~1.5	~4	6.5	8.5

acting on the drop. In Table 2, some values for the terminal velocity as a function of drop radius are given.

These values pertain to normal surface conditions. At higher altitudes the fall speed increases as a result of a decrease in air density. These fall speeds are determined in wind tunnel measurements because an analytical calculation using the balance between the acting forces is not possible. This is due to the fact that large drops are no longer spherical. They get deformed by the airstream and develop an indentation on the upwind side. Furthermore, they start to oscillate because of internal and external vortices that develop and because of electrical charges in the atmosphere and the drop. These features do not allow a correct analytical formulation of the drag.

Collision and Coalescence of Drops

Because of the difference in their size, drops have different terminal velocities. Thus, they can overtake each other while falling and collide to form a larger drop with the sum of the original masses. The probability for a small drop r_2 that is located inside the geometrical sweep-out volume of the larger drop r_1 to collide with this drop is given by the collision efficiency E_{coll} (Figure 1). This collision efficiency is strongly dependent on the size of the two drops. If the large drop is smaller than 20 μm, a collision is essentially impossible, as the terminal velocity is too small and the small drop is just carried around the large drop by the airstream. In a wide-size range, the collision efficiency takes values of unity. When the two drops are roughly of equal size, E_{coll} can even exceed unity because of the wake capture of the trailing drop (see Pruppacher and Klett, 1997, for details).

$$E_{\text{coll}} = \frac{\pi y_c^2}{\pi (r_1 + r_2)^2} \tag{2}$$

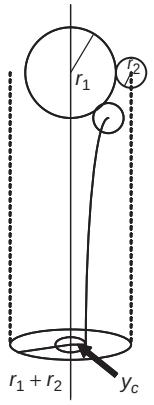

Figure 1 Schematical display of the collision efficiency

The process of collision is not always accompanied by coalescence, a fact that is described by the coalescence efficiency. Colliding drops may bounce apart, coalesce, coalesce temporarily, and then separate again later, or coalesce temporarily and then shatter.

The collection efficiency of the process of drop–drop collision can be written as the product of the collision and the coalescence efficiency:

$$E(m_1, m_2) = E_{\text{coll}} E_{\text{coal}} \tag{3}$$

and this efficiency will determine the rate of precipitation formation in clouds that do not develop an ice phase.

It is important to note that collection is enhanced by a broad droplet size spectrum that depends essentially on the dynamics of the clouds but also on the nature and sizes of the aerosol particles, as well as turbulence in clouds, and even radiative cooling effects. The broadness of the distribution is influenced not only by the number of CCN but also by the presence of giant or ultragiant particles, which can serve as coalescence embryos.

Breakup of Drops

Drops in the atmosphere do not grow indefinitely. The upper size limit is around 6 mm in diameter. Drops arriving at this size range develop a tendency to break up. We can distinguish two main mechanisms:

- *Spontaneous breakup:* the deformation of large drops and the induced oscillation becomes so important that the drop becomes hydrodynamically unstable and breaks up
- *Collisional break up:* during the process of collision/coalescence, the newly formed drop is too unstable and breaks up forming two large drops, slightly smaller than the original drops, and a number of small satellite droplets (see discussion on coalescence above)

Nucleation of Ice Particles

In the atmosphere, liquid drops can exist even at temperatures well below 0 °C, that is, in a supercooled state. In fact, significant numbers of ice particles start to form only below −5 °C coexisting mostly still with liquid drops. Homogeneous freezing of liquid droplets depends on the size; large droplets can freeze homogeneously at temperatures of around −33 °C, whereas by −40 °C even the smallest

droplets freeze homogeneously. Thus, at $-40\,^{\circ}C$ the last liquid has disappeared. In the temperature range between -5 and $-40\,^{\circ}C$, the presence of ice-forming nuclei is necessary to initiate the formation of an ice crystal. These ice nuclei (IN) are aerosol particles that can act in four main ways:

- *Deposition mode:* water is adsorbed directly from the vapor phase onto the surface of an IN where it is transformed into ice
- *Condensation–freezing mode:* this is a hybrid process that requires supersaturation with respect to water. Here, the CCN that has formed the drop acts now as an IN. This process seems far more effective than the deposition mode.
- *Freezing mode:* the IN, scavenged by the drop, initiates the ice phase from within a supercooled water droplet
- *Contact mode:* the IN initiates the ice phase at the moment of contact with the supercooled drop

The number of IN depends on the chemical properties of the aerosol particles. It has been found that there exists a dependency on supersaturation (Meyers *et al.*, 1992) and also on temperature (Fletcher, 1962). In contrast to CCN, a good IN should be insoluble and have already a crystalline-type structure to facilitate the formation of the ice lattice (e.g. silicate). Some bacteria have also been identified as excellent IN. For a comprehensive review of the biogenic versus anthropogenic sources of IN, see Szyrmer and Zawadzki (1997).

Deposition and Sublimation

Water droplets in the atmosphere have a spherical appearance facilitating their analytical treatment. Ice crystals present more problems since they appear in a number of different shapes depending on temperature and the grade of water supply. Here we find densely packed structures like needles, columns, and plates, as well as light dendritic structures (for details see e.g. Pruppacher and Klett, 1997). The actual growth rate of these crystals by water vapor deposition depends on the crystal form as well as temperature and humidity.

This deposition growth can take place at the same time as the condensation growth of droplets, if the ambient relative humidity is high enough to maintain supersaturation over liquid-water and over ice. However, the equilibrium curves of H_2O also allow occurrences of air supersaturated with respect to ice and subsaturated with respect to liquid water. Then, the drops evaporate and the vapor condenses onto the ice crystals (Bergeron–Findeisen effect; Pruppacher and Klett, 1997).

Fall Speed of Ice Particles

Ice particles like droplets have a terminal velocity that depends heavily on the size of the particle. Additionally, they depend on the shape of the particle and its density, which can take values between $0.98\,g\,cm^{-3}$ and $0.2\,g\,cm^{-3}$. A light dendritic structured ice particle will, thus, have a lower terminal velocity than a dense plate-like crystal even if both have the same diameter. For aggregated and rimed structures, the same applies.

Aggregation and Riming

For droplets we noted that condensation alone cannot develop precipitation, and we need the process of collision/coalescence. The same applies for ice crystals. Their growth by deposition of water vapor alone is also limited. Thus, a process of collision is necessary to produce larger aggregates. Two different mechanisms are possible:

- *The collision of ice crystals among themselves:* this process is called *aggregation*. It is responsible for the formation of snow crystals. This process is efficient in two different temperature regimes, around -10 to $-15\,^{\circ}C$ and around $0\,^{\circ}C$. Around -10 to $-15\,^{\circ}C$, the crystals develop a dendritic structure and, thus, upon the collision of two crystals they easily succeed in interlinking with their branches. Around $0\,^{\circ}C$, the crystals develop a "pseudo liquid layer" (a micro layer of melting ice) at their surface which enables them to create a link with the other crystal via freezing. Outside these specific temperature regions, the collision of two ice crystals is rarely successful, thus, not resulting in a snow flake.
- *The collision of ice crystals with liquid drops:* this process is called *riming*. Here, the drop is frozen upon collision with the crystal and several of these collisions transform the ice crystal into a graupel and then into a hail particle. This is a very efficient way of precipitation production. Sometimes the latent heat involved in this riming process is so important that not all the total captured liquid can be frozen. Normally, the remaining liquid will be incorporated into the solid structure forming a "spongy" ice. In a current mesoscale model(MSL), this is not treated. Thus, the excess liquid is shed and reattributed to the liquid water, a process called *wet growth*.

Secondary Ice Particle Formation

During the above-discussed processes of aggregation and riming, an ice multiplication mechanism can occur. If the crystals involved in the collision have a dendritic structure, parts can easily break off and form new ice crystals. Hallett and Mossop (1974) also proposed a process leading to

secondary ice formation during the process of riming. If the drop involved freezes from the outside-in, then first a solid shell will form with a liquid core. When the liquid core starts to freeze, the volume inside the ice shell is too small to receive the forming ice. This fact will explode the shell and eject liquid material in the air, which will immediately freeze and form new ice crystals. This process is called *splintering*.

Melting

Even though a precipitating particle might have formed through riming of ice crystals, it can arrive at the ground as a liquid raindrop. This depends on the altitude of the 0 °C level in the atmosphere. Below this level, ice aggregates will start to melt and, depending on the fall distance, will arrive at the ground as partly or completely melted hydrometeors. A 3-mm ice particle can fall at a distance between 1 and 3 km before complete melting, depending on its initial density and its warm environment (see Pruppacher and Klett, 1997, for details).

THE SCALE PROBLEM

Models are an assembly of equations that describe the phenomenon to be studied. For a cloud model, this includes equations describing the change in time of temperature, humidity, pressure, density, and three-dimensional (3-D) wind field, and some variables that represent the cloud, such as drop or crystal numbers or liquid water content. These equations emerge from the concepts of conservation of mass and energy, Newton's law, and the perfect gas law and can be written in a general form:

$$
\begin{aligned}
&\frac{\partial \rho}{\partial t} + \mathrm{div}(\rho \vec{v}) = 0 \\
&\frac{\partial \rho T}{\partial t} + \mathrm{div}(\rho \vec{v} T) = -\frac{1}{c_\mathrm{p}} \mathrm{div} \vec{F}_T + \frac{1}{c_\mathrm{p}} \frac{\mathrm{d}p}{\mathrm{d}t} + \frac{L}{c_\mathrm{p}} C_\mathrm{con} \\
&\qquad + \frac{L_\mathrm{sub}}{c_\mathrm{p}} C_\mathrm{sub} + \frac{L_\mathrm{melt}}{c_\mathrm{p}} C_\mathrm{melt} \\
&\frac{\partial}{\partial t} \rho \vec{v} + \mathrm{div}(\rho \vec{v} \vec{v}) = \mathrm{grad}\ p - \rho \vec{g} + \mathrm{div}\tau \\
&\frac{\partial}{\partial t} \rho q_\mathrm{v} + \mathrm{div}(\rho \vec{v} q_\mathrm{v}) = -\mathrm{div} \vec{F}_\mathrm{v} - C_\mathrm{con} - C_\mathrm{sub} - C_\mathrm{melt} \\
&\frac{\partial N_\mathrm{drop}}{\partial t} + \mathrm{div}(\vec{v} N_\mathrm{drop}) + \frac{\partial}{\partial z}(V_{\infty,\mathrm{drop}} N_\mathrm{drop}) \\
&\qquad = -\mathrm{div} \vec{F}_\mathrm{drop} + S_\mathrm{drop} \\
&\frac{\partial N_\mathrm{crystal}}{\partial t} + \mathrm{div}(\vec{v} N_\mathrm{crystal}) + \frac{\partial}{\partial z}(V_{\infty,\mathrm{crystal}} N_\mathrm{crystal}) \\
&\qquad = -\mathrm{div} \vec{F}_\mathrm{crystal} + S_\mathrm{crystal} \\
&\qquad p/\rho = nRT
\end{aligned}
\tag{4}
$$

with ρ: density of air, $\vec{v}$: 3-D wind field, T: temperature, q_v: water vapor mixing ratio, c_p: specific heat at constant pressure, $\vec{F}_T$: sensible heat-flux, p: pressure, L, L_sub, L_melt: latent heat of condensation, sublimation, and melting, $C_\mathrm{con}, C_\mathrm{sub}, C_\mathrm{melt}$: rate of phase change of condensation, sublimation, and melting, $\vec{g}$: acceleration of gravity, τ: friction tensor, N_drop, N_crystal: number of drops and crystals of a given size per unit volume, $\vec{F}_\mathrm{drop}$, $\vec{F}_\mathrm{crystal}$: diffusion fluxes of drops and crystals, S_drop, S_crystal: source, sinks, and transfer terms of drops and crystals, n: number of moles, R: universal gas constant. (Instead of temperature, models often calculate potential temperature $\theta = T(p_0/p)^{(R/cp)}$.)

These equations are, then, solved numerically at a number of points in space and time, while the points represent a certain interval in time or space. As the equations result from continuity principles, these intervals should be infinitely small. In practice, the grid boxes have a finite size. Thus, to be correct, we need to average the equations over finite increments in space and time:

$$
\begin{aligned}
&\overline{\psi} = \frac{1}{\Delta t \Delta x \Delta y \Delta z} \int_t^{t+\Delta t} \int_x^{x+\Delta x} \int_y^{y+\Delta y} \int_z^{z+\Delta z} \psi \, \mathrm{d}z \, \mathrm{d}y \, \mathrm{d}x \, \mathrm{d}t \\
&\psi = \overline{\psi} + \psi'
\end{aligned}
\tag{5}
$$

This modifies the equations in such a way that we now calculate average values over a grid box that modifies the equations so that a new term appears in every prognostic equation taking into account the subgrid changes of space and time inside the box:

$$
\begin{aligned}
&\frac{\partial \overline{\rho}}{\partial t} + \mathrm{div}(\overline{\rho} \overline{\vec{v}}) = 0 \\
&\frac{\partial \overline{\rho} \overline{T}}{\partial t} + \mathrm{div}(\overline{\rho} \overline{\vec{v}} \overline{T}) - \frac{1}{c_\mathrm{p}} \mathrm{div} \vec{F}_T^\mathrm{turb} = -\frac{1}{c_\mathrm{p}} \mathrm{div} \overline{\vec{F}}_T + \frac{1}{c_\mathrm{p}} \frac{\mathrm{d}\overline{p}}{\mathrm{d}t} \\
&\qquad + \frac{L}{c_\mathrm{p}} \overline{C}_\mathrm{con} + \frac{L_\mathrm{sub}}{c_\mathrm{p}} \overline{C}_\mathrm{sub} + \frac{L_\mathrm{melt}}{c_\mathrm{p}} \overline{C}_\mathrm{melt} \\
&\frac{\partial}{\partial t} \overline{\rho} \overline{\vec{v}} + \mathrm{div}(\overline{\rho} \overline{\vec{v}} \overline{\vec{v}}) - \mathrm{div} \tau^\mathrm{turb} = \mathrm{grad} \overline{p} - \overline{\rho} \vec{g} + \mathrm{div} \overline{\tau} \\
&\frac{\partial}{\partial t} \overline{\rho} \overline{q}_\mathrm{v} + \mathrm{div}(\overline{\rho} \overline{\vec{v}} \overline{q}_\mathrm{v}) - \mathrm{div} \vec{F}_\mathrm{v}^\mathrm{turb} = -\mathrm{div} \overline{\vec{F}}_\mathrm{v} \\
&\qquad - \overline{C}_\mathrm{con} - \overline{C}_\mathrm{sub} - \overline{C}_\mathrm{melt} \\
&\frac{\partial \overline{N}_\mathrm{drop}}{\partial t} + \mathrm{div}(\overline{\vec{v}}\, \overline{N}_\mathrm{drop}) + \frac{\partial}{\partial z}(\overline{V}_{\infty,\mathrm{drop}} \overline{N}_\mathrm{drop}) \\
&\qquad - \mathrm{div} \vec{F}_{Nd}^\mathrm{turb} = -\mathrm{div} \overline{\vec{F}}_\mathrm{drop} + \overline{S}_\mathrm{drop} \\
&\frac{\partial \overline{N}_\mathrm{crystal}}{\partial t} + \mathrm{div}(\overline{\vec{v}}\, \overline{N}_\mathrm{crystal}) + \frac{\partial}{\partial z}(\overline{V}_{\infty,\mathrm{crystal}} \overline{N}_\mathrm{crystal}) \\
&\qquad - \mathrm{div} \vec{F}_{Nc}^\mathrm{turb} = -\mathrm{div} \overline{\vec{F}}_\mathrm{crystal} + \overline{S}_\mathrm{crystal} \\
&\qquad \overline{p}/\overline{\rho} = nR\overline{T}
\end{aligned}
\tag{6}
$$

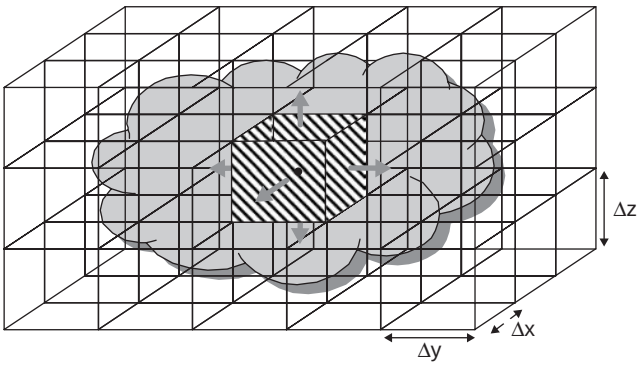

Figure 2 Scheme of grid boxes that resolve a cloud

The new terms have the form:

$$\vec{F}_{\psi}^{\,\mathrm{turb}} = -\overline{\rho\psi'\vec{v}'}, \quad \tau^{\mathrm{turb}} = -\overline{\rho\vec{v}'\vec{v}'} \tag{7}$$

and depend on the subgrid fluctuations ψ' in space and time of the considered variables. These terms need to be parameterized as a function of the variables $\overline{\psi}$ of the resolved scale. This approach is known under the term *closure*, whereby different theories of closure (first, second order, etc.) can be found in the literature Stull (1991). In the following, for simplicity of writing, the overbar will be dropped; however, all equations are averaged equations.

Considering, that an appropriate closure approach has been selected, the foregoing equations can be solved numerically in a type of grid such as that displayed in Figure 2, covering the entire cloud area and the affected environment. The averaging done in equations (6) and (7) now allows finite grid increments. However, the microphysical processes discussed above make it evident that essential processes in clouds operate at the scale of micrometers, requiring very small intervals in space. But, on the other hand, clouds sometimes form systems of several thousand kilometers, requiring a large spatial domain to be covered. One is, thus, confronted with the problem that actual computer power does not allow us to cover domains of $1000\,\mathrm{km}^2$ with grid increments of $1\,\mathrm{m}^2$ (this would require 10^{12} grid boxes).

A similar argumentation applies to the time increment. Time and space increments are linked in an explicit numerical treatment of the system of equations by the Courant–Friedrich–-Levy (CFL) criterium (Jacobson, 1999):

$$\left(\frac{\Delta t}{\Delta x}\right) U \leq 1 \tag{8}$$

with U being the maximum transport velocity considered. This criterium insures that the fasted signal does not jump a grid box in one time step. The fasted transport velocities in the atmosphere are those of the sound. They are not physically relevant in cloud models and are, thus, filtered by suppressing local density fluctuations in the equations (an elastic or soundproof assumption) (Ogura and Phillips, 1962).

However, the numerical effort for a high resolution of the processes stays considerable. Consequently, strategies to reduce the simulation time need to be developed. These consist in compromises concerning the dynamics, the microphysics, and the resolution.

SIMPLIFICATION IN THE DYNAMICS

3-D Models

The appropriate way to simulate the dynamics of the atmosphere is a 3-D representation of space. Here, a classical coordinate system would be a Cartesian one with x, y, and z in the directions of space (*see* Figure 2). In order to take into account the topography, often the vertical coordinate z is replaced by one that follows the terrain. Phillips (1957) designed such a terrain-following coordinate system for use in hydrostatic, numerical prediction models by defining:

$$\sigma = \frac{p}{p_{\mathrm{s}}} \tag{9}$$

where p_s represents surface pressure and σ varies from a value $\sigma = 1$ at the ground to $\sigma = 0$ at the top of the atmosphere. Nowadays, however, most of the 3-D models (Clark, 1977; Dudhia, 1993; Pielke *et al.*, 1992) devoted to cloud simulations use the vertical coordinate:

$$z^* = H\frac{z - z_{\mathrm{s}}}{H - z_{\mathrm{s}}} \tag{10}$$

The surface height above some reference level is given by z_s (e.g. sea level) and the height of the model top is given by H.

Three-dimensional models that cover an entire continent equally need to take into account in the horizontal grid the deformation of the coordinate system by the curvature of Earth and the large-scale Coriolis force. These models use stereographic coordinate systems. Some of the most widely used 3-D models are currently RAMS (Pielke *et al.*, 1992; Cotton *et al.*, 2003), MM5 (Dudhia, 1993), and Clark (1977), among others (*see* **Chapter 32, Models of Global and Regional Climate, Volume 1**).

2-D Models

For special case studies concerning phenomena that are mainly two-dimensional (2-D; flow over a mountain range, e.g.) or in order to reduce computer calculation times, 3-D dynamics can be reduced to two dimensions. This eliminates one coordinate (e.g. y in a Cartesian coordinate system) (e.g. Orville and Kopp, 1977; Soong and Ogura, 1980)

Another configuration, especially adapted in simulating isolated cumulus clouds consists of a cylindrical model with a symmetry with respect to the angular coordinate. Such a model configuration has been used, for example in the models of Shiino (1983), Murray and Koenig (1975), and Reisin *et al.* (1996).

1-D and 0-D Models

The cylindrical model philosophy has also been applied in the 1.5-D model of Asai and Kasahara (1967) where in fact two one-dimensional models are connected to represent the updraft and the downdraft region of a convective cloud.

Nowadays, one-dimensional models are mainly used to test microphysical schemes. In this case, there exists just a vertical axis z, subdivided into several layers, representing the updraft region of the cloud.

Finally, the least sophisticated dynamics is that of an air parcel. In this concept, we consider a volume of air separated from the environment by an immaterial surface. For the entraining air parcels, they exchange mass and heat with the environment; otherwise, they are considered as adiabatic. Air parcels can represent an interesting concept if they are driven by a 3-D flow field, because they permit highly resolved microphysics to be followed in a larger-scale dynamics that does not consider microphysics (Feingold *et al.*, 1998a). Here, care needs to be taken to ensure that the parcel bulk properties are adequately constrained to those from the driving 3-D model.

MODELS OF CLOUD MICROPHYSICS

Drops and ice crystals exist in a cloud in varying number concentrations and with different sizes. We distinguish cloud drops of radii between 1 μm and 30 μm, drizzle drops of up to 200 μm, and rain drops up to 6 mm. Ice crystals have diameters of up to 100 μm, snow flakes, graupel, and hail particles have no clear upper size but can become larger than raindrops. The number of hydrometeors per unit volume of a given size is fundamental for the evolution of the cloud and, thus, should be considered in a cloud model.

Explicit or Bin-resolving Cloud Models

The most logical approach is to introduce an explicit number density distribution function $f(m)\ \mathrm{d}m$, which follows the number per unit volume of a given type of hydrometeors in a given mass class between m and $m + \mathrm{d}m$ (see Figure 3). Inside a bin class most models assume a uniform value. There exist, however, also models that assume inside a drop bin class a distribution of aerosol particles or chemical compounds (e.g. Wobrock *et al.*, 2002).

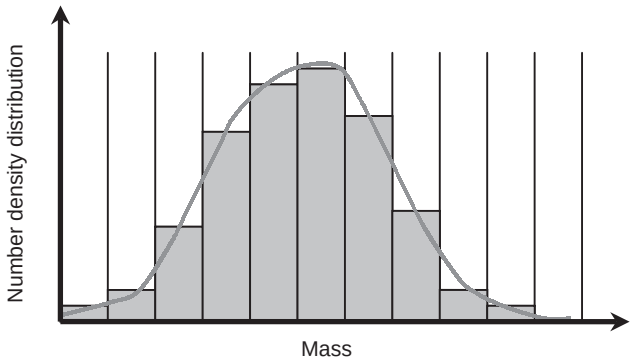

Figure 3 Number density distribution function $f(m)\,\mathrm{d}m$ which follows the number per unit volume of air of a given type of hydrometeors in a given mass class between m and $m + \mathrm{d}m$

Warm Clouds

Most ground fogs or low-level clouds contain only liquid drops, and no ice crystals. If they develop precipitation, this will take place by the collision and coalescence of liquid drops. These clouds are called *warm* clouds. In order to model the size distribution of droplets in warm clouds, a drop number density distribution function $f_{\mathrm{d}}(m)$ is defined. It allows the continuous distribution of drops over the entire spectrum to be captured in a discrete function.

Since the liquid hydrometeors need to cover a range from 1 μm drops up to 6 mm raindrops, which covers at least three orders of magnitude, an equidistant grid in size or mass is not appropriate. Consequently, Berry and Reinhardt (1974a–c) have introduced a logarithmic size grid which allows a doubling of mass every *JRS* category:

$$r(j) = r(1)2^{(J-1)/3JRS} \tag{11}$$

$r(1)$ gives the minimum radius (e.g. 1 μm) and JRS can be 1, 2, 3, or more. In most models $JRS = 2$ is chosen, as a compromise between the necessary resolution of drop spectrum (Silverman and Glass, 1973) and the computer times of the simulation. For each of the resulting drop-size classes (on the order to 70), the following prognostic equation has to be solved:

$$\begin{aligned}\frac{\partial f_{\mathrm{d}}(m,\vec{r},t)}{\partial t} &= -\mathrm{div}(\vec{v}\, f_{\mathrm{d}}(m,\vec{r},t)) \\ &+ \frac{\partial}{\partial z}(V_\infty f_{\mathrm{d}}(m,\vec{r},t)) + \mathrm{div}(\vec{F}_{fd}^{\,\mathrm{turb}}) \\ &+ \left[\frac{\partial}{\partial t} f_{\mathrm{d}}(m,\vec{r},t)\right]_{\mathrm{nuc}} + \left[\frac{\partial}{\partial t} f_{\mathrm{d}}(m,\vec{r},t)\right]_{\mathrm{con/eva}} \\ &+ \left[\frac{\partial}{\partial t} f_{\mathrm{d}}(m,\vec{r},t)\right]_{\mathrm{coll}} + \left[\frac{\partial}{\partial t} f_{\mathrm{d}}(m,\vec{r},t)\right]_{\mathrm{breakup}}\end{aligned} \tag{12}$$

The term on the left-hand side calculates the change of the number of drops at a certain location $\vec{r}$ per unit volume between a mass m and $m + \mathrm{d}m$ per time interval $\mathrm{d}t$ because of the physical effects represented by the terms on the right-hand side which are: transport with the scale velocity $\vec{v}$, the sedimentation with the terminal velocity V_∞, transport through turbulence, the change in number concentration due to nucleation of drops, due to condensation or evaporation, due to collision and coalescence among the drops, and due to breakup of drops. The mathematical expressions for these terms follow the physics detailed above.

A simple way to calculate the nucleation of drops is to prescribe the number of cloud condensation nuclei as a function of supersaturation:

$$N_{\mathrm{CCN}} = c s_{\mathrm{vw}}^{k} \tag{13}$$

with c, k constants which are adapted to the air mass considered, as, for example, in Twomey (1959). In addition, an assumption is necessary on the size of the freshly nucleated drops. More sophisticated models (Flossmann *et al.*, 1985) follow the number of aerosol particles and their chemical composition in order to calculate as a function of supersaturation (Köhler equation, Pruppacher and Klett, 1997) the number and the size of activated aerosol particles.

Once formed, the drops grow or shrink by condensation or evaporation respectively:

$$\left[\frac{\partial}{\partial t} f_{\mathrm{d}}(m)\right]_{\mathrm{con/eva}} = -\frac{\partial}{\partial m}\left(\frac{\mathrm{d}m_{\mathrm{con/eva}}}{\mathrm{d}t} f_{\mathrm{d}}(m)\right) \tag{14}$$

where the individual droplet growth rate is given from equation (1). The process of collision and coalescence of drops is calculated following Berry and Reinhardt (1974a–c):

$$\left[\frac{\partial}{\partial t} f_{\mathrm{d}}(m)\right]_{\mathrm{coll}} = \int_0^{m/2} f_{\mathrm{d}}(m - m')\, f_{\mathrm{d}}(m')\, K(m - m', m')\, \mathrm{d}m' - \int_0^{\infty} f_{\mathrm{d}}(m)\, f_{\mathrm{d}}(m')\, K(m, m')\, \mathrm{d}m' \tag{15}$$

Here, the first term on the right-hand side describes the gain of m-sized drops due to collision between drops of sizes $(m - m')$ and m'. The second term describes the loss of m-sized drops due to all types of collision. K represents the coalescence kernels that give the probability of such a collision to happen. E is the collection efficiency.

$$K(m, m') = \pi (r + r')\, |V_{\infty,\mathrm{drop}}(m) - V_{\infty,\mathrm{drop}}(m')|\, E(m, m') \tag{16}$$

The breakup term can be parameterized either as a spontaneous breakup (see e.g. Hall, 1980; Srivastava, 1971) or as a collisional breakup (Low and List, 1982a,b).

In solving these equations coupled with the 1, 2, or 3–D dynamics as detailed above, the calculation of the evolution of the drop-size distribution as a function of time and space inside and below the cloud, as well as on the ground is allowed.

However, because of the large number of variables to be updated at every time step, only a few models available can calculate explicit cloud microphysics in a 3-D framework (e.g. Feingold *et al.*, 1994 Kogan, 1991 Khvorostyanov, 1995). Most models are restricted to two dimensions (Hall, 1980) or one dimension (Ogura and Takahashi, 1973). The parcel model discussed above is an exception, since it does not allow precipitation to be calculated. It can, thus, only be used to simulate the evolution of a nonprecipitating cloud (Feingold *et al.*, 1998a), or at the most estimate the amount of precipitable water.

Cold Clouds

Most clouds in midlatitudes form ice particles and the formation of precipitation involves the ice phase. The ice phase can also be modeled by a bin approach if a certain number of additional size distributions are considered – one distribution function to follow the pristine (non or little rimed) crystals: f_{i}, one distribution function for the heavily rimed particles like graupel or hail f_{h}, and one distribution function for snow flakes, that is, aggregates of crystals f_{s}. As ice particles generally can become larger than liquid drops, more categories need to be considered. Also, because of the different possible forms of ice crystals (columns, needles, plates, etc.) additional distribution functions can be added. However, most models follow just one species of crystal shape (plate-like; e.g. Alheit *et al.*, 1990). Only a few models calculate the explicit cold microphysics in three-dimensions (Ovtchinnikov and Kogan, 2000). Most models use reduced dynamics, for example, 2-D (Respondek *et al.*, 1995), 1 – D, or parcel models (Alheit *et al.*, 1990). Takahashi had the first paper on bin-resolved microphysics of mixed-phase clouds in the 1970s. Reisin *et al.* (1996) is another review on mixed-phase bin models of considerable sophistication. It has been used in 2-D models of cumuli and also Arctic stratus clouds (Harrington *et al.*, 2000).

Bulk Parameterizations

Between 1965 and 1975, when cloud modeling started, due to the limitations of early computers, bin modeling in a reasonable dynamic framework was completely out of reach.

Warm Clouds

Consequently, Kessler (1969) proposed a simple parameterization of the microphysics of a warm cloud (Figure 4).

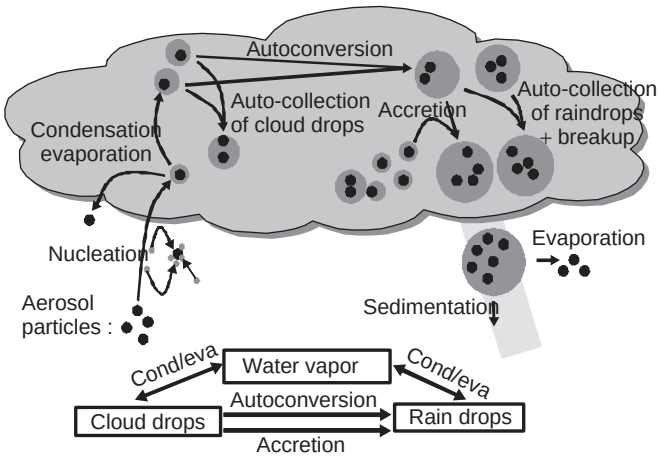

Figure 4 Schematic display of warm cloud processes and the simplification of the Kessler parameterization

It aimed to simulate a convective cloud and just calculated the amount of liquid water attached to the small, nonprecipitating drops (r smaller than 50 μm) and the amount of liquid water attached to precipitation-sized drops (r larger than 50 μm). However, due to its simplicity this scheme was quickly adapted to all types of clouds, and still has its place in many weather prediction models.

The basic equations of this model allow calculation of the evolution with time of the water vapor mixing ratio q_v, the cloud water mixing ratio q_c, and the rain water mixing ratio q_R.

$$\begin{aligned}
\frac{\partial \rho q_v}{\partial t} &= -\mathrm{div}(\vec{v}\rho q_v) + \mathrm{div}(\vec{F}_v^{\mathrm{turb}}) \\
&\quad - C_{\mathrm{con},c} + C_{\mathrm{eva,R}} \\
\frac{\partial \rho q_c}{\partial t} &= -\mathrm{div}(\vec{v}\rho q_c) + \mathrm{div}(\vec{F}_c^{\mathrm{turb}}) \\
&\quad - P_{\mathrm{auto}} - P_{\mathrm{acc}} + C_{\mathrm{con},c} \\
\frac{\partial \rho q_R}{\partial t} &= -\mathrm{div}(\vec{v}\rho q_R) + \frac{\partial}{\partial z} V_R \rho q_R \\
&\quad + \mathrm{div}(\vec{F}_R^{\mathrm{turb}}) + P_{\mathrm{auto}} + P_{\mathrm{acc}} - C_{\mathrm{eva,R}} \qquad (17)
\end{aligned}$$

Here, Kessler (1969) proposes for the condensation rate of cloud drops $C_{\mathrm{con},c}$ a saturation adjustment. This means that all dynamically generated supersaturation is immediately converted to cloud water. And in cases of subsaturation, an amount of cloud water is evaporated that restores saturation, if possible. Obviously, this is a rather crude treatment that does not consider the role of the *CCN* population and the supersaturation.

P_{auto} is the autoconversion rate, that is, the collision of cloud water that forms rain water. It is assumed to be a linear function of the cloud water content, only influenced by threshold values q_{crit} determining the onset of the autoconversion process. In the literature, numerous different values for q_{crit} have been proposed.

$$P_{\mathrm{auto}} = k(\rho q_{\mathrm{crit}} - \rho q_c) \quad k = 10^{-3} s^{-1} \text{ if } \rho q_c > \rho q_{\mathrm{crit}},$$
$$\text{otherwise } k = 0 \qquad (18)$$

The accretion rate P_{acc} details the amount of rainwater created by further collision with cloud water. Kessler (1969) calculates the accretion rate by:

$$P_{\mathrm{acc}} = \int_0^\infty \frac{\mathrm{d}m_{\mathrm{acc}}}{\mathrm{d}t} N_R(r)\,\mathrm{d}r \qquad (19)$$

by calculating the increase of mass of one raindrop m_{acc} of radius r due to the collision with a cloud water population presumed monodisperse represented by q_c with a collision efficiency of E.

$$\frac{\mathrm{d}m_{\mathrm{acc}}}{\mathrm{d}t} = \pi r^2 E V_R(r) \rho q_c \qquad (20)$$

In assuming that the raindrops obey a Marshall–Palmer distribution, (Marshall and Palmer, 1948):

$$N_R(r) = N_{R,0} e^{-2\lambda r} \qquad (21)$$

where λ: shape parameter, and assuming a simple analytical function for the drop terminal velocity:

$$V_R(r) = 130\sqrt{2r} \qquad (22)$$

yielding

$$V_R = \frac{\int_0^\infty V_R(r) N_R(r)\,\mathrm{d}r}{\int_0^\infty N_R(r)\,\mathrm{d}r} \qquad (23)$$

in $\mathrm{m\,s^{-1}}$.

Autocollection of cloud or raindrops are not considered in this approach. The evaporation rate of raindrops below cloud base can be calculated by

$$C_{\mathrm{eva,R}} = -\int \frac{\mathrm{d}m_{\mathrm{con/eva}}}{\mathrm{d}t} N_R(r)\,\mathrm{d}r \qquad (24)$$

Numerous authors have since modified the terms for the parameterizations of the different processes, keeping, however, the basic concept (Berry,1965; Orville and Kopp, 1977, among others).

Cold Clouds

The basic concept of the warm cloud bulk parameterization was soon extended to cold clouds, distinguishing two or three categories of ice. One, corresponding to nonprecipitating cloud drops is called *cloud ice*. For the precipitating

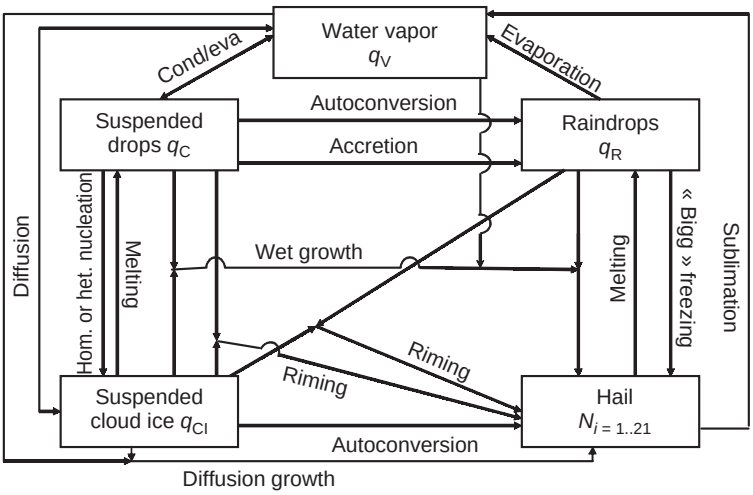

Figure 5 Scheme of the interaction taken into account in a hybrid scheme combining a bulk approach for cloud water, cloud ice, and rain drops and an explicit approach for hail (Adapted from Wobrock *et al.*, 2003)

cloud ice, one can, for example, distinguish *graupel* from *snow*.

An example for cloud ice and graupel can be found in Orville and Kopp (1977), an example for cloud ice, graupel, and snow can be found in Lin *et al.* (1983), and an example using pristine, such as non- or little-rimed crystals (ice A) and rimed crystals (ice B) can be found in Koenig and Murray (1976). A new approach to couple bulk and explicit microphysics can be found in Farley and Orville (1986), which was recently applied to a 3-D model (Figure 5, Wobrock *et al.*, 2003). It should be mentioned that the approach of Farley and Orville is a hybrid approach in which hail is simulated in bins, although continuous accretion approximations are used.

Examples for pure bulk ice physics in a 3-D model can be found in Reisner *et al.* (1998) and for a 2-D model in Grabowski *et al.* (1996).

The Semispectral Microphysics Parameterizations

As a compromise between the bin schemes that follow the spectra of hydrometeors in discrete size classes or bins and the bulk parameterizations that follow just the water mass associated to 5 or 6 classes of hydrometeors, recently, semispectral parameterizations have been developed.

These parameterizations, similar to the bulk ones, follow a limited number of categories. Within one category, however, they assume a size distribution of a log-normal or gamma type, and then calculate the time evolution of the first (total number) and third (mass) moment of these distribution functions. Example of these approaches can be found in Ferrier (1994), Meyers *et al.* (1997), Cohard and Pinty (2000), and Caro *et al.* (2003). Actually, Meyers *et al.* was already extended to the ice phase. Moreover, their approach used approximate solutions or look-up table solutions to the stochastic collection equations as opposed to the continuous accretion approximations to collection. Subsequently, Feingold *et al.* (1998b) extended the emulation of a bin model in a bulk scheme to autoconversion and sedimentation.

More recently Saleeby and Cotton (2004) added a second mode to the cloud droplet spectrum which permitted a more accurate representation of collection (autoconversion) and sedimentation, and permitted the explicit activation of CCN (including a concept for giant CCN) and IN. Others such as extended this approach to a three-moment scheme in which all degrees of freedom in the specified basis functions are predicted. This approach offers an interesting compromise between the detailed bin approach and bulk schemes. The reduction in computational effort will probably mean that even operational forecast models will move towards these schemes in the future.

CUMULUS PARAMETERIZATIONS

If the size of the grid increments becomes larger than 10 km, it is no longer possible to resolve the convective clouds explicitly (stratiform clouds with large horizontal extension can still be resolved). But since the energetic processes associated with convective clouds are important, their net impact on the scale values needs to be parameterized, in addition to the turbulence parameterization already discussed. This gives rise to cumulus parameterizations which can be traced back to the development of numerical prediction models. Smagorinsky (1956) was the first to introduce a cumulus parameterization when he adjusted the vertical derivative of an "effective static stability" which included the heat released during condensation. This gave rise to the first approaches of cumulus parameterizations called *convective adjustment* (e.g. Krishnamurti and Moxim, 1971;

Manabe *et al.*, 1965; Kurihara, 1973). As these approaches turned out too crude, a second generation of schemes attempted to link the convection to the large-scale mass, moisture, or energy convergence, while using some form of "cloud model" (mostly rising plumes and compensating downdrafts) to vertically distribute mass, moisture, and energy by a flux scheme (e.g. Kuo, 1965, 1974; Anthes, 1977, Fritsch and Chappel, 1980; Tiedke, 1989). Another large-scale control was introduced by Arakawa and Schubert (1974). They assumed that the rate of stabilization by an ensemble of cumulus clouds balances the rate at which the large scale makes buoyant energy available for convection. For a complete review of the approaches, see Emanuel and Raymond (1993).

All cumulus parameterization schemes depend severely on the size of the grid box, which they need to stabilize completely or only partially. Consequently, they will only apply to the case for which they were developed and cannot easily be generalized for other grid sizes.

A recent approach, for example, Grabowski *et al.* (2001) and Khairoutdinov and Randall (2001) concerns the development of so-called "super-parameterizations" that have now been implemented in several global circulation models. This approach consists basically in running a 2-D cloud-resolving model at each grid point and average the cloud-resolving model data to determine heating, moistening, and precipitation rates.

NUMERICS

The forgoing physical treatments of the different processes involved in clouds enter the balance equations. These equations, then, need to be solved numerically on a computer. However, before coding, the differential expressions in the terms need to be discretized in order to be linked to the scale variables. The real art of cloud models these days lies here. Numerous studies have been performed on the best numerical scheme to solve the transport equation (positive-definite schemes; e.g. Smolarkiewicz, 1984; Bott, 1989) and the integrals in the drop–drop collision/coalescence process (e.g. Berry and Reinhardt, 1974a-c; Bott, 2000), and it is the best way to distribute the calculated values in a grid, among others. Another serious numerical problem lies in the calculation of the supersaturation due to dynamical and microphysical tendencies. These tendencies should be solved at the same time and not one after the other as in the models. As these tendencies are very sensible, they require extremely small time steps, which in connection with the timescales of the other processes introduce a numerical stiffness problem. Numerous approaches concerning this problem have been proposed in the literature. Next to the explicit method, implicit methods were also developed. Equally, the state-of-the-art cloud models now dispose of an interactive two-way grid nesting. This allows zooming with finer resolution into a domain of special interest and transferring this information to the larger grid outside afterwards. These techniques create a new way to address the scale problem, in following the large-scale dynamics in a coarse grid and then, to zoom with a finer grid into the cloud region. Another technique that advances cloud modeling is the assimilation of remote sensing data (e.g. from satellite) into a model in order to improve model initialization. Furthermore, the calculated evolution can be constrained by observation or outputs of other models. For a summary of current modeling techniques, see Jacobson (1999).

CONCLUSION

This article attempts to provide an introduction to the complex subject of modeling clouds, the production of precipitation, and the development of cloud and storm systems. The elements intervening in cloud modeling have been exposed, starting from a description of the physical phenomena. On the basis of the occurring scale problem, a number of approaches for simplification were presented. These parameterizations are generic and can be combined as a function of the addressed problem. In addition, other modules that have not been discussed in the article need to be added, such as a radiation model, a surface model, a chemistry model, and so on. The main problem is achieving a balance between the degree of parameterization, the number of physical and chemical processes relevant to a particular problem, and the available computing resources. Owing to the increasing capacity of computers, however, less and less parameterizations are necessary and the resulting models are more and more complete. Consequently, the current state-of-the-art MSMs (e.g. RAMS, MM5, Clark, etc.) have large capacities. Essentially the same models can be used to study problems as diverse as rainfall over large areas and over many hours, resulting from frontal cloud systems, the development of local storms with damaging hail and flooding, transport of pollutants by small convective clouds, and photochemical reactions in fog. Next to these models a variety of different models exist which are more or less restricted to a specific question.

32: Models of Global and Regional Climate

HANS VON STORCH

Institute of Coastal Research, GKSS Research Centre, Geesthacht, Germany

The concept of climate simulations with quasi-realistic climate models is discussed and illustrated with examples. The relevant problem of deriving regional and local specifications is considered as well.

When we speak about "climate", we refer to the statistics of weather. The statistics of weather can be described by first and second moments, that is, by time means and time variability on different timescales and its spectrum, by covariability between different variables, characteristic patterns, and the like. The climate is thought to be conditioned by external forcing, such as the presence of greenhouse gases in the atmosphere, changing solar output, and other factors. Thus, external forcings cause changes in the statistics of weather, but weather itself varies independently of the presence of changing external factors.

Key methods to unravel the dynamics of the climate system are the analysis of observed data and experimentation with climate models of varying complexity.

"Observed" data cover a wide range of data sets. Examples are *in situ* readings of precipitation, wind-speed and other variables, stream flow in rivers, conventional oceanographic and atmospheric vertical soundings, and also pixel data derived from satellite retrievals, and sophisticated "analyses". The latter are subjective or empirical (kriging-based) spatial interpolations of point observations, or model simulations into which the observed data have been assimilated using the concept of *state-space* modeling. All weather maps are such analyses. Important data sets of 6-hourly weather maps since 1948 or 1960 have been prepared by National Centers for Environmental Prediction (NCEP) and by European Center for Medium Range Forecast (ECMWF) (e.g. Kalnay *et al.*, 1996; Gibson *et al.*, 1997).

Climate models are process-based dynamical models (for further reading, refer to Müller and von Storch, 2004), which operate on the entire globe or in limited regions of the world. Climate models describe several compartments of the climate system, as for instance, the atmosphere, the oceans, the cryosphere, the surface hydrology, the vegetation, or cycles of matter. Thus, climate models may have different qualities of "complexity" – they may describe fewer components, but describe these components in greater detail. GCM-based models (GCM stands for "General Circulation Model"; such models operate with the "Primitive Equations", which describe the relevant atmospheric dynamics in detail – for further information refer to the references given), which are named quasi-realistic in the following, are of that sort (e.g. Washington, 1999). Another modeling strategy is to consider more components but in less detail – an example is the CLIMBER model (e.g. Ganopolski *et al.*, 1997). The former are often called *complex* and the latter *medium complexity* – these terms are in use but are not really precise semantics in describing the differences between the two classes of models.

In the following, we discuss the utility of "quasi-realistic" models. There are many books and articles on this subject. The books by Washington and Parkinson (1986), McGuffie and Henderson-Sellers (1997) and von Storch *et al.* (1999) describe the challenges of numerical modeling on a technical level, while the monograph by Müller and von Storch (2004) deals more with the philosophical problems related to the usage of such models. Also the collection of papers offered by Trenberth (1993) or von Storch and Flöser (2001), the articles by Bengtsson (1997) and Manabe (1997), and the description of the state-of-the-art in the Intergovernmental Panel on Climate Change (IPCC) reports (Houghton *et al.*, 1996, 2001) may be helpful for the interested reader.

Section "Quasi-realistic climate models (surrogate reality)" discusses the construction and validation of quasi-realistic global models, Section "Free simulations and forced simulations for reconstruction of historical climate"

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

the performance of such models in reconstructing historical climate, and Section "Climate change simulations" climate change simulations. The problem of how to infer a description of the impact-relevant regional and local climate is dealt with in Section "Downscaling"; the major downscaling tools are regional models; the construction of such models is considered in Section "Regional climate modeling". The success in reconstructing the climate of the past decades of years is demonstrated in Section "Reconstructions", and scenarios of plausible future climate change are discussed in Section "Regional scenarios". The article concludes with the Section "Conclusions".

The examples used throughout the text are chosen subjectively – and with a bias towards work done in the mostly European academic milieu of the author. It would have been equally possible to write this article with a very different set of examples, without compromising the representativity and usefulness of this article.

QUASI-REALISTIC CLIMATE MODELS (SURROGATE REALITY)

Models that can realistically simulate the sequence of weather events are called *quasi-realistic* climate models. They comprise circulation models of the atmosphere and the ocean and other components such as the land surface and sea ice. The components of such a model are sketched in Figure 1 (Hasselmann, 1990).

Such models are complex models – their degree of complexity is a compromise of computation possibilities and the required length of the integration. If the model is supposed to be integrated for 1000 years, then a coarser spatial resolution is chosen and some processes are described in a less detailed manner. For such an integration, a spatial grid size of about 300 km is often used. In order to achieve a higher spatial resolution, so-called downscaling methods have to be applied (see below; von Storch, 1999).

In the climate system, processes are operating at all timescales. On the other hand, the numerical formulation of the dynamical equations requires a cut-off at a certain scale. Figure 2 sketches the situation for atmospheric dynamics – with faster processes on smaller scales, and slower processes on larger scales. The space/time truncation, sketched in Figure 2 by hatching, leads to the disregard of many processes such as cumulus convection. These processes are, however, essential for the formation of the general circulation of the atmosphere – therefore they are included into the numerical equations as "parameterizations". That is, the expected effect of such processes on the resolved processes conditional upon the resolved state is specified. All models, atmospheric and oceanic, global and regional, contain many of these parameterizations, and they are a major cause for the different performance of dynamical models.

The skill of models in describing the real world depends on the spatial scale. Phenomena on larger scales are better described than smaller scales. Grid point values are

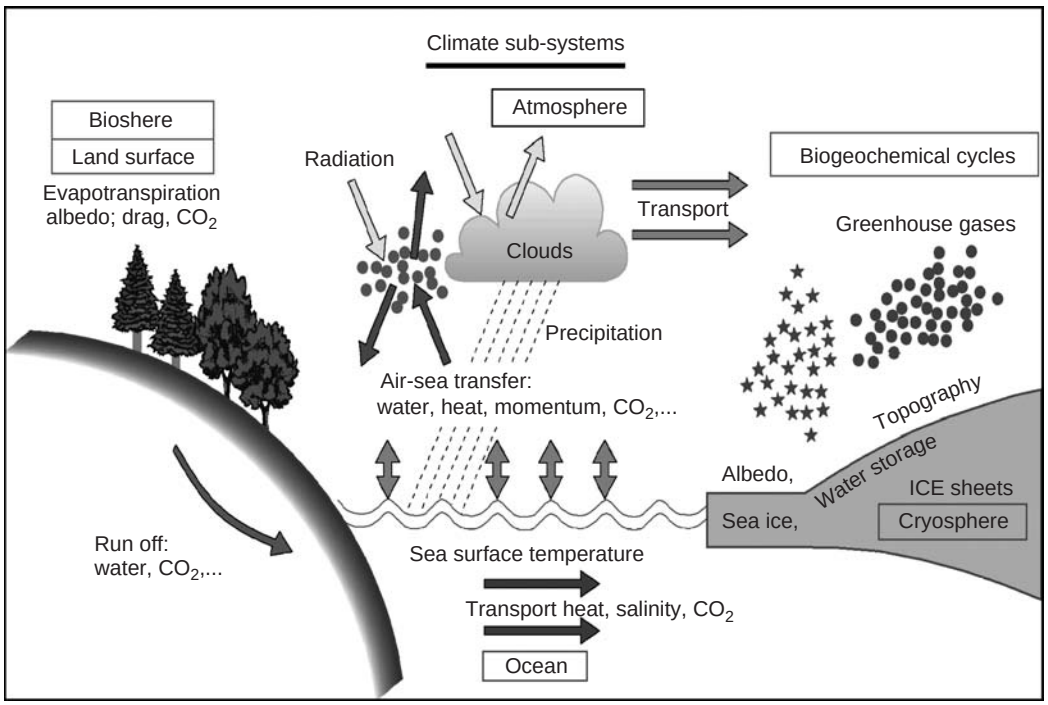

Figure 1 Components of a dynamical climate model (Hasselmann, 1990, © JCB Mohr, Tübingen). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

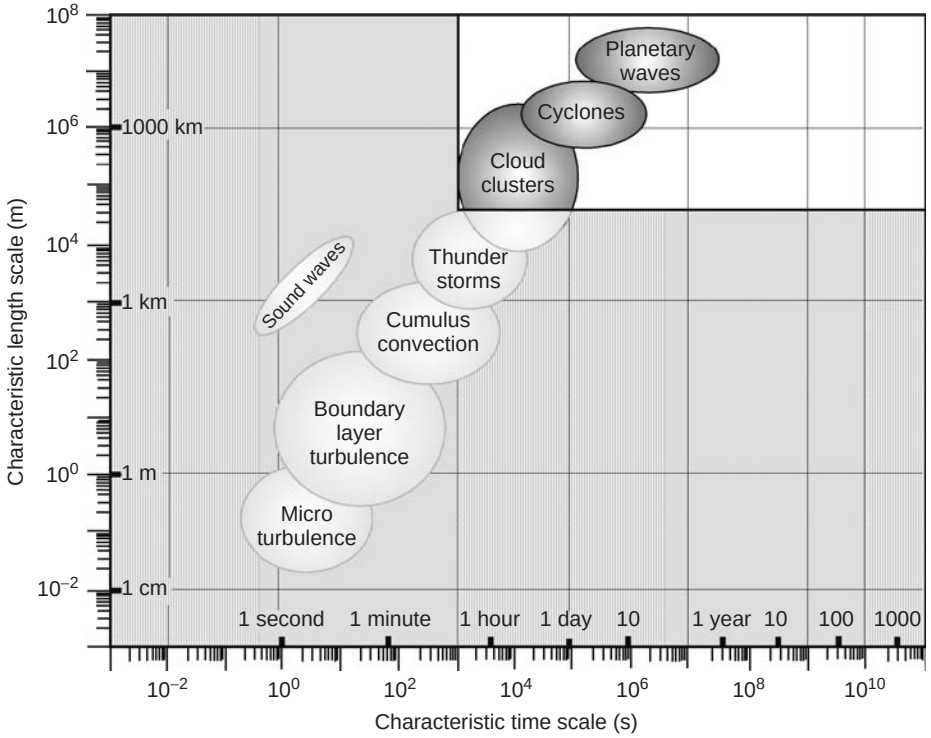

Figure 2 Resolved and unresolved processes and scales in a contemporary atmospheric model (Müller and von Storch, 2004, © Springer Verlag)

usually meaningful only if the variables are smooth so that the grid point value is representing a larger area. However, when the considered variables vary strongly from grid point to grid point, such as rainfall, the sequence of events at a grid point and at the geographic location, formally corresponding to the grid point, likely will not compare well. Grid point values do not represent local values when there is a great amount of spatial variability of scales of the grid size and smaller. For larger areas, represented by many grid boxes, this is no longer a problem.

Such models have been shown to have considerable skill in reproducing many aspects of contemporary climate, such as the annual cycle, the level of stochastic variability, and the formation of extratropical storms. These models strive to be as realistic as possible. Since these models are, nevertheless, significant simplification of the complex real system, we (Müller and von Storch, 2004) use the term *quasi-realistic* for such models.

Figure 3 provides an example of a sophisticated characteristic of atmospheric dynamics, namely, the "storm track" in the North Atlantic. The storm track is conveniently defined by the intensity of the band-pass filtered variance of 500 hPa geopotential height. The variations on timescales between 2.5 and 6 days are shown in the diagrams – variations on these timescales are related to the formation and migration of baroclinic storms. The model generates a pattern and intensity of the storm track (Figure 3, bottom) which is very similar to pattern and intensity derived from ECMWF analyses (Figure 3, top). The intensity in the model output is smaller than in the analyses – but the difference is usually considered acceptable within the range of uncertainties.

Figure 4 provides another example of a validation of GCMs. It compares the performance the analyses of rainfall determined in the ERA-40 data set (prepared by the European Center for Medium Range forecast; ECMWF) with the precipitation simulated in many GCMs (Kharin *et al.*, 2004). Specifically, the spatial distributions of the time-mean precipitation and 20-year return values are studied and compared with their counterparts derived from ERA-40.

The diagram is not easily understood, but it provides a compact description of the skill of a set of models. In the first step, the spatial average of the spatial distributions is subtracted – so that "anomaly fields" are obtained. From these anomaly fields, three characteristic numbers are calculated and displayed in Figure 4 by one symbol for each model. The trick is that in this diagram three characteristic numbers are displayed by one symbol in a two-dimensional diagram.

- The *mean-squared difference* between the anomaly field of the considered model and the ERA-40 reference

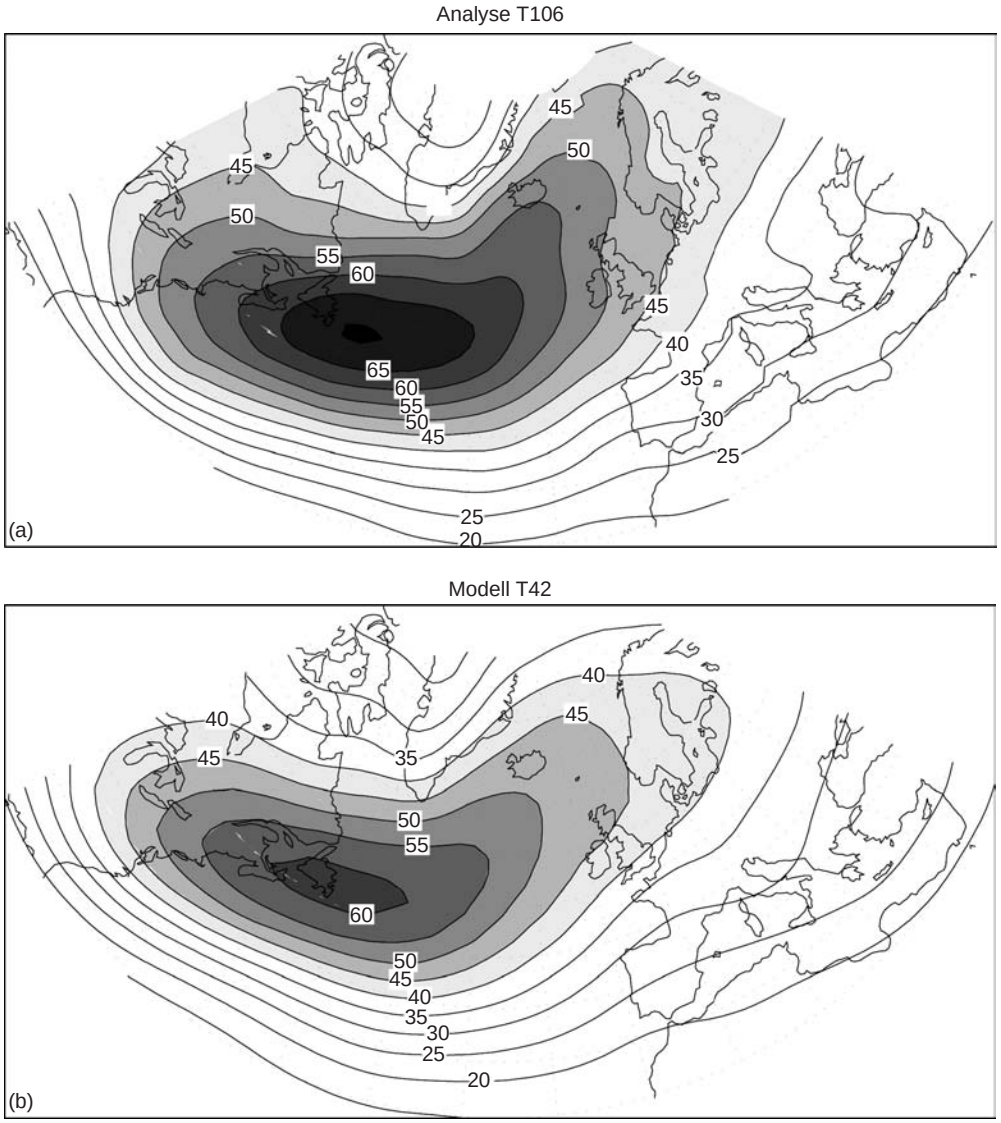

Figure 3 North Atlantic storm track as given by the band – passed filtered variance of 500 hPa geopotential height (band – pass: 2–5 to 6 day variability is retained) in ECMWF analyses (a) and in an extended simulation with the T42 ECHAM3 model (b) (von Storch *et al.*, 1999, © Springer Verlag)

anomaly. To facilitate easier comparison, the mean-squared difference is normalized by the variance of the reference anomaly. This characteristic number is given by the light blue circles emanating from the horizontal axis, where the units are given.

- The *ratio of variances* of model anomaly and of the reference anomaly (given by green dashed circles emanating from right vertical axis).
- The *correlation* indicated of the model and reference anomalies. This is given by the by pink straight lines emanating from left vertical axis.

The ERA-40-reference itself has a ratio of variances of one, a mean-squared difference of zero and a pattern correlation of one – its dot is placed on the lower margin of the diagram.

Usually the spatial variance of the simulated *time means* is underestimated (dashed circles, 50–80%), while the normalized mean-squared difference is moderate (light blue circles, 20–40%). The pattern correlation is high (typically 80%). The spread for the *20-year return values* is much larger (circles in Figure 4). Some of the models are doing similarly well as the mean precipitation, while other models produce a much too small variability (less than 20%) but a large high mean-square difference (100%). The pattern correlation is less than 80%, in some cases, as little as 50 and less percent. Interestingly, the comparison of the ERA-40 analysis with other analyses by NCEP

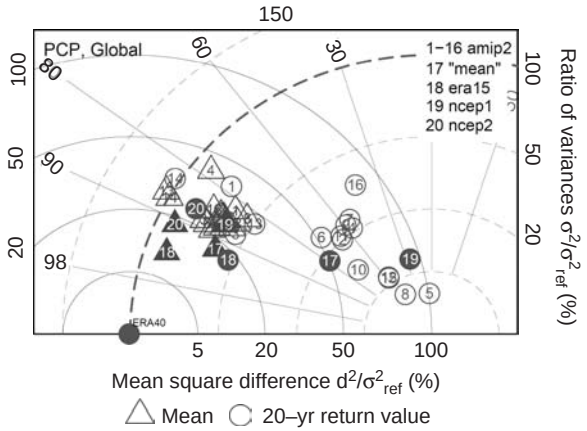

Figure 4 Comparison of the simulation of the time mean (triangles) and 20 year return values (circles) of precipitation in a series of 16 GCMs with the ERA-40 analysis (Kharin *et al.*, 2004). Also shown are the comparison with two NCEP-reanalyses, an earlier, shorter ERA reanalysis and the average of all 16 considered GCMs. Three characteristic measures are shown – the mean-squared difference, the ratio of spatial variances and the anomaly correlation. The mean-squared difference of the ERA-40 anomaly field and the model anomaly field is indicated by the light blue circles emanating from the units given on the horizontal axis. This parameter is normalized by the spatial variance of the reference anomaly field. The ratio of spatial variances of the reference and model anomaly fields is given by the green dashed circles emanating from the vertical axis. Figure 5 Result of a survey among climate modelers on the confidence into the description of processes in atmospheric (a) and oceanic (b) models. Answers were requested on a scale varying between ''very bad'' and ''very good''. The units on the vertical axis are in percent. (Bray and von Storch, 1999, © 1999 AMS)

(numbers 18 and 19) indicates substantial difference among reanalyzes. Obviously, the estimation of precipitation in reanalyzes provides further improvements, if space/time details are needed.

Figure 5 displays the outcome of a survey among 104 climate modelers, who have been asked to subjectively assess the skill of contemporary climate models in the end of the 1990s in describing a number of processes (Bray and von Storch, 1999). They were requested to respond to a seven-graded scale, varying between "very good" and "very bad". For obvious reasons, the response "very good" is almost never heard. Hydrodynamics, that is, the implementation of the laws of conservation of mass and momentum, is considered to be well reproduced. However, thermodynamic processes, related to convection or clouds, are assessed by many experts as being insufficiently represented. Of course, this assessment is partly reflecting the wish of modelers to continue their work in improving their models, but the outcome of the survey is also strong evidence that models really need to be improved.

Quasi-realistic models are considerably less complex than reality, but nevertheless, *very* complex. They can react in ways that cannot be foreseen by simple conceptual models. This is a virtue of such models, as they make them to laboratories to test hypothesis with – they constitute a *virtual* or *substitute reality* (Müller and von Storch, 2004).

FREE SIMULATIONS AND FORCED SIMULATIONS FOR RECONSTRUCTION OF HISTORICAL CLIMATE

Climate models are run in different modes. There are "free" simulations and "forced" simulations.(The wording "free" and "forced" is somewhat misleading. All climate simulations are, in a sense, forced, as they are exposed to a series of prescribed factors external to the model. In case of "free" simulations, these external factors do not vary, except for a fixed annual cycle. Variations in "free" simulations are therefore entirely due to the internal dynamics of the model and cannot relate to specific external factors. In contrast, "forced" simulations respond to a forcing, which varies irregularly. Thus, such model simulations exhibit a mix of externally induced variability and internally generated variability.) The former are useful to generate purely internal variability, whereas the latter allow the analysis of the effect of external factors. Figure 6 shows an example of a free simulation. The climate model ECHO-G was integrated over 1000 years – with continuously repeated annual cycles of solar insolation and no other external factor

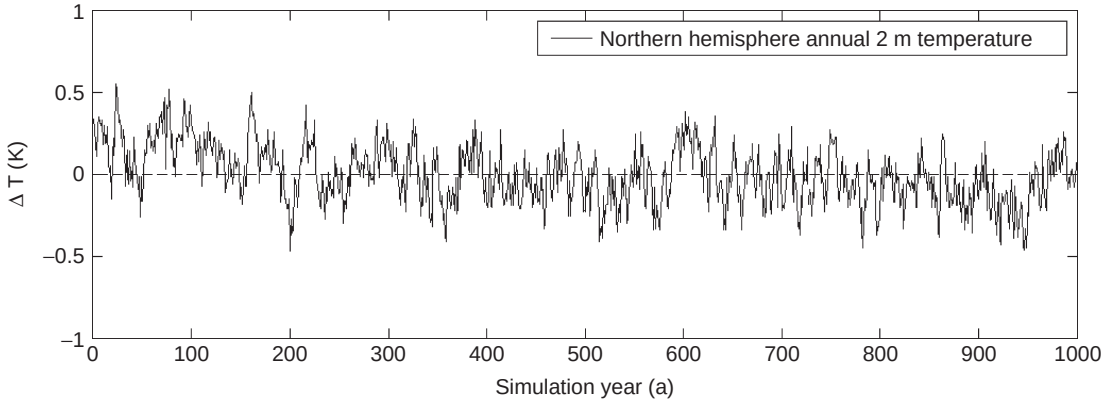

Figure 6 Air temperature anomalies (deviation form the long-term mean) simulated in a 1000-year ''free'' simulation (Wagner *et al.*, 2005, © Springer Verlag)

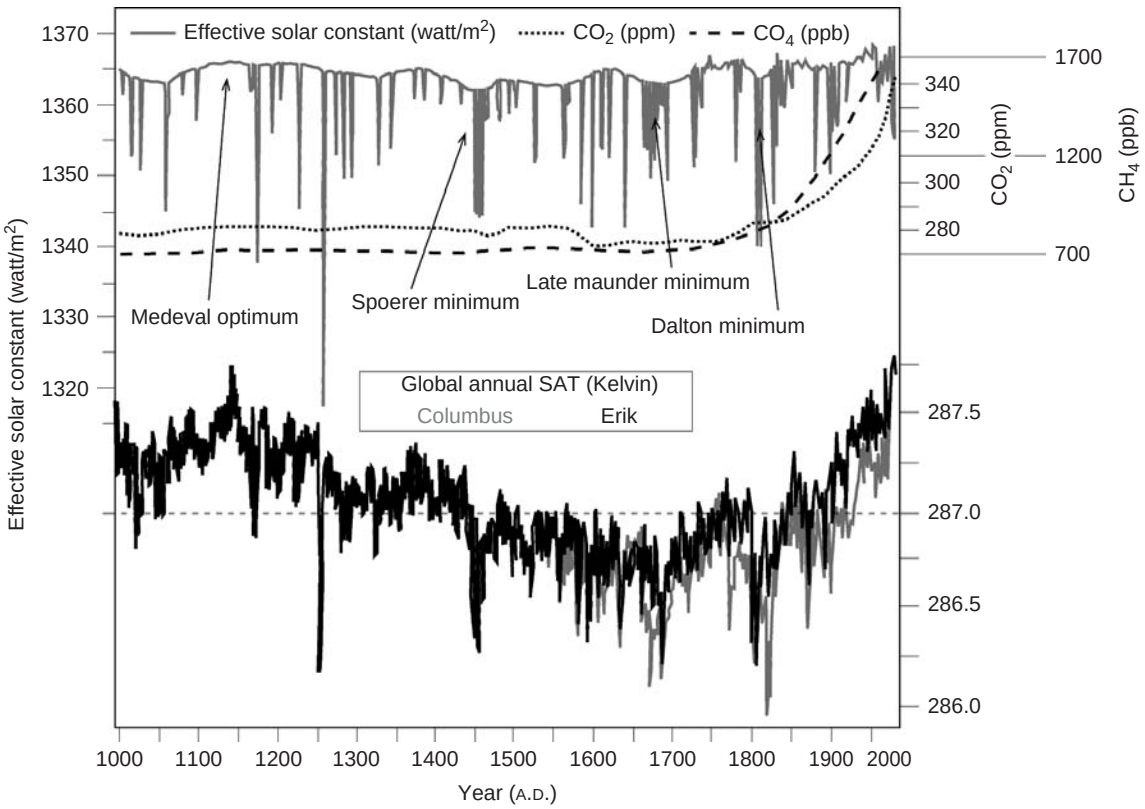

Figure 7 Time variable forcing (a) and temperature (b) in a 1000-year simulation and in a 500-year ''forced'' simulation

(Wagner *et al.*, 2005). The variable shown is air temperature averaged across the Northern Hemisphere. Obviously, the temperature undergoes significant variations, which cannot be traced back to "causes". The reason for this "smoke without fire" effect is the presence of myriads of nonlinear chaotic processes. The sum of all these chaotic processes may be conceptualized by the mathematical concept of stochastic noise (e.g. von Storch *et al.*, 2001). This noise is integrated by the slow components in the climate system, so that variations on all timescales appear with a first-order approximation red spectrum (Hasselmann, 1976).

On the other hand, characteristic cause-and-effect features emerge when external time-variable factors are added (González-Rouco *et al.*, 2003; Lionello *et al.*, 2004). Figure 7 shows time series of atmospheric forcing by time-variable solar output and the effect of stratospheric volcanic

aerosols, and by variable atmospheric concentration of the two greenhouse gases carbon dioxide and methane. Here, the radiative effect of the volcanic aerosols is accounted for by reducing the solar insolation for a short time. The time series of global mean air temperature is also displayed. This series is composed of variations unrelated to the forcing, like in the free simulation, and to variations excited by the forcing. A close inspection reveals that the variable output of the sun (including the volcanic effect) is the dominant factor until the middle of the nineteenth century. Since then, the effect of the ever-increasing greenhouse gas concentration is becoming dominant.

The overall development of the simulated temperature during the last millennium is consistent with the historical account, but the range of the variations is larger than what has been reconstructed from proxy-data, like tree rings.

The emergence of variability unrelated to external forcing factors makes also a forced simulation to a random experiment – the resulting weather stream is not determined by the forcing, but *conditioned*. For instance, the details of cyclones and anticyclones will vary from one simulation to the next, but the statistics of the formation of cyclones and anticyclones will be similar in any two realizations. In order to get a robust statistic, several simulations with identical forcing are preferable (*ensemble* simulations). To make them different realizations, several measures are possible; a popular method is to use a slightly different initial state.

CLIMATE CHANGE SIMULATIONS

In climate change simulations, assumed changes of the forcing are administered to the model. These changes are "scenarios" of possible and plausible changes. In most cases they refer to the emission of greenhouse gases, sometimes to the emission of anthropogenic aerosols. These emissions themselves are based on scenarios of economic and social development. The output of the climate models is then named a "climate change scenario" of a possible and plausible future climate.

The scenarios are not predictions; they do not describe the most probable development; instead usually several different scenarios are presented, which differ significantly from each other. Scenarios are plausible and consistent images of a possible future; have an impact on the future itself. (The movie "The day after tomorrow" provides a story of future climate change; it is, however, not the scenario as it describes a climate which is impossible to emerge as it is not consistent with the physical laws of climate.) Thus, scenarios are not only depictions of possible futures, but also active agents forming the future. (In the context of global warming, various scenarios of possible future development are prepared to emphasize the severity of the threat of global warming. As such, they help the formation of a climate policy mitigating the envisaged anthropogenic climate change.)

The consensus of the models given a specific emission scenario on larger scales is illustrated in Figure 8. A total

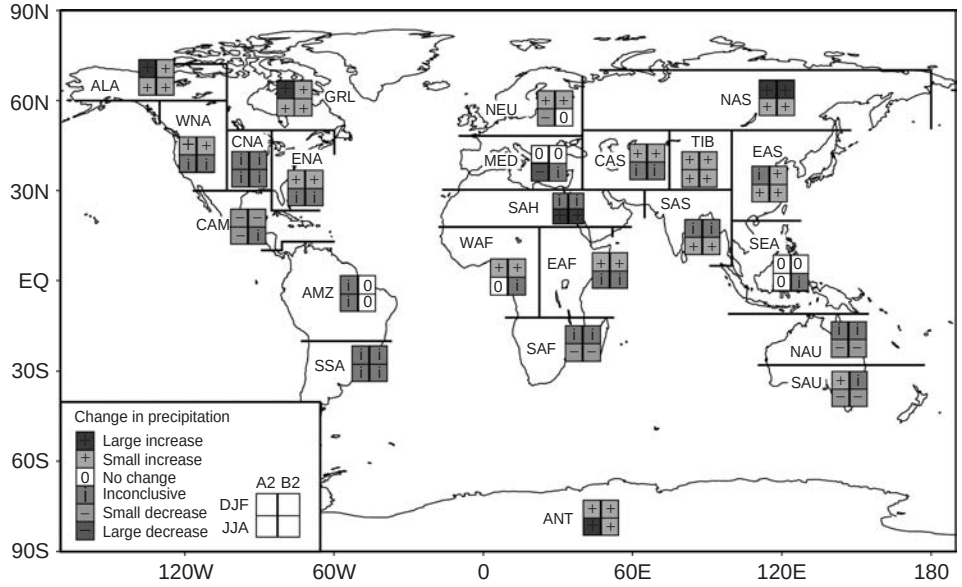

Figure 8 Convergence of climate models in simulating the same regional change in precipitation according to the greenhouse gas emission emissions scenarios A2 (left two boxes) and B2 (right two boxes) at the end of the twenty-first century. The top two boxes refer to northern winter (DJF), the bottom to the northern summer (JJA). For further details, refer to the text (Reproduced from Giorgi *et al.,* 2001a by permission of American Geophysical Union). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

of 9 models was analyzed with respect to their similarity in the change of precipitation averaged over subcontinental areas (Giorgi *et al.*, 2001a). All nine models have been forced with the same Special Report on Emissions Scenarios (SRES) scenarios provided by the IPCC for its Third Assessment Report. Whenever 7 out of the 9 models produced similar responses, the models were considered agreeing in envisaging a small or large increase or small or large decrease of precipitation, or no change in precipitation. The symbol "i" was introduced in Figure 8 if the models were found to generate conflicting assessments. This exercise was done for a series of subcontinental areas, for both scenarios A2 and B2 and for the two seasons December-January-February (DJF) and June-July-August (JJA) (A2 is a scenario, which describes a rather steep increase in the usage of fossil fuels and emissions into the atmosphere. B2, on the other hand, assumes more efficient measures to curb emissions.). For each of the regions, a square provides the assessment for the two scenarios and two seasons. Obviously, the models agree in most cases – and indeed the pattern of responses is the same, also if a number of earlier climate change experiments exploiting somewhat different scenarios are checked (not shown; Giorgi *et al.*, 2001a).

The argument seems to indicate that the similarity among models would be a proof for the reality of the response. This is certainly not so; the arguments certainly demonstrate the stability of the response across models – but since the models are not developed independently of each other, they may all suffer from the same limitations.

The climate change simulations provide useful information on large scales. Here "large" means global, continental, and subcontinental scales. A rough rule is that contemporary models are skillful on scales of 10^7 km^2. On smaller scales, the model output will often depend on the specifics of the considered model.

This is insofar a severe limitation as the effect of changing climate is felt on a regional scale; assessing the impact of climate change requires scenarios on the regional and even local scale. Thus, extra efforts are required to derive the required impact-relevant regional scenarios. Tools for that purpose are discussed next.

DOWNSCALING

The idea of downscaling is that the smaller scale climate may be understood as the outcome of an interaction of larger-scale dynamics and smaller-scale physiographic details (e.g. von Storch, 1999). The concept is based on the observation that the global scale circulation is already formed on an aqua planet without any physiographic features (a planet entirely covered by the ocean, without any land and topography); the formation of stationary planetary features needs the presence of the gross land–sea contrast and the largest mountain ranges.

There are several downscaling methods in use (Giorgi *et al.*, 2001b).

One main group is utilizing empirically determined transfer functions, which relate variables of regional or local interest to well-simulated large-scale variables (for an overview, refer to Giorgi *et al.*, 2001). Such transfer functions are often regression equations, but also nonlinear techniques like neural nets are in use. Sometimes the transfer functions relate statistical parameters to each other, such as intramonthly percentiles of an impact variable and monthly mean air pressure fields. Another approach is to directly relate meteorological state variables like free tropospheric temperature and humidity to relevant surface variables (Wilby and Wigley, 1997). Weather generators are also used for downscaling, with their parameters conditioned on the large-scale state (e.g. Busuioc and von Storch, 2003).

The other group of methods is based on the use of regional climate models (Giorgi and Mearns, 1991). In most cases, the 6-hourly large-scale weather stream generated by a global climate model is enforced on the regional domain; the dynamical model is constructing a regional-scale weather stream, which is consistent with both the global weather stream and the physiographic details of the considered region. In the following, we will deal with this approach in more detail.

One has to keep in mind that downscaling operates with the assumption that the large scales are properly represented by the global simulation or the global analysis. This is usually not a problem in case of analyses, but for (free or forced) global simulations this is a nontrivial assumption. For instance, the formation of blocking situations, which may be considered large scale in certain downscaling applications, is not sufficiently simulated if the global model has too low a resolution.

REGIONAL CLIMATE MODELING

Regional climate modeling (for a recent overview, refer to Wang *et al.*, 2004) is in most cases just regional atmospheric modeling with some basic parameterization of the thermodynamics of the upper soil layer. The other climatically relevant state at the surface of the earth, in particular, the sea surface temperature, sea ice and lake ice conditions, the state of the vegetation – are in these cases prescribed. Since a few years, significant efforts are made to construct coupled regional models, which feature regional oceans and lakes, run-off or vegetation explicitly together with the regional atmosphere. For instance, the model system BALTIMOS (Jacob; personal communication), designed for Baltic Sea catchments studies, is made up of the Baltic Sea ocean model, a hydrological model and the regional atmospheric model REMO (Jacob *et al.*, 1995). The Swedish Rossby Center is working with

a system featuring a Baltic Sea model, regional hydrology, and a regional atmosphere (Räisänen *et al.*, 2004)

Commonly, the regional models are forced by boundary conditions along the lateral boundaries and, as discussed above, at the surface of water bodies. The lateral conditions are enforced with the help of a "sponge" zone (Davies, 1976) of a few grid points. In the sponge zone, the simulated state is nudged to the externally given state, with stronger nudging coefficients near the model's margin, and weaker ones in the interior. That this concept is practically working fine has been demonstrated convincingly by the "Big Brother Experiment" by Denis *et al.* (2002). In that experiment, a 50-km grid, regional model covering a large area ("big brother") was run over an extended time; then a smaller domain within the larger domain was chosen. The meteorological variables simulated in the large domain along the margin of the small area were selected. The same regional model, with a 50-km grid, was then run on the smaller domain ("little brother"), forced with the boundary values provided by the large-area model after "coarsening", that is, the data was not given every 50 km along the margin, but every 100, 200 or even 500 km. The research question was whether the fine scale features simulated in the smaller domain in the big brother setup would be recovered by the little brother setup. The answer was positive; after a few days, differences between the large-area simulation and the small-area simulation were small. The area considered was the well-flushed Eastern North America and Western North Atlantic. (A region is "well flushed" if the information is quickly advected from the boundaries into and through the interior.)

Mathematically, the problem of inferring the dynamical state of a fluid by providing lateral boundary conditions is not a well-posed problem. The lateral boundaries do not determine a unique "solution" in the interior; instead, several different states in the interior are consistent with a given set of lateral boundary conditions. The tendency to form very different solutions in the interior as a response to the same boundary conditions depends on how well the region is flushed, that is, how efficiently a boundary steering is established. In midlatitudes, such as Europe or in Denis *et al.*, (2002) case, the regions are mostly well flushed; in areas with little "through-flow", like the Arctic, this is not so. Thus, any two extended simulations that are run with the same boundary values but slightly different initial states (which may simply be two observed states 12 hours apart) will generate more or less frequently very different behavior. For a region like Europe, such a "divergence" is rare (Weisse *et al.*, 2000), but Caya and Biner (2004) report a dramatic case in eastern North America. For the Artic, such divergence is more frequent (Rinke and Dethloff, 2000). This phenomenon of intermittent divergence is reflecting the conflicting influences of control by inflow boundary conditions and of regional chaotic dynamics.

Figure 9 shows an example of this intermittent divergence. The observed zonal wind at a location in the German Bight is shown together with grid-box-simulated zonal winds. (There is a problem of comparing local wind affected by local particularities with grid box averages. Deviations between simulated numbers and observed numbers may be due to local effects not described by the model's resolution.) In this case, six simulated time series are shown. They are generated by the same regional model, forced with the same lateral boundary conditions but with slightly different initial values. The reason for these different developments is not that the initial conditions would be very different, leading to different forecasts; instead miniscule differences in the initial conditions excite the chaotic divergence of the dynamical system "regional atmosphere". After a few days, after January 8, the divergence has ceased and the development is the same in all six simulations. This convergence following an episode of divergence reflects the fact that the system moves into a configuration with a more westerly weather regime, so that the information provided with lateral boundary conditions is efficiently "flushed". After several months, a similar divergence episode emerges (not shown).

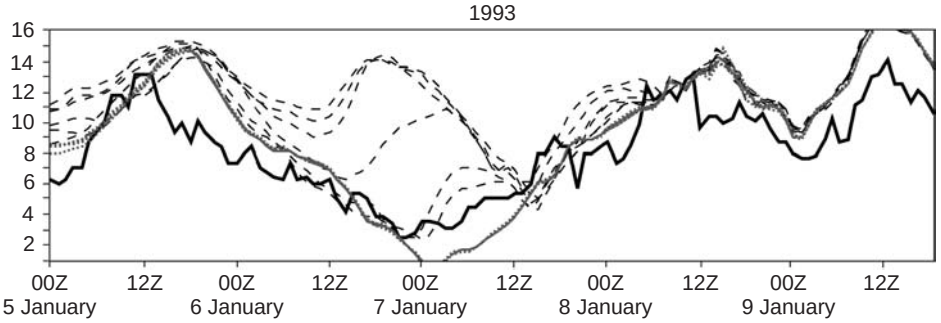

Figure 9 Intermittent divergence in a regional atmospheric model. Shown is the zonal wind at a location in the German Bight, as observed (solid) and as simulated in six simulations with a regional model with conventional lateral boundary forcing (dashed) and with spectral nudging (grey) (Reproduced from Weisse and Feser, 2003, by permission of Elsevier)

A method to overcome this intermittently emerging divergence is to cast the whole regional modeling problem not as a boundary problem but as a state space problem (e.g. Müller and von Storch, 2004), in which the dynamical model is used to augment existing knowledge about the regional state of the atmosphere. The latter is knowledge about the large-scale state of the atmosphere above a certain vertical level, where the influence of the regional physiographic details is small. This concept leads to *spectral nudging* (von Storch *et al.*, 2000; Miguez-Macho *et al.*, 2004), which consists of the addition of penalty terms in the equations of motion. These terms are getting large if the simulated large-scale state deviates from the prescribed large-scale state, but vanish if the model remains close to the prescribed large-scale state. The method has been tested, and it is found that this approach is better in capturing regional details than when the model is forced only with lateral conditions (a case demonstrating this claim is provided by von Storch *et al.*, 2000). In addition, the emergence of intermittent divergence is suppressed (Weisse and Feser, 2003). This is demonstrated by the other set of curves in Figure 9, displaying the development in the six simulations, starting with the same set of initial conditions as in the conventional lateral boundary forcing cases – the curves differ so little that they appear as a somewhat broader grey line.

RECONSTRUCTIONS

One important application of regional models is the high-resolution reconstruction of the weather stream of the past 40 or 50 years (Feser *et al.*, 2001 – "Feser reconstruction"). Using the spectral nudging technique, using the European weather stream on spatial scales of 1500 km and more, reliably analyzed by NCEP since 1948 (Kalnay *et al.*, 1996) as constraint, regional details of the atmospheric state were reconstructed continuously with the regional atmospheric model REMO for 40 and more years on a 50-km grid. The data was stored once an hour.

The added value of this exercise is an increased resolution in space and time; thus it is expected that the tails of the distributions (i.e. of climate) are better described. Figure 10 demonstrates that this improvement has indeed been achieved, at least for wind over the sea (Sotillo, 2003). Quantiles are derived for wind-speed-time series recorded at two buoys. They are compared with quantiles derived from the NCEP reanalysis and from the Feser-reconstruction. In one case, both model quantiles are very similar to the observed quantiles; in the other, only the Feser-reconstruction exhibits the right level of strong windiness. In the former case, the buoy data have entered the NCEP reanalysis, but in the latter the buoy data have not. Thus, it may be concluded that the reconstruction using a regional atmospheric reconstruction together with a spectral nudging approach, is recovering relevant detail to regional climate statistics. However, further analysis of the added value, in particular, in terms of precipitation and wind over land, needs to be done.

This added value is used in assessment studies, for instance, about ocean wave conditions (EU project HIPOCAS; Soares *et al.*, 2002). An example of successfully reproducing local wave conditions at an island in the North Sea is shown in Figure 11. The high wave results, obtained as response to the Feser-winds, are in very good agreement with the local observations, recorded either by a local buoy or by a local radar system. In fact, the wind data set is being increasingly used by regional decision makers.

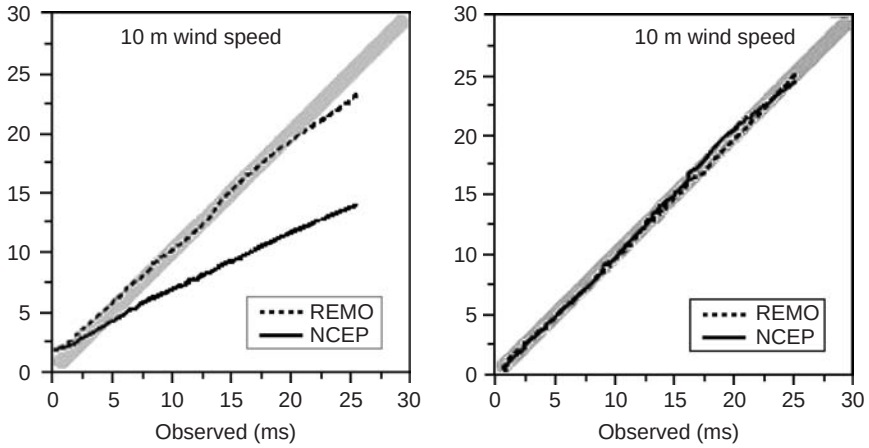

Figure 10 Quantile–quantile plot of 10 m-wind speed at two buoy locations in the east Atlantic (a) and in the Ionian Sea (b). The vertical axis represents the quantiles from the buoy data, the vertical the quantiles derived either from NCEP reanalyses (solid) or from the regional model reconstruction (dashed). Note that the data from the Atlantic buoy has been assimilated into the NCEP reanalysis, while the data from the Ionian Sea buoy are independent (Sotillo, 2003)

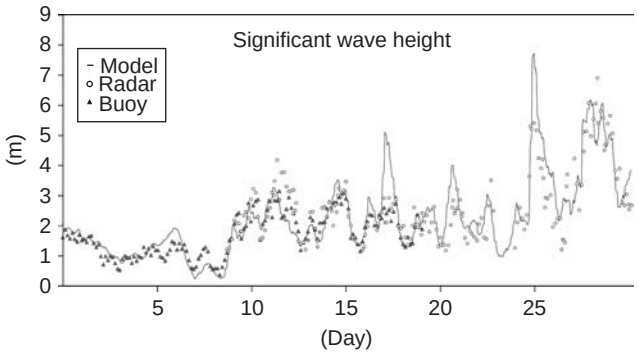

Figure 11 Simulated significant wave height off the island of Heligoland in the German Bight during one month. The line is the significant wave height obtained by running a wave model with the Feser-reconstructed winds in the North Sea domain; the triangles are wave height recorded by a local buoy and the open dots estimates derived from a local radar system (By courtesy of Gaslikova)

The data set has so far not been systematically studied with respect to the reconstruction of precipitation. However, it is already clear that a one-to-one association of grid box precipitation in the model to 50 km by 50 km real averages derived from observations is not possible. Only averages over several grid boxes are meaningful. Figure 12 shows an example for the catchment of the river Odra (Messal, personal communication). The similarity is not perfect but encouraging, considering the uncertainty in the "observed" rainfall. Other aspects which have been examined are related to cloud cover and cloud amounts (Meinke *et al.*, 2004)

REGIONAL SCENARIOS

In the European project PRUDENCE (Christensen *et al.*, 2002), the same set of global climate change scenarios are processed with a large number of regional climate models. Most of the models are purely atmospheric models, but some have added oceanic and hydrological components.

The global scenarios were prepared by the model HadAM3 of the Hadley Center, using A2 and B2 emission scenarios. The boundary values as well as the sea surface temperature and the sea ice conditions from the global run during a 1961–1990 control and during the interval 2071–2100 were used to force the regional models, which were integrated over 30 years. Additionally, in the 2071–2100 runs, the radiative conditions in the regional models were changed according to the emission scenario.

So far, the process of comparing the responses of the various models is not yet completed. First results indicate that during winter the regional models deviate little from each other. The simulated expected changes due to global warming coincide across most models in terms of strong winterly windiness and heavy summer rainfall events (Beniston *et al.*, 2005).

The added value produced by the regional models is expected to consist in a better simulation of the spatially and temporarily smaller scales. In fact, a better description of

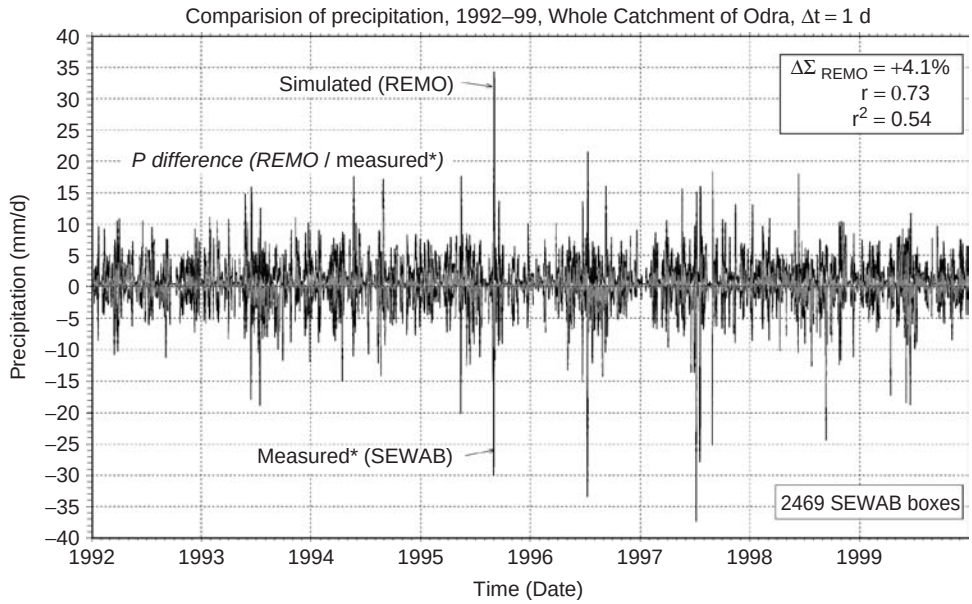

Figure 12 Simulated (upward; black) and analyzed (downward; black) daily precipitation in the catchment of the Odra River in 1997. The correlation is 0.73, the amount of variance described 54%. The grey curve shows the difference. The bias is 4%, which is within the limit of uncertainty (By courtesy of Hillmar Messal)

the details of frequency distributions is obtained (Beniston *et al.*, 2005).

As an example, the precipitation during summer time has been examined, (Christensen and Christensen, 2003) as well as wind conditions over the North Sea (Woth, personal communication). In both cases, a similar result is obtained, namely, the mean conditions are weakened – that is, the total amount of precipitation was found to be decreased, but the intensity of rare events was found to be increased by up to 40% (Figure 13). Similarly, the mean wind speed over the North Sea is envisaged to become slightly weaker on average, while strong westerly winds may increase by a few percent (not shown).

The PRUDENCE experience seems to indicate that the differences resulting from the use of the same global climate change scenario but different regional models are moderate. On the other hand, experiences at the Rossby–Center (e.g. Bergström *et al.*, 2001) indicate that the use of different global climate change scenarios and the same regional model induces much larger uncertainties. Figure 14 shows simulated regional annual precipitation changes in Europe derived by postprocessing (downscaling) two global climate change scenarios (prepared by the Hadley Center and the Max–Planck–Institute of Meteorology) with the Rossby–Center regional model. While broad features are similar, like more rainfall in the northern part and less in the southern, regional details contradict each other, for example, for the terrain of Poland.

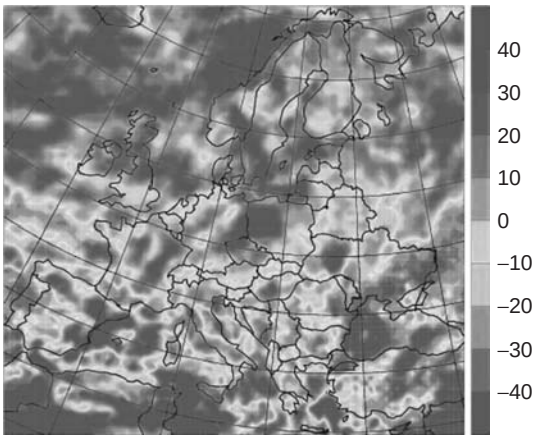

Figure 13 Change in precipitation intensity or the rare summer events as envisaged by a regional climate model for the end of the twenty-first century. The quantity shown is the change in five-day mean exceeding the 99th percentile (Christensen and Christensen, 2003). CONCLUSIONS

Climate modeling is a standard exercise, which has matured in the past years after its introduction into the 1960s by pioneers like Manabe and Bryan (1969). Climate modeling is commonly understood as the space-time detailed modeling of at least the atmosphere, the ocean, and the sea ice. In such "quasi-realistic" models, the considered components are described in as much detail as is consistent with the anticipated application of the model (in particular the length of the integration time), and is feasible, given the computational platform. The atmospheric components describes baroclinic instability and the associated macroscale vortices (extratropical storms), while the dynamically relevant role of eddies in the ocean is parameterized by a certain type of diffusion (one could say, a climate model's ocean is not filled with water but with mustard).

Nowadays, such models are extended to contain more components of the earth system, in particular, surface hydrology, pathways and cycles of matter, vegetation and ice shelves and sheets.

Global models are meant to simulate phenomena of several grid length sizes; phenomena on scales of a few

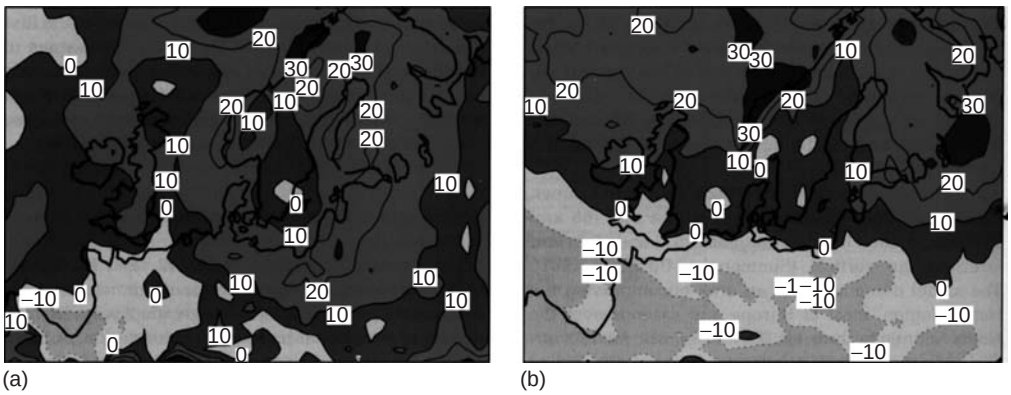

Figure 14 Simulated changes (%) in annual precipitation in Europe in two similar greenhouse gas emission scenario runs with different global climate models (Reproduced from Bergström *et al.*, 2001 by permission of Inter-Research). 100 km or less are usually not simulated reliably. Thus, global model output is of limited utility for areas such as the North Sea, Colorado, or Taiwan. A thumb of rule gives 10^7 km^2 as threshold for skillful presentations for global models at this time. (This length scale is certainly a moving target. With increasing computer power, global models will be run with higher spatial resolution, and the skillful spatial scales will further decrease.) If smaller scaled descriptions and scenarios are needed, then one has to resort to a downscaling method, in particular, to the regional climate modeling. Such regional models are also readily available nowadays, and are presently extended – as their global siblings – to take into account more and more other components of the earth system.

For scientists not working with such climate models, the following items may be useful to remember:

- Global climate modeling allows the representation of global, continental, and subcontinental scales. Global models are not designed for, and thus not well suited for the regional and local scale.
- Global climate is varying because of both internal dynamics as well as external forcing.
- Scenarios of future climate change hinge on the validity of economic scenarios.
- Simulation of regional climate is a downscaling problem and not a boundary value problem.

Acknowledgments

I am thankful to Nikolaus Groll, Brigit Hüncke, Viacheslav Kharin, Hillmar Messal, Sebastian Wagner, and Katja Woth for their helpful comments. Many thanks to Beate Gardeike, who adapted many diagrams for this article. Two reviewers provided useful advice.

33: Human Impacts on Weather and Climate

STEPHEN H SCHNEIDER[1] AND MICHAEL D MASTRANDREA[2]

[1]Department of Biological Sciences, Stanford University, Stanford, CA, US
[2]Interdisciplinary Program in Environment and Resources, Stanford University, Stanford, CA, US

Climate change is a worldwide environmental, social, and economic challenge. It includes issues of air pollution, land use, toxic waste, transportation, industry, energy, government policies, development strategies, and individual freedoms and responsibilities. Human use of the atmosphere as an unpriced dumping space has led to the buildup of gases and particles such as carbon dioxide and methane that can alter the energy exchange between the Earth's surface and space. There is a great deal of confusion among policy makers and the public about just how much is known about our climate, and what makes it change. However, although many aspects of the science of climate change are laced with major uncertainties, many others are actually scientifically well established. Human modification of the climate system has far-reaching implications for human welfare and the health of our planet. Are our actions causing the climate to change in ways or at rates that will threaten natural systems or make human adaptation difficult? This chapter outlines the current state of scientific knowledge regarding human impacts on the climate system.

INTRODUCTION

Throughout human history, climate has both promoted and constrained human activity. In fact, humans only very recently have been able to substantially reduce their dependence on climate variability through advances in technology and organization, such as high yield agriculture, and food distribution and storage systems which have virtually eliminated famine in most countries with developed or transitioning economies. On the other hand, human action can also affect climate. Human use of the atmosphere as an unpriced dumping space has led to the buildup of gases and particles that can alter the energy exchange between the Earth's surface and space. Carbon dioxide (CO_2), methane (CH_4), and water vapor are the principal heat-trapping greenhouse gases. Carbon, the main element in the top two human-enhanced greenhouse gases (CO_2 and CH_4), is the underpinning of most fuels used in transportation and energy production. Carbon also makes up about half of the dry weight of most vegetation. Thus, the carbon that cycles through species, air, water, and soils is both an essential nutrient and a potential problem. Human modification of the carbon cycle has far-reaching implications for human welfare and the health of the biosphere. Are our actions causing the climate to change in ways or at rates that will threaten natural systems or make human adaptation difficult?

Climate change is a worldwide environmental, social, and economic challenge. It includes issues of air pollution, land use, toxic waste, transportation, industry, energy, government policies, development strategies, and individual freedoms and responsibilities. There is a great deal of confusion among policy makers and the public about just how much is known about our climate, and what makes it change. However, although many aspects of the science of climate change are laced with major uncertainties, many others are actually scientifically well established. This chapter outlines the current state of scientific knowledge regarding human impacts on the climate system.

IS THE CLIMATE CHANGING?

The Global Temperature Record

Modern temperature records, derived from thermometers sufficiently accurate and geographically dispersed to permit computation of a global average temperature, date back to the mid-nineteenth century. Extracting a global average from the data is complicated by many factors ranging

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

from the growth of cities, with their "heat island" warming of formerly rural temperature measuring stations, to such mundane effects as changes in the types of buckets used, to sample seawater temperature from ships (Harvey, 2000, Chapter 5). Early data suffer from a dearth of measurements and a bias toward the more developed regions of the planet. But climatologists understand how to account for these complications, and essentially all agree that Earth's average temperature increased by approximately 0.6 °C since the mid-nineteenth century (IPCC, 2001a). Throughout this chapter, many research findings we refer to are taken from Intergovernmental Panel on Climate Change (IPCC) Assessment Reports, which present the worldwide consensus on climate change science every five years. Figure 1 shows the global temperature record as a plot of the yearly deviations from the 1961–1990 average temperature.

A glance at Figure 1 shows that Earth's temperature is highly variable, with year-to-year changes often masking the overall rise of approximately 0.6 °C. Nevertheless, the long-term upward trend is obvious. Especially noticeable is the rapid rise at the end of the twentieth century. Indeed, all but three of the ten warmest years on record occurred in the 1990s, with 1998 marking the all-time record high through 2000. There is good reason to believe that the 1990s would have been even hotter had the eruption of Mt. Pinatubo in the Philippines not put enough dust into the atmosphere to cause global cooling of a few tenths of a degree for several years. Looking beyond the top ten years, Figure 1 shows that the 20 warmest years include the entire decade of the 1990s and all but three years from the 1980s as well. Clearly the recent past has seen substantial surface warming.

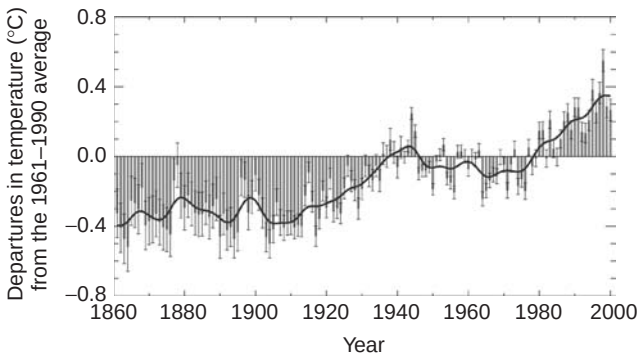

Figure 1 Variation in Earth's average global temperature from 1860 to 1999. Data are taken from global networks of thermometers, corrected for a variety of effects, and combined to produce a global average for each year. Wider, solid bars represent temperature deviations for each year, relative to the 1961–1990 average temperature, and narrow gray bars show uncertainties in the yearly temperatures. Black curve is a best fit to the data (Adapted from Wolfson and Schneider, 2002)

A Natural Climate Variation?

Could the warming shown in Figure 1, especially of the past few decades, be a natural occurrence? Might Earth's climate undergo natural fluctuations that could result in the temperature record of Figure 1? Increasingly, we are finding that the answer to that question is "no". We would be in a better position to determine whether the temperature rise of the past century is natural if we could extend the record further back in time. Unfortunately, direct temperature measurements of sufficient accuracy or geographic coverage simply do not exist before the mid-1800s. But by carefully considering other quantities that do depend on temperature, climatologists can reconstruct approximate temperature records that stretch back hundreds, thousands, and even millions of years.

Figure 2 shows the results of a remarkable study that attempts to push the Northern Hemisphere temperature record back a full thousand years (Mann *et al.*, 1999). In this work, climatologist Michael Mann and colleagues performed a complex statistical analysis involving 112 separate indicators related to temperature. These included such diverse factors as tree rings, the extent of mountain glaciers, changes in coral reefs, and many others. The resulting temperature record of Figure 2 is a "reconstruction" of what one might expect had thermometer-based measurements been available. Although there is considerable uncertainty in the millennial temperature reconstruction, as shown by the error band in Figure 2, the overall trend is most consistent with a gradual temperature decrease over the first 900 years, followed by a sharp upturn in the twentieth century. That upturn is a compressed representation of the

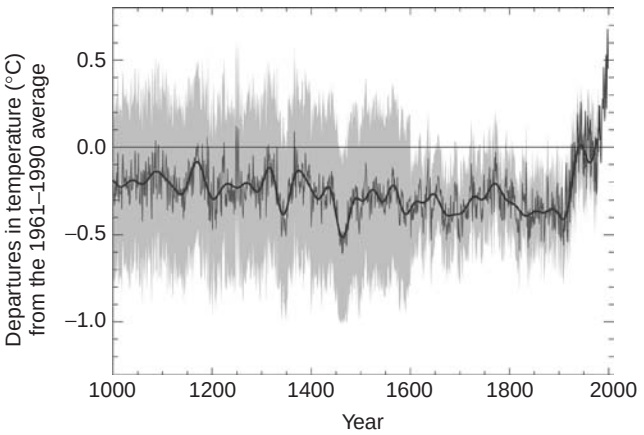

Figure 2 Reconstruction of the 1000-year temperature record for the Northern Hemisphere. Black curve is a best fit to the millennial temperature record; gray is the 95% confidence interval, meaning that there is a 95% chance that the actual temperature falls within this band. Date from the mid-nineteenth century on are from the thermometer-based temperature record of Figure 1 (Adapted from Wolfson and Schneider, 2002)

thermometer-based temperature record shown in Figure 1. Among other things, Figure 2 suggests that the 1990s was the warmest decade not only of the twentieth century but also of the entire millennium. Taken in the context of Figure 2, the temperature rise of last century clearly is an unusual occurrence.

ARE WE CHANGING THE CLIMATE?

Is the change documented in Figure 2 caused by human activities or natural variability? Or is it a combination of both? Mann *et al.* approached that question by correlating their temperature reconstruction with several factors known to influence climate, including solar activity, volcanism, and humankind's release of heat-trapping gases (greenhouse gases). They found that solar variability and volcanism (natural influences) were the dominant influences in the first 900 years of the millennium, but that much of the twentieth century variation could be attributed to human activity. Given the indirect, statistical nature of the study, this result can hardly be taken as conclusive evidence that humans are to blame for twentieth century global warming. But the Mann *et al.* result does provide independent corroboration of computer climate models that also indicate a human influence on climate.

''Fingerprint'' Analysis

Methods used to attribute observed warming trends to human-induced climate change are often called "fingerprint analysis". Although each fingerprint may be a circumstantial piece of evidence for human-induced climate changes taken together, several such lines of evidence have led the IPCC to conclude that there is a discernible human fingerprint on climate change (IPCC, 2001a). These different types of fingerprints include the fact that the Earth's stratosphere cooled while the surface warmed – a fingerprint of changes due to increased atmospheric CO_2 rather than, for example, a fingerprint of an increase in the heat output of the sun which should have warmed all altitudes in the atmosphere (Schneider, 2003).

Figure 3 shows three different attempts, using the same basic climate model (*see* **Chapter 32, Models of Global and Regional Climate, Volume 1**), to reproduce the historical temperature record of Figure 1. In the model runs of Figure 3(a), only estimates of solar variability and volcanic activity – purely natural forcings, or climatic influences – were included in the model. The projected temperature variation, represented by a thick band indicating the degree of uncertainty in the model calculations, does not show an overall warming trend and clearly is a poor fit to the actual surface temperature record. The runs of Figure 3(b) include only anthropogenic, or human-induced,

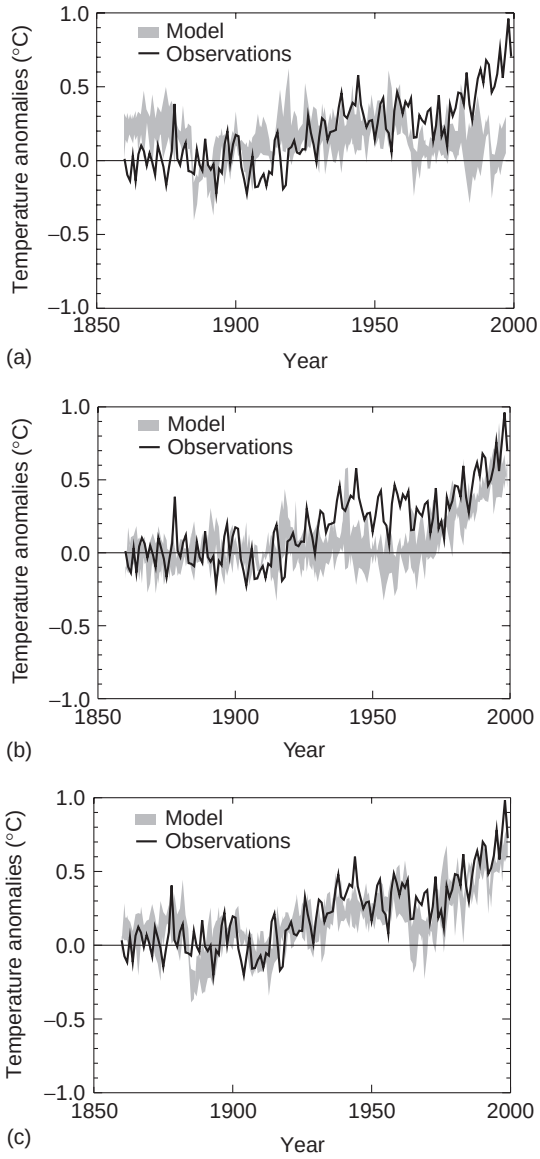

Figure 3 Attempts to model Earth's temperature from the 1860s using different model assumptions. In all three graphs, the solid curve is the observed surface temperature record of Figure 1. Gray bands represent model projections. In each graph, the bands encompass the results of four separate model runs. In (a), only natural forcings – volcanic activity and solar variability – are included. Clearly this simulation lacks the upward trend in the observed temperature record, suggesting that the temperature rise of the last century and a half is unlikely to have a purely natural explanation. Simulation (b), including only anthropogenic forcings, does much better, especially with the rapid temperature increase of the late twentieth century. Simulation (c), combining both natural and anthropogenic forcings, shows the best agreement with observations (Adapted from Wolfson and Schneider, 2002. Data from IPCC, 2001a)

forcings such as emissions of greenhouse gases and particulates. This clearly does a much better job, especially in the late twentieth century, but deviates significantly from the historical record around mid-century. Finally, Figure 3(c) shows the results from runs that include both natural and anthropogenic forcings. The fit is excellent, and it suggests that we can increase our confidence in this model's projections of future climate. Furthermore, the model runs of Figure 3 taken together strongly suggest that the temperature rise of the past few decades is unlikely to be explained without invoking anthropogenic greenhouse gases as a significant causal factor. Thus, the "experiments" of Figure 3 illustrate one way of attempting to pry an anthropogenic climate signal from the natural climatic noise. In other words, Figure 3 provides substantial circumstantial evidence of a discernible human influence on climate, and, with the other evidence mentioned, supports the IPCC conclusion that "most of the warming observed over the last 50 years is attributable to human activities" (IPCC, 2001a).

Keeping a Planet Warm

How can human activities affect the Earth's climate? What ultimately determines climate, and specifically, the Earth's temperature? That question is at the heart of climate science and of the issues surrounding human-induced climate change.

The gases that comprise the Earth's atmosphere are largely transparent to visible light. Therefore, much of the incident sunlight penetrates the atmosphere to reach the surface where it is absorbed, warming the surface, which then reemits the energy as infrared radiation. But the atmosphere is not so transparent to infrared radiation. Certain naturally occurring gases and particles – particularly clouds (*see* **Chapter 196, The Role of Water Vapor and Clouds in the Climate System, Volume 5**) – absorb infrared radiation and hinder its ability to escape from the atmosphere. That infrared energy that is trapped in the atmosphere is reemitted, both up to space and back down towards the surface – the latter primarily adding heat to the lower layers of the atmosphere. As a result, the Earth's surface warms further, emitting infrared radiation at a still greater rate, until the emitted radiation is in balance with the incident sunlight and the other forms of energy coming and going from the surface (*see* **Chapter 25, Global Energy and Water Balances, Volume 1**). The difference between the upward and downward energy flows, in the steady state, is just the right amount to maintain energy balance between absorbed solar radiation, evaporation, thermal energy lost via rising plumes of heated air, and the net infrared radiation balance. So, the Earth is in nearly perfect energy balance but with a surface temperature significantly higher than it would be in the absence of greenhouse gases. This is what accounts for the 33 °C difference between the Earth's actual surface air temperature and that which it would be were there no such gases in the atmosphere.

Because the atmosphere functions, in a crude sense, like the heat-trapping glass of a greenhouse, this heating has earned the nickname greenhouse effect, and the gases responsible are greenhouse gases. (The greenhouse analogy is not such a good one; a greenhouse traps heat primarily by preventing the wholesale escape of heated air, with the blockage of infrared playing only a minor role). The 33 °C warming due to natural greenhouse gases is the natural greenhouse effect, and is a good thing because it makes our planet much more habitably warm than it would be otherwise. However, human activities have been and are continuing to enhance the greenhouse effect by adding additional greenhouse gases into the atmosphere. Such emissions add to the "blanket" of heat-trapping gases, further increasing the Earth's temperature. It is important to understand that the basic greenhouse phenomenon is well understood and solidly grounded in basic science. More controversial is the extent to which we have already caused climate change and by how much we will enhance future climate disturbance.

CO_2 and Past Climate

Human activities add to the atmospheric concentrations of a number of naturally-occurring greenhouse gases, and introduce other potent greenhouse gases which are not naturally occurring. The greenhouse gas that has been most affected by anthropogenic emissions is CO_2. In the last 140 years, atmospheric CO_2 concentrations (see Figure 4) have increased by 30% from 280 to 370 parts per million (ppm) (Neftel *et al.*, 1994; Keeling and Whorf, 2000). The reality of this CO_2 increase is unquestioned, and virtually all climatologists agree that the cause is human activity, predominantly the burning of fossil fuels, and to a lesser extent deforestation and other land use changes, along with industrial activities such as cement production.

Figures 1 and 4 taken together show concurrent increases in global temperature and CO_2 concentration, both occurring during an era of rapid industrialization. So, are anthropogenic CO_2 emissions a direct cause of recent warming? As the study summarized in Figure 2 suggested, it looks increasingly like the answer is "yes". But the connection between the past 140 years' warming and the coincident rise in CO_2 is not conclusive. For example, global temperature actually declined in the period after World War II, a time of rapid industrialization when CO_2 concentrations began an especially rapid increase. On the other hand, CO_2 increases do not induce immediate changes in temperature, so we should not expect to find that recent temperature and CO_2 are instantaneously correlated. Moreover, there are other factors that can influence climate fluctuations or trends, and all of these are confounded in the data shown in Figures 1 and 4. Separating the anthropogenic "signal"

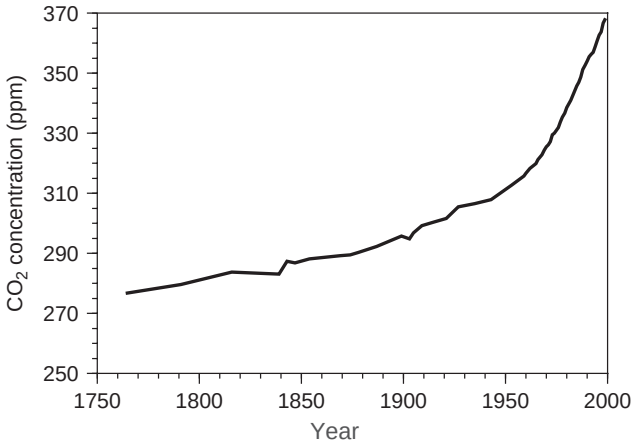

Figure 4 Atmospheric carbon dioxide has increased by more than 30% since preindustrial times (Adapted from Wolfson and Schneider, 2002. Data are from Neftel *et al.*, 1994; and Keeling and Whorf, 2000)

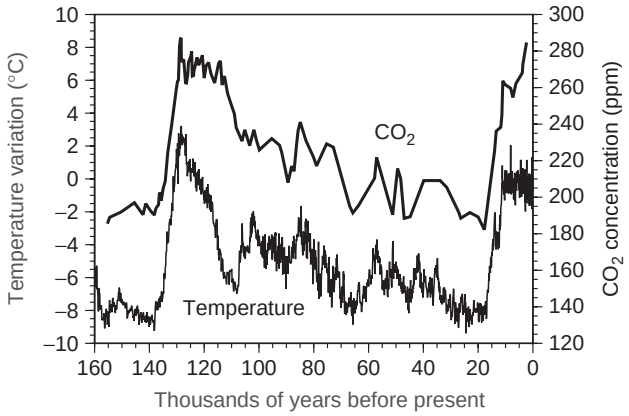

Figure 5 Atmospheric carbon dioxide (upper curve) and temperature variation (lower curve) over the past 160 000 years, from ice cores taken at Vostok, Antarctica. The record shows long stretches of low temperature (ice ages) separated by brief, warm interglacial periods. The correlation between CO_2 and temperature is quite obvious. Note also the small change, averaging perhaps 6 °C, between the present warm climate and the recent ice age. Data do not extend to the present, but stop well before the industrial era (Adapted from Wolfson and Schneider, 2002. CO_2 data are from Petit *et al.*, 2000; temperature data from Jouzel *et al.*, 1987, as reproduced in the Carbon Dioxide Information Analysis Center)

of climate change from the "noise" of natural fluctuations is a complex process.

A clearer relationship emerges when past climate is examined (*see* **Chapter 34, Climate Change – Past, Present and Future, Volume 1**). Ice cores bored from the Greenland and Antarctic ice sheets provide estimates of both temperature and atmospheric CO_2 going back hundreds of thousands of years (Petit *et al.*, 2000; Jouzel *et al.*, 1987). Variations in ice density associated with seasonal snowfall patterns provide a year-to-year calibration of the age of given points in the ice core, and analysis of air bubbles trapped in ancient ice gives an indication of CO_2 concentration. Temperature inference is accomplished by comparing a ratio of oxygen isotopes that is sensitive to temperature. Temperature differentially affects the concentration of the isotopes in evaporating water, and therefore their concentration in precipitation and in the ice itself. The result of such an ice core analysis, shown in Figure 5, gives dramatic evidence that temperature and carbon dioxide concentration are correlated over the long term.

It is not clear from the graph alone that the CO_2 variations in Figure 5 are the cause of the temperature changes. Sometimes a CO_2 increase precedes a warming, but sometimes not. In fact, climatologists suspect a feedback process whereby a slight increase in temperature, probably caused by subtle changes in the Earth's orbit, results in an increase in atmospheric CO_2 through a variety of mechanisms such as the release of CO_2 dissolved in the oceans (IPCC, 2001a; *see* **Chapter 195, Acceleration of the Global Hydrologic Cycle, Volume 5**). The increased atmospheric CO_2, in turn, leads to greenhouse warming, amplifying the initial temperature increase. The result is a nearly simultaneous and substantial increase in both CO_2 and temperature. Eventually, orbital changes trigger a modest temperature decrease, and again feedback mechanisms amplify the decrease, driving down both CO_2 and temperature. Some paleoclimatologists also posit biotic feedback mechanisms, such as an initial cooling, which causes a drying of the continents, producing more windblown dust (IPCC, 2001a). This dust contains minerals needed by phytoplankton in the oceans. As dust settles on the ocean surface, it fertilizes these tiny oceanic organisms. The phytoplankton, in turn, increase their productivity by drawing down atmospheric CO_2, thus making the move toward an ice age even more rapid and deep. But despite such complexities, there is still much regularity in the record. The pattern of varying temperature and carbon dioxide concentration shown in Figure 4 is believed to repeat on a timescale of roughly every 100 000 years over most of the past million years, at least in part as a result of periodic changes in the Earth's orbit and the inclination of its polar axis.

Note that Figure 5 shows brief periods of warmth punctuated by much longer, cooler ice ages, which are characterized by dramatically different climatic conditions, with ice sheets 2 km thick covering what is now Canada, the northeastern United States, and northwestern Europe, and engulfing high mountain plateaus all around the world. Today we enjoy the warmth of an interglacial period, but not long ago, geologically speaking, conditions were very different. Figure 5 shows that the difference in temperature between an interglacial and an ice age is on the order

of 6 °C. Climate models driven by standard assumptions about population, land use, and energy consumption project a warming over the next century of 1.5 °C to 6 °C. The difference between the higher and lower ends of this range has substantial implications for sea level rise, extreme weather, redistribution of species ranges, and other impacts. Policymakers and the general public often ask how a few degrees can matter all that much. Figure 5 provides one striking answer: Downward changes on the same order as the largest projected warming are enough to make the difference between our current climate and an ice age. A few degrees, sustained in time and taken over the entire globe, can make a significant difference – especially when the change occurs many times faster than the comparable changes of the last ice age.

A second important point follows from comparing Figures 4 and 5. Note in Figure 5 that the maximum CO_2 concentration in the ice core record of the past 160 000 years is less than 300 ppm. This does not include the very recent past, but only the preindustrial period. The present-day concentration of 370 ppm in Figure 4 is far above anything the Earth has seen, probably for millions of years. Figure 6 shows the effect of adding the recent rise in CO_2 to the ice core data. Clearly, the anthropogenic increase in CO_2 concentration is unprecedented in both its size and its rapidity. We have made truly dramatic changes in the Earth's atmosphere over the past century or so, and we can almost certainly expect significant climate change to result. To begin to predict the extent of this change, we must examine all of the changes human activities are making to the climate system.

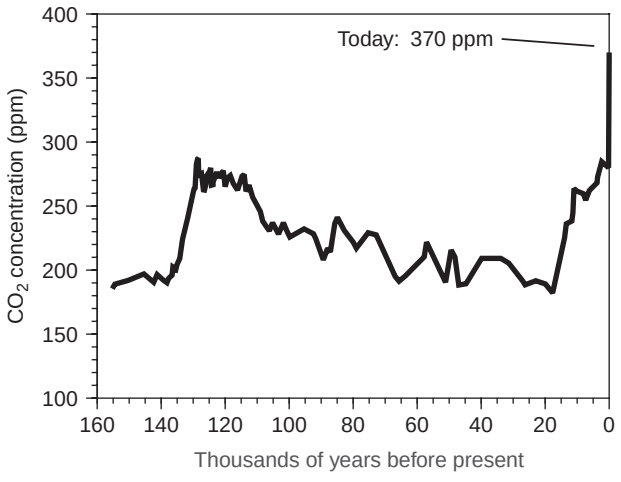

Figure 6 The CO_2 record of Figure 5, with data up to 1999 included. The CO_2 rise of Figure 3 is shown here as a dramatic jump to levels not seen on Earth for hundreds of thousands (and probably millions) of years (Adapted from Wolfson and Schneider, 2002)

HOW ARE WE CHANGING THE CLIMATE?

Although CO_2 is the most significant anthropogenic influence on the climate system, accounting for some 60% of the enhanced infrared blockage, a host of other influences also result from human activities: emissions of other greenhouse gases; feedback effects, whereby human-induced greenhouse warming may influence other processes that either exacerbate or dampen the warming; and emissions of particulate pollution from cars and fossil-fueled power plants, that can result in regional cooling that may mask or reduce the effects of greenhouse warming. We quantify these influences below.

Greenhouse Gases and Radiative Forcing

Carbon Dioxide

CO_2 is the most important of the anthropogenic greenhouse gases in terms of its direct effect on climate, but other gases play a significant role too. On a molecule-to-molecule basis, most other greenhouse gases (except water vapor) are far more potent absorbers of infrared radiation than is CO_2, but they are released in much lesser quantities, so their overall effect on climate is smaller. Climatologists characterize the effect of a given atmospheric constituent by its radiative forcing, the rate at which it alters absorbed solar or outgoing infrared energy. Currently, anthropogenic CO_2 produces a radiative forcing estimated at about 1.5 watts for every square meter of Earth's surface (all forcings cited in this section are from IPCC, 2001a). Relative to the 235 W m^{-2} of solar energy that is absorbed by the Earth and its atmosphere, the CO_2 forcing is a modest perturbation of the overall energy balance; but regardless of its size, any forcing affecting the energy balance will shift climate over time.

Methane

The second most prevalent anthropogenic greenhouse gas is methane (CH_4), produced naturally and anthropogenically, when organic matter decays anaerobically. Such anaerobic decay occurs in swamps, landfills, rice paddies, land submerged by hydroelectric dams, the guts of termites, and the stomachs of ruminants such as cattle. Methane is also released by oil and gas drilling, coal mining, volcanic eruptions, and the warming of methane-containing compounds on the ocean floor. One methane molecule is roughly 30 times more effective at blocking infrared than is one CO_2 molecule, although this comparison varies with the timescale involved, and the presence of other pollutants. Whereas CO_2 concentration increases tend to persist in the atmosphere for centuries or longer, the more chemically active methane typically disappears in decades, making its warming potential relative to that of CO_2 lower on longer timescales. Currently, methane accounts for about

$0.5\,W\,m^{-2}$ of anthropogenic radiative forcing, about one-third that of CO_2.

Nitrous Oxide and Halocarbons

Other anthropogenic greenhouse gases include nitrous oxide, produced from agricultural fertilizer and industrial processes, and the halocarbons used in refrigeration. (A particular class of halocarbons – the chlorofluorocarbons (CFCs) – is also the leading cause of stratospheric ozone depletion. Newer halocarbons do not cause severe ozone depletion but are still potent greenhouse gases.) Together, nitrous oxide and halocarbons account for roughly another $0.5\,W\,m^{-2}$ of radiative forcing. A number of other trace gases contribute roughly $0.05\,W\,m^{-2}$ of additional forcing. All the gases mentioned so far are well mixed, meaning that they last long enough to be distributed in roughly uniform concentrations throughout the lowest 10 km of the atmosphere.

Ozone

Another greenhouse gas is ozone (O_3), familiar because of its depletion by anthropogenic CFCs. Ozone occurring naturally in the stratosphere (some 10–50 km above the surface) absorbs incoming ultraviolet radiation and protects life from UV-induced cancer and genetic mutations, hence the concern about ozone depletion and in particular the polar "ozone holes". Unfortunately, ozone depletion and global warming have become confused in the public mind, even among political leaders and some environmental policymakers. But the two are very distinct problems. The ozone depletion problem is not the same as the global warming problem. Ozone depletion eventually will come under control because of the 1987 Montreal Protocol and its subsequent strengthening accords, international agreements that ban the production of the chlorinated fluorocarbons that destroy stratospheric ozone.

Because ozone is a greenhouse gas, there are some direct links between greenhouse warming and anthropogenic changes in atmospheric ozone. Ozone in the lower atmosphere – the troposphere – is a potent component of photochemical smog, resulting largely from motor vehicle emissions. Tropospheric ozone contributes roughly another $0.35\,W\,m^{-2}$ of radiative forcing, although, unlike the well-mixed gases, tropospheric ozone tends to be localized where industrialized society is concentrated. In the stratosphere, the situation is reversed. Here the anthropogenic effect has been ozone depletion, resulting in a negative forcing of approximately $-0.15\,W\,m^{-2}$. Thus stratospheric ozone depletion, on its own, would cause a slight global cooling. Taken in the context of the more substantial positive forcings of other gases, though, the effect of stratospheric ozone depletion is a slight reduction of the potential for global warming, an effect that will diminish as the ozone layer gradually recovers under the Montreal Protocol's ban on chlorofluorocarbons. The net effect of all anthropogenic ozone (both tropospheric and stratospheric) probably amounts to a slight positive forcing. The net forcing to date from all anthropogenic gases probably is about $3\,W\,m^{-2}$, and is expected to become much larger if business-as-usual development scenarios are followed in the twenty-first century.

Aerosols

Fuel combustion, and to a lesser extent agricultural and industrial processes, produce not only gases but also particulate matter. Coal-fired power plants burning high-sulfur coal, in particular, emit gases that become sulfate aerosols that reflect incoming solar radiation and thus result in a cooling trend. Natural aerosols from volcanic eruptions and the evaporation of seawater also produce a cooling effect. However, diesel engines and some biomass burning produce black aerosols such as soot, which can warm the climate. Recent controversial estimates suggest that these could offset much of the cooling from sulfate aerosols, especially in polluted parts of the subtropics (Jacobson, 2001). The IPCC estimates the total radiative forcing resulting directly from all anthropogenic aerosols very roughly at about $-1\,W\,m^{-2}$. However, this figure is much less certain than the radiative forcings caused by the greenhouse gases. Furthermore, aerosol particles also exert an indirect effect, in that they act as "seeds" for the condensation of water droplets to form clouds (*see* **Chapter 196, The Role of Water Vapor and Clouds in the Climate System, Volume 5**). Thus, the presence of aerosols affects the size and number of cloud droplets. An increase in sunlight reflected by these aerosol-altered clouds may result in $-2\,W\,m^{-2}$ of potential radiative forcing. Similarly, soot particles mixed into clouds can make the droplets absorb more sunlight, producing some warming. Taken together, aerosols add an element of uncertainty into anthropogenic radiative forcing of about $1\,W\,m^{-2}$ and complicate attempts to discern an anthropogenic signal of climatic change from the noise of natural climatic fluctuations.

Solar Variability

Another important influence on the climate system not affected by human activities should be mentioned here, variation in the Sun's energy output. Variations caused by the 22-year solar activity cycle amount to only about 0.1% and are too small and occur too rapidly to have a significant climatic effect. However, long-term solar variations, either from variability at the Sun itself, or from changes in the Earth's orbit and inclination, have substantially affected Earth's climate over geologic time. Although accurate, satellite-based measurements of solar output are available for only a few decades, indirect evidence of solar activity allows us to estimate past

variations in solar energy output (Hoyt and Schatten, 1997). Such evidence suggests that solar forcing since preindustrial times amounts to about $0.3\,W\,m^{-2}$, which is enough to contribute somewhat to observed global climate change, but far below what is needed to account for the warming of recent decades. However, there is some speculation that magnetic disturbances from the Sun can influence the flux of energetic particles impinging on the Earth's atmosphere, which in turn affect stratospheric chemical processes and might thus indirectly alter the global energy balance. These speculations have led some to declare the warming of the past century to be wholly natural, but this notion is discounted by nearly all climatologists for two reasons: first, there is no demonstrated way in which solar energetic particles can have a large enough effect to account for the recent warming and, second, because it is unlikely that such solar magnetic events happened only in the past few decades and not any other time over the past 1000 years. Assessment groups such as the IPCC are convened to sort out such claims and to weigh their relative probabilities. That is why we report primarily the IPCC assessments rather than the claims of a few individual scientists.

Radiative Forcing: The Overall Effect

Figure 7 summarizes our current understanding of radiative forcings caused by greenhouse gases, aerosols, land use changes, solar variability, and other effects since the start of the industrial era. The negative forcings from some of these anthropogenic changes might appear sufficient to offset the warming caused by anthropogenic greenhouse gases. This implication is misleading, however, because the effects of aerosols are short-lived and geographically localized compared with the long-term, global effects of the well-mixed greenhouse gases. The most advanced climate models (*see* **Chapter 32, Models of Global and Regional Climate, Volume 1**, **Chapter 201, Land-Atmosphere Models for Water and Energy Cycle Studies, Volume 5**) are driven by a range of plausible assumptions for future emissions of all types and make it clear that the overall effect of human activity is almost certainly a net positive forcing.

Feedback Effects

Knowing the radiative forcing caused by changes in atmospheric constituents would be sufficient to project future climate if there were no additional climatic effects beyond the direct change in energy balance. But a change in climate caused by simple forcing can have significant effects on atmospheric, geological, oceanographic, biological, chemical, and even social processes. These effects, in turn, can further alter the climate. If that further alteration is in the same direction as its initial cause, then the effect is called a *positive feedback*. If the further alteration tends to counter the initial change, then it is a negative feedback. In reality, numerous feedback effects greatly complicate the full description of climate change. Here we list just a few to give a sense of their variety and complexity.

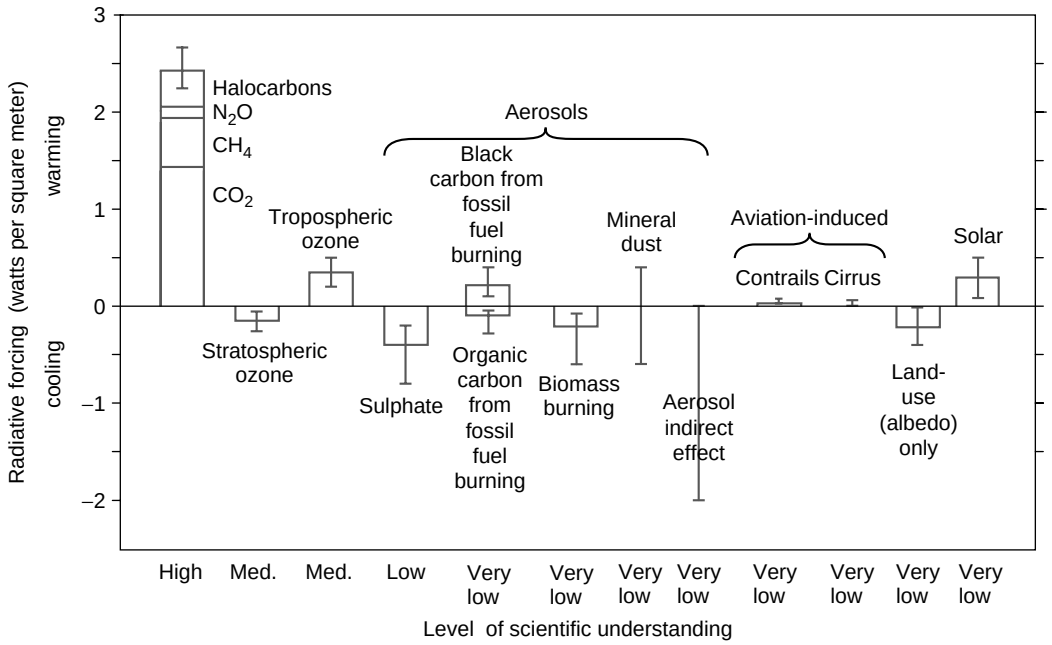

Figure 7 Radiative forcings caused by anthropogenic greenhouse gases, particulate emissions (aerosols), and other processes. Vertical bars indicate relative uncertainties, and the overall level of scientific understanding of and confidence in these processes is listed below the graph. (Adapted from Wolfson and Schneider, 2002. Data from IPCC, 2001a)

Ice-albedo Feedback

Albedo is a planet's reflectance of incident sunlight. The Earth's albedo is about 0.31, meaning that 31% of incident sunlight is reflected back to space. A decrease in that number would mean more sunlight absorbed, which would increase global temperature. One likely consequence of rising temperature is the melting of some ice and snow, that would eliminate a highly reflective surface and expose the darker land or water beneath the ice. The result is a decreased albedo, increased energy absorption, and additional heating. This is a positive feedback.

Hydrologic Feedbacks

Rising temperature also results in increased evaporation of water from the oceans (*see* **Chapter 195, Acceleration of the Global Hydrologic Cycle, Volume 5**). That means more water vapor in the atmosphere. Because water vapor is itself a greenhouse gas, this effect results in still more warming and is thus a positive feedback. But increased water vapor in the atmosphere might mean more widespread cloudiness, which reflects sunlight and thus raises the albedo, resulting in less energy absorbed by the Earth-atmosphere system. The result is a negative feedback, tending to counter the initial warming. On the other hand, clouds also absorb outgoing infrared, resulting in a warming – a positive feedback. There are actually a number of processes associated with clouds, some of which produce warming, and some, cooling (*see* **Chapter 196, The Role of Water Vapor and Clouds in the Climate System, Volume 5**). These effects vary with the type of cloud, the location, and the season. Our limited understanding of cloud effects is one of the greatest sources of uncertainty in global climate sensitivity and thus in climate projections. However, the best estimates suggest that the overall effect of increased water vapor is a positive feedback that causes a temperature increase at least 50% higher than would occur in the absence of this feedback mechanism (Harvey, 2000, Chapter 9).

Biological Feedbacks

Some feedbacks are biological. For example, increased atmospheric CO_2 stimulates plant growth, and plants in turn remove CO_2 from the atmosphere. This is a negative feedback. On the other hand, warmer soil temperatures stimulate microbial action that releases CO_2 – a positive feedback effect. Drought and desertification resulting from climate change can alter the albedo of the land by replacing dark plant growth with lighter soil and sand. Greater reflection of sunlight results in cooling, so this is a negative feedback. But here, as so often with the climate system, the situation is even more complex. If sand is wet, as on a beach, then it is darker, and therefore absorbs more sunlight than dry sand. Yet dry sand is hotter. The resolution of this conundrum is that the wet sand is cooler because of the cooling effects of evaporation, but the Earth is warmed by the wet sand because the evaporated water condenses in clouds elsewhere and puts the heat back into the overall system. Thus, cooling or warming of the Earth-atmosphere system does not always imply cooling or warming of the Earth's surface at that location. There are even social feedbacks. For example, rising temperature causes more people to install air conditioners. The resulting increase in electrical consumption means more fossil fuel-generated atmospheric CO_2 – again giving a positive feedback.

Accounting for all significant feedback effects entails not only identifying important feedback mechanisms but also developing a quantitative understanding of how those mechanisms work. That understanding often includes research at the boundaries of disciplines such as atmospheric chemistry and oceanography, biology and geology, even economics and sociology.

With positive feedback, there is a danger of runaway warming, whereby a modest initial warming triggers a positive feedback that results in additional warming. This feedback could lead to extreme climate change. That is what has happened on Venus, where the thick, CO_2-rich atmosphere produced a runaway greenhouse effect that gives Venus its abnormally high surface temperature. Fortunately, we believe that the conceivable terrestrial feedbacks, at least under the Earth's current conditions, are incapable of such dramatic effects. But while that means we are not going to boil the oceans away, it does not preclude potentially disruptive climatic change.

HOW MUCH WILL THE CLIMATE CHANGE?

Climate Model Projections

Uncertainty in greenhouse gas emissions, the magnitude of their influence on the changing climate, and the host of other processes affected by increases in radiative forcing from greenhouse gas emissions demonstrate that projected future climate change is a complex task. The most sophisticated tools we have are global models of the climate system. Today's climate models (*see* **Chapter 32, Models of Global and Regional Climate, Volume 1**) provide geographic resolution down to the scale of a small country. Not only can they reproduce global temperature records, as shown in Figure 3, but the best model results reproduce, although not completely, the detailed geographic patterns of temperature, precipitation, and other climatic variables seen on a regional scale. These pattern-based comparisons of models and reality provide further confirmation of the models' essential validity.

No one model validation experiment alone is enough to give us high confidence in future climate projections. But considered together, results from the wide

range of published experiments probing the validity of climate models give considerable confidence that these models are treating the essential climate-determining processes with reasonable accuracy. Therefore, we can expect from them moderately realistic projections of future climate, given credible emission scenarios. However, we still expect variations in the projections of different models. And because future greenhouse gas emissions depend on human behavior, future projections will differ depending on what assumptions modelers make about the human response to global climate change. The uncertainties in projections of human behavior cause about as much spread in estimates of future warming as do uncertainties about the sensitivity of the climate system to radiative forcings.

Consequences from Global Climate Change

Taking all of these issues into account, the current consensus modeling estimate, as mentioned previously, is a global average temperature increase over the current century of anywhere between 1.5 and 6 °C (IPCC, 2001a). This increase may seem modest, but as we noted, it could imply quite serious impacts. What might be the consequences? The most sophisticated climate models speak to a wide variety of possible impacts from global climate change. Recall that a 6 °C temperature drop means the difference between the Earth's present climate and an ice age. Fortunately, it does not appear that a comparable rise will have consequences as devastating as 2-km-thick ice sheets over populated areas of the Northern Hemisphere. But that does not mean the consequences of a few degrees' global warming will not be substantial and disruptive. How will the temperature rise be distributed in time and in space? In fact, global climate change will vary substantially from one geographical region to another, and it will have different effects during night and day, winter and summer, and on land and sea.

Climate models provide rough consensus on many temperature-related projections. In general, projected temperature rises are greatest in the polar regions, and they affect the polar winter more dramatically than the summer. Similarly, nighttime temperatures are projected to rise more than daytime temperatures. Land temperatures are projected to rise more than oceans for the most part, influencing the patterns of monsoons and life-giving rains (and deadly floods) that they engender (*see* **Chapter 195, Acceleration of the Global Hydrologic Cycle, Volume 5**). Other temperature-related consequences include increases in maximum-observed temperatures and more hot days, increases in minimum temperatures and fewer cold days, and longer growing seasons owing to earlier last frosts and later first frosts. All these trends have already been seen in the climate change of the past few decades, and all are projected to continue through the present century. Climatologists' assessed confidence in these projections ranges from "likely" (two-thirds to 90% probability) to "very likely" (90 to 99% probability). Table 1 summarizes these and other effects of global climate change, and gives the IPCC's quantitative estimates of the probability of each effect (IPCC, 2001b).

The broadest impacts of direct temperature effects on human society are likely to be in agriculture and water supplies. However, health effects, including the spread of lowland tropical diseases, vertically upward to plateaus and mountains and horizontally into temperate regions, may also be significant depending on the effectiveness of adaptive measures to reduce the threat. Natural ecosystems may also respond adversely to global climate change. With temperatures changing much more rapidly than in most natural sustained climatic shifts, temperature-sensitive plant species may find themselves unable to migrate fast enough to keep up with the changing climate. Even though their suitable habitat may shift only a few hundred kilometers, if plant species cannot reestablish themselves fast enough then they – and many animal species that depend on them – will go at least locally extinct. This is not just theory. Recent analyses of over 1000 published studies have shown that, among other impacts, birds are laying eggs a few weeks earlier, butterflies are moving up mountains, and trees are blooming earlier in the spring and dropping their leaves later in the fall. In her capacity as a lead author for IPCC Working Group II, Terry Root led a group that combed recent literature to conclude that the most consistent explanation for these observed changes in environmental systems over the past few decades is warming on a global scale, and it appears that there is a discernible impact of regional climate change on wildlife and other environmental systems (Root and Schneider, 2002). The responses observed are, in about 80% of the cases, in the direction expected with warming.

Rising temperature also means rising sea level. A popular misconception holds that this is because of melting arctic ice. Actually, ice now floating on the oceans has no direct effect on sea level if it melts. Glaciers and the large ice sheets covering Greenland and Antarctica are a different story, as meltwater from these sources does increase sea level. But the bulk of sea level rise observed to date or expected in the next century comes from the simple thermal expansion of seawater – the same process that drives up the liquid in a mercury thermometer. Determining a global average level for the world ocean is difficult, but measurements suggest that sea level rose some 10–20 cm during the twentieth century. Climate models suggest that the rate of rise should increase as much as fourfold through the current century, resulting in a rise most likely near half a meter. This may not seem like much, but it adds to the highest tides and to

Table 1 Projected effects of global climate change in the twenty-first century (Adapted from Wolfson and Schneider, 2002)

Projected effect	Probability estimate	Examples of projected impacts with high confidence of occurrence (67–95% probability) in at least some areas
Higher maximum temperatures, more hot days and heat waves over nearly all land areas	Very likely (90–99%)	• Increased deaths and serious illness in older age groups and urban poor • Increased heat stress in livestock and wildlife • Shift in tourist destinations • Increased risk of damage to a number of crops • Increased electric cooling demand and reduced energy supply reliability
Higher minimum temperatures, fewer cold days, frost days and cold waves over nearly all land areas	Very likely (90–99%)	• Decreased cold-related human morbidity and mortality • Decreased risk of damage to a number of crops, and increased risk to others • Extended range and activity of some pest and disease vectors • Reduced heating energy demand
More intense precipitation events	Very likely (90–99%) over many areas	• Increased flood, landslide, avalanche, and mudslide damage • Increased soil erosion • Increased flood runoff increasing recharge of some floodplain aquifers • Increased pressure on government and private flood insurance systems and disaster relief
Increased summer drying over most mid-latitude continental interiors and associated risk of drought	Likely (67–90%)	• Decreased crop yields • Increased damage to building foundations caused by ground shrinkage • Decreased water resource quantity and quality • Increased risk of forest fire
Increase in tropical cyclone peak wind intensities, mean and peak precipitation intensities	Likely (67–90%) over some areas	• Increased risks to human life, risk of infectious disease epidemics and many other risks • Increased coastal erosion and damage to coastal buildings and infrastructure • Increased damage to coastal ecosystems such as coral reefs and mangroves
Intensified droughts and floods associated with El Niño events in many different regions	Likely (67–90%)	• Decreased agricultural and rangeland productivity in drought- and flood-prone regions • Decreased hydropower potential in drought-prone regions
Increased Asian summer monsoon precipitation variability	Likely (67–90%)	• Increase in flood and drought magnitude and damages in temperate and tropical Asia
Increased intensity of mid-latitude storms	Uncertain (current models disagree)	• Increased risks to human life and health • Increased property and infrastructure losses • Increased damage to coastal ecosystems

Source: IPCC, 2001b.

the surges associated with major storms (the intensity of which is also expected to increase – see Table 1). Given that much of the world's population lives close to sea level, even a half-meter rise could have serious consequences in some regions, particularly those such as Bangladesh, which possess minimal resources and infrastructure to adapt to rising seas and higher storm surges. However, slow processes such as glacial melting would go on for many centuries, even after greenhouse gas emissions had long been replaced with nonemitting alternative energy systems. Thus, if humans use a substantial fraction of remaining fossil fuels and dump the greenhouse gases produced from their combustion into the atmosphere, then sea level is expected to go on rising, perhaps by several meters or more, over the thousand years that would follow the end of the fossil fuel era (IPCC, 2001c).

Other weather-related projections include increased frequency of intense precipitation events, more heat waves in which the temperature remains at high levels for an extended time, fewer cold waves, more summer droughts,

Table 2 Regional Adaptive capacity, vulnerability, and key concerns[a,b] (relevant sections of the technical summary of IPCC, 2001b for each example are given in square brackets)

Region	
Africa	• Adaptive capacity of human systems in Africa is low due to lack of economic resources and technology, and vulnerability high as a result of heavy reliance on rain-fed agriculture, frequent droughts and floods, and poverty. [5.1.7] • Grain yields are projected to decrease for many scenarios, diminishing food security, particularly in small food-importing countries *(medium to high confidence*[6]). [5.1.2] • Major rivers of Africa are highly sensitive to climate variation; average runoff and water availability would decrease in Mediterranean and southern countries of Africa *(medium confidence*[6]). [5.1.1] • Extension of ranges of infectious disease vectors would adversely affect human health in Africa *(medium confidence*[6]). [5.1.4] • Desertification would be exacerbated by reductions in average annual rainfall, runoff, and soil moisture, especially in southern, North, and West Africa *(medium confidence*[6]). [5.1.6] • Increases in droughts, floods, and other extreme events would add to stresses on water resources, food security, human health, and infrastructures, and would constrain development in Africa *(high confidence*[6]). [5.1] • Significant extinctions of plant and animal species are projected and would impact rural livelihoods, tourism, and genetic resources *(medium confidence*[6]). [5.1.3] • Coastal settlements in, for example, the Gulf of Guinea, Senegal, Gambia, Egypt, and along the East–Southern African coast would be adversely impacted by sea level rise through inundation and coastal erosion *(high confidence*[6]). [5.1.5]
Asia	• Adaptive capacity of human systems is low and vulnerability is high in the developing countries of Asia; the developed countries of Asia are more able to adapt and less vulnerable. [5.2.7] • Extreme events have increased in temperate and tropical Asia, including floods, droughts, forest fires, and tropical cyclones *(high confidence*[6]). [5.2.4] • Decreases in agricultural productivity and aquaculture due to thermal and water stress, sea level rise, floods and droughts, and tropical cyclones would diminish food security in many countries of arid, tropical, and temperate Asia; agriculture would expand and increase in productivity in northern areas *(medium confidence*[6]). [5.2.1] • Runoff and water availability may decrease in arid and semiarid Asia but increase in northern Asia *(medium confidence*[6]). [5.2.3] • Human health would be threatened by possible increased exposure to vector-borne infectious diseases and heat stress in parts of Asia (*medium confidence*[6]). [5.2.6] • Sea level rise and an increase in the intensity of tropical cyclones would displace tens of millions of people in low-lying coastal areas of temperate and tropical Asia; increased intensity of rainfall would increase flood risks in temperate and tropical Asia *(high confidence*[6]). [5.2.5 and Table TS-8] • Climate change would increase energy demand, decrease tourism attraction, and influence transportation in some regions of Asia *(medium confidence*[6]). [5.2.4 and 5.2.7] • Climate change would exacerbate threats to biodiversity due to land use and land-cover change and population pressure in Asia *(medium confidence*[6]). Sea level rise would put ecological security at risk, including mangroves and coral reefs *(high confidence*[6]). [5.2.2] • Poleward movement of the southern boundary of the permafrost zones of Asia would result in a change of thermokarst and thermal erosion with negative impacts on social infrastructure and industries *(medium confidence*[6]). [5.2.2]
Australia and New Zealand	• Adaptive capacity of human systems is generally high, but there are groups in Australia and New Zealand, such as indigenous peoples in some regions, with low capacity to adapt and consequently high vulnerability. [5.3 and 5.3.5] • The net impact on some temperate crops of climate and CO_2 changes may initially be beneficial, but this balance is expected to become negative for some areas and crops with further climate change *(medium confidence*[6]). [5.3.3] • Water is likely to be a key issue *(high confidence*[6]) due to projected drying trends over much of the region and change to a more El Niño-like average state. [5.3 and 5.3.1] • Increases in the intensity of heavy rains and tropical cyclones *(medium confidence*[6]), and region-specific changes in the frequency of tropical cyclones, would alter the risks to life, property, and ecosystems from flooding, storm surges, and wind damage. [5.3.4] • Some species with restricted climatic niches and which are unable to migrate because of fragmentation of the landscape, soil differences, or topography could become endangered or extinct *(high confidence*[6]). Australian ecosystems that are particularly vulnerable to climate change include coral reefs, arid and semiarid habitats in southwest and inland Australia, and Australian alpine systems. Freshwater wetlands in coastal zones in both Australia and New Zealand are vulnerable, and some New Zealand ecosystems are vulnerable to accelerated invasion by weeds. [5.3.2]

Table 2 (*continued*)

Region	
Europe	• Adaptive capacity is generally high in Europe for human systems; southern Europe and the European Arctic are more vulnerable than other parts of Europe. [5.4 and 5.4.6] • Summer runoff, water availability, and soil moisture are likely to decrease in southern Europe, and would widen the difference between the north and drought-prone south; increases are likely in winter in the north and south *(high confidence*[6]). [5.4.1] • Half of alpine glaciers and large permafrost areas could disappear by end of the twenty-first century *(medium confidence*[6]). [5.4.1] • River flood hazard will increase across much of Europe *(medium to high confidence*[6]); in coastal areas, the risk of flooding, erosion, and wetland loss will increase substantially with implications for human settlement, industry, tourism, agriculture, and coastal natural habitats. [5.4.1 and 5.4.4] • There will be some broadly positive effects on agriculture in northern Europe *(medium confidence* 6); productivity will decrease in southern and eastern Europe *(medium confidence*[6]). [5.4.3] • Upward and northward shift of biotic zones will take place. Loss of important habitats (wetlands, tundra, isolated habitats) would threaten some species *(high confidence*[6]). [5.4.2] • Higher temperatures and heat waves may change traditional summer tourist destinations, and less reliable snow conditions may impact adversely on winter tourism *(medium confidence*[6]) . [5.4.4]
Latin America	• Adaptive capacity of human systems in Latin America is low, particularly with respect to extreme climate events, and vulnerability is high. [5.5] • Loss and retreat of glaciers would adversely impact runoff and water supply in areas where glacier melt is an important water source (high confidence[6]). [5.5.1] • Floods and droughts would become more frequent with floods increasing sediment loads and degrade water quality in some areas (high confidence[6]). [5.5] • Increases in intensity of tropical cyclones would alter the risks to life, property, and ecosystems from heavy rain, flooding, storm surges, and wind damages (high confidence[6]). [5.5] • Yields of important crops are projected to decrease in many locations in Latin America, even when the effects of CO_2 are taken into account; subsistence farming in some regions of Latin America could be threatened (high confidence[6]). [5.5.4] • The geographical distribution of vector-borne infectious diseases would expand poleward and to higher elevations, and exposures to diseases such as malaria, dengue fever, and cholera will increase (medium confidence[6]). [5.5.5] • Coastal human settlements, productive activities, infrastructure, and mangrove ecosystems would be negatively affected by sea level rise (medium confidence[6]). [5.5.3] • The rate of biodiversity loss would increase (high confidence[6]). [5.5.2]
North America	• Adaptive capacity of human systems is generally high and vulnerability low in North America, but some communities (e.g., indigenous peoples and those dependent on climate-sensitive resources) are more vulnerable; social, economic, and demographic trends are changing vulnerabilities in subregions. [5.6 and 5.6.1] • Some crops would benefit from modest warming accompanied by increasing CO_2, but effects would vary among crops and regions *(high confidence*[6]), including declines caused by drought in some areas of Canada's Prairies and the U.S. Great Plains, potential increased food production in areas of Canada north of current production areas, and increased warm-temperate mixed forest production *(medium confidence* 6). However, benefits for crops would decline at an increasing rate and possibly become a net loss with further warming *(medium confidence*[6]). [5.6.4] • Snowmelt-dominated watersheds in western North America will experience earlier spring peak flows *(high confidence*[6]), reductions in summer flows *(medium confidence*[6]), and reduced lake levels and outflows for the Great Lakes-St. Lawrence under most scenarios *(medium confidence*[6]); adaptive responses would offset some, but not all, of the impacts on water users and on aquatic ecosystems *(medium confidence*[6]). [5.6.2] • Unique natural ecosystems such as prairie wetlands, alpine tundra, and cold-water ecosystems will be at risk and effective adaptation is unlikely *(medium confidence*[6]). [5.6.5] • Sea level rise would result in enhanced coastal erosion, coastal flooding, loss of coastal wetlands, and increased risk from storm surges, particularly in Florida and much of the U.S. Atlantic coast *(high confidence*[6]). [5.6.1] • Weather-related insured losses and public sector disaster relief payments in North America have been increasing; insurance sector planning has not yet systematically included climate change information, so there is potential for surprise *(high confidence*[6]). [5.6.1] • Vector-borne diseases – including malaria, dengue fever, and Lyme disease – may expand their ranges in North America; exacerbated air quality and heat stress morbidity and mortality would occur *(medium confidence*[6]); socioeconomic factors and public health measures would play a large role in determining the incidence and extent of health effects. [5.6.6]

(*continued overleaf*)

Table 2 (*continued*)

Region	
Polar	• Natural systems in polar regions are highly vulnerable to climate change and current ecosystems have low adaptive capacity; technologically developed communities are likely to adapt readily to climate change, but some indigenous communities, where traditional lifestyles are followed, have little capacity and few options for adaptation. [5.7] • Climate change in polar regions is expected to be among the largest and most rapid of any region on the Earth, and will cause major physical, ecological, sociological, and economic impacts, especially in the Arctic, Antarctic Peninsula, and Southern Ocean (*high confidence*[6]). [5.7] • Changes in climate that have already taken place are manifested in the decrease in extent and thickness of Arctic sea ice, permafrost thawing, coastal erosion, changes in ice sheets and ice shelves, and altered distribution and abundance of species in polar regions (*high confidence*[6]). [5.7] • Some polar ecosystems may adapt through eventual replacement by migration of species and changing species composition, and possibly by eventual increases in overall productivity; ice edge systems that provide habitat for some species would be threatened (*medium confidence*[6]). [5.7] • Polar regions contain important drivers of climate change. Once triggered, they may continue for centuries, long after greenhouse gas concentrations are stabilized, and cause irreversible impacts on ice sheets, global ocean circulation, and sea level rise (*medium confidence*[6]). [5.7]
Small Island States	• Adaptive capacity of human systems is generally low in small island states, and vulnerability high; small island states are likely to be among the countries most seriously impacted by climate change. [5.8] • The projected sea level rise of 5 mm per year for the next 100 years would cause enhanced coastal erosion, loss of land and property, dislocation of people, increased risk from storm surges, reduced resilience of coastal ecosystems, saltwater intrusion into freshwater resources, and high resource costs to respond to and adapt to these changes (*high confidence*[6]). [5.8.2 and 5.8.5] • Islands with very limited water supplies are highly vulnerable to the impacts of climate change on the water balance (*high confidence*[6]). [5.8.4] • Coral reefs would be negatively affected by bleaching and by reduced calcification rates caused by higher CO_2 levels (*medium confidence*[6]); mangrove, sea grass beds, and other coastal ecosystems and the associated biodiversity would be adversely affected by rising temperatures and accelerated sea level rise (*medium confidence*[6]). [4.4 and 5.8.3] • Declines in coastal ecosystems would negatively impact reef fish and threaten reef fisheries, those who earn their livelihoods from reef fisheries, and those who rely on the fisheries as a significant food source (*medium confidence*[6]). [4.4 and 5.8.4] • Limited arable land and soil salinization makes agriculture of small island states, both for domestic food production and cash crop exports, highly vulnerable to climate change (*high confidence*[6]). [5.8.4] • Tourism, an important source of income and foreign exchange for many islands, would face severe disruption from climate change and sea level rise (*high confidence*[6]) . [5.8.5]

[a]Because the available studies have not employed a common set of climate scenarios and methods, and because of uncertainties regarding the sensitivities and adaptability of natural and social systems, the assessment of regional vulnerabilities is necessarily qualitative.
[b]The regions listed in Table 2 are graphically depicted in Figure TS-2 of the Technical Summary of IPCC, 2001b.
Note: Adapted from Wolfson and Schneider, 2002.
Source: IPCC, 2001b.

and more wet spells in winter. The intensity of tropical cyclones (hurricanes and typhoons) is likely to increase, although it is less clear whether the frequency or average locations of these storms will change. Hail and lightning are also likely to become more frequent. The large-scale Pacific Ocean fluctuation known as the *El Niño/Southern Oscillation* could become more persistent, which would have a substantial climatic impact on the Americas and Asia. All these projected changes will impact agriculture and may increase flooding and erosion, with concomitant effects on health and on the insurance industry. As shown in Table 1, confidence in this group of consequences ranges from medium (likelihood between one-third and two-thirds) to high (greater than two out of three chances). Keep in mind, however, that the probabilities given in Table 1 are not based on conventional statistical analysis because they refer to future events that do not follow past patterns – and obviously, the future has not occurred yet. Rather, these are subjective odds based on scientific judgment as sound as current understanding permits.

Finally, there is the remote possibility of dramatic changes such as alterations in large-scale patterns of ocean

circulation or the disintegration of the West Antarctic Ice Sheet. These could occur because the climate system is inherently nonlinear, meaning that a small change in some conditions can produce a disproportionately large change in others. Changes in the Gulf Stream – part of the so-called ocean thermohaline circulation – caused by greenhouse gas emissions, could eventually leave northwest Europe with a much colder climate. Climate models predict with high confidence that the thermohaline circulation will weaken over the present century. But they also suggest, fortunately, that wholesale disruption is very unlikely at least before the year 2100. However, the models also warn that what humans do in the twenty-first century can precondition what the ocean currents will do in the twenty-second century and beyond. Potentially irreversible events could be built into the long-term planetary future even if those of us living in the twenty-first century are spared the experience of those effects (Rahmstorf, 1999; Schneider and Thompson, 2000). Similarly, recent studies suggest that the West Antarctic Ice Sheet is likely to remain stable for the foreseeable future, which is a very good thing because its breakup would result in a rise in sea level by some six meters. But that "unlikely possibility" is not ruled out and looms as a potential threat that we need to check for periodically as we advance our understanding of the climate system and its potential for surprises.

There is one final note on the issue of climatic impacts. In the above example of Bangladesh suffering from sea level rises or more intense storms, we mentioned that adaptation would be difficult. This is much less the case for a richer, more technologically advanced country such as the Netherlands. In fact, as is illustrated in Table 2 (in which IPCC, 2001b authors summarize a comprehensive list of potential climate-change impacts for most regions of the world and economic sectors), a consensus is building in the scientific community that the damages that climatic changes might inflict on societies will depend in part on the adaptive capacities of those future societies, which in turn depend on their resource bases and technological and infrastructure capabilities (IPCC, 2001b). This suggests, as Table 2 notes, that damages may be asymmetrically felt across the developed/developing country divide. The scenario where the northern rich countries get longer growing seasons, and the poor tropical nations get more intense droughts and floods is clearly a situation ripe for increasing tensions in the world of the twenty-first century.

We have given a brief description of the causes and anticipated consequences of global climate change. Even if we humans get our greenhouse gas emissions under control – not a likely occurrence in the near future – global temperature will continue to rise toward a new equilibrium value that will take at least many decades – more likely centuries – to become established. The effects of global climate change, in particular sea level rise, will almost certainly continue to increase beyond the end of the twenty-first century, and they may well become far more dramatic over the following centuries.

34: Climate Change – Past, Present and Future

HENRY HENGEVELD

Meteorological Service of Canada, Toronto, ON, Canada

Local climate is a major determinant of both the composition and behavior of a region's ecosystems and of the infrastructure and culture of human society residing within the region. Hence, climatic statistics are an important factor in ecosystem management and planning for socioeconomic development. However, although decision makers often treat these statistics as a constant, there is clear evidence that climate has changed, is changing, and will change. Large natural changes have occurred in the geologic past. However, these have been relatively modest during the past few millennia. On the other hand, human interference with the climate system, primarily through land use change and changes in atmospheric composition, is now adding an unprecedented and increasingly dominant force for change. There is convincing evidence that this interference has already caused a substantial increase in global mean temperatures over the past 50 years. Projected changes for the next century will likely exceed anything yet experienced in human history and could rival the magnitude of very large changes during the past million years, but at a much more rapid rate. Such rapid change will have dramatic implications for, inter alia, the global hydrological cycle and the frequency and severity of extreme weather events.

INTRODUCTION

Climate is commonly defined as average weather. That is, the climate of a particular locale or region is the average of the day-to-day variations in temperature, precipitation, cloud cover, wind, and other atmospheric conditions that normally occur there over an extended period of time (usually three decades or more). But climate is more than just the sum of these average values. It is also defined by the variability of individual climate elements, such as temperature or precipitation, and by the frequency with which various kinds of weather conditions occur. Indeed, any factor that is characteristic of a particular location's weather pattern is part of its climate.

Although the very notion of climate as described above assumes a long-term consistency and stability in these patterns, climate is, nevertheless, a changeable phenomenon. That is because the Earth's climate system is a dynamic system that continuously responds to forces, both internal and external, that alter the delicate balances that exist within and between each of its components. Often, these changes are relatively small in magnitude and short in duration – like a period of cool climate conditions following a large volcanic eruption. However, evidence from the Earth's soils, its ocean, and lake bottom sediments, its coral reefs, its ice caps, and even its vegetation collectively indicate that such forces can also cause major, long-term shifts in climate. For example, over long timescales of hundreds of thousands of years or more, the Earth's climate has undergone very large shifts from glacial to interglacial conditions and back again – changes that caused global redistributions of flora and fauna. However, during the past 10 000 years of the current interglacial, changes in climate have been of relatively small magnitude and, while from time to time disruptive on a regional scale, have allowed global vegetation to flourish over most land masses.

The focus of this article will be on changes that have occurred over the past century of the current interglacial and that can be expected to occur over the next century. It is within the relatively short time span of the past century that the first real evidence of human interference with the natural processes governing the climate system has become apparent. It is within the next century that such interference is expected to pose the real risk of danger to the well being of global ecosystems and society. However, to understand how these human influences affect climate, it is necessary to

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

provide context by first describing how the climate system works and to discussing in greater detail how and why the Earth's climate of the more distant past has varied and changed.

EARTH'S CLIMATE SYSTEM

Global Energy Balance

In many respects, the Earth's climate system can be thought of as a giant heat engine fueled by incoming energy from the sun. As the solar energy passes through the engine, it warms the Earth and surrounding air, setting the atmospheric winds and the ocean currents into motion and driving the evaporation-precipitation processes of the water cycle. The result of these motions and processes is weather and, hence, climate.

To avoid overheating the climate system, the energy entering the climate system must eventually be released again back to space. As long as the same amount of energy leaves the system as enters it, our atmospheric heat engine will be in balance and the Earth's average temperature will remain relatively constant. However, if the amount of energy entering or leaving the climate system changes, the balance will be upset and global temperatures will change until the system adjusts itself and reaches a new equilibrium. This flow of energy through the climate system is largely regulated by the Earth's atmosphere, although the radiative properties of the Earth's surface are also important factors. The fundamental processes involved are described in the paragraphs below (*see* **Chapter 25, Global Energy and Water Balances, Volume 1**).

Incoming Solar Radiation

Averaged around the world, the amount of sunlight entering the atmosphere is about 342 W m^{-2}. However, as illustrated in Figure 1 (Baede *et al.*, 2001), about 31% of this incoming short wave energy is reflected back to space by the atmosphere and the Earth's surface, unused by the climate system. The remaining 69% (about 235 W m^{-2}) is absorbed within the atmosphere (~20%) and by the Earth's surface (~49%) as the fuel that drives the global climate system. The left side of Figure 1 shows how this incoming energy is reflected and absorbed by the atmosphere and surface. The processes are as follows:

Reflection by the atmosphere and Earth's surface – Clouds and aerosols (fine solid particles and liquid droplets) within the atmosphere reflect and scatter a significant amount of incoming solar radiation back to space. Highly reflective aerosols include tiny droplets of sulfuric acid from volcanic eruptions, sulfates from vegetation fires and industrial processes, salt from sea spray and dust. The amount of shortwave radiation returned to space by clouds and aerosols varies considerably with time and space. For example, major volcanic eruptions can abruptly produce large amounts of highly reflecting sulfate aerosols in the stratosphere that can remain there for several years before they settle out due to the forces of gravity. Alternatively, human emissions of sulfate aerosols into the lower atmosphere can significantly increase the reflection of incoming sunshine in industrialized regions compared to less polluted areas

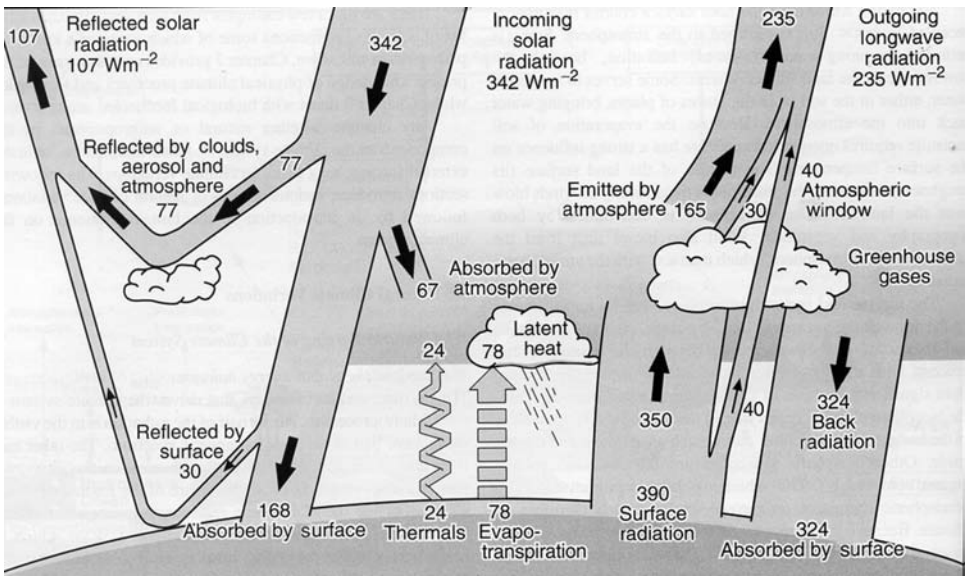

Figure 1 Illustration showing how the atmosphere and earth's surface affects the climate system's incoming and outgoing energy (IPCC Third Assessment Report 2001. Reproduced by permission of Intergovernmental Panel on Climate Change)

of the world. Observational data indicate that, on average, clouds and aerosols currently reflect about 22.5% of incoming radiation back to space. In addition, almost 9% of the solar energy is reflected back to space by the Earth's surface. Like the atmosphere, the albedo (or reflectivity) of the Earth's surface depends on the time of year and the location. That is because snow and ice, which cover much of the Earth's surface in mid to high latitudes in winter, are highly reflective, while ice-free oceans surfaces and bare soils are low reflectors.

Absorption in the atmosphere – In addition to reflecting and scattering solar radiation, the atmosphere also absorbs almost 20% of this energy. About two-thirds of this absorption is caused by water vapor. A second significant absorber is the ozone layer in the stratosphere, which absorbs much of the ultraviolet part of incoming solar energy. Thus, this layer not only protects the Earth's ecosystem from the harmful effects of this radiation but also retains a portion of the sun's energy in the upper atmosphere. Another one-tenth of the absorption can be attributed to clouds. Finally, a small fraction of the absorption can be attributed to other greenhouse gases and to aerosols (particularly dark aerosols such as soot). However, most of the gases of the atmosphere are relatively transparent to incoming sunlight.

Outgoing Heat Radiation

The Earth's atmosphere and surface, heated by the unreflected portion of the sun's rays, eventually release this energy back to space again by giving off long-wave infrared radiation. When the climate system is in equilibrium, the total amount of energy released back to space by the climate system must, on average, be the same as that which it absorbs from the incoming radiation – that is, $235\,W\,m^{-2}$. However, as the infrared radiation tries to escape to space, it encounters several major obstacles. These can be described as follows:

Clouds. Besides reflecting incoming solar radiation, clouds also absorb large quantities of outgoing heat radiation. The energy absorbed by clouds is reradiated, much of it back to the surface. That is why air near the Earth's surface is usually much warmer on a cloudy night than on a clear one. The amount of radiation absorbed and returned depends on the amount, thickness, and type of cloud involved.

Absorbing gases – A number of naturally occurring minor gases within the atmosphere, most of which are relatively transparent to incoming sunlight, absorb most of the infrared heat energy being transmitted by the Earth toward space. This absorbed energy is then reradiated in all directions, some back to the surface and some upward where other absorbing molecules at higher levels in the atmosphere are ready to absorb the energy again. Eventually, the absorbing molecules in the upper part of the atmosphere emit the energy directly to space. Hence, these gases make the atmosphere opaque to outgoing heat radiation, much as opaque glass will affect the transmission of visible light. Together with clouds, they provide an insulating blanket around the Earth, keeping it warm. Because they retain heat in somewhat the same way that glass does in a greenhouse, this phenomenon has been called the *greenhouse effect*, and the absorbing gases that cause it, *greenhouse gases*. Important, naturally occurring greenhouse gases include water vapor, carbon dioxide, methane, ozone, and nitrous oxide.

The magnitude of the thermal-insulating effect caused by greenhouse gases and clouds can be estimated fairly easily. Theoretically, the average radiating temperature required to release $235\,W\,m^{-2}$ to space is $-19\,^{\circ}C$. Yet, we know from actual measurements that the Earth's average surface temperature is more like $+14\,^{\circ}C$, some $33\,^{\circ}C$ higher. This additional warming is a result of the greenhouse effect. It is enough to make the difference between a planet that is warm enough to support life and one like the moon that is not.

Dynamics of the Climate System

Climate and climate variability at the Earth's surface are ultimately consequences of the way the atmosphere and the oceans redistribute and release heat energy that the Earth has absorbed from the sun. Because the intensity of the solar radiation changes with latitude, time of day and seasons, all parts of the planet are not heated equally. The heating effect is greatest in the tropics, where more energy is received from the sun then is reradiated back to space. Temperatures here are subsequently much warmer than the global average, remaining consistently within a few degrees of $30\,^{\circ}C$ during all seasons of the year. At the opposite extreme, the Earth's polar regions experience a net loss of energy to space. The magnitude of this loss varies significantly with time, being largest in winter seasons and weakest in summer. Hence, temperatures in polar regions can vary from highs of nearly $20\,^{\circ}C$ in northern polar summers to a low of $-60\,^{\circ}C$ in southern polar winters.

These large temperature differences between the tropics and the poles are the primary driving force for Earth's atmospheric winds and ocean currents. Essentially, these carry warm air and water from the equator to the poles, while cold air and water move in the opposite direction. This flow is modified, however, by the Earth's spin about its axis and the effects of landmasses and topography to produce a complex pattern of vertical and horizontal circulation of air masses and ocean waters.

Much of the sun's energy absorbed at the Earth's surface is used to evaporate water from ocean and land surfaces and ecosystems. The more heat at the surface and the warmer the air temperature, the greater the amount of water vapor that can be evaporated from the surface and retained within the atmosphere. Once air becomes

saturated with water vapor, it condenses again into tiny water droplets or ice crystals that form clouds. When the conditions are right, these droplets or crystals fall to the ground as precipitation. Where, when, how much, and what type of precipitation falls will depend on the characteristics of a range of local atmospheric and surface factors. Furthermore, since atmospheric moisture is also transported horizontally by air currents, the precipitation patterns that emerge around the Earth are also influenced by the global atmospheric circulation patterns. As a result, the distribution of precipitation around the globe presents an even more complex pattern than that for atmospheric circulation. Some areas receive large surpluses of rainfall, which support very lush, rich ecosystems, while others do not receive enough to nourish vegetation and so become deserts (*see* **Chapter 195, Acceleration of the Global Hydrologic Cycle, Volume 5**).

Numerous other factors also affect the Earth's climate. In addition to the circulation of the air, the currents of the ocean and the surface properties that influence evaporation processes, we must also consider the effects of clouds and of snow and ice, the influence of topography and the impact of processes and activities within the biosphere. To these we must add the variations in solar heating with time, not only between seasons but also during each day.

All of these elements are interconnected, interacting parts of the climate system. If a change in one of these parts upsets the balance of that system, it is likely to initiate complex reactions in some or all of the other parts as the system adjusts to establish a new equilibrium. Some reactions occur very rapidly, while others occur very, very slowly. Furthermore, some may increase the initial change (a process known as *positive feedback*), while others may oppose and partially offset it (a *negative feedback*). For example, anything that changes the amount of solar energy entering the atmosphere or the amount of this energy absorbed by the atmosphere will alter the amount of input energy that drives the climate system. Likewise, a change in the net amount of energy released by the climate system back to space will cause a change in the Earth's cooling mechanism. Such initial changes will cause reactions and feedbacks in the rest of the system and accompanying changes in surface climates until the system adjusts to a new balance at the top of the atmosphere between the incoming and outgoing energy.

CLIMATES OF THE PAST

Reconstructing Past Climates

Within the rich diversity of living species around the world, there are those that thrive in hot climates and others that prefer cooler and even cold climates. Some like it wet, and some like it dry. The result is a broad range in the composition of regional ecosystems, with the characteristics of each largely determined by its prevailing climate. Therefore, if the climate of a particularly region changes over time, so will its ecological composition. As these species procreate and eventually die, they also leave vestiges of their presence in the surrounding ice, soils, rocks, corals, and/or lake and ocean sediments – letting the paleoclimatologists who later analyze these repositories know that they have been there, and informing these researchers about the environment within which they existed. These indicators of past ecological composition provide an abundance of evidence as to how climates have varied and changed over timescales that vary from hundreds to many millions of years. There are also other nonbiotic proxies for past climate, such as the vertical heat profile in the Earth's crust or the isotopic composition of ice buried in polar or alpine ice sheets. For more recent times, there are the added proxy data available from human anecdotal records – like information on dates of harvest, the types of crops grown, major weather catastrophes – that can help the climate detective reconstruct climate patterns of the past (Beltrami, 2002; Mann, 2002; Shrag and Linsley, 2002).

The Past 1.5 Million Years

During the last 1.5 million years (the Quaternary), Earth's climate has undergone large swings between lengthy periods of extreme minimum temperatures accompanied by extensive glaciation and shorter periods of warm interglacial conditions. Ice core data extracted from the ice sheets of Antarctica provide valuable information about the last four of these large cycles. As illustrated in Figure 2 (Folland *et al.*, 2001a), these data indicate that the glacial-interglacial cycles occurred about once every 1 00 000 years. During each cycle, there was a slow transition from interglacial to glacial conditions, but a rapid deglaciation at the end of each cold period. Over Antarctica, for example, local temperatures warmed by a dramatic 8 to 10 °C over an interval of 5000 years or so during each glacial-interglacial transition. Within this 1 00 000-year cycle, smaller anomalies have occurred with regularity. Similar patterns are found in data extracted from Greenland ice cores and from ocean sediments, although the latter suggest a more modest change in temperatures for tropical regions. Model studies, in fact, suggest that the global average change in temperature during a glacial-interglacial cycle may be a more moderate 4 to 6 °C, producing an average rate of warming during deglaciation of about 0.1 °C century^{-1} (Weaver *et al.*, 1998; Bush and Philander, 1999).

Although many theories have been advanced to explain these large temperature variations, the most widely accepted hypothesis involves changes in the precession, obliquity, and eccentricity of the Earth's orbit around the sun, occurring with frequencies of 22 000, 41 000, and 1 00 000 years

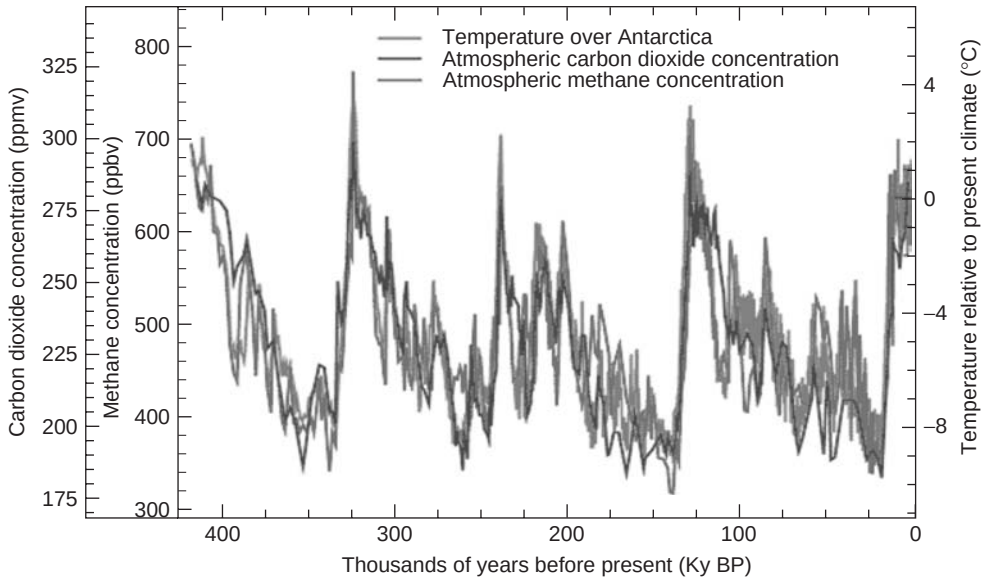

Figure 2 Long-term variations in Antarctic temperatures, carbon dioxide concentrations and methane concentrations over the past 4 20 000 years, as reconstructed from ice core data (IPCC Third Assessment Report 2001. Reproduced by permission of Intergovernmental Panel on Climate Change). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

respectively. These changes affect the seasonal distribution of incoming sunlight across the Earth's surface. However, while the large glacial-interglacial cycles that occur at the 1 00 000-year timescale correlate well with changes in orbit eccentricity, the net annual forcing (i.e. imbalance between incoming and outgoing radiative energy flux at the top of the atmosphere that causes the climate system to adjust until a new balance is achieved) caused by those changes is far too weak to fully explain the amplitude of the glacial-interglacial cycles. Hence, various feedback processes appear to significantly amplify this forcing. Paleo studies indicate that responsive changes in atmospheric greenhouse gas concentrations and altered surface albedos are two such important positive feedback mechanisms. For example, recent analyses of Antarctic and Greenland ice cores indicate a strong correlation between past long-term changes in climate and the natural atmospheric concentrations of carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O), all important greenhouse gases. As Figure 2 indicates, the correspondence between atmospheric carbon dioxide, methane concentrations, and local Antarctic temperatures during the past 4 20 000 years has been remarkable. However, the various processes involved in such millennial scale changes in climate are very complex, and can differ between hemispheres. Furthermore, they may also differ from one cycle to the next, suggesting that past events may not be good analogs for the current interglacial. Some researchers argue that the current interglacial could, in fact, last another 50 000 years. Human factors may further dampen or even prevent the next reglaciation, thus ushering

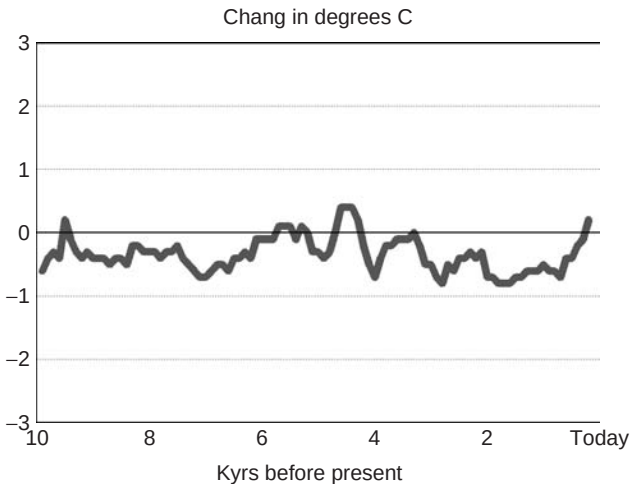

Figure 3 Variations in Antarctic temperatures over the past 10 000 years, as reconstructed from ice core data

in the "Anthropocene" stage of Earth's climate (Berger and Loutre, 2002; Crowley, 2002; Pepin *et al.*, 2001).

Figure 3 (Petit *et al.*, 2000) provides a more detailed depiction of Antarctic temperature variations for the past 10 000 years. During this interglacial period (known as the *Holocene*), average mid- to high-latitude temperatures peaked slightly about 5000 to 6000 years before present, and have gradually cooled since then. This warm peak of the interglacial is commonly referred to as the *Holocene Maximum*. During this high-latitude Holocene Maximum, central North American climates were generally warmer,

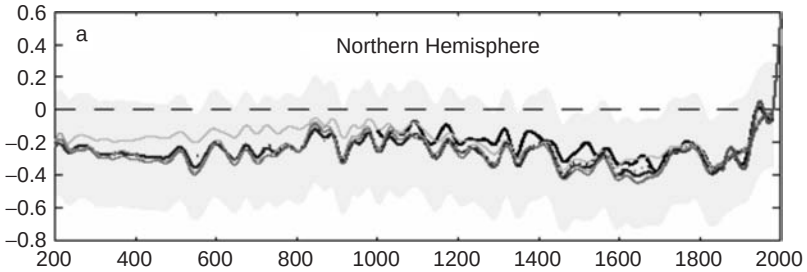

Figure 4 Northern hemispheric climate trends of the last 2000 years, as reconstructed from multiple proxy data sources. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

drier, and windier than that of today. In contrast, European climates during that period were initially warmer and wetter, then they also became drier. Climates in arid regions of Africa and Asia were also significantly wetter than today. However, both paleo data and model studies suggest that mid-Holocene temperatures may have been slightly cooler than today in low-latitude regions. Hence, average global temperatures appear to have been remarkably stable during the entire Holocene. Several "little ice ages", or short periods of cooling, appear superimposed upon the Holocene record at approximately 2500-year intervals, the latest having occurred between about 1400 A.D. and 1900 A.D. (Adams, 1997; Gajewski *et al.*, 2000).

Figure 4 (Mann and Jones, 2003) illustrates how average global temperatures have varied during the past 2000 years. On the basis of multiple proxy data sources at many different locations around the world (although predominantly from the Northern Hemisphere), it suggests that average temperatures today are warmer than at any previous time during the past two millennia. However, it appears likely that current temperatures are still slightly cooler than those of the Holocene maximum, and perhaps 1 to 2 °C cooler than the peak of the last interglacial of 1 35 000 YBP.

For fluctuations during the past several millennia, there have been encouraging results from efforts at correlating changes in temperature with volcanic forcing and solar irradiance cycles. Such comparisons, for example, indicate that volcanic forcing can be important in inducing long-term cooling on a global scale, but less so at the regional scale. In contrast, solar forcing can create significant long-term regional climate changes as well as global scale anomalies similar to the Little Ice Age events noted above. In fact, much of the higher frequency variations in climate over the past 300 years appear to be closely linked to changes in sunspot cycle behavior. However, the mechanisms by which relatively small change in solar irradiance can significantly affect climate are as yet not well understood (Shindell *et al.*, 2003; Rind, 2002).

While Figure 4 indicates that average Northern Hemispheric temperatures about 1000 years ago were still cooler than today, some regions may have been somewhat warmer at that time. These regions include western Europe, Greenland, and eastern Canada. This regional warm period, often referred to as the *Medieval Warm Period*, lasted several hundred years. Hence, during this period, local tree lines and other natural vegetation boundaries gradually moved northwards. Milder Arctic climates brought substantial decreases in sea ice cover. These conditions may have encouraged the migration of Inuit within the Arctic and have been a determining factor in the settlement and survival of European Vikings in Iceland and Greenland. These Vikings appear to have navigated freely throughout much of the Canadian archipelago, and, in Greenland, they were able to carry on a viable agriculture. Ironically, European attempts from the seventeenth to the nineteenth centuries to find a northwest passage to India failed. This was primarily because they began after the Medieval Warm Period gave way to the Little Ice Age, which lasted from 1400 to about 1850 A.D. Since temperatures in some of these regions have now returned to something similar to the Medieval Warm Period, it is likely that the local vegetation and ice regimes that prevailed years ago will return, even if climates do not become any warmer than they are now (Briffa and Osborn, 2002).

Paleo reconstructions can also provide important information on changes in circulation patterns and precipitation regimes. They indicate, for example, that the wind strength of the southwestern Asian monsoon has increased over the past four centuries. While it remains uncertain whether this trend was linked to a warming of global climates, it is consistent with projections for increased intensity of the southwest monsoon under future warming. Changes in monsoonal behavior can have large impacts on regional societies, causing severe droughts when the intensity of the monsoons decrease and severe flooding when their intensity increases (Anderson *et al.*, 2002).

CLIMATES OF THE TWENTIETH CENTURY

Monitoring Recent Climate Behavior

While the Earth's natural environment and human anecdotal information recorded over time have been valuable

sources of proxy data to help provide approximations of past climate behavior, they have major limitations in terms of spatial and temporal details and provide little information on aspects of climate other than temperature and precipitation.

With the advent of instrumental climate record keeping in Europe several centuries ago, systematic observations of temperature, precipitation, and many other climate variables began to remove some of these limitations. Initially the spatial coverage of climate monitoring systems was sparse, particularly in polar regions and parts of North America, Africa, China, and Russia. However, global coverage was much improved by mid-twentieth century. The advent of satellite observing systems some 25 years ago has further added to this coverage.

In addition to the possible bias introduced by changes in observing coverage and density over time, there are other significant challenges in analyzing these data records for trends and variations in regional and global climate conditions. For example, observing methods have changed over time. Furthermore, land use change such as deforestation or increased urbanization has caused significant biases in many local temperature records. Various research groups have worked meticulously to identify possible systematic biases in these records and to adjust them accordingly. Although there continue to be uncertainties in results, the high level of consistency between the various independent analyses undertaken to date and between corrected sea and land data where they abut along coastlines lends considerable confidence in the significance of the trends observed, particularly at the global scale (Folland *et al.*, 2001b).

Analyzing global trends in precipitation and other hydrometeorological variables (including cloud) is even more problematic, since hydrological variables are more significantly influenced by local influences that increase their inhomogeneity over space and time. Furthermore, there is relatively little information for monitoring trends in precipitation over oceans. Hence, while good estimates for precipitation trends are available for some land regions with long records and reasonably dense network of monitoring stations, there are no reliable estimates of global trends (Folland *et al.*, 2001a).

Over the past 50 years, there has also been an increasing array of complementary measurements of meteorological conditions within the atmosphere provided by balloon-borne instrument packages. More recently, satellite systems have added to this database. These data have helped understand global trends in atmospheric conditions better, including cloud cover, humidity, and atmospheric temperatures. Finally, there are many indirect indicators of recent and current trends in climate provided by monitoring of the global cryosphere (snow cover, sea ice, and glaciers) and of behavior of flora and fauna (Folland *et al.*, 2001a).

Temperature Trends

Globally, average surface temperatures have increased by about 0.7 °C (±0.2 °C) over the past century. However, as shown in Figure 5 (National Climatic Data Center, 2004), the observed global trends in temperature have not been uniform in time. While average temperatures changed very little between 1860 and 1920, they increased relatively rapidly over the next two decades. The climate cooled moderately from midcentury until the early 1970s, then warmed rapidly at about 0.15 °C decade^{-1} during the past 30 years. During the more recent warming period, nighttime minimum temperatures have been increasing at about twice the rate of daytime maximum temperatures, thus decreasing the diurnal temperature range. Land surface temperatures have also been rising at about twice the rate of sea surface temperatures. Together, these factors have contributed to a lengthening of the frost-free period over lands in mid to high latitudes (Jones and Moberg, 2003; Stone and Weaver, 2002).

When compared with the proxy data for climate variations of the past two millennia (Figure 4), it seems likely that the twentieth century is now the warmest over that time period, and that the 1990 s was the warmest decade. Furthermore, the *rate* of warming in recent decades appears to be unprecedented over at least that time period. This evidence has led experts to conclude that recent climate behavior has been very unusual and thus increasingly difficult to explain on the basis of natural variability and/or natural forcing factors such as changing intensity of solar irradiance or atmospheric dust loading from volcanic eruptions. In contrast, there is increasing evidence that recent temperature behavior is consistent with how the climate should

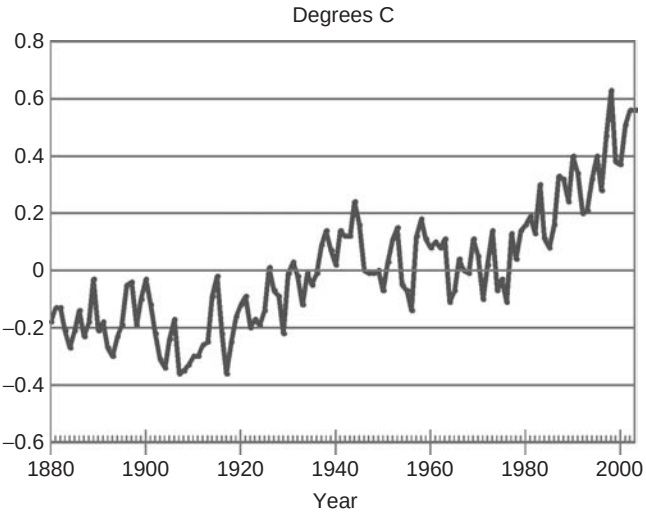

Figure 5 Trends in global average surface temperatures over the past 140 years, shown as departures from the long-term mean. Based on US National Climatic Data Center data files

have responded to increasing human interferences with the climate system, and therefore likely due to anthropogenic causes (Folland *et al.*, 2001b; Mann *et al.*, 2003).

Although the monitoring of temperatures within the Earth's atmosphere has a much shorter history than that for surface temperatures, climatologists now have some 45 years of data directly recorded by radiosondes borne aloft by balloons and almost 25 years of information obtained indirectly by instruments onboard satellites, particularly the Microwave Sounding Unit (MSU). Comparison of the longer radiosonde records with surface observations show that the long-term trend of globally averaged temperatures in the lower atmosphere since 1957 is very similar to that at the surface. However, there are significant and varying differences in trends on shorter timescales. For example, the lower atmosphere warmed more rapidly than the surface between 1957 and 1975, but warmed at a slower rate since that time. The satellite MSU data shows a similar slower atmospheric warming relative to that at the surface since 1979. On the other hand, satellite system data for skin temperatures right at the Earth's surface show trends since 1982 that are very similar to those for the near-surface data collected at the climate stations. Hence, while measurements and analysis errors may be a factor, experts suggest that much of the difference between surface and lower atmospheric trends is real. There are indications that they may be caused by changing atmospheric lapse rates with time, perhaps because of factors such as El Nino Southern Oscillation (ENSO) events, volcanic eruptions, and global warming. Over longer timescales, these differences are expected to average out (Gaffen *et al.*, 2000; Christy *et al.*, 2001; Hegerl and Wallace, 2002; Jin and Dickinson, 2002; Jin and Treadon, 2003; Vinnikov and Grody, 2003).

The radiosonde and satellite data also indicate that the lower stratosphere has been cooling in recent decades. This appears to be related to the combined effects of stratospheric ozone depletion and enhanced greenhouse gas concentrations. The former results in less *in situ* absorption of incoming solar UV radiation, while the latter causes a greater insulation against heat loss from the surface and lower atmosphere to the stratosphere above (Christy *et al.*, 2001).

There is also increasing evidence that all other parts of the global climate system are slowly warming and thus storing up more heat. Snow melt, for example, has been occurring earlier across most of the Northern Hemisphere. Most glaciers and ice sheets in polar and alpine regions have been shrinking, particularly in Alaska and Europe, with many of the small glaciers expected to completely disappear within decades. There is also evidence that at least some of the large ice shelves in Antarctica have been thinning (Arendt *et al.*, 2002; Reichert *et al.*, 2002; Rignot and Thomas, 2002; Thompson *et al.*, 2002; Meier *et al.*, 2003; Shepherd *et al.*, 2003; Stone *et al.*, 2002). Meanwhile, sea ice cover has been retreating dramatically across the Arctic (Comiso, 2002). The rate of heat uptake through these cryospheric melting processes is estimated to be similar to that occurring within the atmosphere. Likewise, borehole temperature measurements of the Earth's lithosphere indicate that this component of the climate system is storing additional heat at similar rates (Beltrami *et al.*, 2002). More dramatically, waters within the upper 3 km of the world's oceans have increased their heat content at rates some 10 times greater than this (Levitus *et al.*, 2001).

Although the above evidence indicates that the world is becoming warmer, the spatial and temporal patterns of these trends are varied and complex. Some regions have warmed much more rapidly than the global average and others much less so, or even cooled. For example, the Antarctic Peninsula has warmed rapidly in recent decades, while other parts of Antarctica have cooled (Turner *et al.*, 2002; Thompson and Solomon, 2002; Doran *et al.*, 2002). Likewise, parts of the Arctic in the northwestern region of the Northern Hemisphere and in Siberia have warmed as much as 3 °C over the past 50 years, while other regions like that for the North Atlantic and North Pacific and the northeastern United States have actually cooled slightly (Przyblak, 2002; Robinson *et al.*, 2002). In general, winter and spring seasons have also warmed more than summer and fall seasons. These complex patterns reflect shifts in global atmospheric circulation patterns that are occurring concurrently with the gradual rise in average temperatures.

While such circulation changes have always occurred as normal climate variability, there are indications that the recent behavior could also be influenced by the general warming of the global climate system (Mortiz *et al.*, 2002; Visbeck *et al.*, 2001).

Precipitation Trends

Available precipitation data records are much less representative of global trends than are those for temperature, since precipitation by its very nature is far more inhomogeneous than temperature. Furthermore, there is scant precipitation data for the world's ocean areas, which represent 70% of its surface. As illustrated in Figure 6 (Folland *et al.*, 2001a), available records indicate a recent increase in annual average precipitation of about 0.5 to 1% per decade over most land areas in the mid- to high-latitudes of the Northern Hemisphere and a somewhat more modest increase over the tropics. There also appears to be a corresponding upward trend in both cloud cover and tropospheric water vapor content over much of the Northern Hemisphere. Relative humidity in the lower troposphere, for example, has increased by about 10% since 1973 over a number of regions, including the United States, Alaska, the Caribbean,

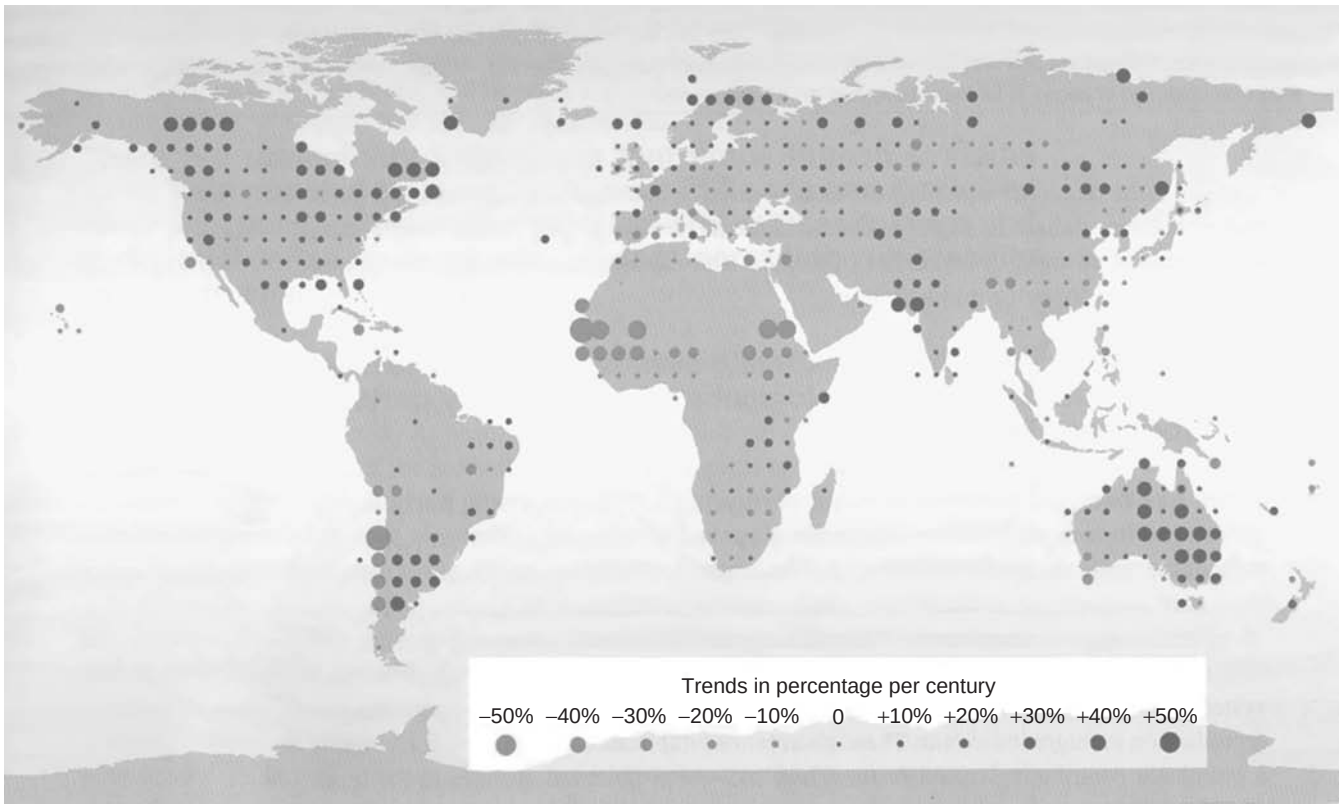

Figure 6 Net change over the twentieth century in annual precipitation amounts in percent estimated for various land regions of the world (IPCC Third Assessment Report 2001. Reproduced by permission of Intergovernmental Panel on Climate Change). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

and China. Water content in the comparatively dry stratosphere has also been increasing by about 1% per year over the past four decades. In contrast, there has been a modest decline (about 0.3%/decade) in precipitation over the Northern Hemisphere subtropics. There are no clear indications of precipitation trends in the Southern Hemisphere, although some regions within South America and Africa show decreases. A number of countries have experienced increased number of wet days, and an increased proportion of total precipitation as heavy rain. Most land areas also have increased persistence of wet spells (New *et al.*, 2001; Rosenlof, *et al.*, 2001; Ross and Elliott, 2001; Frich *et al.*, 2002; Milly *et al.*, 2002; Trenberth *et al.*, 2003).

Other Climatological Trends

The melting of global glaciers and ice sheets and the thermal expansion of ocean waters as they warm are both contributing to a rise in average global sea levels. Evidence suggests that sea levels have risen on average by some 1 to 2 cm per decade over the past century. Recent satellite data suggest current rates of increase may have accelerated to about twice that amount (Church *et al.*, 2001; Cabanes *et al.*, 2001). Meanwhile, atmospheric pressures at sea level over the past half century show decreases over the Arctic, Antarctica, and the North Pacific, and increases over the subtropical Atlantic. These observed changes are believed to have caused a northward displacement of dominant storm tracks, thus increasing the frequency and intensity of unusual weather events in Europe in recent decades (Gillett *et al.*, 2003). They are also the likely cause for altered wave action in the North Atlantic, where extreme wave heights have increased in the northeast sector in winter. Significant increases in wave height have also occurred off the Canadian coasts in summer and fall, but other areas and seasons have experienced decreases (Lozano and Swail, 2002; Wang and Swail, 2002).

There is a broad range of indicators to suggest that global ecosystems are already responding to the recent changes in climate discussed above. Recent surveys of related studies indicate that about 80% of changes in behavior of some 1500 to 1700 biological species studied were consistent with that expected due to regional changes in climate. On average, species have shifted their distributions poleward by some 6 km per decade and advanced the onset of spring activities by 2 to 5 days per decade. Tropical ocean corals have also undergone massive bleaching in recent years. If such ecological responses to changes in

climate differ significantly amongst species, this could seriously disrupt their interdependence within ecosystems and effectively tear such communities apart (Parmesan and Yohe, 2003; Root *et al.*, 2003; Walther *et al.*, 2002; Penuelas and Filella, 2001).

Finally, a variety of indicators show significant trends in climate extremes. For example, warm summer nights have become more frequent over the past few decades, particularly in midlatitude and subtropic regions. This has contributed to a reduction in the annual number of frost days and in the intra-annual extreme temperature range. There has also been an increase in some regions in the extreme amount of precipitation derived from wet spells, in the number of heavy rainfall events, and/or in the frequency of drought. Most of the major river basins of the world have experienced a significant shift towards a higher frequency of extreme floods, with three-quarters of extreme events recorded during the past century or so occurring since 1953. Such trends appear to be very unusual, with an estimated 1.3% probability of being entirely due to natural variability. However, they are consistent with expected responses to warmer climates. These results, however, may not apply to more modest flood events and cannot be extrapolated to smaller river basins, where most floods occur (Frich *et al.*, 2002; Milly *et al.*, 2002; Vinnikov *et al.*, 1999). These changes in extreme weather behavior have also caused a global rise in related economic losses. In 2002, for example, record setting floods in Europe and other disasters around the world resulted in economic losses in excess of US$55 billion (Schnur, 2002; Schiermeier, 2003).

FUTURE CLIMATES

Climate Models – the Primary Tool for Projecting Future Climates

As noted in the preceding sections, proxy data and climate observations provide invaluable information on *what* has happened to the Earth's climate in the past and *how* it is behaving today. However, because the climate system is complex and nonlinear in its behavior, these data by themselves are limited in their usefulness to explain *why* the climate system changes with time and in space.

To develop such predictive capability, the complex feedbacks that inextricably couple together the various components of the climate system must be carefully studied with the help of differing types of climate models, ranging from very simple energy budget models to multidimensional physical–chemical models (*see* **Chapter 32, Models of Global and Regional Climate, Volume 1**; **Chapter 201, Land-Atmosphere Models for Water and Energy Cycle Studies, Volume 5**). Results of such studies must then be used to approximate these feedbacks as complex mathematical equations that capture the fundamental physical, chemical, and biological processes involved. These can then be integrated within a complex model of the entire dynamic global system. Such climate system models have been under development for some four decades, and are now sufficiently advanced to include a dynamic circulating atmosphere coupled to a circulating global ocean system with a responsive ice cover. Some have now also coupled the dynamics of global ecosystems within the system, thus allowing them to replicate the biogeochemical feedbacks between the climate and biosphere systems. These models, generally referred to as *coupled climate models*, provide intricate approximations of how the Earth's biogeochemical system functions and require the largest and most advanced supercomputers available to run. However, they continue to be limited by computing capacity, by inadequate observational data for describing, calibrating, and verifying the physical and chemical processes included in the models, and by gaps in scientific knowledge of feedbacks within the climate system. Despite these limitations, they have become valuable tools for adding to the scientific understanding of why climate changes, and how it may change in the future.

There is now a large suite of coupled models available internationally to undertake climate change experiments. One of the key performance indicators of these models is model *climate sensitivity* – that is, the change in global temperature simulated by a model in response to a specified imbalance in net radiative flux at the top of the atmosphere. This is usually described as the amount of warming predicted by the model as a result of an equilibrium response to a doubling of carbon dioxide concentrations. Since the models available today vary considerably in how they deal with various climate processes and feedbacks, they also vary considerably in their climate sensitivity. However, in general, all advanced models have a climate sensitivity somewhere between a 1.5 and 4.5 °C equilibrium response to a doubling of atmospheric CO_2 concentrations (Cubasch *et al.*, 2001).

Human Interference with the Climate System

The preceding sections have described how natural variations internal to the climate system as well as external natural factors (primarily solar and volcanic) have affected past climates. These factors will continue to modify future global climates. However, the range of such variations and naturally induced changes during the next century are unlikely to exceed that observed over the past few millennia.

There is, however, another major factor at work on the climate system that is rapidly increasing in magnitude and is expected to dominate over all other natural forces and variations likely to occur over the next century and beyond – that is, human activities. The following paragraphs describe two prominent aspects of the climate system that humans have altered in the past, and how these are likely to change in

the future (*see* **Chapter 33, Human Impacts on Weather and Climate, Volume 1**).

Human Influences on Regional Surface Albedo and Hydrology

Humans have been significantly transforming the Earth's regional landscape ever since the onset of civilization in Asia and Africa some 8000 years ago (Ruddiman, 2003). Over the millennia, they have changed vast areas of forested lands into agricultural fields (and, in some places, back again), dry lands into wetlands or wetlands into dry, and rural landscapes into city environments. Such changes in land use have altered the local albedo of the Earth's surface and hence have influenced how much sunlight is reflected back to space. In some cases, these changes have reduced surface reflection of incoming sunlight and caused a warming influence. In others, particularly in regions covered with winter snow, they have increased surface reflection and thus caused a local cooling. For example, the albedo effects of change from forest to crops landscapes may have caused a net global cooling effect of between 0.09 and 0.22 °C during the past three centuries (Matthews *et al.*, 2003).

In addition to changing albedos, land use change also affects regional evaporation, evapotranspiration, rainfall, atmospheric circulation, and cloud cover. Some experts argue that the net accumulated effect of land use change over the millennia may have been a significant factor in changing climate on a global scale as well. However, the regional and seasonal complexities of this forcing factor are poorly understood and hence its importance in helping to explain past changes in climate is still difficult to quantify (Chase *et al.*, 2001; Zhao and Pitman, 2002; Heck *et al.*, 2001; Matthews *et al.*, 2003).

Future land cover change and hence its effect on surface albedo and hydrology will largely be determined by a range of demographic and climate factors. Although the demographic factors involved are difficult to predict, experts suggest that changes in land use over the next century have finite limits that range between a worst-case scenario of a continued deforestation until the world's virgin forests have been depleted and a best-case scenario of gradually increasing global forest cover from both a decline in deforestation activities and increased reforestation efforts (Watson *et al.*, 2000; Nakicenovic and Swart, 2000).

The effect of future climate change on land cover can vary from enhanced forest cover in polar regions as treelines respond to warmer climates to increased desertification or conversion of forests to grasslands through natural successional processes in others. Advanced climate models are now beginning to include such vegetation feedbacks within their simulations, and hence related albedo and hydrological feedbacks become an inherent part of these simulations (Bergengren *et al.*, 2001; Betts, 2000; Cox *et al.*, 2000; Douville *et al.*, 2000, Foley *et al.*, 2000; Harding *et al.*, 2002).

Changing Atmospheric Composition

The other major way in which humans are interfering with the climate system is through emissions into the atmosphere of greenhouse gases and aerosols that gradually change its composition, and hence its role in regulating the flow of energy into and out of the Earth's climate system. For example:

- Over the past 150 years, humans have cumulatively emitted approximately 1500 billion tons of carbon dioxide into the atmosphere. About two-thirds of these emissions were caused by the combustion of fossil fuels for energy and the remainder by deforestation. Emissions from the latter have been relatively stable in recent decades (at about 6 billion tons of CO_2 per year). However, those from fossil fuel use continue to rise quite rapidly, increasing from an average of about 11 billion tons per year in the 1960s to about 23 billion tons per year during the 1990s. Fortunately, natural processes are removing a significant fraction of these human emissions from the atmosphere through enhanced absorption in surface oceans and increased biological growth on land. However, the amount of CO_2 in the atmosphere still increased at the rate of some 12 billion tons per year during the 1990s. Atmosphere concentrations, which were at a remarkably stable level of about 260 to 280 parts per million by volume (ppmv) throughout the Holocene, have increased to levels of about 374 ppmv by 2002. This is an increase over preindustrial levels of about 33%. There are indications, in fact, that current levels may be unprecedented in the past 20 million years (Carbon Dioxide Information and Analysis Center, 2003; Climate Monitoring and Diagnostic Laboratory, 2002; Prentice *et al.*, 2001).
- Human activities have contributed to dramatic increases in other greenhouse gases as well. Atmospheric methane concentrations have more than doubled over the past century, while those for nitrous oxide have increased by about 15%. Tropospheric ozone has also increased substantially over much of the industrialized world, and entirely new and powerful greenhouse gases such as halocarbons and sulphur hexafluoride are now being added in significant amounts. In contrast, halocarbons have contributed to a decrease in ozone within the stratosphere.
- Finally, there has also been a progressive increase in the anthropogenic emissions of aerosols and their precursors into the atmosphere. While most of these aerosols have relatively short lifetimes within the atmosphere of days to weeks, their continuous production in industrialized regions of the world has resulted in a large and sustained increase in their concentrations over and

down-wind of these regions. From a climate perspective, these aerosols have several important roles. First, they directly affect the amount of incoming sunlight that is reflected back to space or absorbed within the atmosphere. Secondly, fine aerosols also function as condensation nuclei and hence alter the amount and properties of cloud. They thus indirectly affect the absorption and reflection of incoming radiation through the role of these clouds. Finally, as these aerosols settle out of the atmosphere onto the Earth's surface, they can affect the surface albedo. This is particularly true for soot on snow or ice. While there are large uncertainties associated with these effects, experts suggest that the net direct effect of increased concentrations of all aerosols over the past century is likely negative (on the order of $-0.5\,W\,m^{-2}$), hence offsetting some of the warming effects of rising greenhouse gas concentrations. Their indirect effects through altered cloud conditions may be larger, but are even more uncertain.

Radiative studies indicate that the observed increase in greenhouse gas concentrations during the past century have enhanced net average surface energy flux by about $2.5\,W\,m^{-2}$. This has been partially offset by a net cooling by increased aerosol concentrations (direct and indirect), although the magnitude of this offset is poorly understood. Hence, the net radiative forcing from all human causes may be somewhere in the range of 1 to $2\,W\,m^{-2}$. Simulations of past climate response to both these human forcings and those estimated for natural factors (see above) have quite successfully simulated the observed climates of the past 100 years. Furthermore, these model results, together with the paleo evidence for the range of natural climate variations over the past 2000 years, have led researchers to conclude that "most of the observed warming over the past 50 years is attributable to human activities" (Ramaswamy *et al.*, 2001; Mitchell *et al.*, 2001).

As with surface albedo and hydrological processes, projections of future emissions of greenhouse gases and aerosols are highly sensitive to both demographic behavior and climate feedbacks. After carefully considering the range of plausible futures for the various socioeconomic, technological, and biological factors involved, experts have suggested that, unless deliberate measures are taken to curtail future emissions, another 3600 to 8000 billion tons of carbon dioxide will be emitted into the atmosphere over the next century as a result of fossil fuel combustion and land use change. Allowing for terrestrial and ocean removal processes, they project that this will almost certainly result in a doubling of preindustrial atmospheric CO_2 concentrations by 2100, and a tripling could be possible. Over the same time period, projected concentrations of other greenhouse gases also range from modest to significant increases. In contrast, aerosol emissions are projected to eventually decline relative to current levels because of expected measures to curtail their emissions for local environmental reasons. The net climatic effect of these projected changes in both greenhouse gases and aerosols is an increase in net global radiative forcing by 2100 relative to preindustrial levels of between about 4 and $9\,W\,m^{-2}$ (Nakicenovic and Swart, 2000; Cubasch *et al.*, 2001).

Projected Climate Change for the Next Century

Temperature

Climate models are the primary tools used to project how future changes in radiative forcings might affect the climates of the next century. In its Third Assessment Report, the IPCC uses these models to project that average surface temperatures will warm by some 1 to 2.5 °C by 2050, increasing to between 1.4 and 5.8 °C by 2100, relative to current climates (Houghton *et al.*, 2001). Delayed effects from changes in radiative forcings to date already commit the world to 0.5 °C of that warming, even if all emissions of greenhouse gases were to stop immediately (Hansen *et al.*, 2002). Some researchers have attempted to put some probabilities on these projections. In general, they suggest only a 5% probability that global climates will warm by less than 1.7 °C by 2100, or by more than 4.9 °C (Reilly *et al.*, 2001; Webster *et al.*, 2003). As illustrated in Figure 7 (Cubasch *et al.*, 2001), at the lower end of this range, changes will be unprecedented in the history of human civilization, while at the upper end they are comparable to the magnitude of change during the last deglaciation, but at about 50 times the rate.

While the above results indicate that there is considerable agreement between models on the significance of global scale changes in temperature, there is much less agreement with respect to regional changes. However, despite these differences, there are a number of common features amongst all of the models (Cubasch *et al.*, 2001). For example:

- Land areas warm more than ocean surfaces. This is simply a consequence of the thermal inertia of oceans. This ocean inertia is also the primary reason for a significant delay of decades in achieving a new equilibrium climate in response to an enhanced forcing regime.
- The Arctic polar region warms more than the tropics. The primary reason for this polar amplification is the positive feedback provided by snow and ice. Although such amplification is also expected to eventually occur in the Antarctic region, models predict a delayed response of that region's cryosphere.
- Nighttime temperatures will, on average, warm more than daytime temperatures, thus reducing the daily temperature range.

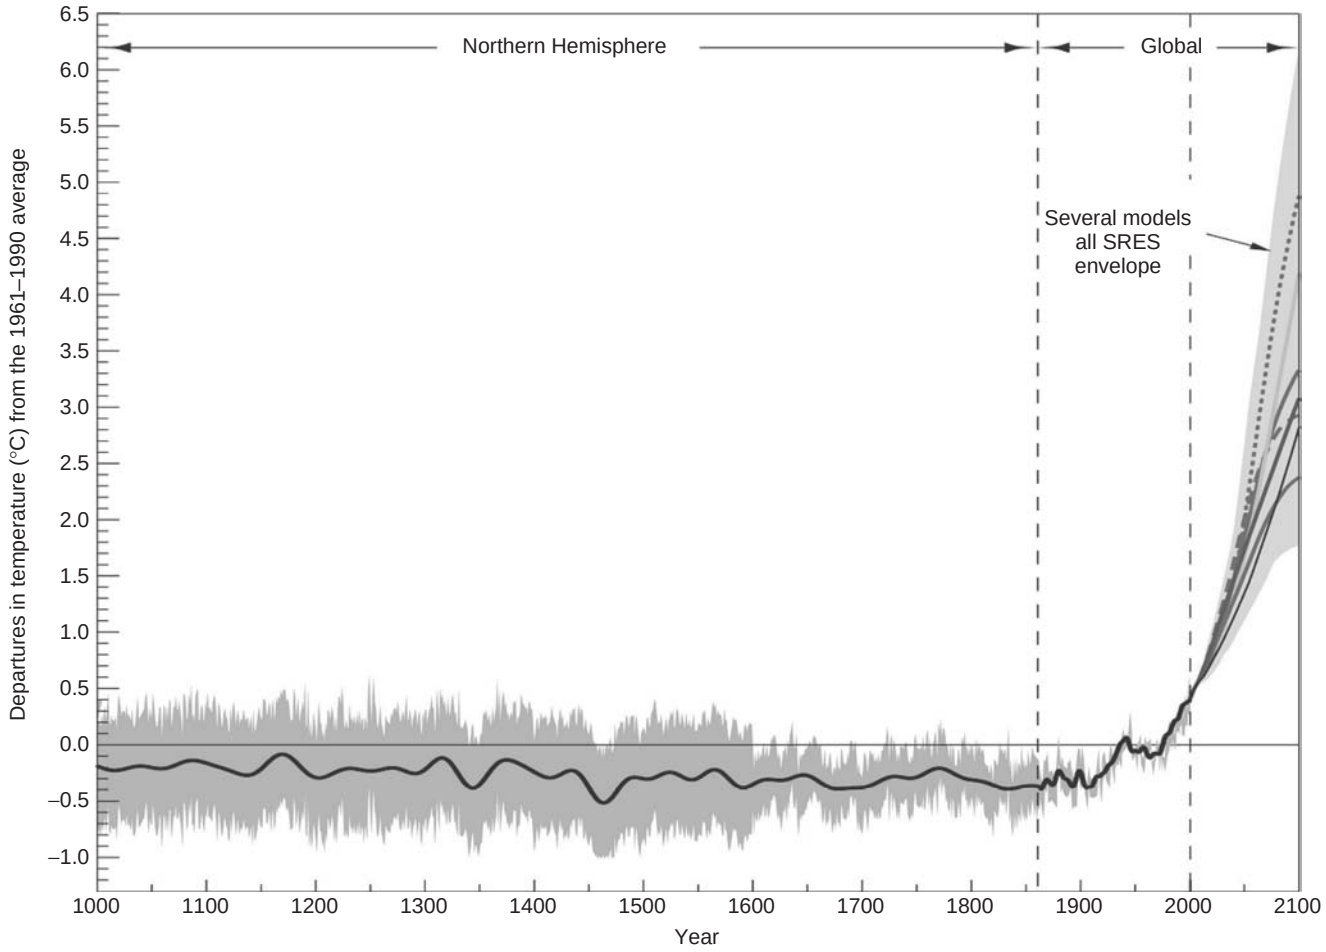

Figure 7 Projected changes in average global temperatures to 2100, in comparison with trends of the past millennium. Individual colored lines represent projections for six representative emission scenarios using a model of intermediate climate sensitivity, while the broader gray shading between 2000 and 2100 is indicative added uncertainty due to varying model sensitivities. Gray shading in the proxy data indicates estimates uncertainty in the data (IPCC Third Assessment Report 2001. Reproduced by permission of Intergovernmental Panel on Climate Change). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

- Ocean circulation is expected to slow down. The turnover of the global oceans is largely determined by thermohaline (i.e., temperature and salinity) processes that affect surface water densities. All models agree that enhanced precipitation in the high latitudes of the Northern Hemisphere is likely to decrease the rate of deep water formation in the North Atlantic and hence weaken the thermohaline circulation system. This may cause some surface ocean regions, like areas of the North Atlantic, to actually cool while the rest of the world warms.
- Natural oscillations in the climate system will be superimposed upon the projected upward trends in temperatures, and hence will modulate both the temporal and spatial response of climates to enhanced radiative forcing. This adds significantly to the uncertainty of the model projections, particularly at the regional scale.
- There is also increasing evidence that the pattern of future warming will increasingly be like that of current El Nino years, with enhanced warming in the central and eastern tropical Pacific relative to the western Pacific. This, in turn, causes global atmospheric circulation patterns to change (Boer *et al.*, 2004).

Precipitation

Warmer surface temperatures will increase surface evaporation and hence enhance the global hydrological cycle (*see* **Chapter 195, Acceleration of the Global Hydrologic Cycle, Volume 5**). Various model projections suggest global precipitation response to projected warming by mid-century could be anywhere between a small decrease of −0.2% to an increase of 5.6% (Yang *et al.*, 2003). However, in general, the global hydrological cycle (and hence precipitation) is likely to be enhanced by about 1 to 2%

per degree Celsius of warming. The atmospheric holding capacity for water vapor should also increase by about 7% per degree Celsius of warming. This means increased surface water loss through evaporation processes will likely exceed increases in precipitation. It also suggests a greater average increase in atmospheric moisture content per degree of warming for low latitudes than for higher latitudes. Since the additional release of latent heat when water vapor condenses within the atmosphere will further invigorate storms, there will be a greater increase in rate of heavy precipitation than for average precipitation. That is, precipitation events (including snow storms) are likely to become fewer, but more intense. The fraction of precipitation falling as snow will decrease, as will the duration of the snow season. However, concurrent shifts in atmospheric circulation and hence precipitation patterns suggest that these changes will vary significantly from region to region and season to season. In general, the El Nino–like pattern indicated in many of the models suggests an eastward shift of precipitation in the tropical Pacific. Various models also suggest an enhanced positive Arctic Oscillation under warmer climates. Most high-latitude areas are expected to experience significant increases in precipitation, while much of the subtropical regions are likely to experience decreases in mean rainfall. In the tropics, projected changes are smaller and less consistent between models. On average, the intensity of rainfall increases. Most models project an increase in precipitation variability where mean values increase, and an increase in droughtiness of mid-continental regions in summer. Several simulations indicate that, by the time atmospheric CO_2 concentrations double relative to preindustrial levels, the Saharan desert will have shifted northwards by about 0.55° of latitude and will thus have become significantly hotter and drier (Räisänen, 2002; Douville *et al.*, 2000; Gillett *et al.*, 2002; Liu *et al.*, 2002; Wilby and Wigley, 2002; Boer *et al.*, 2004; Trenberth *et al.*, 2003).

Sea, River, and Lake Ice

In the Arctic, sea ice is projected to decrease in extent and thickness, particularly in summer. By 2100, most of the Arctic will likely be entirely free of ice in late summer. While winter ice cover will continue to be extensive, it will consist of thinner and more brittle first-year ice, form much later in autumn, and disappear earlier in the spring. Reduced ice cover will, in general, make Arctic shipping much easier, but could be a major threat for some of the important Arctic species that rely on ice for their habitat. It will also present challenges for the people in the region who rely on these species. Furthermore, reduced sea ice in the margins of the Arctic Ocean will expose coastlines to accelerated erosion caused by an intensification of the ocean wave regimes. The low-lying coastlines of the delta regions of the great Arctic rivers are particularly vulnerable (Kerr, 2002; Armstrong and Brodzik, 2001; Gregory *et al.*, 2002; Falkingham *et al.*, 2003). In Antarctic, where sea ice already disappears in summer today, the changes in ice cover during the next century are expected to be less dramatic. This is primarily because of projected changes in Southern Ocean circulation patterns that are expected to delay ocean surface warming relative to oceans surfaces elsewhere. (Anisimov *et al.*, 2001; Cubasch *et al.*, 2001).

The duration of ice cover and ice thickness on inland lakes and rivers are also expected to decrease substantially. Experts suggest, for example, that ice growth seasons on lakes in the northern United States, could be reduced by up to 100 days, and mean ice thickness by as much as 40 cm (Fang and Stefan, 1998).

Land Ice and Sea Levels

Most temperate glaciers are expected to decline significantly, with many disappearing entirely within the next century. The Greenland ice sheet is also expected to decline slowly. However, in Antarctica, a more maritime type climate may sufficiently enhance snowfall onto the interior of the ice sheets to more than offset enhanced melting at its margins, thus causing a slow increase in net ice volume. Collectively, these changes in land ice volume are expected to add to ocean volume and cause sea levels to rise. Thermal expansion of ocean waters as they warm will add to this rise, resulting in a net sea level rise of somewhere between 9 cm and 88 cm by 2100 and continuing for centuries thereafter (Van Lipzig *et al.*, 2002; Vaughan and Spouge, 2002; Church *et al.*, 2001).

Meanwhile, the permafrost that underlies some two-thirds of the Arctic land mass is expected to undergo extensive thawing, increasing the thickness of the active layer overtop continuous permafrost zones by 30 to 40% in most regions by 2100. Since snow acts as an insulator that slows down the penetration of winter cold temperatures into the ground, any decrease in snow cover under warmer climates could help offset some of permafrost loss. Much of the permafrost would completely disappear in discontinuous zones. These changes would cause significant ground settlement in most affected regions, and catastrophic slope movement in some locations. While much of the melting ground ice may evaporate, it will also have pronounced effects on the permeability of soils, the melting of surface ice and the seasonality of stream flow. These changes, in turn, will affect ecosystems. There is also a risk that permafrost degradation could cause the release of large amounts of methane gas from natural gas hydrates, perhaps explosively (Stieglitz *et al.*, 2003; Nelson *et al.*, 2002; Stendel and Christensen, 2002; Hecht, 2002).

Severe Weather

Much of the potential risks of danger associated with warmer climates relate to the frequency of severe weather events that exceed the tolerance levels of ecosystems and/or socioeconomic systems. These events are often regional and local in scale and by definition occur infrequently. Hence, they are much more difficult to simulate than larger-scale climate phenomena. However, various types of climate studies using model outputs have helped provide some useful clues as to how the behavior of these events might change under warmer climates (Timmermann, 2001; Herbert and Dixon, 2003; Palmer and Raisanen, 2002; Milly *et al.*, 2002; Huntingford *et al.*, 2003). For example:

- Temperature extremes. An increase in average global temperatures will very likely cause a disproportionately larger increase in the frequency and intensity of extreme hot days and a decrease in the probability of extreme cold days. Because of the added discomfort of higher humidity, periods of intense heat stress become even more frequent.
- Precipitation extremes increase more than their means, and intense rainfall events become almost twice as frequent in many regions. Length of wet and dry spells both increase. Extreme rainfall events over the United Kingdom that now only occur, on average, about once every 20 years could occur once every 3 to 5 years within the next century. Over central and northern Europe, winter precipitation extremes that now occur about once in 40 years may increase to once in 8 years by the time of a atmospheric CO_2 concentrations double preindustrial levels. A similar increase occurs for summer monsoonal rainfall extremes over much of southern Asia. However, such events are projected to become less frequent over the Mediterranean and northern Africa.
- While there is no general agreement amongst models, some studies suggest that the total number of storms in midlatitudes is likely to decrease, but that the number of intense storms will rise. Dominant storm tracks may also be displaced poleward.
- Intense El Nino and La Nina events, which can be very disruptive to normal weather patterns, may become more frequent in the future.
- While it is uncertain whether the frequency of these storms will rise, warmer ocean surfaces imply that the potential upper threshold for storm intensity will increase.
- Most large river basins will experience a decrease in average flows, but an increase in extreme flows and related flood risks. These changes in precipitation extremes, together with changes in timing of snowmelt, will have significant impacts on river flows and flood risks. In one study, 6 of 14 large river basins assessed are projected to experience a higher probability of floods, while two show a decrease. In this region, poor farmers and consumers are expected to bear most of the related costs. Figure 8 (Milly *et al.*, 2002) shows results from another study that projects,

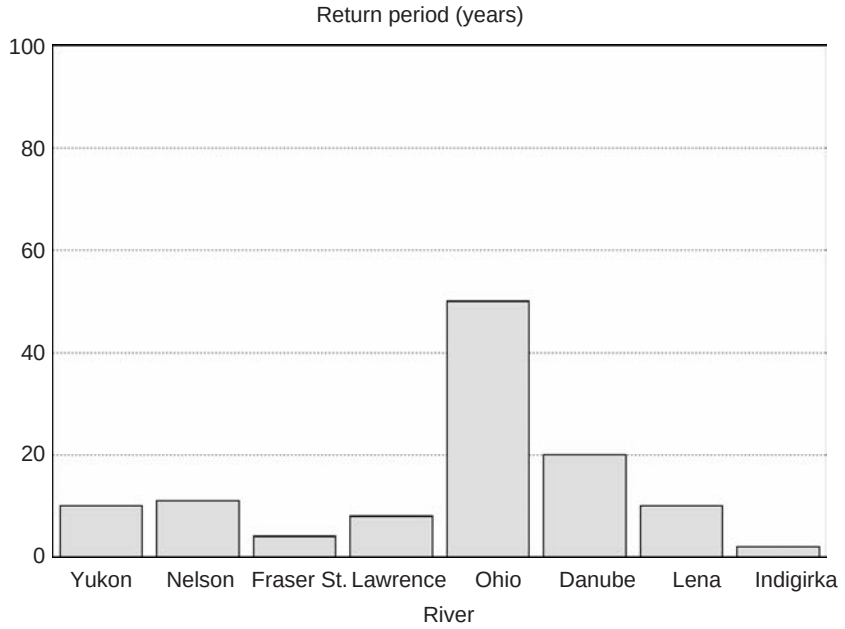

Figure 8 Return periods for the current 100-year flood for selected North American and Russian River basins under a $4 \times CO_2$ scenario. The control bar is the current 100-year flood event

for a quadrupled CO_2 climate, that some extratropical river basins, particularly in Russia, could see current one in 100-year flood events increase in frequency to once every 2 to 3 years. However, most high-latitude rivers will have lower severe spring flood risks because of less snowmelt.

Risks of Large-scale Abrupt Changes in Climate

In general, climate models suggest that global climates will evolve in a continuous transient response to enhanced radiative forcings. However, there is considerable evidence from paleoclimatological data that the Earth's climate can change abruptly from one relatively stable mode to another. Such abrupt changes would be far more catastrophic in nature, since the changes would be large and very rapid, and hence the potential for progressive adaptation of ecosystems and socioeconomic infrastructures would be minimal. Experts have identified three possible processes by which enhanced radiative forcing could cause such abrupt discontinuities in climates over the next decade (Alley *et al.*, 2003; Vaughan and Spouge, 2002; Smith *et al.*, 2001).

The first is the risk of a complete shutdown of the global ocean thermohaline circulation. Since this circulation system is the driver for the Gulf Stream that keeps western Europe some 10 °C warmer than it would be in its absence, its cessation could cause a calamitous cooling in that region even as the rest of the world warms. It would also dramatically alter the global atmospheric circulation patterns and hence the distribution of rainfall.

The second is the possible collapse of the West Antarctic Ice Sheet. This ice sheet is considered to be unstable and its collapse through glacial surging (rather than *in situ* melting) could be triggered within the next century. That ice sheet stores enough water to raise global sea levels by 5 to 6 m. A panel of experts has noted that there is a 5% risk of a collapse of the West Antarctic Ice Sheet within 200 years (which would cause sea levels to rise by 1 m/century) and a 30% chance that rapid decay of the ice sheet would add 20 cm per decade to sea levels.

The third risk relates to the potential release of large amounts of methane contained within the solid hydrates found in the Arctic permafrost zone. Paleo studies indicate that such large releases from hydrates below the ocean bottom likely occurred during an abrupt climate warming some 55 million years ago, and could happen again. Since methane is a potent greenhouse gas, such releases could abruptly launch the Earth into a super-greenhouse effect era.

While the impacts of each of these abrupt discontinuities would be globally catastrophic, experts considered the risks of such events within the next century to be quite small.

Concluding Remarks

While there continue to be significant uncertainties with respect to attributing past climate change to specific causes and in projecting the rate and characteristics of future climate change, there are a number of fundamental conclusions about climate change that now have both wide acceptance within the science research community and significant implications for global ecosystems and society. These include the following:

- Global climate is constantly changing in response to a range of external and internal forces acting upon the climate system.
- The magnitude and rate of average global surface warming during the last 50 years appear to be unprecedented in at least the past two millennia.
- Other aspects of the global climate system have changed significantly in recent decades.
- The balance of evidence indicates that these changes are likely due to human interference with the climate system.
- Projections for future warming suggest that changes in global temperatures by 2100 will be unprecedented in human history.
- Warmer climates will alter many aspects of local and regional weather and thus have major impacts on ecosystems, hydrology, and human infrastructures.

Acknowledgments

In preparing this overview of climate and climate change science, the author has relied heavily on the assessments provided by the Intergovernmental Panel on Climate Change, particularly the Third Assessment completed in 2001. That assessment can be accessed on line at **www.ipcc.ch.** The author also wishes to acknowledge the valuable input and review comments provided by Elizabeth Bush, Patti Edwards, Dr Venkata Neralla, and Bob Whitewood.

PART 4

Hydrometeorology

35: Rainfall Measurement: Gauges

BORIS SEVRUK

Institut für Atmosphäre und Klima (ETH), Zürich, Switzerland

It is difficult to measure precipitation without introducing systematic errors or biases. The quality of any measurement will depend on the type of gauge used and the details of the installation, as well as the characteristics of the gauge site including exposure and the prevailing weather. All precipitation measurements using can-type gauges are subject to systematic errors, mostly due to deformation of the wind field above the precipitation gauge orifice, wetting and evaporation losses, splash-out and splash-in, blowing snow, and so on. Because these measurement errors are systematic, precipitation gauges frequently show different precipitation figures. This is the case when the gauges are of different construction, or the same construction, but from different manufacturers, or are installed at different heights at the same site near each other, or under different gauge site exposure. With the exception of measurements of blowing and drifting snow, they show less precipitation than the "true" precipitation falling on the ground. Correction procedures are different for rain and snow. They were developed for different types of precipitation gauges and various time intervals according to the availability of necessary input data. Corrections are based either on empirical field methods using the World Meteorological Organization reference standard, laboratory experiments, or numerical simulation.

INTRODUCTION

Precipitation measurements are important for many applications in meteorology, hydrology, agriculture, and climate research. In hydrology, they are used to assess the areal precipitation, which is a basic component of water balance and precipitation-runoff models. To achieve these aims, elevated can-type precipitation gauges are operated in networks consisting of several gauge sites selected according to the main characteristics of the area and precipitation fields of interest (*see* **Chapter 36, Precipitation Measurement: Gauge Deployment, Volume 1**). Such simple point measurements are converted to areal precipitation using various interpolation techniques, including empirical and geostatistical (kriging) methods. They are also used to check the results of more complex methods to assess areal precipitation such as radar (*see* **Chapter 63, Estimation of Precipitation Using Ground-based, Active Microwave Sensors, Volume 2**), satellites (*see* **Chapter 64, Satellite-based Estimation of Precipitation Using Microwave Sensors, Volume 2**), and mesoscale forecast model (**Chapter 31, Models of Clouds, Precipitation and Storms, Volume 1**). Methods of precipitation measurements and definitions in English, French, Russian, Chinese, and Spanish are described briefly in WMO (1994), and with more details being given in German by Sevruk (2004). For further discussion and details of the most significant and recent papers, the reader is referred to the review by Sevruk (2004).

TYPES OF PRECIPITATION GAUGES

According to the definition, precipitation gauges are universal instruments to catch all forms of liquid and solid precipitation, including fog, dew, rime, and so on. They consist of a cylindrical collector to catch the precipitation, and a container to accumulate it during the recording time interval. The collector and the container are connected through a funnel with an outflow. Sometimes minor changes are made to measure snowfall in places where snow makes up a large portion of the total precipitation. (The funnel is removed to increase the depth of the collector, or a snow cross is inserted into the collector to reduce the blowing-out of snow.) To ensure the orifice area remains at the

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

standard size and to protect it against deformation, the orifice is reinforced by a hard metal rim of a given diameter with sharpened upper edge. The orifice level has to be kept horizontal. To protect it against splash-in, drifting, and blowing snow, it is fixed on a pole at a standard height above the ground, or placed on the ground and surrounded by antisplash material. The precipitation is measured as a volume and converted into depth units, that is, millimetres (or inches) to the accuracy of 0.1 mm (or 0.1 in). There are three basic types of precipitation gauges. They differ according to the recording time interval as follows: recording gauges have a resolution of one minute, standard (daily) gauges of a few hours up to one day, and storage gauges (totalizer) of months up to one year. The latter have a big container to accumulate annual precipitation, and are installed mostly in mountains at the heights well above the depth of snow cover, of at least 3 m above the ground, to be protected against blowing and drifting snow. The standard gauges and storage gauges are measured manually using calibrated cylinders or sticks graduated in 0.1 mm (or 0.1 in). Precipitation depths smaller than 0.05 mm are recorded as a trace. Recording gauges have different systems of measurements. The demand for precipitation data of very short time intervals to record high rainfall intensities (up to 5 mm min^{-1}), which are important variables for many engineering applications, has resulted in various instrument designs and operational data processing and archiving procedures. These designs may use a float to record the water level in the container, or mechanical and electronic weighing systems weigh continuously the water in the container or falling from the collector (tipping-bucket). Drop counters and optical systems are also used. Distrometers are used to measure the drop-size distribution. To melt the snow accumulated in a precipitation gauge, standard daily gauges are brought to a warm room, heating devices are used by recording gauges, and antifreeze liquid is used by storage gauges. The accumulated precipitation in storage gauges is protected against evaporation by a thin oil layer.

Precipitation gauges vary from country to country. Sevruk and Klemm (1989) showed that there were more than 50 types of manual, national standard precipitation gauges in use at that time around the world. Gauges differ considerably in design, shape, size, and material. The orifice area varies from 7 to 1000 cm^2, most gauges having an area of 100–200 cm^2. Materials used are primarily galvanized iron and copper, but plastic is popular as well. The installation height varies between countries from 0.2 to 2.0 m. Up to 90 countries use installation heights of 1 m and less, 2 m was used only in the countries of the former Soviet Union but 0.3 m in the former British Empire. To reduce adverse wind effects, seven types of gauges are permanently fitted with different designs of windshield. In each country, one specific type of gauge installed at the same standard height, is used as the standard gauge. Even so, in regions where snow is common, the installation height is usually bigger. The most widely used standard manual gauges appear to be the German Hellmann gauge, followed by the Chinese type and the English (Snowdon) Mk2 gauge. These types account for one-half of all precipitation gauges (approximately 200 000 worldwide) but they are concentrated in an area of only 31×10^6 km^2. Of the recording precipitation gauges, float systems are the most common, followed by tipping-bucket gauges. Weighing systems are used far less, and drop counter and optical systems are rarely used (Sevruk, 2002). The oldest method of precipitation recording, a pen and time chart, is still used in most countries, followed by modern data logging and other intermediate methods. Punched paper tape is used only in a few countries. The most used method of data transmission is by conventional post, followed by telephone, radio, and satellite. But data loggers, telex, e-mail, telegraph, and PC networks are all also used. In contrast to the standard manual gauges, a particular country may use different recording gauges at different installation heights.

ERRORS OF PRECIPITATION MEASUREMENTS

It is difficult to measure precipitation without introducing systematic errors or biases (Sevruk, 1982, 1986a; WMO, 1994). Some observers have a tendency to roundup smaller fractions of precipitation than 0.1 mm, others round it down. Moreover, even the method of employing the measuring glass or stick during readings can change between different observers. Small deviation in the gauge orifice from the horizontal level can also result in errors (Sevruk, 1984). Both error sources cause random errors. Other errors arise from the fact that the can-type gauges with a horizontal orifice are not able to measure properly all forms of precipitation such as fog, dew, and so on, as well as the oblique precipitation falling on exposed slopes. This causes deficits in certain regions (e.g. Andes, tropical forests, mountains, slopes etc.), and in these cases special instruments should be used to measure precipitation more accurately. On exposed windward slopes, precipitation is frequently falling because of strong winds, perpendicular to the slope or drifting along the slope, and the horizontal orifice does not catch the precipitation properly. The windward side of the gauge collector presents an obstacle to the airflow, and the precipitation particles are carried out over the horizontal orifice. In addition, the horizontal projection of a slope results in a smaller area than the true area of the slope. Consequently, the volumes of precipitation and runoff are in fact greater than assessed from the measurements. Therefore, orifices parallel with the slope are preferably on exposed slopes in hydrological and agrometeorological studies (e.g. erosion, land slides) (Sevruk, 1972; Sharon, 1980). The quality of measurements also depends on the type of gauges used and

how they are installed, as well as the characteristics of the gauge site and the prevailing weather. Generally, recording gauges seem to be less accurate than manual gauges (Sevruk, 1996), in that they tend to measure less precipitation. Particularly, the tipping-bucket gauge is not very accurate (Sevruk, 1996; Upton and Rahimi, 2004). These gauges should be calibrated at least once a year. Losses due to heating in the winter season are large (Zweifel and Sevruk, 2003). Frequent failures such as blocking of the tipping-bucket, clogging of the outflow by insects, leaves, bird droppings, and so on, increase the maintenance costs. Electronic weighing systems seem to be better, but they show also shortcomings such as temperature effects, and software is needed to filter the effects of wind shocks and sudden changes of weight (Sevruk, 2004). However, all precipitation measurements using can-type gauges are subject to systematic errors mostly due to wind field deformation above the precipitation gauge orifice, wetting and evaporation losses, splash-out and splash-in, blowing snow, and so on (Sevruk, 1982, 1993). With the exception of snow blowing and drifting, they show less precipitation than the "true" precipitation falling on the ground. An elevated precipitation gauge systematically distorts the wind field above the gauge orifice and forces the wind speed to increase over the gauge orifice (blocking effect). This phenomenon has been demonstrated many times by experiments in wind tunnels and by numerical simulation (Sevruk *et al.*, 1989; Nespor and Sevruk, 1999). The adverse effect of the wind is that some of the lighter precipitation particles are borne away before reaching the gauge and are lost from the measurement. The wind-induced loss depends on windspeed, the weight of precipitation particles, and the gauge construction (e.g. the shape of the gauge and orifice rim, and the use of windshields). Windshields reduce the height/diameter ratio of the gauge, which improves aerodynamic properties, shift the gauge leeward to the zone of lower windspeed, and displace the airflow downward. In this way, they reduce the wind-induced losses. Consequently, the wind-induced loss is smaller for large intensities (i.e. heavy raindrops), small installation heights (smaller windspeeds), and gauges with windshield and those that are placed at protected gauge sites. (The effect of windshields is generally small for rains, as shown by Duchon and Essenberg, 2001.) In contrast, it is large for small intensities, large installation heights, unshielded gauges, and at exposed gauge sites. The loss amounts on average to 2–10% of measured values of rain and up to 60% of snow for unshielded gauges and windspeeds greater than $4\,\mathrm{m\,s^{-1}}$ (Goodison *et al.*, 1998). Since the wind-induced losses during snowfall can be ten times larger than for rain, the fraction of snow in the total precipitation is a very important variable to consider when assessing the losses. The error resulting from the blowing of snow into the gauge should be considered during snowstorms with windspeed larger than $5\,\mathrm{m\,s^{-1}}$ (Bogdanova *et al.*, 2003). In dry cold regions, the overcatch due to blowing snow can more than compensate for the wind-induced losses and the trace precipitation (Sugiura *et al.*, 2003). Some types of windshields also cause overcatch of snow during small windspeeds. (The zone of concentrated precipitation is shifted over the gauge.) Wetting losses depend on age, material, and the depth of the collector relative to its diameter, as well as on the frequency of events and types of precipitation. Snowfalls cause smaller wetting losses than raindrops, which stick on the inner walls of the collector and container and evaporate. Generally, wetting losses amount to 0.2 and 0.1 mm per rain and snow event, respectively. The evaporation loss from the container depends on the shape of the gauge and weather characteristics (e.g. saturation deficit of the air, windspeed, and duration of evaporation, see Sevruk and Klemm, 1989; WMO, 1994).

CONSEQUENCES OF ERRORS OF PRECIPITATION MEASUREMENT

The systematic measurement errors in precipitation gauges frequently result in different precipitation figures. This is the case when the gauges are of different construction, or the same construction, but from different manufacturers, or when gauges are installed near to each other but at different heights at the same site, or at different gauge sites. (Windspeed increases with the height above the ground.) Because different types of precipitation gauges as used in the same or different countries, the global and local precipitation data sets are often not compatible (Sevruk, 1994). Comparing precipitation figures and intensities among countries, or within a single country, often shows systematic differences. To eliminate these spatial inhomogeneities of precipitation time series, the performance of precipitation gauges has to be checked and the precipitation measurements corrected. Similarly, changing to a different type of gauge at a site, or moving the gauge to a new site with different exposure, can also cause inhomogeneities (Peterson *et al.*, 1998). Sevruk and Klemm (1989) showed that in 50 countries, changes in national standards such as the replacement of a long-used type, or lowering or increasing the installation height, have taken place in the last 50 years. The most decisive change was related to the replacement of a certain number of standard manual precipitation gauges with recording precipitation gauges (Sevruk, 1996). The effect of gauge site exposure on the quality of precipitation measurements is most readily assessed using four classes of exposure (exposed, mostly exposed, mostly protected, and protected). They are based on analysis of metadata stored in archives of meteorological services (De Smedt *et al.*, 2003). Exposed sites are characterized by only small obstacles such as bushes, group of trees, or a small house. Mostly, exposed sites are surrounded by small groups of trees or bushes or one or two houses. They frequently occur on islands, lake

shores, in high mountains, prairies, and so on. Mostly, protected sites are found in parks, forest edges, village centers, farms, groups of houses, or yards. Protected sites are typically young forests, small forest clearings, parks with big trees, city centers, closed deep valleys, strongly rugged terrain, or leeward of big hills and buildings, and so on. The classes can be based on direct measurements of the vertical angle of obstacles. In some cases, fish-eye pictures of gauge sites are also available. Because of considerable wind-induced losses, the first two classes should not be used for hydrological studies, unless precipitation measurements are corrected.

CORRECTIONS OF PRECIPITATION MEASUREMENT ERRORS

Correction procedures are different for rain and snow, and different corrections have been developed for different types of precipitation gauge and various time intervals according to the availability of necessary input data as shown by Sevruk (1982, 1986a). They are applied in many parts of the world (e.g. Scandinavia, Germany, Switzerland, Baltic countries, former USSR, Greenland, Tibet, Slovakia etc.). Input data include windspeed, the precipitation intensity and weather situation (different drop-size distributions exist for different types of rain with the same intensity), temperature, rain/snow amounts, frequency of events, and so on. Corrections are based either on empirical field methods, using the World Meteorological Organization (WMO) reference standard, or on numerical simulation as described by Nespor and Sevruk (1999). In addition, the water equivalent of fresh snow and snow cover and the snow depth have also been used to assess the "true" snowfall and to derive correction procedures (Sevruk, 1983, 1986b; Sevruk *et al.*, 1998). The WMO reference standard consists of a pit gauge with antisplash grid for rain measurements, and the double-fence for snow measurements (Figure 1). The pit gauge is sunk into a pit to make the gauge orifice level with the ground. A metallic or plastic grid protects the gauge against splash-in. Because the windspeed at ground level is reduced almost to zero, the wind-induced error of pit gauges is small. However, such a gauge cannot be used for snow measurements as drifting snow would fill it and falsify the measurements. The double-fence was developed to overcome this problem. It consists of two circular lath-fences of different diameters: 12 m for the outer one and 4 m for the inner one. The respective heights are 3.5 m and 3 m. A precipitation gauge with a windshield is situated in the center and elevated 3 m above the ground. The WMO organized two international intercomparisons using these references with the aim of developing correction procedures for the wind-induced losses, as reported

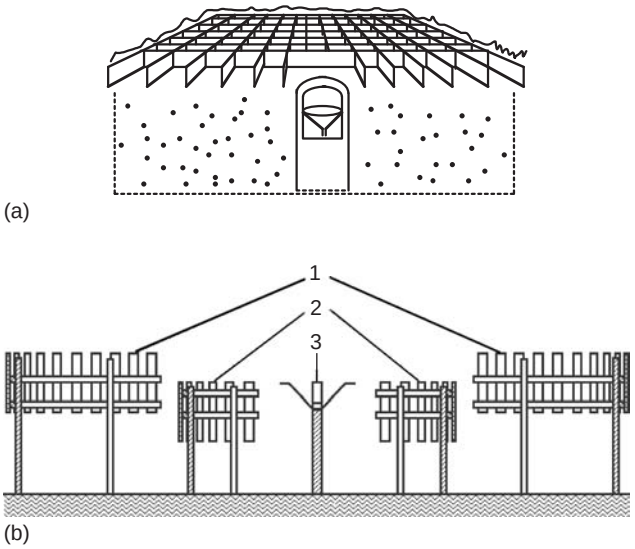

Figure 1 The WMO reference standard precipitation gauges. (a) the pit gauge with antisplash grid for rain measurements and (b) the double-fence for snow measurements. The latter consists of two fences of different diameters of 12 m (the outer one: 1) and 4 m (the inner one: 2). The respective heights are 3.5 m and 3.0 m. 3: indicates the Russian Tretjakov gauge with windshield

by Sevruk and Hamon (1984) and Goodison *et al.* (1998). The conversion factor k, defined as the ratio of precipitation values of the reference, P_k, and the elevated gauge, P_m, is used to correct the wind-induced losses ($P_k = k P_m$,). k is related to the windspeed, and the parameters of precipitation structure such as the mean intensity of rain, temperature, and the fraction Q of solid precipitation in total precipitation. Such a dependency for monthly means is shown in Figure 2 and for daily values in Figure 3. Because the structure of snow depends on temperature intervals, the diagram in Figure 2(b) is valid for snowfalls in the range of temperature from -1 to $-9\,^{\circ}\mathrm{C}$ (Sevruk, 1982). It is important to note that there is a certain threshold value of precipitation intensity for a specific windspeed interval, because below a certain threshold value, despite the same windspeed, the wind-induced error increases rapidly (Sevruk, 1989a, Figure 3). The smaller the actual intensity, the greater the fraction of small precipitation particles, which are blown away even by very small windspeeds. This process is nonlinear as shown in Figure 3. Generally, the intensity of rain i of $0.03\,\mathrm{mm\,min^{-1}}$ is considered as the threshold value for monthly precipitation and all windspeeds (Sevruk, 1982). The fraction of rain in the total monthly precipitation, being below such an intensity is termed the parameter of rain structure N'. Because precipitation intensity measurements are missing at many gauge sites, the parameter N' was derived from the mean monthly temperature, T, the measured precipitation depth, N_g, and number q of days with precipitation as shown in

the insert in the left corner in Figure 2(a) (Sevruk, 1989b). Considering the nature of the wind-induced losses from the point of view of fluid dynamics, it is clear that the results of field intercomparison measurements are valid for a particular precipitation gauge type, defined by relevant parameters. Such international intercomparisons provide important information on the accuracy, reliability, and corrections of the measurements, and good guidance for the selection of the most reliable type of precipitation gauge.

In the case of simulations, the wind-induced error is estimated by computing the wind field around the gauge, using computational fluid dynamics methods and by numerical simulation of precipitation particle trajectories in the computed flow field. Nespor and Sevruk (1999) and Sevruk *et al.* (2000) show the results of simulations for two unshielded precipitation gauges used in Switzerland: the common daily gauge by Hellmann and the automatic station gauge ASTA (tipping-bucket). Simulation computations have many advantages when compared with the rather costly empirical methods. Once the methodology is developed, correction procedures for any type of precipitation gauge and any range of variables and very small time intervals can be made quickly on a computer, whereas, for field tests, years of data are necessary and the range of variables is limited. Usually, the most interesting events with high windspeeds and small intensities of precipitation, showing the greatest wind-induced losses are missing. Moreover, during field tests with heated gauges, the losses of precipitation catch caused by heating should be accounted separately for. This presents a rather difficult problem. The agreement between the results of empirical and theoretical procedures

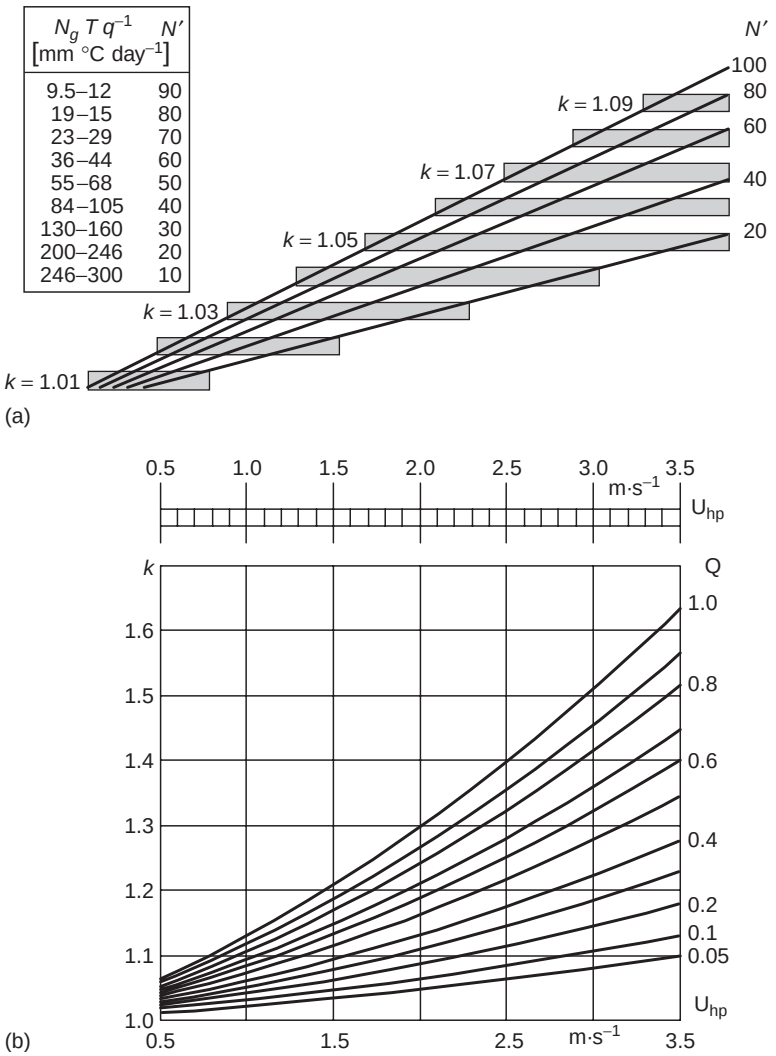

Figure 2 Mean monthly values of conversion factor k of precipitation measurements using the Hellmann gauge to reference measurements as a function of wind speed u_{np} and the structure parameter N' for rain (a) and fraction Q of snow in total precipitation (b). The latter is valid for the monthly temperature range from −1 to −9 °C

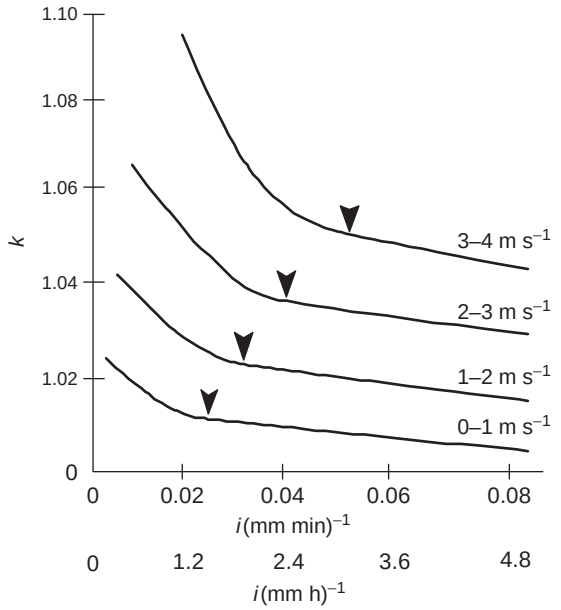

Figure 3 Wind-induced daily conversion factor k as related to the mean daily intensity of rain i and windspeed. The arrows indicate the threshold values of rain intensity. Below the threshold values the conversion factors k increase rapidly. According to Sevruk (1989b)

is fairly good, as shown by Nespor and Sevruk (1999), and Chvíla *et al.*, (2002). Having a developed correction procedure for a given type of gauge, the problem consists primarily in the resolution and availability of input data. This poses no problems for the automatic meteorological stations where hourly values of many variables are available, but it is a serious disadvantage for common gauge sites with only one precipitation observation per day. Here, interpolations are needed of practically all variables (Sevruk, 1986c). Wind measuring instruments are usually installed 10–20 m about the ground, which is up to ten times higher than the precipitation gauge orifice level (1.0–2.5 m). This discrepancy can be accounted for using the reduction procedure on the basis of the logarithmic vertical wind profile and degree of gauge site protection (De Smedt *et al.*, 2003). The latter can be directly measured at a site using a theodolite or assessed from the metadata as discussed above.

It is difficult to measure precipitation without introducing systematic errors or biases. All precipitation measurements using can-type gauges are subject to systematic errors, mostly due to wind field deformation above the precipitation gauge orifice, wetting and evaporation losses, splash-out and splash-in, blowing snow, and so on. The errors depend on the type of gauges used and their installation specifics, as well as the characteristics of the gauge site including exposure and weather situations. At present, precipitation measurements are not corrected regularly for systematic errors by national meteorological and hydrological services using standard procedures – as other meteorological variables, for example, temperature, humidity, and so on, are. Correction procedures are based on field and laboratory tests, or numerical simulations. Corrections have been developed for different types of precipitation gauges and various time intervals, according to the availability of the necessary input data, and are therefore gauge site dependent. Because these procedures are not yet standardized and will develop further in the future, it is important to preserve both the corrected and the original measured precipitation values.

36: Precipitation Measurement: Gauge Deployment

MARK ROBINSON

Centre for Ecology and Hydrology, Wallingford, Oxfordshire, UK

The deployment of a network of rain gauges involves two stages: first, the broad distribution of gauges across a region or catchment and, second, the specific location of each gauge. The spatial distribution of gauges across a region will be determined by a combination of: (a) physical characteristics of the region, including the topography and the natural variability of precipitation, and (b) institutional factors, such as the purpose of the network (setting the accuracy and level of detail of data required as well as the resources available). The specific location of gauges will be determined by purely local factors, which would affect the accuracy of the measurements. These are primarily concerned with site exposure and wind effects that could lead to errors in catch and make the data unrepresentative of a larger area.

INTRODUCTION

Precipitation is a major factor controlling the hydrology of a region and is of fundamental importance to many human activities. The number and distribution of rain gauges needed for a particular area will depend upon the natural variability of precipitation and upon the purpose for which the data are collected, since this will determine the detail and accuracy of measurements required. Much more detailed information will, for example, be required for urban storm drainage design and for research purposes than for general water resource and water supply projects. In addition, the form of the precipitation may also influence the network of gauges: snow presents special problems (*see* **Chapter 35, Rainfall Measurement: Gauges, Volume 1**) and may need to be tackled in different ways, including the use of remote sensing and snow lines. In some coastal or mountain areas, large quantities of fine water droplets in low cloud or mist may be deposited directly onto vegetation and other surfaces and special measurements may be needed (*see* **Chapter 38, Fog as a Hydrologic Input, Volume 1**).

The primary measure of precipitation is the catch in a rain gauge. The amount of water collected may be measured by manually emptying a storage rain gauge and noting the amount of accumulated water. This is done at regular intervals, most commonly each day at a set time. Alternatively a recording rain gauge may be used, which automatically registers the rate of accumulation of rainfall. The main type of recording rain gauges uses a tipping bucket mechanism to record increments of rain, typically at a resolution of 0.1 to 0.5 mm, over hourly intervals or less. Guidelines on procedures for collecting and processing rain gauge data are provided by Meteorological Office (1982, 2001) and WMO (1994). Gunston (1998) provides advice particularly for developing countries.

Despite the history of rainfall measurement dating back over 2000 years (Biswas, 1970; NIH, 1990) many problems remain in the collection and accuracy of precipitation data. The major source of error is due to wind turbulence generated around the gauge, which usually results in underestimates (Sevruk, 1982). This may be affected by the type of rain gauge (*see* **Chapter 35, Rainfall Measurement: Gauges, Volume 1**) and, also very importantly, by the local exposure of the site.

The deployment of rain gauges within an area needs to consider two aspects:

- The design of the rain gauge network, defining its purpose, the anticipated variability of precipitation, and the resources available to operate the network.
- The selection of suitable gauge sites within this framework which will provide catches that are accurate and representative

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Deployment of a Network of Gauges

A network of rain gauges represents a finite number of point samples of the two-dimensional pattern of precipitation depths. The accuracy of areal estimation depends on both the total number of gauges and their spatial distribution.

Although there are numerous technical "Guidelines" to the density of gauges needed to define areal rainfall, the actual number of gauges likely to be deployed will depend very much upon two groups of factors:

1. The natural variability of the precipitation distribution across an area. This will be determined by many physical factors, of which the most important include the topography and climate characteristics. Precipitation is more likely to be variable in areas of hilly or mountainous topography and where rainfall results from localized convectional storms rather than widespread frontal systems over flat terrain. In estimating the areal pattern of precipitation from a given gauge network, errors will occur because of the random nature of storms and their paths relative to the gauges. The accuracy of the network will depend on the spatial variability of precipitation; thus more gauges would be required in areas of steeply sloping terrain or in areas prone to random localized thunderstorms rather than to widespread frontal systems.
2. The purpose of the network (including the accuracy required) and funding available for the installation, operation, and maintenance of the gauges will have an important influence on the network of gauges deployed. There are very important nonhydrological constraints and considerations (social, economic) in determining network density. A rain gauge or any other network exists to serve certain objectives in developing and managing water resources, and must do this "on a scale commensurate with the overall level of economic development and environmental needs of the country" (WMO, 1994). The density of gauges required will, for example, depend upon the timescale of interest. For water resource purposes in large basins, monthly or seasonal totals may be sufficient whilst in some studies, such as urban runoff design, rainfall depths over only a few minutes' duration may be required. In short-duration local storms, the spatial distribution of precipitation is very heterogeneous and precipitation gradients may be quite steep. As larger areas and longer time periods are considered, the distribution of precipitation becomes more homogeneous and gradients are less steep. Denser networks of rain gauges are needed for smaller space and time intervals studies. This is why the purpose of a precipitation gauge network design is one of the limiting factors of the accuracy of areal precipitation assessment.

In situations where only manually read gauges are in use, there is an obvious need for these gauges to be at sites near to centers of population and road access. Historically, this has resulted in gauge distributions with a concentration in river valleys and near to towns and villages, and with relatively fewer in adjacent hill areas, despite the often greater precipitation depths. The development of automatic recording gauges has not only provided much increased information on the short-term rates of rainfall, but, importantly, it also means that gauges can be distributed more easily into unpopulated areas, although snow measurement is still an unresolved problem.

In practice, rain gauge distributions generally reflect a mixture of both the physical and social or institutional factors described above and the resulting "network" is simply "an aggregation of gauges or stations that have no coherence in their objectives" (WMO, 1994). Rain gauge network design is usually concerned with modifying an existing network, either to expand it to meet new requirements or to reduce it to lower costs. Only very rarely does it involve creating an entirely new network from scratch. If a new network is envisaged, then there are several different approaches. If an area has no existing gauges to indicate the spatial distribution of precipitation, it is necessary to transpose information on its variations in time and space from a similar area, in order to design a preliminary network. This is more often the case for developing countries. In developed countries, in contrast, some form of network is usually already in place but probably evolved in an arbitrary manner. One approach to network design is to define *a priori* those factors that are likely to control precipitation patterns – such as altitude, distance to the sea, ground slope and aspect – and to divide the area into domains representing classes with different ranges of these geographical and topographic characteristics.

An alternative approach, in an area without rain gauges, would be to initially install a large number of gauges in order to identify the predominant areal pattern of precipitation. Subsequently, "redundant" gauges that are not needed to define the average or the spatial patterns to the desired level of accuracy would be removed (ASCE, 1996). This method is likely to be expensive and time-consuming since the full network of temporary gauges may need to be operated for a considerable time in order to encompass a full range of precipitation conditions.

The areal distribution of gauges in an area should reflect the intended use for the network; thus, if the main purpose of precipitation measurement is for runoff studies, then more gauges should be deployed in those areas that contribute most to runoff. Similarly, if the gauges are to be used to calibrate a weather radar, then their distribution would be influenced by their position (quadrant and distance) relative to the radar.

Deriving Areal Average Values

A basic requirement in many hydrological applications, including water balance and rainfall–runoff studies, is to estimate the mean precipitation depth over a given area in a specified time period. This is often referred to as "areal rainfall". There are a large number of techniques that can be used to calculate areal rainfall from a network of often comparatively widely separated point measurements, and to refine the location and number of gauges required. Singh (1989) provides a detailed discussion of 15 different methods. These include polygonal weighting, inverse distance weighting, isohyetal, trend surface analysis, analysis of variance and kriging.

Whilst the accuracy of areal precipitation estimates will increase with the number of gauges in the network, a dense network is difficult and expensive to maintain. A number of general guidelines for gauge density have been produced. The World Meteorological Organization (Perks *et al.*, 1996) evaluated the adequacy of hydrological networks on a global basis for the *Basic Hydrological Network Assessment Project* and gave the following broad guidelines for the minimum gauge density of precipitation networks in various geographical regions: one rain gauge per 25 km^2 for small mountainous islands with irregular precipitation; 250 km^2 per gauge for mountainous areas; 575 km^2 elsewhere in temperate, Mediterranean, and tropical climates, and 10 000 km^2 for arid and polar climates.

Comparable actual values of the average area (km^2) per storage rain gauge for a range of countries include France (110), Netherlands (130), China (470), India (790), Australia (1010), United States (1040), and Mongolia (47 420). It is, however, salutary to note that even for the United Kingdom, which has one of the highest densities of storage rain gauges in the world – an average of one gauge per 60 km^2 (WMO, 1995) – the total collecting area of all its rain gauges combined is less than one standard football pitch!

1. Arithmetic mean. The simplest technique to calculate areal precipitation is to calculate the arithmetic mean of all the rain gauge totals within the area of interest. This assumes that each gauge is representative of an equal portion of the total area. This may be satisfactory in regions of flat topography with little systematic variation in precipitation and a uniform distribution of rain gauges. Such conditions are not generally found in practice, and there is often a tendency for the distribution of gauges to be in clusters that mirror human populations, which results in the potential for biased estimates (Figure 1). Thus, gauges are often most frequent in river valleys and most widely spaced in mountainous areas where precipitation depths are greatest, and the spatial variability is typically largest due to the influence of altitude and slope orientation.

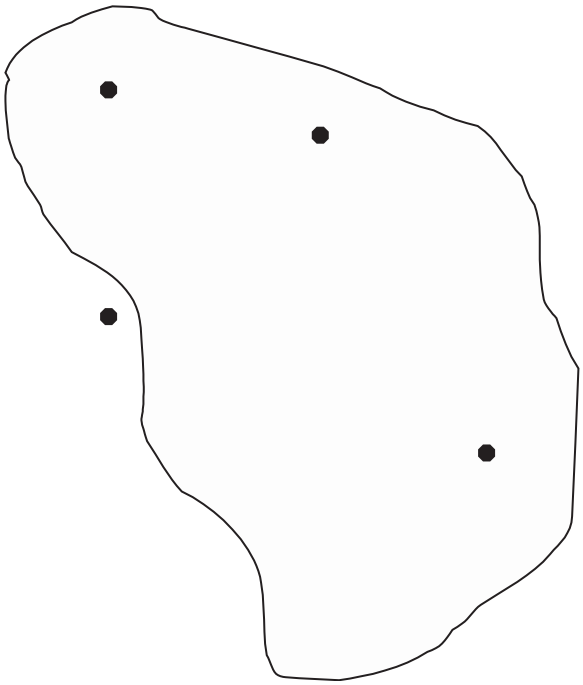

Figure 1 The areal precipitation calculated from arithmetic mean of this uneven spatial distribution of gauges could be seriously biased if there was a strong rainfall gradient across the area. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

2. Thiessen. This method is suited to flat areas where each gauge is assumed to be the best measure of the fall on all of the land that is closer to it than to any other gauge. The catch at each gauge is weighted by the proportion of the total basin that it represents to calculate the basin mean rainfall. The Thiessen polygon method (Thiessen, 1911) has been widely adopted as a better method for calculating areal depths than the arithmetic mean. It allows for a nonuniform distribution of gauges by assigning "weights" to the measured depths at each gauge according to the proportion of the catchment area that is nearest to that gauge (Figure 2). The individual weights are multiplied by the gauge reading and the values are summed to obtain the areal mean precipitation. The method may be carried out graphically, or can be programmed for computer application by superimposing a regular grid over the area and allocating each grid point value to the nearest gauge. This assumes that each gauge is representative of its portion of the area, and the resulting precipitation surface is a series of polygonal plateaus with sharp steps between them. A modification is to allocate a region or "domain" to each gauge on the basis of physical factors such as local meteorological conditions and topography, thought likely to influence precipitation. Voronoi interpolation (Gold, 1989) is a development of the Thiessen method and has the advantage for hydrological applications that it

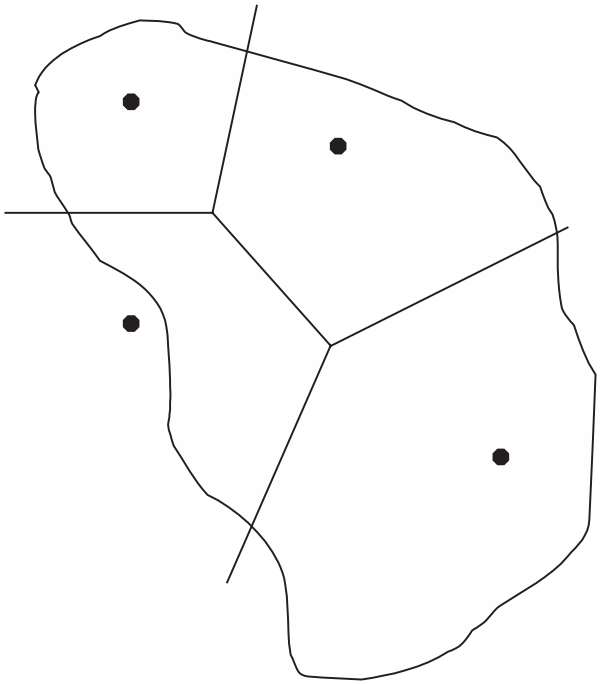

Figure 2 Thiessen polygons allow rain gauge catches to be weighted by the size of area they are nearest to. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

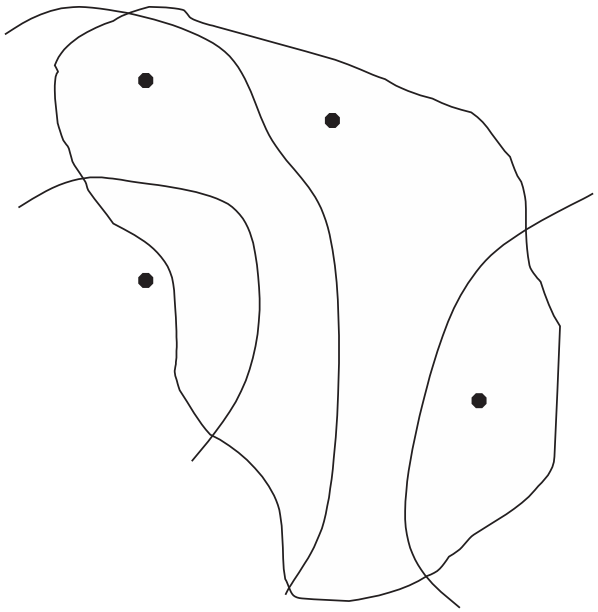

Figure 3 Isohyets between point gauge values allow other qualitative factors to be considered. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

produces a much more realistic surface (BSI, 1996). Neither method allows for precipitation gradients with altitude, slope orientation, and aspect. Their results can be strongly influenced by the positions of the gauges and where they are very unevenly distributed, quite small changes in gauge location may result in large changes in the weighting factors.

3. Isohyetal. This is a graphical technique, which enables topographic effects and any other subjective or "local" knowledge about meteorological patterns to be incorporated. It is probably the most reliable, but subjective, of the standard methods of areal precipitation calculation. It involves drawing estimated lines of equal precipitation (isohyets) on a map between gauges, making allowance for factors such as topography and distance from the sea. It can incorporate local knowledge and experience of factors such as windward and leeward effects related to the prevailing wind direction (e.g. Chater and Sturman, 1998). Areal precipitation is then computed by calculating the areas between the isohyets (Figure 3). This method thus uses all the data and knowledge about precipitation patterns in an area, but the results are subjective and can involve a considerable amount of time to construct the maps.

4. Geostatistical methods. The accuracy of the estimation at each point or grid will be a function of the distance from the nearest gauges. A large number of studies have used techniques including multiple regression and kriging to quantify the statistical structure of precipitation patterns, and to identify a more effective network design (e.g. Periago *et al.*, 1998). The simplest technique is to use an inverse distance weighting of gauge values to each point. In this method, weights are calculated depending on the distances between the location where an estimate is required and the location where the rainfall are measured (Figure 4). For each grid point, weights are assigned to each gauge value based on the distance from the grid point. In using any method based on the correlation between gauges, it is of paramount importance to ensure the homogeneity of record of each gauge. Unrecorded changes in siting or exposure may weaken correlations between gauges, resulting in networks that are denser than necessary. Kriging is a statistical method that uses the variogram of the precipitation field (i.e. the variance between pairs of points at different distances apart) to estimate interpolated values. The resulting precipitation field is optimal in the sense of identifying gauge weightings to minimize the estimation error. It has the advantage that it can be used to generate a map of the standard error of the estimates that indicates where additional gauges would be of most benefit. Bastin *et al.* (1984) use the technique to estimate areal rainfall, to indicate the degree of redundancy in a gauge network and to identify locations where the deployment of additional gauges might be most useful.

Different methods for estimating mean areal rainfall have been used in different studies. The selection of

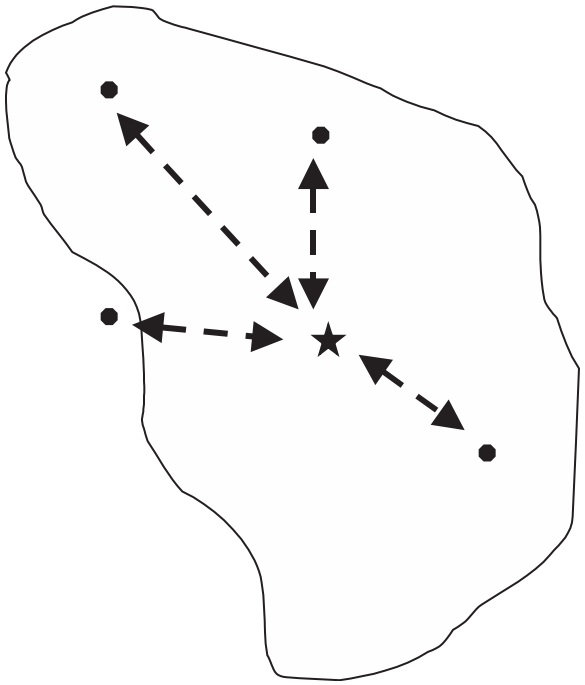

Figure 4 Estimating precipitation at a point by weighting gauge catches by their distance from that point. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

the most appropriate one for a particular problem will depend upon a number of factors, including: the time available and the expertise of the hydrologist, the density of the gauge network, and the spatial variability of the precipitation. In general, the accuracy of all the methods for estimating areal rainfall will increase with: (a) the density of gauges, (b) the length of period considered, and (c) the size of area. Comparisons of the methods have perhaps not surprisingly shown smaller differences where time interval selected is long and the topography of the area is subdued (Singh, 1989).

Rain gauge Deployment – Local Site Factors

In addition to considerations of the broad regional pattern of gauge locations, it is necessary to ensure that each point gauge site should give an unbiased catch that avoids purely local (small scale) effects and so is representative of a larger area. The detailed site conditions will be paramount in determining their actual locations. There are a number of sources of error in catch, but by the far the most important is usually wind turbulence across the gauge resulting in underestimation of the true value. Measures that may be taken to reduce wind effects include the design of rain gauge used and the choice of location. Aspects of rain gauge design that may affect its susceptibility to catch errors are discussed separately (*see* **Chapter 35, Rainfall Measurement: Gauges, Volume 1**).

The siting and exposure of a rain gauge is very important for obtaining accurate measurements. Sites should be chosen to minimize the effects of wind on catch. Gauges should not be located close to objects and obstructions that would distort local wind flow patterns; nor should they be so exposed that the gauge catch may be seriously reduced when the wind is strong. The best location is where the gauge is uniformly protected in all directions, by objects that are at a distance of at least twice their height above the gauge (Meteorological Office, 1982). In some open situations exposed to strong winds, it may be necessary to construct a low turf wall around the gauge with a sloping outer edge and a flat crest on the same plane as the gauge rim (see Figure 5).

Rain gauge measurements may be crucially sensitive to the immediate environment surrounding the gauge. As a general rule, the windier the gauge location is, the greater the precipitation error will be. Rodda and Smith (1986) examined the records for 43 sites across the United Kingdom where a standard gauge (rim height 30 cm) operated alongside a ground-level gauge. Record lengths varied between sites but were generally of at least 10 years duration. The long-term percentage error of the standard gauges (assuming the ground-level gauge to represent the "true" rainfall) was generally an average of about -3 to -6%, but at some exposed upland sites this figure rose to -15%, with considerably higher errors over shorter periods and in individual storms. There was a strong correlation between average wind speeds and gauge error at the different sites. Price (1999) found that comparable gauges in upland Scotland had a systematic undercatch of about 10%.

Figure 5 The construction of a low turf wall around the gauge with a crest on the same plane as the gauge rim can help reduce undercatches. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

General advice on rain gauge siting dates back over a century (Symons, 1864; Mills, 1901) and remains broadly the same today in texts such as Meteorological Office (1982); NWS (1989); WMO (1994). A site should not be overexposed to strong winds, nor should it be unduly sheltered by nearby obstacles. Gauges should be positioned in a flat area, away from any obstructions that might cause air turbulence and consequent nonuniform deposition of rain droplets. As a general rule, the gauge should be at a distance of at least twice (and preferably four times) the height of any obstacle. But these guides also recognize that some degree of shelter is needed, since a very open site with no shelter would be too exposed and subject to excessive wind effects. Where this is difficult to achieve, providing good exposure to the most common directions of wind should be the priority.

In practice, there may be considerable constraints placed on those locations where rain gauges can be deployed. Some landowners may refuse to allow gauges on their land, whilst others may place severe restrictions – for example, in farmed areas that gauges are put at the edge of fields rather than in the center. Pressure for gauges to be sited close to the office of the organization responsible for the readings may result in poor exposure (see Figure 6a, b).

Consideration of wind effects on gauge catch is of particular importance when interpreting precipitation records from less than ideal sites. In the eighteenth and nineteenth centuries, rain gauges were often placed on a roof or a high wall to be safe from human or animal interference, thus inadvertently increasing the potential undercatch. This practice is still common today in many developing countries (Farquharson, 2003), and particular care must be made when interpreting such records. For many urban and suburban areas, the only sites available for rain gauges are on rooftops (see Figure 7).

These considerations demonstrate the crucial importance of site visits and metadata – records of site changes, which include instrumentation, and site exposure. These data may be crucial to be able to separate true climate trends from local site effects. Good exposures are not always permanent. Manmade alterations to the area and the growth of vegetation may change an excellent exposure to an unsatisfactory one in a very short time, necessitating the moving of precipitation gauges to sites having better exposures. In such a situation, it is not desirable to move a badly placed gauge immediately, as that would break the long-term homogeneity of the record. The better plan is to place the new gauge nearby in a more suitable location and to observe both gauges for a minimum of a year so that a correlation can be obtained and a correction may be applied to the old observations.

Despite the availability of international guidelines for rain gauge exposure, local and national standards vary widely. In an attempt to address the crucial problem of site exposure, Sevruk and Zahlavova (1994) attempted to devise an objective and quantitative measure relating to the angle above the horizontal from the gauge rim to the surrounding obstacles in eight compass directions. This may be calculated using a fish-eye lens and a digitizer, or alternatively from site photographs, sketches and station reports. De Smedt *et al.* (2003) found this approach was superior to several simpler alternative methods. Unfortunately, the potential use of this approach to correct rain gauge errors is limited as the necessary measurements are available at only a few sites (Ungersböck *et al.*, 2000).

Special Site Considerations

There are particular circumstances where the measurement of precipitation poses special problems: these are where the topography is very steep and uneven, where the ground is covered by a continuous expanse of forest, where the precipitation falls as a fine mist or as snow.

In very steep terrain, not only is rainfall spatially very variable but a standard gauge with horizontal rim will tend to undercatch precipitation in winds blowing upslope, and overcatch in winds blowing downslope (Hamilton, 1954). The best solution may be a ground-level gauge with its rim inclined parallel with the ground slope. The effective catch area must then be converted to a horizontal plan area by dividing by the cosine of the slope angle.

About one-third of the Earth's land surface is covered by forests. It is not always possible to measure precipitation in clearings and it may be necessary to install a rain gauge on a tower at tree top (canopy) level. It is possible for catches very similar to ground-level gauge values to be achieved in this way because the airflow disturbance of the gauge is similar to the roughness of the forest canopy, but this is very dependent upon the height of the gauge relative to the canopy. If the gauge is too high it will experience wind-induced undercatch, whilst if it is too low it may suffer from overcatch as a result of drip from adjacent branches or undercatch because of sheltering. It is difficult to define a suitable height for the gauge rim where the trees are of irregular height or the topography is uneven. Furthermore, the level of the gauge must also be regularly raised in-line with growth of the trees (Robinson *et al.*, 2004).

In some parts of the world, appreciable quantities of water may be deposited by fine water droplets carried in the wind impacting on vegetation surfaces (*see* **Chapter 38, Fog as a Hydrologic Input, Volume 1**). This will not be recorded in conventional rain gauges, and so it may be necessary to deploy special cloud water collectors in order to determine the water content of these clouds and then to theoretically calculate their likely rate of deposition onto vegetation surfaces according to their respective aerodynamic roughnesses.

Snow

Information on the spatial distribution of snow was traditionally based on reports from observers at meteorological stations. The difficulties in measuring the amount of snowfall in gauges are even greater than those of rainfall. Snowflakes are even more prone than raindrops to turbulence around gauges, resulting in severe undercatches. Although wind effects can be greatly reduced by using windshields around the gauges, the errors due to undercatches are often still too great to be acceptable (Sevruk, 1982). Windshields may be used to minimize the loss of precipitation. This loss is much greater during snowfall than rainfall, so shields are seldom installed at gauges unless at least 20% of the annual precipitation falls as snow. In areas where heavy snowfall occurs (e.g. mountainous areas in the western USA), gauges may be mounted on towers at a height considerably above the maximum level to which snow accumulates (see Figure 8).

The WMO initiated a comparison of the catches of some of the most widely used precipitation gauges with those of a *Double Fence Intercomparison Reference gauge* (DFIR) comprising a *Tretyakov* gauge within two concentric fence shields (Goodison *et al.*, 1989). Undercatches by the standard gauges relative to the DFIR increased from only a few percent for rain in light winds, up to 50% or more for snowfall in strong winds. Eventually it may be possible to derive correction procedures to reduce the catch errors of standard gauges, but this may require detailed information including wind speed and the discrimination between "solid" and "liquid" precipitation.

Figure 8 In areas of heavy snowfall, gauges may have to be mounted on towers above. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

In many cases, it may be better to measure the depth of snow lying at particular locations. This may be converted to the snow water equivalent using the density of the snow. The density of freshly fallen snow varies from 50 to 200 kg m^{-3}, depending on the temperature during the storm. This increases over time due to settling and compaction as well as to any partial melting and refreezing of the snow pack, and may reach values of up to 600 kg m^{-3}.

The depth of snow may vary greatly with topography and with drifting, resulting in spatial sampling problems that are even more severe than those already discussed for rainfall. For this reason, depth and density measurements may be made along predetermined snow courses, selected to be representative of conditions over a wide area.

37: Rainfall Trend Analysis: Return Period

ROBIN T CLARKE

Instituto de Pesquisas Hidráulicas, Porto Alegre RS, Brazil

This article describes the concept of return period, with particular reference to the analysis of rainfall records. Methods are described for calculating return levels, corresponding to different return probabilities, when rainfall is accumulated over different time intervals. In the case of intense, short-duration rainfalls, threshold models are illustrated. The article points out that the concept of return period is most easily interpreted where stationarity in the rainfall regime can be assumed, so that it is important to establish whether rainfall records show evidence of trends over time. Procedures are discussed for testing whether time trends exist in annual and monthly rainfall, in the occurrence and magnitude of daily rainfalls, and in annual maximum rainfall intensities over different durations. Where a trend in rainfall regime is apparent, an alternative to the concept of return period is suggested, on the basis of the probability of occurrence of an extreme event of specified magnitude, during a period extending into the future during which the observed trend can be assumed to continue.

INTRODUCTION: DEFINITION OF RETURN PERIOD

In the context of this article, the term *return period* refers to the frequency with which a given characteristic of rainfall will occur, over a very long period extending into the indefinite future. The return period is commonly measured in years. In the absence of changing hydrological regime, an event with return period T years is also the event that may occur in any one particular year with probability $1/T$.

To develop the idea of return period, consider the annual rainfall X at a particular measurement site. This varies unpredictably from one year to the next, and observations of the random variable X over a sequence of N years will give recorded values $x_1, x_2, x_3, \ldots x_N$, or $\{x_i\}$, $i = 1, 2, \ldots N$. In many cases, it is reasonable to assume that while the values $\{x_i\}$ vary throughout the period in an unpredictable way, the statistical characteristics of this sequence (such as the mean value μ about which they vary) remain unchanged over time: that is, the observed values are a *realization* of a *stationary process.* In the case of some rainfall characteristics, such as annual total rainfall, physical considerations may suggest that the rain falling in year t is statistically independent of the rain that fell in the preceding year $t-1$, since atmospheric conditions may change rapidly over periods as short as even a few days. By contrast, in the case of rain falling on successive days, meteorological conditions may persist from one day to the next, so that the rainfalls measured on days $t-1$ and t cannot be regarded as statistically independent. This article begins by concentrating on the simple case, like that of annual total rainfall ("annual rainfall", for the sake of brevity), in which the underlying statistical process is (i) stationary, with (ii) observations statistically independent.

By assuming that the mean μ and other parameters defining the statistical characteristics of rainfall are constant, the variability amongst the observed annual rainfalls $\{x_i\}$ may be expressed in terms of a probability density function $f_X(x)$, the form of which is sometimes suggested by theoretical considerations, but more often is taken as an empirical function that satisfactorily describes the characteristics of the observed sequence $\{x_i\}$. Then, in a very long period of rainfall measurement, the proportion of years with annual rainfall lying within the short interval $[x, x + \Delta x]$ is, with very small error, $f_X(x).\Delta x$. The same idea may be expressed in a slightly different way. Since $f_X(x)$ is a probability density function (pdf), the probability that the total rainfall X in any year is equal to or greater than some given value x_0 is

$$P[X \geq x_0] = \int_{x_0}^{\infty} f_X(u)\,\mathrm{d}u \qquad (1)$$

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

where u is any dummy variable, and $P[.]$ denotes the probability of the event in square brackets. In the left-hand side (LHS) of equation (1), x_0 is given, and the quantity on the right-hand side (RHS) is calculated from it using the known properties of $f_X(x)$. But it is equally possible to define the magnitude of the probability on the RHS, say $1/T$, where T is measured in years, and then use an inverse calculation to estimate the rainfall x_0. Thus, the equation to be solved for x_0 (commonly referred to as the *return level*) is

$$\int_{x_0}^{\infty} f_X(u)\,\mathrm{d}u = \frac{1}{T} \tag{2}$$

If, in equation (2), the value of T is set at 100, then $1/T = 0.01$ and the value of x_0 is the annual rainfall with 100-year return period: that is, the rainfall that in any randomly selected year would be exceeded with probability $1/100 = 0.01$. Stated in another way, in a very long period of rainfall record, the annual rainfall would equal or exceed x_0 in a proportion 1/100 years. Stated in yet another way, the annual rainfall will be greater than x_0 once in 100 years, in the long run. Obviously, T may be set to any value, but in practice extreme events (that is events with long return period, i.e., large T) are of more interest. Trivially, if $T = 1$, equation (2) immediately gives $x_0 = 0$, showing that the annual rainfall with 1-year return period is 0 mm. Annual rainfall, by definition, must be nonnegative.

An important phrase in the preceding paragraph is "in the long run". Because annual rainfall varies randomly, it does not follow that in any single consecutive 100-year sequence, the annual rainfall with 100-year return period will occur exactly once. Indeed, it is easy to show that in a period of 100 years, the probability that the 100-year rainfall will occur once *or more* is high, 0.634 or 63%, even though the expected number of occurrences of the T-year rainfall during this period is 1.

Solution of equation (2) gives the value of annual rainfall that is exceeded once in T years in the long run. It is equally possible to work with the lower "tail" of the pdf $f_X(x)$, and in an arid region this is likely to be of greater interest. Thus, once in T years in the long run, annual rainfall will be less than x_0, where x_0 is now given by

$$\int_{u=0}^{x_0} f_X(u)\,\mathrm{d}u = \frac{1}{T} \tag{3}$$

Furthermore, although we have taken the annual rainfall X as an example, the same procedure can be followed for many other rainfall characteristics, of which the following are just a few examples: annual maximum rainfall during a 24-h period; depth of rain falling in the month prior to a crop-planting date; annual maximum rainfall intensity of 15-min duration; length of period of consecutive days without rain in any year. For each example, the form of $f_X(x)$ will be different, but the procedure for calculating the event with T-year return period is basically as set out in equations (2) and (3) above. In each case, too, the units of the calculated x_0 will be those of the data sequence: millimeters in the case of annual rainfall, days in the case of duration of longest dry period, millimeters per hour ($\mathrm{mm\,h^{-1}}$) in the case of rainfall intensities over different durations.

THE PROBABILITY DENSITY FUNCTION $f_X(x)$

It will be clear that the numerical value obtained for the rainfall event x_0 with T-year return period will depend on the function $f_X(x)$ used in equations (2) and (3), and the question arises: How is $f_X(x)$ to be obtained? Three points are relevant to this question.

The (rare) Case where x_0 can be Calculated without Explicit Knowledge of $f_X(x)$

Suppose that the recorded rainfall sequence from N years of record is $\{x_i\}$, $i = 1, 2 \ldots N$, so that $x_1, x_2, \ldots x_N$ are the annual rainfalls (or maximum intensities) in years $1, 2, \ldots N$ of the sequence. Then, provided that (i) $T < N + 1$ and (ii) the values $x_1, x_2, \ldots$ are statistically independent, it may not be necessary to define the function $f_X(x)$, because the following argument can be used. Put the values $\{x_i\}$ in increasing order of magnitude, to give the sequence $x_{(1)}, x_{(2)} \ldots x_{(N)}$, where $x_{(1)}, x_{(N)}$ are the smallest and largest values respectively in the sequence. Then, the probability that (say) annual rainfall in any randomly selected year is greater than $x_{(N)}$ is $1/(N + 1)$, and the probability that it is less than $x_{(1)}$ is also $1/(N + 1)$. Equally, the probability that annual rainfall is greater (less) than $x_{(N-1)}$ ($x_{(2)}$) is $2/(N + 1)$, and so on. By interpolation, it is therefore possible to estimate the annual rainfall x_0 with T-year return period, without specifying $f_X(x)$. However, in many cases, T will be larger than $N + 1$, and the method fails. It then becomes necessary to specify a mathematical form for the distribution $f_X(x)$. This may be indicated by theoretical considerations or, more commonly, by empirical knowledge of what has proved appropriate in the past. In either case, $f_X(x)$ will almost certainly contain *parameters* that must be estimated from whatever rainfall record is available: hence, it is appropriate to write $f_X(x)$ in a more general form $f_X(x, \boldsymbol{\theta})$ where $\boldsymbol{\theta} = [\theta_1, \theta_2, \ldots \theta_m]$ is the set of m parameters defining the statistical characteristics (e.g., mean value, dispersion about the mean value, skewness, etc.) of the pdf. In many cases, distributions with $m = 2$ or 3 are adequate.

Estimation of $f_X(x)$ by Means of a Kernel Function

It is possible to calculate a form of distribution representing the data using a kernel estimate. Kernel density estimation

is a useful tool for exploring the unknown underlying distribution of a sample; Silverman (1986) gives a general introduction to density estimation by kernel methods, which can be regarded as a formal development of the simple histogram. The kernel method constructs an estimate $f_X(x)$ of the true density function by placing a kernel function $K(x; x_i, h)$ over each observation x_i in the sample $\{x_i\}$, $i = 1, 2, \ldots N$. The kernel function $K(x; x_i, h)$ is a density function with location parameter x_i and scale parameter h, also called *bandwidth* in this context. The density estimate is then given by

$$f_X(x) = \left(\frac{1}{Nh}\right) \sum_{i=1}^{N} K\left(\frac{x - x_i}{h}\right) \tag{4}$$

where N is the sample size. It turns out that the choice of kernel function K is not very critical for the resulting estimate $f_X(x)$ (see Silverman (1986)). The Gaussian kernel is commonly used and is therefore adopted here as kernel function, that is,

$$K(u) = \frac{1}{\sqrt{(2\pi)}} \exp\left(\frac{-u^2}{2}\right) \tag{5}$$

For example, Table 1 shows the annual rainfall for the years 1976–2002 at Fortaleza in the Brazilian Northeast. Over the 27-year period, the annual rainfall X varied from 978 mm in 1990 to 2836 mm in 1985. Figure 1 shows the distribution $f_X(x)$ fitted using equation (4); using $T =$ 100 years in equation (2) gives the annual rainfall x_0 with 100-year return period as 3032 mm. Using equation (3), the annual rainfall exceeded in 99 years out of 100, in the long run, is 517 mm. Both the values lie outside the range of observed rainfalls shown in Table 1. The two values are the 1% and 99% quantiles of the pdf. The bandwidth h used in this example was proportional to the standard deviation of the data; the choice of bandwidth requires care, since if h is small, the fitted distribution will be multimodal, while if it is too large, the fitted distribution is oversmoothed.

Use of an Explicit Form for $f_X(x)$

Continuing the example using annual rainfall data, a much more common alternative to estimating the pdf by the kernel method is to select a pdf of some known form, with characteristics determined by parameters that are estimated using relevant data in the form of rainfall records. A histogram (not shown) of the Fortaleza data in Table 1 shows that the distribution of annual rainfall has positive skew, suggesting that a Normal (Gaussian) distribution may provide a good fit if the data are first transformed by taking natural logarithms. This is confirmed by Figure 2, which shows a plot of the log of the ordered sample $x_{(1)}, x_{(2)} \ldots x_{(N)}$ (vertical axis) against the quantiles of the standard Normal distribution N(0,1). All 27 points lie within the confidence region shown in the figure, so that $\ln(x_i)$ can be represented by a Normal distribution, whose estimated mean and standard deviation are $\hat{\mu} = 7.3073 \pm 0.0590$ and $\hat{\sigma} = 0.3065 \pm 0.0417$ (the "hats" indicating estimates, obtained from the data, of the relevant parameters μ and σ). Equation (2) then becomes

$$\frac{1}{\{\hat{\sigma}\sqrt{(2\pi)}\}} \int_{x_0}^{\infty} \exp\left[-\frac{(\ln(x) - \hat{\mu})^2}{2\hat{\sigma}^2}\right] \frac{\mathrm{d}x}{x} = \frac{1}{T} \tag{6a}$$

or

$$\Phi\left(\frac{\ln(x_0) - \hat{\mu}}{\hat{\sigma}}\right) = 1 - \frac{1}{T} \tag{6b}$$

where $\Phi(z)$ denotes the cumulative probability $\mathrm{P}[Z < z]$ for the standard N(0,1) distribution. For the annual rainfall

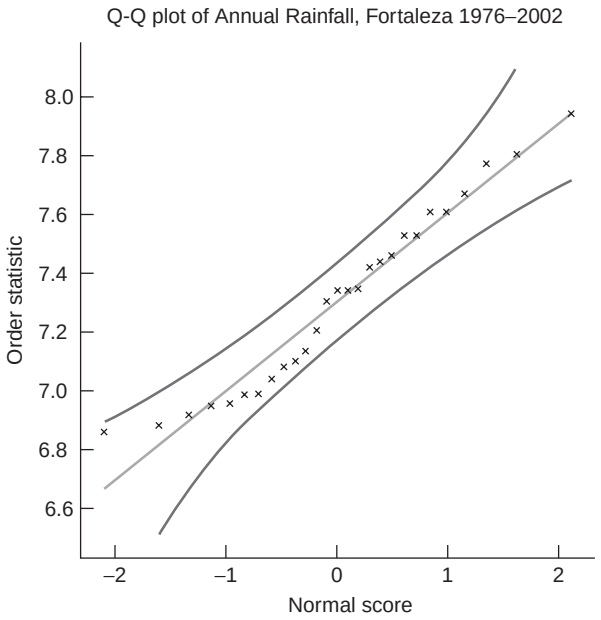

Figure 2 Quantile–Quantile plot, showing goodness of fit between ln(x) and a Normal distribution, where x is annual rainfall at Fortaleza, Northeast Brazil. ''Normal score'' shows the expected values of order statistics from the standardized N(0,1) distribution; ''Order statistic'' shows the 27 values of ln(x) in ascending order. The overall probability of the plotted data lying completely within the confidence bands is approximately 95% under the null hypothesis that ln(x) is a random sample from the normal distribution. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

with $T = 100$-year return period, it is found from a table of Normal deviates that $[\ln(x_0) - \hat{\mu}]/\hat{\sigma} = 2.326$, so that x_0 is estimated as $\exp[\hat{\mu} + 2.326\hat{\sigma}] = \exp(7.3073 + 2.326 \times 0.3065) = 3042$ mm. This compares with the estimate $x_0 = 3032$ mm found by the kernel method described above.

Thus, we have considered three ways of estimating the value a random variable that corresponds to a return period of T years. In the approach described above, the pdf was found to be of simple form after transformation of the data, but in very many cases, distributions other than the Normal will be more appropriate. If, for example, the data $x_1, x_2, x_3, \ldots x_N$ are the maximum daily rainfalls in each of the N years, then it is likely that the Gumbel distribution will be more appropriate; maintaining the notation $f_X(x)$ for the pdf of the random variable X that is under statistical analysis, the Gumbel distribution is

$$f_X(x, \boldsymbol{\theta}) = \sigma^{-1} \exp\left[-\frac{x-\mu}{\sigma} - \exp\left\{-\frac{x-\mu}{\sigma}\right\}\right] \quad -\infty < x < \infty \tag{7}$$

where in this case the two-element vector $\boldsymbol{\theta}$ of parameters is $\boldsymbol{\theta} = [\mu, \sigma]^T$. Putting $y = (x - \mu)/\sigma$, the cumulative distribution function (cdf) has the simple form

$$F_1(y) = \exp(-\exp[-y]) \qquad -\infty < y < \infty \tag{8}$$

which is the first of three max-stable (Cox *et al.*, 2002; Coles, 2001) limiting forms of cdf for maxima of samples of values drawn independently from a probability distribution, as the sample size increases indefinitely. The other two limiting forms

$$\begin{aligned} F_2(y) &= \exp(-y^{-\alpha}) \qquad y \geq 0 \\ &= 0 \qquad\qquad\quad y < 0 \end{aligned} \tag{9}$$

and

$$\begin{aligned} F_3(y) &= \exp(-(-y)^{\alpha}) \qquad y \leq 0 \\ &= 1 \qquad\qquad\quad y > 0 \end{aligned} \tag{10}$$

are the Fréchet and Weibull distributions. All three forms, known respectively as EVI, EVII, and EVIII, are particular cases of the generalized extreme-value (GEV) distribution

$$f_X(x) = \left(\frac{1}{\sigma}\right)\left[\frac{1 + \xi(x-\mu)}{\sigma}\right]^{-(1/\xi)-1} \times \exp\left\{-\left[\frac{1 + \xi(x-\mu)}{\sigma}\right]^{-1/\xi}\right\} \tag{11}$$

defined for x such that $1 + \xi(x - \mu)/\sigma > 0$, with parameters μ, σ, and ξ satisfying $-\infty < \mu < \infty$, $\sigma > 0$, $-\infty < \xi < \infty$. The three special cases EVI (Gumbel), EVII (Fréchet), and EVIII (Weibull) correspond to the three cases $\xi = 0$, $\xi > 0$, and $\xi < 0$. Where the data consist of annual maximum rainfalls accumulated over time periods of a day or less, distributions such as equation (7) or equation (11) are appropriate for use in equation (2) for determining the value of x_0 with T-year return period.

There is a very large literature concerning procedures for estimating the parameters of distributions (such as equation 7, equation 11, and the log-Normal distribution used in equation 6a). One method with strong theoretical appeal is the method of maximum likelihood (Cox and Hinkley, 1974), which estimates the parameters $\boldsymbol{\theta}$ by maximizing the probability of the observed dataset $\{x_i\}$, $i = 1, 2 \ldots N$. However, a method that has come into widespread use in recent years (see, for example, Institute of Hydrology, 1999) is the method of L-moments, described by Hosking and Wallis (1997). In this method, linear combinations of the order statistics of the data – that is, linear combinations of the values $x_{(1)}, x_{(2)} \ldots x_{(N)}$ – are fitted to their equivalents calculated from the pdf, which are functions of the distribution parameters $\boldsymbol{\theta}$. Hosking *et al.*(1985) argue that in the relatively small data samples

provided by hydrological and meteorological records, the L-moment approach outperforms maximum likelihood in the estimation of GEV parameters (see equation 11) as judged by mean square errors. Cox *et al.*(2002) note that such comparisons depend on the particular choice of parameters, while Coles and Dixon (1999) contend that this apparent superiority is a result of a constraint placed upon the shape parameter by the L-moment approach. Cox *et al.*(2002) also note that "an attractive feature of likelihood-based methods is the flexibility afforded by the possibility of incorporating the effects of temporal and/or spatial non-stationarity and covariates." It is this flexibility that is exploited in later sections for the analysis of trends.

STATISTICAL METHODS FOR DETECTING TREND IN RAINFALL RECORDS

Much of the remainder of this article addresses the problem of testing whether a rainfall record shows evidence of time trend. Spatial trends are not considered, since there exists a very large literature on statistical procedures appropriate for the analysis of spatial trends (Cressie, 1993; Isaaks and Srivastava, 1989; Ripley, 1991). A useful reference on methods for detecting trends in hydrological data in general is Kundzewicz and Robson (2000).

Where it is required to test whether a time trend exists in a rainfall record, and to estimate its magnitude, the methods available depend on the time interval over which rainfall is accumulated. Four cases are considered in the text below: (i) trends in annual total rainfall; (ii) trends in monthly rainfall; (iii) trends in occurrence and/or depth of daily rainfall; and (iv) trends in annual maximum rainfall intensity of different durations, possibly 15 min, 1 h, 3 h, and so on. We note that where a time trend is shown to exist, the assumption that the random variable X varies about a constant mean μ becomes invalid, and the concept of return period becomes of questionable validity. If, for whatever reason, rainfall regime is in process of change, the parameters $\boldsymbol{\theta}$ of the pdf $f_X(x, \boldsymbol{\theta})$, and possibly even its mathematical form, are also changing. The phrase "in the long run" – necessary for defining a return period – then has little meaning. We return to this difficulty later.

Trends in Annual Rainfall Totals

Since annual rainfall is the sum of the daily rainfalls occurring through the year, a reasonable working hypothesis is that the random variable "annual rainfall" is approximately Normally distributed, by virtue of the central limit theorem. In most cases, it will also be reasonable to assume that annual rainfalls are serially independent: this means that the pdf of the random variable "annual rainfall in year t", denoted by X_t, satisfies $f_X(x_t|x_{t-1}) = f_X(x_t)$, showing that knowledge of x_{t-1}, the rain that fell in the preceding year, conveys no information about X_t. Given serial independence, standard linear regression methods can then be used to test for the existence of linear (quadratic, etc.) trend in a record. Where annual totals are not Normally distributed, and cannot be transformed to Normality by transformation (such as the log-transformation used above), nonparametric tests for trend are appropriate.

Where it is required to test for time trends in records from several sites within a region, it will be necessary to allow for the probable existence of spatial correlation between the annual total rainfall registered at neighboring sites. Multivariate regression can be used to test whether a homogeneous time trend exists over the region as a whole, or whether the time trend varies spatially. Thus, a multivariate model for k sites within a region could be proposed, of the form

$$\mathbf{X} = \mathbf{T}\boldsymbol{\beta} + \mathbf{E} \tag{12}$$

where $\mathbf{X}$ is a matrix of dimension $N \times k$ in which the tth row is the annual rainfall in the tth year of the N years of record at each of the k sites; $\mathbf{T}$ is a matrix of dimension $N \times (q+1)$ in which the tth row is $1, t, t^2, \ldots t^q$; $\boldsymbol{\beta}$ is a matrix of dimension $(q+1) \times k$, whose mth column is the vector of regression coefficients for the mth site, namely, $[\beta_0^{(m)}\ \beta_1^{(m)} \ldots \beta_{q+1}^{(m)}]^T$; and $\mathbf{E}$ is a $N \times k$ matrix of residuals, with rows that are independent and multivariate Normal $N_k(\mathbf{0}, \boldsymbol{\Sigma})$, possibly after transformation of the k rainfall records. The parameters $\boldsymbol{\beta}$ and $\boldsymbol{\Sigma}$ can be estimated by maximum likelihood, and a likelihood-ratio test can be used to test whether the trend is homogeneous over all k sites. In this test, the null hypothesis is that the m columns of the matrix $\boldsymbol{\beta}$ are equal for all m. The model equation (12) fits polynomial functions of order q in time t at each site, and is best restricted to small values of q (≤ 2) if instabilities are to be avoided. Even if statistically significant polynomial trends are identified in records at the k sites, it would be extremely inadvisable to extrapolate such empirical relations far into the future: it is only possible to extrapolate with any degree of confidence when the physical processes giving rise to the trend are understood and have been expressed in mathematical terms.

Trends in Monthly Rainfall Totals

Various statistical tests for trend are possible, depending on the characteristics of the monthly rainfall record. Linear regression or nonparametric methods can be applied separately to rainfall in each month of the year, giving 12 separate significance tests; however, even if the 12 tests can be considered statistically independent, the probability of at least one apparently significant trend being detected at the 5% level of significance, even where no trend exists in reality, is high, nearly 46%. Erroneous conclusions can

be avoided by using the Bonferroni inequality (e.g., Johnson and Wichern, 1992), which reduces the Type I error in each month (i.e., the probability of concluding that significant trend exists in the month when it does not) from 5% to 5%/12 = 0.42%, the overall Type I error for all 12 tests remaining at 5%. The picture is further complicated if rainfalls in successive months are serially correlated (where, say, a sequence of months all record rainfall that is greater then the corresponding monthly averages) since the 12 tests are then not statistically independent. These complications apply whether the tests used are parametric tests (based on regression theory) or nonparametric (Mann–Kendall).

An alternative approach is to test for trend (in addition to seasonality) in the single sequence of $12N$ monthly rainfalls derived from the N years of record. This approach is useful when, as may often happen, records in some months are missing. Multiple regression models of the form

$$x_t = \beta_0 + \beta_1 t + \beta_2 t^2 + \cdots + \beta_{k+1}\cos\left(\frac{2\pi t}{12}\right) + \beta_{k+2}\sin\left(\frac{2\pi t}{12}\right) + \cdots + \varepsilon_t \tag{13}$$

or

$$x_t = \boldsymbol{\beta}_{\text{tr}}^T \boldsymbol{f}(t) + \boldsymbol{\beta}_{\text{ha}}^T \boldsymbol{h}(t) + \varepsilon_t \tag{14}$$

with Normally and independently distributed residuals $\varepsilon_t \sim N(0, \sigma^2)$ are a point of departure; the vector $\boldsymbol{\beta}_{\text{tr}}^T$ is a vector of trend parameters multiplying a vector $\boldsymbol{f}(t)$ of known trend functions (such as polynomials in t) and $\boldsymbol{\beta}_{\text{ha}}^T$ is a vector of parameters multiplying a vector of known harmonic functions $\boldsymbol{h}(t)$ describing seasonality. A test of whether there is a trend superimposed on seasonality is given by a test of the hypothesis H_0: $\boldsymbol{\beta}_{\text{tr}} = 0$ against the alternative H_1: $\boldsymbol{\beta}_{\text{tr}}$ not all zero. However, where there is marked seasonality in rainfall distribution, it is unlikely that the residual variance σ^2 will be constant; this must be checked by calculating the variances, month by month, of the calculated residuals $\hat{\varepsilon}_t$, obtained after fitting the regression model equation (14). Checks will also be needed to explore whether the calculated residuals are serially correlated, which may occur if months of higher-than-usual rainfall tend to be followed by months in which rainfall is also higher than usual, and conversely. Where this occurs, the regression in equation (14) may need to be modified to allow for the serially correlated residuals. One such model might be:

$$x_t = \boldsymbol{\beta}_{\text{tr}}^T \boldsymbol{f}(t) + \boldsymbol{\beta}_{\text{ha}}^T \boldsymbol{h}(t) + \varepsilon_t \tag{15a}$$

$$\varepsilon_t - \phi_1 \varepsilon_{t-1} - \phi_2 \varepsilon_{t-2} - \phi_3 \varepsilon_{t-3} - \ldots = a_t \tag{15b}$$

where now the a_t are independently distributed N(0,σ_a^2). Extensions in which the residuals ε_t are of type ARMA (p, q) (see, e.g., Box and Jenkins, 1970) are possible, and can be easily fitted using available statistical software (S-plus; GenStat, SAS, and others).

Trends in Occurrence and Depth of Daily Rainfall

The characteristics of daily rainfall are (i) alternating sequences of dry days and wet days, the sequences being of variable length; (ii) the durations of the alternating periods of wet and dry days are determined by a random process, having a structure that must be identified from the daily rainfall record; (iii) the quantities of rain falling on wet days are determined by a random process, which must also be identified from data; and (iv) the random processes that govern rainfall occurrence and rainfall amount vary throughout the year. The hydrological literature has references to many models of daily rainfall; a typical model structure, adopted as a basis for discussion in the present paper, uses a two-state Markov model to describe rainfall occurrence (the two states 0 and 1 representing dry and wet days respectively, so that any record of daily can be represented by a sequence of 0's and 1's), and a skewed distribution, such as exponential or gamma, to describe depth of rain occurring on days when rain falls. As noted above, the 0's and 1's will rarely be independent because meteorological conditions may persist from one day to the next. A convenient way of representing this dependence is by means of a Markov chain, in which probabilities are defined as transitions from the states 0 to 0 (dry day followed by dry day), 0 to 1 (dry day followed by wet day), 1 to 0 (wet followed by dry), and 1 to 1 (wet followed by wet). The transition probabilities of the Markov process for rainfall occurrence, and the parameters of the probability distribution of rainfall depths, are time-variant, typically being represented in terms of harmonic functions $\cos(2\pi kt/365)$, $\sin(2\pi kt/365)$, $k = 1, 2, \ldots$ (Stern and Coe, 1984) to incorporate seasonality.

To fix ideas, suppose that the Markov model of rainfall occurrence is of first order with the four transition probabilities $P_{ij}(t), i, j = 0, 1$, so that $P_{01}(t)$, for example, is the probability that a dry day (0) on day $t-1$ is followed by a wet day (1) on day t of the year, for $t = 1, 2, \ldots 365$. Then since, for each day t, $P_{00}(t) + P_{01}(t) = 1$, $P_{10}(t) + P_{11}(t) = 1$, it is only necessary to model two of the four transition probabilities, say $P_{00}(t)$ and $P_{10}(t)$, typically using

$$\ln\left(\frac{P_{00}(t)}{1-P_{00}(t)}\right) = \boldsymbol{\beta}_1^T \boldsymbol{f} \tag{16a}$$

$$\ln\left(\frac{P_{10}(t)}{1-P_{10}(t)}\right) = \boldsymbol{\beta}_2^T \boldsymbol{f} \tag{16b}$$

where $\boldsymbol{\beta}_i^T = [\beta_{i0}\, \beta_{i1}\, \beta_{i2}\, \beta_{i3} \ldots]^T$, $\boldsymbol{f} = [1\, \cos(2\pi t/365),\, \sin(2\pi t/365),\, \cos(4\pi t/365),\, \sin(4\pi t/365) \ldots]^T$. This is the approach used by Coe and Stern (1982) and Stern and Coe

(1984). These authors modeled rainfall amounts $x(t)$ on day t by means of a gamma distribution with time-varying mean

$$f(x) = \left(\frac{\kappa}{\mu(t)}\right)^{\kappa} x^{\kappa-1} \exp\frac{[-\kappa x/\mu(t)]}{\Gamma(\kappa)} \qquad (17)$$

and the time dependence in the mean $\mu(t)$ was taken to be of the form $\ln(\mu(t)) = \boldsymbol{\beta}_{\mathrm{ha}}^{T}\ \boldsymbol{h}(t)$. Fitting models of the type (16a,b) for the occurrence of rainfall and of the type (17) for the depth of rainfall is straightforward using statistical software for generalized linear models (GLM; McCullagh and Nelder, 1989) and there are now many software packages (GLIM, GenStat, SAS, amongst others) that fit GLMs and provide the necessary diagnostics for assessing goodness of model fit.

Up to this point, the models in equations (16) and (17) model seasonality, but not trend, and the fitting procedures described by Stern and Coe (1984) treat years as replicates (that is, with N complete years of record, the probability $P_{10}(t)$, for example, is estimated by the proportion, out of the N "trials", in which rain on day $t-1$ of the years was followed by no rain on day t). McCullagh and Nelder (1989) point out that if time trends over the years are also present, it is important not to regard the years as replicates; instead, the N years of daily rainfall record are regarded as a single series of $365 \times N$ Bernoulli observations (with due allowance for leap years; see Stern and Coe, 1984) with values 0 or 1 for the absence or presence of rain, indexed by day, year, and previous day, either wet or dry. This increases the computational burden, but the procedure in which the models are fitted as GLMs remains essentially the same and models can still be comfortably fitted using modern PCs. Time trends in the quantity of rain falling can also be modeled by a similar extension to equation (17), with $\ln \mu(t)) = \boldsymbol{\beta}_{\mathrm{tr}}^{T}\boldsymbol{f}(t)$, the vector $\boldsymbol{f}(t)$ now being a vector of known functions describing trend.

As an example of the procedure suggested by McCullagh and Nelder (1989), we take a 42-year record of daily rainfall from the State of Ceará in the Brazilian Northeast. The record has 15 330 days, and a parallel record is constructed in which, for day t, 1 is entered if day $t-1$ was dry and day t was wet; otherwise, a 0 is entered; thus, the example considers trend in the transition probability P_{01}. (A similar calculation, not given here, could be made for the transition probability P_{11}.) To simplify matters, each year is taken to consist of 365 days, observations on 29 February in leap years being excluded. A parameter d_i $(i = 1 \ldots 365)$ is fitted for each day of the year, and a parameter y_j $(j = 1 \ldots 42)$ is fitted for each year. With $P_{ij}(t)$ representing the probability of a transition from states 0 to 1 between days $t-1$ and t, the model taken is

$$P_{ij}(t) = \frac{1}{1 + \exp[-(\mu + d_i + y_j)]} \qquad (18)$$

or

$$\ln\left[\frac{P_{ij}(t)}{1 - P_{ij}(t)}\right] = \mu + d_i + y_j, \quad i = 1 \ldots 365, \quad j = 1 \ldots 42 \qquad (19)$$

In this model (in which the expression on the LHS of equation 19 is termed a *logit*), the parameters $(\mu,\ d_i,\ y_j)$ were estimated with the results shown in Figure 3. This figure shows the changes in the estimates of the year effects y_j, relative to y_1, the effect in the first year of record; the upper and lower lines connected by asterisks show approximate 95% confidence limits for the changes. The upper and lower limits bracket zero for all years, indicating no evidence that the frequencies of occurrence of transitions between the states 0 and 1 varied over the course of the 42-year record.

An alternative approach, which tests specifically for a linear trend, would be to replace the model in equation (19) by

$$\ln\left[\frac{P_{ij}(t)}{1 - P_{ij}(t)}\right] = \beta_0 + \beta_1 t + \beta_2 \cos\left(\frac{2\pi t}{365}\right) + \beta_3 \sin\left(\frac{2\pi t}{365}\right) \qquad (20)$$

and a test of the hypothesis H_0: $\beta_1 = 0$, against the alternative H_1: $\beta_1 \neq 0$ is possible using likelihood-ratio procedures as described by McCullagh and Nelder (1989). The conclusion from the test is that the daily rainfall record at Ceará shows no evidence that transitions in which a dry day (0) is followed by a wet day (1) show no significant evidence of linear increase or decrease, over the 42-year record.

The discussion of this section has addressed the problem of trend detection and estimation in a daily rainfall sequence at a single site. In practice, it will often be necessary to explore whether a common trend in daily rainfall is found at a number of rain-gauge sites within a region, and the analysis becomes appreciably more difficult because of the need to allow for spatial correlation in rainfall occurrence and amount, in addition to the temporal correlations existing at each site separately.

TRENDS IN ANNUAL MAXIMUM RAINFALL INTENSITY OF DIFFERENT DURATIONS

The pdf of annual maximum rainfall intensity for a given duration D hours is commonly taken as an extreme-value distribution, the Gumbel shown in equation (7) above being widely appropriate (e.g., Buishand, 1993) although it is to be noted that the annual maximum intensities for different durations $D_1, D_2, \ldots D_K$ are correlated. The Gumbel distribution in equation (7) has the location and scale parameters

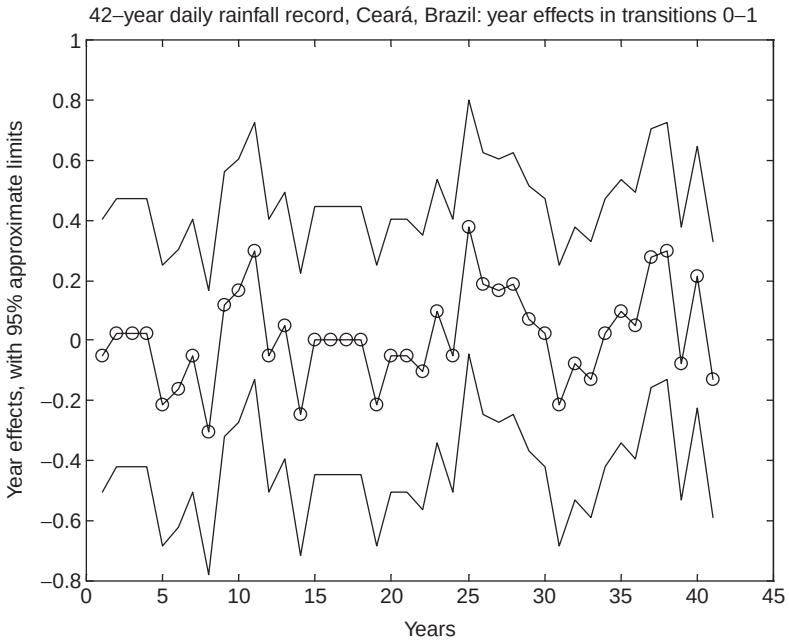

Figure 3 Year effects y_j in the logit model shown in equation (19), for the transition probability $P_{01}(t)$ for a dry day (state 0) followed by a wet day (state 1) in the 42-year record of daily rainfall at Ceará, Northeast Brazil. The 95% confidence limits include zero, indicating absence of trend in $P_{01}(t)$ over the period

μ and σ, while the mean, standard deviation, and skewness are $u + \gamma\sigma, \pi\sigma/\sqrt{(6)}$, and 1.1396 respectively, where γ is Euler's constant, $\gamma = 0.577\,215\ldots$ and $\pi = 3.141\,59\ldots$ One way of allowing for the existence of a time trend in the Gumbel mean is to modify equation (7) to be of the form

$$f(x;\mu,\sigma,\beta) = \left(\frac{1}{\sigma}\right) \exp\left[-\frac{x-\mu-\beta t}{\sigma} - \exp\left\{-\frac{x-\mu-\beta t}{\sigma}\right\}\right] \qquad (21)$$

where t is a time variable, so that equation (19) reduces to equation (7) when $\beta = 0$. The mean of the distribution in equation (21), for a given time t, is $(u + \gamma\sigma) + \beta t$, which as t varies is a line with slope β and intercept $(u + \gamma\sigma)$. More elaborate time trends can obviously be explored by replacing βt in equation (21) by $\boldsymbol{\beta}_{\mathrm{tr}}^T\ \boldsymbol{f}(t)$, with $\boldsymbol{\beta}_{\mathrm{tr}}^T$ a vector of trend parameters. More generally, trends in both position and scale parameters of the Gumbel distribution could be considered, while Coles (2001) provides S-Plus software (available on `http://www.maths.bris.ac.uk/~masgc/ismev/summary.html`) with which trends in all three parameters μ, σ, ξ of the GEV distribution can be explored. There is now a wide choice of software for fitting models for extreme-value data, and drawing inferences from them; GenStat (version 7), for example, has a menu structure, called from a toolbar, with many options for fitting EV distributions. A very useful website leading to other software (evd in R; EVIS in S; Xtreme; and others) can be found on `http://www.maths.lancs.ac.uk/~stephena/software.html`.

PROBLEMS WITH THE CONCEPT OF RETURN PERIOD IN THE PRESENCE OF TREND

The reasoning given above as the basis of return period rested critically on the concept of stationarity: the concept that the record of measurements of rainfall observed in the past provides information about the structure of the random process that will continue unmodified into the indefinite future. Under the assumption of stationarity, it is entirely valid to calculate a value for the rainfall characteristic – whether it be annual total, annual maximum intensity, longest run of consecutive days without rain, or whatever – that will occur in the future, in the long run, with a frequency of once in 10 years, once in 100 years, ...once in T years. Where, however, analysis of a rainfall record shows that trend exists, the assumption of stationarity is inappropriate. It is always possible that a trend detected in a relatively short period of record will prove, in the longer term, to be part of a longer-term fluctuation, so that what appears to be a trend in a 50-year record would, if observation were allowed to continue for say 500 years, appear as part of a longer-term pattern resulting perhaps

from slowly varying climate fluctuations. This is of little consolation, however, when decisions are required and must be based on the limited, apparently nonstationary data currently available. Until the future courses of atmospheric and oceanic processes that give rise to changes of climate can be predicted into the future, estimating how often extreme events will occur in the future will remain a very difficult problem.

Where hydrologic regimes are changing, a different approach to quantifying the probability of occurrence of extreme events is required, which avoids reference to the long-term frequency of occurrence. Recall that, in the first paragraph of this entry, an event with return period T years was defined as the event that may occur in any one year with probability $1/T$; under changing hydrological regime, this probability is no longer constant, and to generalize the concept of return period it is necessary to describe how the probability is changing. Clarke (2003) has suggested the following series of steps by which statements about the future frequency of occurrence of hydrological events become possible, where time trends are found to exist in records. Step 1: identify the extreme event that, if it occurred, would influence the choice of decision. This might be, for example, a particularly intense rainfall over a duration that would lead to severe flooding. Call the magnitude of this event x_{crit}; several values of x_{crit} may be explored. Step 2: Assuming that the trend in regime exhibited in the available hydrologic records continues into the future at the rate hitherto observed, determine the probability distribution of the time to first occurrence of x_{crit}, the event selected at Step 1. Step 3: Determine the probability of the extreme event x_{crit} occurring in the next t years, where t extends up to an acceptable (but limited: see discussion below) planning horizon. Clarke (2003) gave expressions for two cases: first, where trends have been detected in annual maximum rainfall intensity represented by a Gumbel distribution or, more generally, by a GEV distribution, with time-variant means; and second, where trends have been detected in rainfall records consisting of pairs of values $(t,\ x_t)$, where x_t is the magnitude of rainfall intensity exceeding some "threshold" value x_{thresh}, and t is the time at which $x_t > x_{\text{crit}} > x_{\text{thresh}}$ occurs. Thus, Clarke's suggestion, in the presence of trend, is to replace the concept of "event with return period T years", by the concept "the probability that a critical event, suitably defined, will occur at least once during the forthcoming limited period of S years, assuming that the observed trend in the record continues over this limited period at the same rate as that recently observed".

This second case is related, in the rainfall-intensity context, to the "peaks-over-threshold" (POT) approach to modeling the occurrence of floods in rivers; in the case in which x_t denotes a flood discharge, the sequence of pairs $(t,\ x_t)$ is sometimes termed the *partial duration series*. Fitting statistical models to POT-type data, and drawing inferences for both stationary and nonstationary processes, has been the subject of much theoretical analysis (see Smith, 1989; Davison and Smith, 1990). The limiting distribution of the random variable $Y = X - x_{\text{thresh}}$, conditional on $X > x_{\text{thresh}}$, is the generalized Pareto distribution (GPD), which has cdf

$$H(y) = 1 - \left(\frac{1 + \xi y}{\tilde{\sigma}}\right)^{-1/\xi} \tag{22}$$

defined for $y > 0$, $1 + \xi y/\tilde{\sigma} > 0$. The GPD plays an analogous role, in the analysis of partial duration series, to that of the GEV distribution in the analysis of annual maxima. A very clear account of threshold models is given by Coles (2001, Chapter 4); Chapter 6 of the same work discusses trends in nonstationary sequences, and gives references to work in related fields, such as corrosion technology (Laycock *et al.*, 1990). Methods of nonparametric exploratory analysis of time-varying parameters and return levels for EV distributions have also been presented by Ramesh and Davison (2002) and Lanzante (1996).

In conclusion, changes in hydrological regime – whether as a consequence of climate change or of change in land use – require the concept of return period to be redefined. If further evidence in support of climate change accumulates, this will have important consequences for the many kinds of civil engineering project that have long been designed according to principles based on the return level of events with T-year return period, estimated from data sequences that are realizations of stationary processes.

ANALYSIS OF RAINFALL EXTREMES: AN EXAMPLE

Table 2 shows the maximum one-hour rainfall in each of the years 1970–1986 at Eskdalemuir, in the Southern Uplands of Scotland. Since the data consist of annual maxima, it is appropriate to consider using a GEV distribution; when this is fitted by maximum likelihood, the estimates of the three parameters μ, σ, ξ together with their standard errors, are

$$\hat{\mu} = 9.935 \pm 0.7421; \quad \hat{\sigma} = 1.879 \pm 0.5457;$$
$$\hat{\xi} = -0.03115 \pm 0.2978 \tag{23}$$

Having fitted the GEV distribution, use of equation (3) shows that annual one-hour rainfalls (i.e., return levels) for 5-, 10- and 20-year return periods are 12.69, 14.02, and 15.27 mm respectively. However, the estimate of ξ is almost an order of magnitude less than its standard error, so that this parameter, which describes the shape of the GEV, can safely be set to zero and an EV1 (Gumbel) distribution used. The estimates of μ and σ

Table 2 Annual maximum one-hour rainfalls (mm) at Eskdalemuir, Scotland, 1970–1986

Year	1970	1971	1972	1973	1974

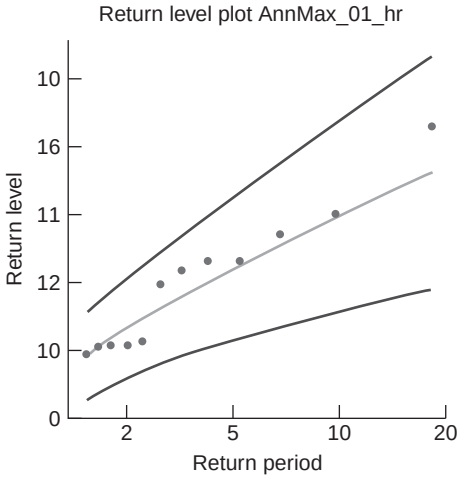

Figure 4 Plot of return level (mm) against return period (years), when an EV1 (Gumbel) distribution is fitted to the 17 annual maximum one-hour rainfalls at Eskdalemuir, 1970–1986 (see Table 2). Some points overlap. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

then become 9.904 ± 0.6720 and 1.860 ± 0.5023 respectively. The return levels for 5-, 10- and 20-year return periods are hardly changed: 12.69, 14.09, and 15.27 mm. A further calculation (see Coles, 2001) gives 95% confidence limits for these estimates as {10.42, 14.96}, {11.18, 17.00}, and {11.86, 18.99}, in units of millimeters. Figure 4 shows the relation between return level and return period, together with the 95% confidence band for predicted return levels.

If the Gumbel distribution is modified as in equation (21) to include a time trend, the trend parameter β is estimated as 0.0979 ± 0.1170 (units: millimeters per year), showing no evidence of trend in annual maximum one-hour rainfalls over the period 1970–1986.

A disadvantage in using annual maxima in an analysis of hourly rainfall extremes is that each year provides only a single observation. A POT analysis, on the other hand, may provide several observations per year that exceed the selected threshold (or, indeed, none, if the threshold is set too high). For the Eskdalemuir record of hourly rainfall 1970–1986, a threshold x_{thresh} was selected as 7.7 mm,

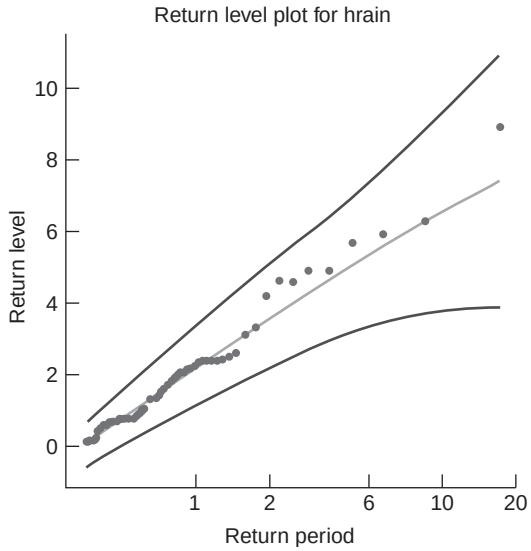

Figure 5 Plot of return level (mm) against return period (years), when a Generalized Pareto distribution is fitted to 49 most intense one-hour rainfalls (''hrain'') exceeding a threshold of 7.7 mm at Eskdalemuir, 1970–1986. Minimum interval between intense rainfalls is taken as 24 h. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

which gave an average of about three events per year. Since the rainfalls exceeding x_{thresh} may occur in clusters, it was also necessary to specify a minimum time interval between clusters of hourly rainfalls to ensure that clusters were independent, and knowledge of weather patterns at Eskdalemuir suggested that this time interval should be taken as 24 h. The variable analyzed was then the peak rainfall in each cluster, and there were 49 clusters in the 17-year period. The parameters σ and ξ of the pdf in equation (22) were estimated as

$$\hat{\sigma} = 2.266 \pm 0.6609; \quad \hat{\xi} = -0.09432 \pm 0.2113 \qquad (24)$$

from which the one-hour rainfalls with 5-, 10- and 20-year return periods were calculated as 13.04, 14.23, and 15.33 mm, slightly greater than where the GEV and EV1 distributions were fitted. Figure 5 shows the relation between return level and return period, together with the 95% confidence band for the predicted return levels; the 49 plotted points correspond to the 49 clusters determined by the selected combination of threshold and time interval between clusters.

Acknowledgments

The Fortaleza data in Table 1 were kindly provided by Mr. Marcio Nobrega; the Eskdalemuir data in Table 2, and the hourly data used in an example, were supplied by the

British Atmospheric Data Centre. The detailed and very constructive comments of two reviewers are acknowledged with gratitude.

38: Fog as a Hydrologic Input

LA SAMPURNO BRUIJNZEEL[1], WERNER EUGSTER[2] AND RETO BURKARD[3]

[1] *Vrije Universiteit, Amsterdam, The Netherlands*
[2] *Swiss Federal Institute of Technology, Zürich, Switzerland*
[3] *University of Bern, Bern, Switzerland*

This article reviews the hydrologic importance of fog in its various forms. Meteorologically, fog is defined as a ground-touching cloud with a visibility in the horizontal of less than 1000 m. The most widely occurring fog types include radiation fog, sea fog and steam fog, and advection fog, but often fog is also referred to by its location of occurrence (coastal, valley, or mountain fog). The physical processes underlying the various types of fog are described briefly. The use, advantages, and limitations of the most common types of fog collectors, fog detectors, and fog droplet spectrometers are dealt with before embarking on a discussion of techniques for the measurement and modeling of fog deposition on forest vegetation. Results of fog deposition measurements made at selected locations (representing coastal vs. inland, lowland vs. montane, and temperate vs. tropical conditions) are compared. The data confirm the importance of fog interception at many coastal and montane sites across the tropical to mediterranean and warm-temperate climatic spectrum. Under more continental conditions, contributions by fog are usually more modest except on windy mountain ridges and summits. Finally, the paper indicates the chief gaps in knowledge regarding the measurement and importance of fog as a hydrologic input.

INTRODUCTION

One of the first scientific publications on fog by Bell (1885) dealt with a practical invention (the fog muskette) to prevent ship collisions with icebergs during foggy conditions. Another example of early scientific interest in fog was documented by Blake (1871), who was interested mostly in the spatial extent of dense fog in the city of London. Even nowadays fog is often associated with negative influences on human activity, such as piracy against ships or aircraft (Ediang, 2001), increased road traffic hazard (Panzram, 1975; Fedorova *et al.*, 2001), or the severe limitations imposed by fog on air traffic (Weinstein, 1974; Mitchell and Suckling, 1987; Robinson, 1989). In addition, persistent fog has been reported to negatively affect the mood and health of patients. Although this may not be solely due to fog, there is a direct relationship between sunlight (or the lack of it) and the length of hospitalization for depression (Benedetti *et al.*, 2001). Fog is also known to negatively influence respiratory conditions of asthmatic children (Kashiwabara *et al.*, 2002).

In hydrology, on the other hand, fog is usually considered a positive entity, and may add much needed moisture to otherwise arid ecosystems, and the animals and people depending on them. An extreme example comes from northern Chile, where frequent occurrence of advective sea fog has given rise to a particular type of forest-like vegetation ("*loma*") that, in the near-complete absence of rainfall, thrives almost exclusively on fog (Aravena *et al.*, 1989; Pinto *et al.*, 2001). It is also believed that there were prehistoric settlements in this area that were sustained by drinking water collected from favorably exposed rock formations ("fog oases"; Larrain *et al.*, 2001). Elsewhere along the American Pacific Coast, moisture additions by fog are sufficiently large to allow the development of tall evergreen forest (including the famous redwoods) in areas where amounts of ordinary rainfall are such that only some sort of Mediterranean scrub vegetation would be expected (Dawson, 1998). Similar examples come from, *inter alia*, East Africa (Hursch and Pereira, 1953), the south Caribbean dry zone (Sugden, 1982; Cavelier and Mejia, 1990), eastern Mexico (Vogelmann, 1973), and Hawaii (Juvik and Nullet, 1995a).

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Table 1 Classification of fog densities in relation to visibility (modified from Wanner, 1979). Selected characteristics of advected mountain fog at Pico del Este, Puerto Rico, in summer 2002 added for comparison: *LWC* = liquid water content, *VMD* = volume-weighted mean droplet diameter, *LWF* = liquid water flux (fog deposition) as measured with the eddy covariance method (R. Burkard and W. Eugster, unpublished data). Negative values denote a net deposition of fog droplets

Visibility (m)	Fog density class	LWC (μm)	VMD	LWF (% of time)	Duration
	(mg m^{-3})		(mg m^{-2} s^{-1})		
<100	Very dense fog	81.9	13.5	−8.90	17.4
100–250	Dense fog	85.4	14.4	−11.58	59.5
251–500	Medium fog	22.6	9.8	−3.08	4.5
501–1000	Light fog	12.6	8.6	−1.45	4.0
1001–2000	Haze	4.1	7.5	−0.57	4.3
>2000[a]	No fog	10.3			

[a]Arbitrary value imposed by the instrument used (Vaisala Present Weather Detector PWD11).

This article reviews the literature on fog as a hydrologic input. Starting off with a working definition of fog and its various forms, the physics and climatology of fog are discussed briefly before presenting a range of techniques to measure fog and quantify fog deposition on vegetation, including a review of current modeling approaches. Key results obtained in different parts of the world are compared and the chief gaps in knowledge identified. Finally, in view of the paucity of reviews of the hydrologic role of fog since Kerfoot (1968) and Golding (1970), the paper concludes with an extensive reference list.

DEFINITION, PHYSICS, AND TYPES OF FOG

According to its meteorological definition, fog is a ground-touching cloud where the horizontal visibility is less than 1000 m (Glickman, 2000). However, this widely adopted definition does not express any quality of the fog other than visibility, such as the spatial extent of the fog in the horizontal and vertical; its liquid water content or droplet size spectrum; whether the droplets are liquid or frozen; or the (minimum) duration of the fog event. This definition has other limitations. Depending on the observer's position, a fog may be reported as a cloud by someone standing at a distance and observing a visibility above 1000 m. Moreover, in public usage, fog and mist have a meaning that clearly extends beyond the rather arbitrary threshold of 1000 m visibility used in the meteorological definition of fog. In the literary sense, fog is always associated with unclear vision, something that obscures an object that would be clearly seen in the absence of fog. Indeed, an electronic search of the scientific literature on "fog" reveals numerous references to "fog of war", that is, the obscuring effect of gunpowder haze. Clearly, this is not a fog in meteorological terms because it consists of smoke and dry dust rather than liquid or frozen particles suspended in air.

Fog as referred to in this article relates to any type of ground-touching cloud having a density that may be expressed (albeit somewhat arbitrarily) in terms of visibility as specified in Table 1 (cf. Wanner, 1979). Several basic fog characteristics associated with each visibility class as observed at a montane site in Puerto Rico (R. Burkard and W. Eugster, unpublished data) have been added to illustrate the changes in fog density and water content associated with different visibility classes.

Fog Physics

Apart from the special case of ice fog, which falls outside the scope of the present article, fog consists of liquid water droplets that are either a condensate of water vapor, or the remnants of larger sea spray droplets or evaporating raindrops. The tiny water droplets blur the vision much more than does gaseous water (atmospheric moisture), although most of the water present in fog is in the gaseous phase rather than as liquid droplets. For example, air at 5 °C can hold as much as 6.8 g of water per m^3, whereas a typical fog, depending on its density, only contains 0.2–0.5 g of liquid water per m^3. The Clausius-Clapeyron relationship between air temperature and the amount of gaseous water that the air can contain is normally used to determine when fog occurs (i.e. when the relative humidity reaches 100%), and when it dissolves again. In the absence of condensation nuclei, relative humidity has to exceed 100% before spontaneous condensation can set in (Curry and Webster, 1999; Figure 1). However, such supersaturation is very rare in practice since even in areas with a minimum of pollution there are usually sufficient condensation nuclei present such that fog droplets start to form as soon as the temperature drops below the local dew point.

The saturation vapor pressure over the curved surface of the droplets decreases as the curvature increases, compared with the saturation vapor pressure over a flat and level water surface (Curry and Webster, 1999). Because the atmosphere tends to be more in equilibrium with the saturation vapor pressure observed over a flat water surface, the droplets will tend to evaporate and the fog will clear. Similarly, an increase in temperature during the day increases the

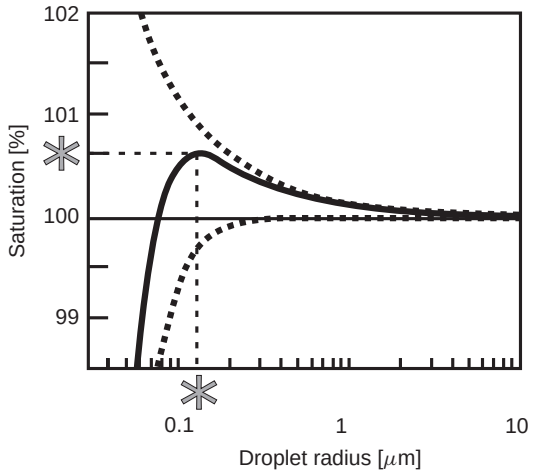

Figure 1 Supersaturation as a function of droplet radius and size of condensation nuclei. Top curve shows the equilibrium saturation ratio in the absence of condensation nuclei. The bottom curve shows the effect of the presence of condensation nuclei, and the solid line in the center shows the resulting 'Köhler' curve, indicating that in the presence of condensation nuclei the droplet radius has to exceed a threshold value r^* before the droplets start growing. Smaller droplets will tend to evaporate even when the atmosphere is saturated with water vapor

potential of the atmosphere to hold water in gaseous form, thereby also promoting the disappearance of the fog. Fog droplets grow primarily owing to condensation – coalescence does not play a significant role unless the nominal diameter of the droplets exceeds a value of ca. 36 μm (Eagleson, 2003). Once coalescence sets in, the droplets can grow much more quickly than by condensation alone, thereby rapidly exceeding the drop sizes that are typically associated with fog (<100 μm diameter). This explains: (i) why fog droplet size spectra tend to show a sharp decline with increasing drop size (Figure 2); and (ii) why fog does not automatically develop into a rain cloud within the typical life cycle of fog (cf. Pruppacher and Klett, 1998). Although fog droplet sizes cover a broad range and can be highly variable in time and space (DeFelice, 2002), the peak of the distribution (or peaks if the distribution is bimodal) usually occurs at a value below 25 μm (Figure 2), reflecting the counteracting processes of reevaporation and condensation of water vapor.

Types of Fog

There is no generally used nomenclature to distinguish between the various types of fog. In the literature, the term "stratus" is often used, regardless of whether the stratiform cloud has a visibility below 1000 m or not. As an illustration, only about one-quarter of scientific articles on the topic of "stratus" actually relate to the various types of fog described below. The nomenclature is particularly variable

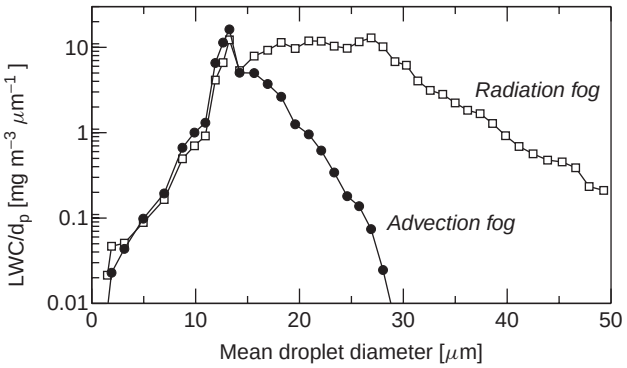

Figure 2 Examples of droplet size distributions in radiation fog (solid circles; fog event of 15 March, 2002) and advection fog (open squares; fog event of 20 February, 2002) at the Lägeren mixed forest site in Switzerland (based on original data from Burkard *et al.*, 2003)

in non-English language publications where authors may refer to a specific type of fog in their own language, which may then become translated into less common English terms (cf. Stadtmüller, 1987). Apart from ice fog and urban fog, seven relatively distinct terms (Figure 3) that are frequently used to describe different types of fog were distilled from the meteorological literature. The first four types of fog are named according to their formation process, the remaining three according to their geography of occurrence. The various types are described briefly below, starting with the most frequently used terms.

Radiation Fog

Radiation fog is the most typical inland fog type. For this kind of fog to develop, the atmosphere must be stable, with a temperature inversion layer almost adjacent to the ground surface (Nakanishi, 2000). The dominant process leading to radiation fog is long-wave radiative cooling of the atmospheric surface layer at night, which reduces the temperature below dew point. The excess water vapor starts to condense on aerosol particles present, thereby forming tiny water droplets with a size distribution typically ranging between 1 and 50 μm (Figure 2). Radiation fog in humid temperate climates occurs most frequently during the cold season, with a reported maximum in fall (Meyer and Lala, 1990; Wanner, 1979; Bendix, 2002). This reflects a combination of sufficient nocturnal cooling and an adequate supply of atmospheric moisture during this time of year. Similarly, in warmer climates radiation fog tends to be most pronounced during the (cool) dry season when cloudiness at night is at a minimum (Liu *et al.*, in press). Because radiation fog can be very shallow and local, it is notorious for causing traffic problems on roads (Panzram, 1975; Fedorova *et al.*, 2001) and airports (Weinstein, 1974; Mitchell and Suckling, 1987; Robinson, 1989). Radiation fog life cycles are generally confined to a relatively short time window, however, being centered mostly

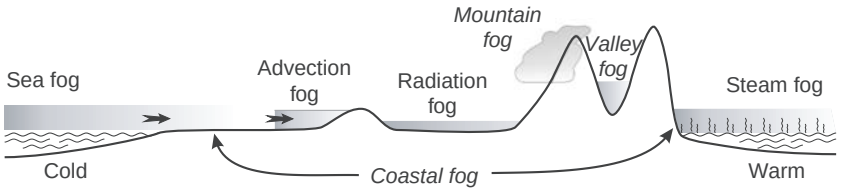

Figure 3 Types of fog. Names in upright font are process-based types, those in oblique font are geographic types

around sunrise when temperatures tend to be at a diurnal minimum (Meyer and Lala, 1990). Initial relative humidity and nocturnal cooling rate are key parameters for forecasting the actual onset of fog formation. Since radiation fog is most likely to occur during calm and cloudless nights, the associated conditions favor the development of a droplet size spectrum with a peak diameter of about 20–25 μm (Figure 2) and relatively high liquid water content (*LWC*) values (up to 500 mg m^{-3}). For example, radiation fog events during the winter of 2001/02 at the Lägeren research site in Switzerland (Burkard *et al.*, 2003) had a significantly higher median *LWC* value (143 mg m^{-3}) than "advection" fog events (see below and Figure 3) owing to the broader droplet size spectrum associated with radiation fog. Radiation fog events had a significant contribution of droplets larger than 20 μm, which were almost absent in advection fog (Figure 2).

Sea Fog

Sea fog occurs mainly in spring and early summer, but occasionally also during summertime. The chief processes leading to the formation of sea fog are cooling and condensation in relation to changes in relative humidity over open sea. Different processes of cooling and condensation create different types of sea fog but, typically, warm, humid air being cooled below its dew point as it moves over a cold water surface may lead to the formation of sea fog (Zhou, 1987; Figure 3). Sea fog constitutes a most hazardous meteorological phenomenon for ships (also because of the enhanced risk of piracy in some parts of the world; cf. Ediang, 2001). Because its occurrence is not restricted to light wind conditions, sea fog can be much more persistent than radiation fog. Also, in contrast to radiation fog over land, sea fog often forms far from the area it is affecting and may thus also be called *advection fog*, depending on the conditions (Roach, 1995; cf. Figure 3). Typical examples include sea fogs that are blown onshore as a dense but shallow layer from which tall buildings may emerge, and where the distance from the coast line may determine the presence or absence of the fog further inland. San Francisco and surroundings probably constitute the most renowned example of a sea-fog affected area (Kerfoot, 1968; Dawson, 1998), but sea fogs have also been reported to limit rice production along the Pacific coast of Japan (Inoue *et al.*, 1997), as well as to affect coastal areas in the UK (Roach, 1995), arctic Alaska (Prudhoe Bay), northern Chile (Cereceda and Schemenauer, 1991), and many other locations around the world.

Steam Fog

Steam fog differs from sea fog in that it typically forms when cold air flows over warmer water, such that vapor evaporating from the sea condenses immediately (Figure 3). In addition, it is caused by the mixing of turbulent eddies with different temperature and humidity (Øfkland and Gotaas, 1995). Visually, the process appears as smoke or steam, hence the occasionally used synonym "sea smoke" (or "*Seerauch*" in German; Tiesel and Foken, 1987). The warm water surface evaporates at much higher rates than the cold air above can take up moisture and the excess vapor condenses to liquid water droplets. A related developing mechanism is thermal convection (Tiesel and Foken, 1987). Nakata (1982) reported that for steam fog to occur in southern Japan (Hiroshima Bay), the minimum temperature difference between the water and the air had to be 9 °C, a prerequisite that was met mostly from October until December. Fenland steam fog is a comparable type of fog that typically forms when a squall line associated with a cold front moves over a relatively warm wetland (such as bogs and fens) (Oliver, 1980).

Advection Fog

Advection fog differs from radiation fog by its typical occurrence in combination with steady winds leading to the horizontal translation ("advection") of the fog layer (Figure 3). While the advective component may occasionally refer to sloping terrain (e.g. Nadezhina and Shklyarevich, 1994), the term is used most frequently in relation to fog occurrence at coastal locations (Goodman, 1977; Cereceda and Schemenauer, 1991), as well as in the context of pollutant transport in industrialized inland areas (Vong *et al.*, 1991). In coastal areas, the strong contrast in surface heating between the land and the ocean during the daytime generates a sea breeze that pushes any fog formed offshore toward the land where it may dissipate again at some distance from the shoreline as a result of the higher temperatures prevailing over land surfaces. Therefore, advection fog in coastal areas is often also referred to as "coastal fog" (see below and Figure 3). Because it is wind-driven, advection fog is usually associated with substantially greater hydrologic (and chemical) fluxes than radiation fogs (Vong *et al.*,

1991), even though advection fog has a much narrower size range (Figure 2). Advection fog is a "warm fog" with liquid droplets that can produce serious surface glazing when occurring over frozen ground (Nadezhina and Shklyarevich, 1994).

Ice Fog

In contrast to the previous fog types (which consist of liquid droplets that may persist as supercooled water even at temperatures well below freezing point; Sakurai and Ohtake, 1979), ice fog is composed of frozen water crystals. Ice fog is basically restricted to very cold arctic and antarctic regions with temperatures below – 25 °C and will not be discussed here.

Coastal Fog

Although fogs are most frequently named according to their formation process or physical characteristics (Figure 3), fog types are often also referred to according to their geography of occurrence (such as coast, valley, mountain, etc.). As indicated earlier, this makes a unique classification of fog types impossible. The four fog types discussed below are the most widely used geographic terms to denote different kinds of fog.

Both advected sea fog coming in with the sea breeze, as well as the reverse (i.e. radiation fog developed over land and subsequently advected to the ocean with the land breeze at night), and even steam fog have been referred to as "coastal fog" in various Californian studies (e.g. Pilié, 1979; Noonkester, 1979; Goodman, 1977). Cereceda and Schemenauer (1991) described a situation with "coastal fog" in northern Chile where a combination of onshore movement of a marine stratocumulus deck and orographic effects resulted in the relatively consistent occurrence of a fog belt between ca. 500 and 1000 m altitude from late afternoon onwards until midmorning. The mean droplet size diameter of this advected sea fog ranged from 10.8–15.3 μm (Schemenauer and Joe, 1989), that is, similar to that observed in advection fog under continental conditions in Switzerland (Figure 2).

Valley Fog

As the name implies, valley fog is radiation fog forming in valleys (Figure 3; Pilié, 1975). Valley fog may occur regardless of the elevation of the valley or the general climate (Fitzjarrald and Lala, 1989; Pristov and Trontelj, 1979; Liu *et al.*, in press), its typical feature being that the life cycle of the fog is strongly governed by the diurnal mountain-valley circulation system. Within a few hours after sunrise, winds moving up the valley tend to erode the core of cold air built up in the valley bottom during the previous night, thereby dissolving the fog layer. The fog may return again after cold air starts to drain from higher ground and the radiative surface energy budget of the valley becomes negative, usually toward sunset (Whiteman and McKee, 1982). The top of the valley bottom radiation fog layer is normally determined by a local thermal inversion that separates the static warmer air above from the cold air in the valley. In climatologic terms, this leads to the occurrence of a warm thermal belt at some elevation along the slope. At higher elevations, fog is frequently observed above the typical lifting condensation level of convective clouds. In Switzerland, for example, valley fog occurrence above the cloud base is much more frequent, especially in summer, than radiation fog forming in valleys lower down. The exact climatology of fog occurrence may differ between areas, depending on local topography and atmospheric humidity regime. A valley with a large hinterland generating cold air draining into the main valley at night tends to experience more frequent radiation fog if the outlet for the air is narrow (e.g. a gorge). Similarly, drainage of cold air will be much more rapid – and valley fog less frequent – in the case of a gradually sloping valley that widens steadily in the downslope direction.

Urban Fog

The occurrence of fog in and around large cities has received particular attention to derive the necessary scientific understanding for fog forecasting, air pollution control (smog!), air traffic planning, and road condition assessment (e.g. London: Blake, 1871; Munich: Sachweh and Koepke, 1997; Shanghai: Zhou, 1991; Zhou and Wang, 1991; Bao *et al.*, 1995; various industrial cities in Central India: Patel *et al.*, 1998; and the surroundings of Mexico City and Puebla in Mexico: Padilla-Gordón, 1998). The various types of urban fog distinguished in the literature can be considered to represent a mixture of the process-based fog types distinguished in Figure 3, with the actual type depending on specific climatologic setting.

Mountain Fog

Mountain fog is an orographically controlled type of fog (Figure 3) that has been shown to strongly affect the hydrologic, nutrient, and pollution budgets of montane forests, both in the temperate zone (e.g. Sigmon *et al.*, 1989; Vong *et al.*, 1991; Collett *et al.*, 2002) and in the so-called tropical montane cloud forest belt (e.g. Gordon *et al.*, 1994a, b; Bruijnzeel and Proctor, 1995; Clark *et al.*, 1998; Hafkenscheid, 2000; Bruijnzeel, 2001). Mountain fogs generally consist of clouds that extend upward along the slope from their lowermost condensation level ("cloud base"). Depending on the height of the cloud base, the vertical extension of the cloud belt, and the height of the mountain, considerable portions of the landscape may thus become more or less regularly immersed in fog. A well-known example of this is the "sea of clouds" that envelops north-facing slopes on the Canary Islands for about one-third of the time during most of the year. The upper limit of the fog belt is controlled by the height of a temperature

inversion layer that generally occurs around 2000 m but is lowered to about 1000 m in summer. Similarly, the cloud base varies seasonally between ca. 700 m in summer and ca. 1100 m in fall. In addition to the strong reduction of the vertical extension of the fog belt in summer, fog duration is also much reduced at that time of year (to ca. 13% of the time; Marzol *et al.*, 1996). The extra moisture provided by the clouds supports tall evergreen forest types within the cloud belt, in strong contrast to the arid vegetation found both above and below the cloud-affected zone (Jiménez *et al.*, 2000).

Because the more or less frequent presence of fog affects both the microclimate and overall water budget of montane vegetation, the altitudinal zonation of montane forest types in general, and of bryophyte cover of trees (mosses) in particular, has been related to the intensity and persistence of fog occurrence on wet tropical mountains (Grubb, 1977; Frahm and Gradstein, 1991; cf. Bruijnzeel, 2001). While tall "Lower Montane Rain Forest" with ca. 10% moss cover is typically associated with largely fog-free conditions, "Lower Montane Cloud Forest" may have up to 25–50 per cent moss cover and experience "frequent" fog incidence. Above the latter so-called "Upper Montane Cloud Forest" is found, having up to 80% bryophyte cover and being subjected to "long and persistent" low cloud. Although quantitative criteria of what constitutes "frequent" or "long persistent" fog are lacking from these definitions (Grubb, 1977), similar zonations are found all over the tropics. In addition, the term "cloud forest" at least reflects the general recognition that fog and low cloud exert a dominant influence on a range of forest hydrologic and ecological processes (Cavelier, 1990; Hutley *et al.*, 1997; Hafkenscheid, 2000).

It is pertinent to note that fog-affected forests in the (sub-)tropics cover a wide altitudinal range in response to changes in prevailing temperatures and atmospheric humidity (rather than rainfall). Away from the equator, the average elevation of the cloud belt tends to decrease with increasing latitude, reflecting the associated reduction in average temperatures. On small oceanic mountains, the fog belt is typically found at much lower elevations than on similar-sized or larger mountains further inland. The resulting compression of vegetation zones on small mountains compared to that on larger mountains is called the "*mass elevation effect*". This somewhat peculiar term relates to the idea that the vertical displacement of the earth's surface in large mountain massifs is capable of raising ambient air temperatures – and therefore cloud condensation levels – above values observed in the free atmosphere at the same elevation, thereby extending the zonation of vegetation in an upward direction (Richards, 1996). However, the fact that the effect is rarely (if ever) observed in the dry tropics and becomes less pronounced on mountains away from the ocean, suggests a major atmospheric humidity effect on cloud condensation and vegetation zonation as well (Stadtmüller, 1987; Bruijnzeel *et al.*, 1993).

Synonyms and Other Types of Fog

Apart from the four process-based (Figure 3) and the four geographic fog types (nos. 5–8) distinguished above, there are numerous other terms in the literature on fog. Fog-related terms as used in the German and French literature are discussed in Stadtmüller (1987) and Dufour (1978), respectively. The following terms may be considered to be synonymous to the respective fog types distinguished in this article, although the consultation of individual scientific papers may reveal minor differences: *marine fog* → sea fog or steam fog; *frontal fog* → advection fog; *ground fog* → radiation fog; *raised fog* → stratus; *offshore fog* → sea fog.

In many places, fog water tends to be enriched with the heavier stable isotopes ^{2}H and ^{18}O compared to rainfall, reflecting differences in the origin and life history of fog and rain (Ingraham, 1998; Scholl *et al.*, 2002; cf. **Chapter 116, Isotope Hydrograph Separation of Runoff Sources, Volume 3**). Recent investigations in the maritime tropics (where mountain fog often occurs together with rain), however, have shown stable isotope contents in fog water to be similar to, or to be depleted even relative to those in rain water (Te Linde *et al.*, 2001; Eugster *et al.*, 2002), indicating that the processes leading to fog formation may differ considerably between sites. Nevertheless, it should be possible to define distinct isotopic signatures for the process-based fog types distinguished in Figure 3, such that the currently not very consistent nomenclature and use of synonyms in the literature may be based on more objective criteria in the future (Ingraham, 2001).

FOG CLIMATOLOGY

Detailed fog statistics that include information on the timing and duration of fog are mostly available for airports but rarely for routine weather stations. Typically, only the number of days with fog is given (Figure 4). However, since fog is not a continuous phenomenon and shows high spatial variability, such counts usually reveal high year-to-year variation (cf. Wanner, 1979). Also, the standard WMO procedure used by most weather services should be kept in mind when interpreting statistical fog data. A modern development is to use satellite imagery (e.g. NOAA, AVHRR) to map the spatial extent of radiation fog layers (e.g. Bendix, 2002) but this approach too has its limitations. For example, it cannot be determined unambiguously whether a cloud layer that looks rather uniform in a satellite image is actually touching the local surface or not. Thus, both ground fog and raised fog are lumped together, whereas in addition only fog fields of a certain minimum spatial extent can be detected in this

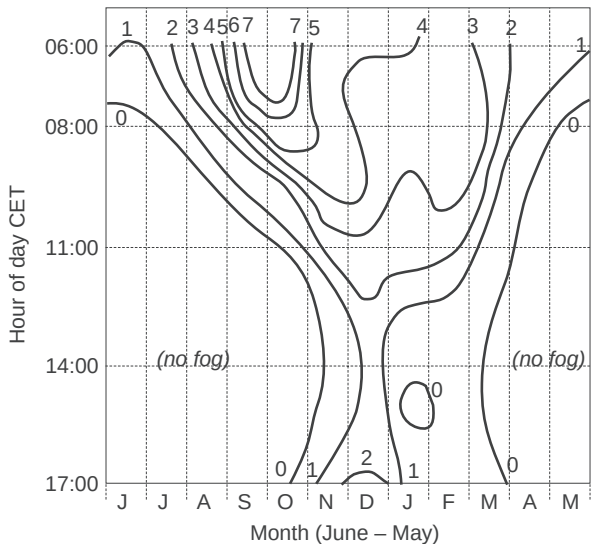

Figure 4 Number of days with fog at the Dübendorf airport, Switzerland, during the period 1938–1944 as a function of time of day and month of year. Redrawn after Zingg (1944)

way. Furthermore, because radiation fog often occurs early in the morning, this may not always match the timing of a satellite's flight over pass. Finally, illumination of the fog in the early morning may be problematic for automatic determination of fog from satellite images. Nevertheless, satellite imagery provides the best spatial overview of radiation fog occurrence, although at the present stage of development the technique completely ignores mountain fog and other fog types, which, unlike radiation fog, do not give a distinct evenly illuminated pattern (Bendix, 2002).

FOG MEASUREMENT TECHNIQUES

There is no single instrument that performs all the possible measurements required or desired in modern fog research. In the following, the main instrument types as well as their chief advantages and disadvantages are discussed briefly.

Fog Collectors

At the lower end of the sophistication range, passive fog gauges are often used to collect fog water, be it for the determination of fog water volume or for subsequent chemical analysis. Many different types of fog gauges are available, ranging from a wire-mesh cylinder placed on top of a rain gauge ("Grunow type"; Russell, 1984), to wire "harps" made of teflon strings within a square frame (Goodman, 1985) or a cylinder (Falconer and Falconer, 1980), cylindrical aluminum louvered screens (Juvik and Nullet, 1995b), and "standard" fog collectors (SFC) consisting of a 1 m^2 polypropylene net (Schemenauer and Cereceda, 1994). Usually, the extra catch recorded by a fog collector over that of an adjacent rain gauge is attributed (and equated) to "fog". However, passive fog collectors suffer various limitations: their efficiency is dependent on prevailing wind speeds; they are not specific to fog in situations where fog and (wind-driven) rain occur simultaneously; and, by nature, they are unable to adequately mimic the complexities of (tall) live vegetation in all but the simplest cases (Joslin *et al.*, 1990; Bruijnzeel, 2001). Two-dimensional screens or harps have the added disadvantage of not presenting the same silhouette and configuration in different wind directions. Adding a protective cover may eliminate some but not all wind-driven rain in particularly wind-exposed situations (Juvik and Nullet, 1995b). For particularly windy situations, Daube *et al.* (1987) proposed a wire harp collector placed within a rain-proof box in which the air flow is restricted by two baffles. The front baffle causes the passing air to accelerate and project heavy rain drops against the rear baffle where they are drained away. The lighter fog droplets are blown onward to impact against the collecting harp (Hutley *et al.*, 1997). Cylindrical gauges, on the other hand, generally represent a much smaller surface area than the "standard" fog collecting screen and the latter may thus generate measurable volumes of fog water where fog liquid water content is low or winds are light (Schemenauer and Cereceda, 1995).

Passive fog collectors are therefore used best as comparative instruments for site characterization, and should ideally be protected against direct rainfall and equipped with a recording device to evaluate the timing and frequency of fog. Nevertheless, caution is needed when interpreting data obtained in this way. For example, using Grunow-type fog gauges to characterize (potential) fog interception as part of a transect study in Panama (Figure 5), Cavelier

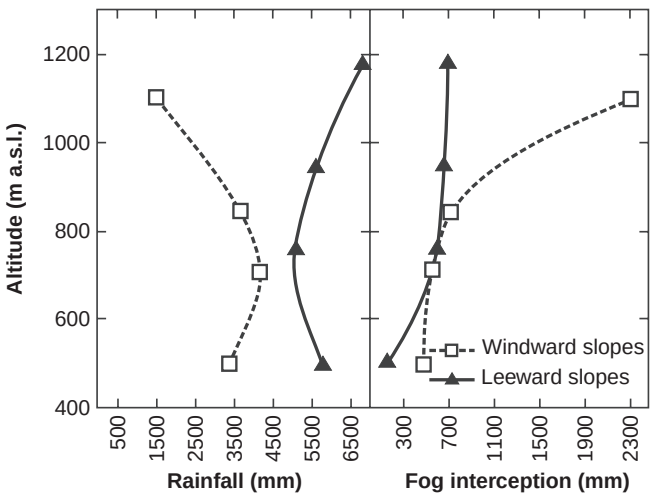

Figure 5 Variation in rainfall and 'fog interception' with altitude in the Central Cordillera of Panamá (modified from Cavelier *et al.*, 1996)

et al. (1996) obtained unrealistically high values (up to ca. 2300 mm year^{-1}) for an exposed site at 1100 m asl near the Pacific-Caribbean water divide. The corresponding rainfall at this very windy site was determined at less than 1500 mm year^{-1} even though rainfall totals at comparable elevations on either side of the divide were above 3500 mm (Figure 5). Such findings suggest severe underestimation of measured rainfall and overestimation of fog interception owing to wind effects (see Bruijnzeel (2001) for a fuller discussion). Apparent values of *LWC* may be derived from information on water volume and wind speed per sampling period if the trapping efficiency of the collector is known, but the fact that collector efficiencies tend to be dependent on wind speed renders the exercise less than straightforward (Mueller and Imhoff, 1989). Collector efficiencies vary widely between types, for example, 0.82–0.87 for the cylindrical Teflon wire harp (for wind speeds between 5.6 and 10.3 m s^{-1}; Lin and Saxena, 1991) versus 0.50–0.66 for the SFC (Schemenauer and Joe, 1989). Dawson (1998) drew attention to the fact that wire harps placed inside a forest collected significantly higher amounts of fog water than similar devices placed in the open. He attributed the difference to higher evaporative losses from the gauges at more exposed locations.

Arguably the best sampling concept is represented by the Caltech collector (Figure 6; Daube *et al.*, 1987). This active sampler is highly efficient and capable of collecting sufficient volumes of fog water even for complex chemical analyses. The instrument may also be used for the derivation of fog *LWC* (see Demoz *et al.* (1996 for details). A further advantage is that rain drops are effectively separated from the sampled fog water (Figure 6). Limitations include the high power consumption of the fan, and the uni-directional intake, which requires measures to ensure the intake is always facing the prevailing wind direction.

Detailed literature is available comparing the performance of the different types of samplers (Collett *et al.*, 1990; Schell *et al.*, 1992). To save power in field applications, fog detectors have been used to decide when to switch on the fog collector (e.g. when visibility drops below 500 m or *LWC* values fall below 20 mg m^{-3} and the efficiency of the Caltech collector becomes greatly reduced; Thalmann *et al.*, 2002).

Fog Detectors

Fog detectors (Krovetz, 1988; Mallant, 1988; Valente, 1989) are widely used in meteorological networks for the monitoring of traffic hazard conditions (fog, icing, heavy precipitation). The detection of fog or cloud is achieved by measuring the degree of optical back- or forward-scattering of emitted light in the near-infrared range. Under clear conditions, there is no such diffuse scattering. Some sensors are more sensitive than others if rain and fog occur at the same time and a careful assessment of the measurement technique is required to meet the requirements of a specific investigation.

There is an inverse (hyperbolic) relationship between visibility and fog liquid water content (Kunkel, 1984; cf. Table 1):

$$LWC = \frac{a}{(b \cdot V - c)^d} \tag{1}$$

where V is the visibility (m), *LWC* liquid water content (mg m^{-3}), and a, b, c, and d are empirical coefficients. The form of equation (1) describes why visibility can drop dramatically in dense fog even if variations in liquid water content are only small. This is illustrated further by the data presented in Table 1. The reason for the breakdown of the apparent relationship between *LWC* and visibility relates to the fact that visibility is mainly a function of droplet size distribution and numbers rather than of *LWC* itself. At low visibilities, there are numerous very small droplets (<2μm) that strongly reduce the visibility but have a limited effect on fog *LWC* (Seinfeld and Pandis, 1998). Visibility and *LWC* data collected at Lägeren, Switzerland suggested average values of $a = 6800$, $b = 1$, $c = 21.5$ and $d = 0.92$. Since the scatter in individual measurements was considerable, a simpler equation with $a = 1\,08\,340$, $b = 1$, $c = 0$, and $d = 1.136$ was equally effective (Burkard *et al.*,

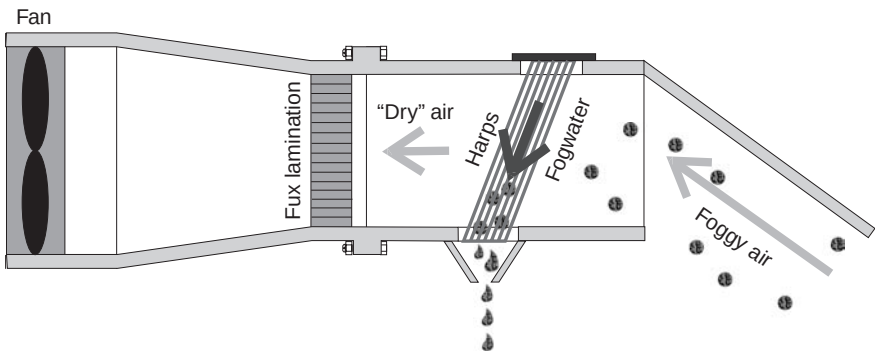

Figure 6 The Caltech Active Strand Cloudwater Collector (CASCC) (redrawn after Daube *et al.*, 1987)

2003). Equation (1) has been used inversely to predict visibility from *LWC* estimates obtained with numerical models (Smirnova *et al.*, 2000).

Fog- and Cloud-Droplet Spectrometers

Droplet spectrometers were initially used on aircraft flying across clouds and their ground-based application in fog research is comparatively recent (Beswick *et al.*, 1991; Kovalski *et al.*, 1997; Burkard *et al.*, 2002). These instruments are relatively expensive (starting at US $ 35 000) and not always designed for continuous long-term usage. The most widely used spectrometers include the Particle Volume Monitor (PVM-100), the Forward-Scattering Spectrometer Probe (FSSP) and its two-dimensional variant the Optical Array Probe (OAP), and the FogMonitor (FM-100). The PVM-100 uses a laser beam whose light is scattered forward at small angles by liquid water droplets present in the probed volume of air. There is a linear relationship between the degree of scattering and fog *LWC* (Arends *et al.*, 1992). The PVM-100 is particularly sensitive to fog droplets in the size range 3–50 μm but not to larger droplets. It is generally considered the reference instrument for fog and cloud physical research (Valente, 1989; Borrmann *et al.*, 1994). The FSSP and OAP also measure drop size distribution photo-electronically. Instrumental designs are available for the probing of precipitation (larger drops) or cloud and fog (smaller drops). However, derived values of *LWC* are quite sensitive to errors related to probe orientation, uncounted particles while the device is processing data, wind gusts, and the rather low air flow rate employed by the FSSP (see Baumgardner, 1983; DeFelice, 1998 for details). The FM-100 is an improved OAP (or FSSP) in which a pump is used to produce an air flow of nominally $13\,\mathrm{m\,s^{-1}}$ across the optical path of the forward-scattering laser (Burkard *et al.*, 2001; Eugster *et al.*, 2001). The FM-100 measures the size of each single drop passing the optical path and counts their number in each of 40 size classes between 1 and 50 μm aerodynamic diameter. The accuracy at small drop sizes is such that the useful range is 2–50 μm. However, because fog droplet spectra tend to tail off at both ends (cf. Figure 2) the poor accuracy for low diameters is not a problem in most applications. The advantage of the FM-100 over earlier instruments is that it uses a clearly measurable flow rate and aperture size of the laser beam, allowing better specification of the sampled air volume. The liquid water content of the fog is computed from the information on droplet sizes and counts, assuming the droplets are spherical. The FM-100 has been applied successfully in eddy covariance fog water flux studies in montane forests in the temperate zone (Eugster *et al.*, 2001; Burkard *et al.*, 2002) and, more recently, in the humid tropics (Holwerda *et al.*, 2005).

Other sensors measure fog *LWC* only (i.e. not its drop size spectrum). The principle of operation is that liquid water collected on a surface is evaporated by heating, and the heating rate required to evaporate the water is used to compute the absolute amount of liquid water. This type of sensor is very accurate because no assumptions on size distribution and shape of the droplets need to be made. However, for studies of fog deposition, knowledge of droplet size spectrum is usually required (see section on modeling below), such that readings of *LWC* with a liquid water sensor are made mostly as a cross-check of *LWC* values derived from droplet size spectral information. The King hot-wire probe and the Rosemount icing probe are examples of liquid water sensors (see DeFelice (1998) for details).

QUANTIFYING FOG INTERCEPTION BY VEGETATION

The fog intercepting capacity of (tall) vegetation has been recognized for centuries. Arguably the most famous example concerns a large laurel-like tree on the island of El Hierro, Canary Islands, which allegedly trapped sufficient water from passing cloud for the entire population (and their cattle) on this otherwise parched island. Such was the importance of this "fountain" tree that not only was it guarded continuously but it also appears on the island's municipal coat of arms. The services of the tree were enjoyed for centuries until it was uprooted in a violent storm in 1610 (Gioda *et al.*, 1995; see also Marzol (in press) for various historic accounts). Other well-known examples include the coastal redwood forests of California and the *fynbos* of South Africa's Western Cape Province, both of which were the subject of fog-related research as early as the first few decades of the twentieth century (see Kerfoot (1968) for a review of early literature), and the Canary pine, tree heath, and *fayal* forests on Tenerife, Canary Islands, which have been investigated increasingly since the 1950s (reviewed by Marzol, in press; Jiménez *et al.*, 2003). Finally, the very high amounts of streamflow emanating from tropical headwater catchments with montane cloud forest are often thought to reflect substantial inputs by fog interception (Zadroga, 1981; for other examples see Bruijnzeel, 2001).

While the hydrologic importance of the extra inputs provided by fog water is thus widely acknowledged, its actual quantification remains notoriously difficult (Kerfoot, 1968; Bruijnzeel, 2001; Holwerda *et al.*, 2005). Key factors affecting rate and amount of fog deposition include wind speed, fog *LWC*, surface area, and geometry (including height) of the vegetation, as well as fog duration (Schemenauer, 1986). Until recently, the two most frequently used approaches have been: (i) the use of passive fog gauges (Cavelier *et al.*, 1996; Hutley *et al.*, 1997; Ataroff, 1998); and (ii) the comparison of canopy drip or net precipitation (P_n, i.e. throughfall T_f + stemflowS_f) as measured

inside the vegetation, with amounts of gross rainfall (P_g) for periods with and without fog (Harr, 1982; Sigmon *et al.*, 1989; Hafkenscheid *et al.*, 2002). The deposition of fog onto vegetation has also been measured directly with the so-called eddy covariance approach (Beswick *et al.*, 1991; Vong and Kovalski, 1995; Kovalski *et al.*, 1997; Holwerda *et al.*, 2005). The two primary transport processes governing the deposition of fog droplets are turbulent diffusion of smaller droplets ($<10\,\mu$m) suspended in the air, and gravitational settling of the larger droplets. The turbulent part of the fog water flux can be measured directly by determining the covariance of vertical wind speed and fog liquid water content. The gravitational part is calculated from Stokes's settling velocities for specific drop diameters and information on fog droplet size distribution (Beswick *et al.*, 1991; Burkard *et al.*, 2002). Before presenting quantitative information on "typical" amounts of fog interception for different forest types and climatic settings, the limitations of the three methods are discussed below. Estimates of fog deposition on to (mostly coniferous) forest canopies using various model approaches are dealt with separately in the next section.

Evaluating Fog Deposition from Measurements of Net Precipitation

The impossibility of equating the (extra) catch of a simple fog gauge with that of a complex forest canopy in most cases (cf. Joslin *et al.*, 1990) has been commented upon already. Because each forest represents a more or less unique situation that defies standardization, the classic approach of comparing gross and net precipitation for events or periods with and without fog at least has the merit of incorporating the influence of the structural characteristics of the forest under consideration. Subtracting amounts of throughfall (T_f) plus stemflow (S_f) from gross rainfall (P_g) gives the amount of precipitation intercepted by the canopy and evaporated back to the atmosphere during and shortly after the event. This process is usually referred to as rainfall interception loss (I) as it represents a *net loss* of water to the forest (cf. **Chapter 43, Evaporation of Intercepted Rainfall, Volume 1**):

$$I = P_g - (T_f + S_f) \tag{2}$$

where the terms are as defined above and expressed in mm of water per time period. Where fog occurs in the absence of rainfall, a similar process of cloud water or fog interception (CW) may be defined as:

$$CW = E_{cw} + T_f + S_f \tag{3}$$

Because neither the actual amount of fog interception (CW, often also termed *fog deposition*, D_f) nor that evaporated again from the wetted vegetation (E_{cw}) are easily quantifiable in a direct manner, a more practical approach is to equate net precipitation (P_{net}) during fog-only events to *net* fog interception CW_{net}:

$$CW_{\text{net}} = T_f + S_f = P_{\text{net}} \tag{4}$$

where the term fog interception now implies a *net gain* of water to the ecosystem. In the more complex case of rainfall plus fog, separate knowledge of evaporation from the wetted vegetation ($\sum E_I$) is required to solve the wet-canopy water budget equation for CW:

$$P_g + CW = \sum E_I + T_f + S_f \tag{5}$$

Often, however, CW (strictly speaking, CW_{net}) is simply equated to the increase in the ratio P_{net}/P_g (or T_f/P_g) when going from events or periods without fog to events/periods with fog. In doing so, not only the stemflow component is neglected but also any differences in evaporation rates from a canopy wetted by rainfall or fog are ignored (Harr, 1982; Sigmon *et al.*, 1989; cf. **Chapter 43, Evaporation of Intercepted Rainfall, Volume 1**). Solving equation (5) for CW under the wet and windy conditions prevailing at many fog-affected forest sites is not easy and the associated error bands of the estimate tend to be wide because of the accumulation of errors in the individual wet-canopy water balance terms (Holwerda *et al.*, 2005). Depending on wind speeds and rainfall intensities, P_g can be severely underestimated because of unaccounted wind-driven rain missed by a standard rain gauge (cf. Figure 5). Although various corrections have been proposed for this (cf. **Chapter 35, Rainfall Measurement: Gauges, Volume 1**), there is the added complication of trees sticking out of the main canopy and catching inclined rainfall (and/or CW) more efficiently than their more sheltered neighbors, thereby increasing the overall catch to a level that exceeds amounts of conventionally measured rainfall in the open (Herwitz and Slye, 1992; Figure 7), particularly in steeply sloping terrain (Sharon, 1980; Holwerda *et al.*, 2005). Furthermore, because net precipitation under such conditions often exceeds P_g it is not possible to estimate $\sum E_I$ in a manner analogous to equation (2). Some investigators have therefore used the wet-canopy variant of the Penman-Monteith equation to approximate $\sum E_I$ although this may result in underestimation owing to problems with advected energy (cf. **Chapter 43, Evaporation of Intercepted Rainfall, Volume 1**). More importantly, the typically high spatial variability of throughfall in natural forests (particularly tropical ones) requires the use of a large number of gauges (usually >20–30). A "roving" gauge arrangement in which the gauges are relocated regularly is believed to sample "drip" points (where rain or fog drip become concentrated because of peculiarities in the configuration of the trees) in a more representative manner than a fixed gauge arrangement (Lloyd and Marques,

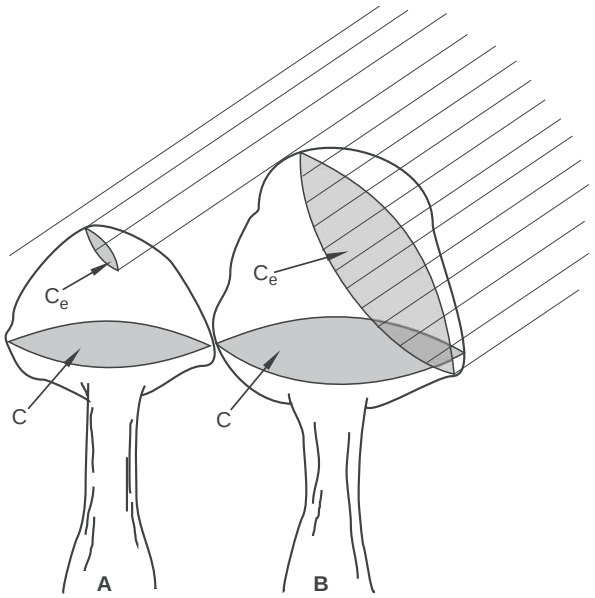

Figure 7 Illustration of the differential interception of inclined rainfall by two neighboring trees (A and B) showing how their effective intercepting crown areas (C_e) differ from their vertically projected crown areas (redrawn after Herwitz and Slye, 1992)

1988). Although the difference in mean T_f catch between the two gauge arrangements (higher T_f for roving gauges) tends to disappear above 25–30 gauges (cf. Czarnowski and Olszewski, 1970), the standard error of the mean is usually much reduced when using roving gauges (Lloyd and Marques, 1988). Because only few throughfall studies have employed a roving gauge technique, errors in published estimates of CW and CW_{net} based on conventionally measured net precipitation are likely to be substantial (see discussions in Hafkenscheid *et al.*, 2002; Holwerda *et al.*, 2005).

It follows that the comparison of P_{net} and P_g for events/periods with and without fog to evaluate CW or CW_{net} only works well when fog contributions are substantial and temporally well-defined; the error bands around the mean T_f estimate sufficiently narrow; and S_f either negligible or quantified separately. However, regression equations linking P_{net} to P_g for conditions with and without fog are often not significantly different at probabilities <0.10 (Sigmon *et al.*, 1989; Hafkenscheid *et al.*, 2002; cf. Holwerda *et al.*, 2005).

Mass-Balance Techniques

Knowing that concentrations of sodium and chloride in fog water are generally much higher than in rainfall but leached in negligible quantities only from within the leaves (Asbury *et al.*, 1994; Sigmon *et al.*, 1989), Hafkenscheid *et al.* (1998) attempted to evaluate the contribution of fog to two nearly adjacent montane cloud forests of different exposure using the sodium mass balance:

$$(P_g \times C_{Pg}) + (CW \times C_{cw}) = (T_f \times C_{Tf}) + (S_f \times C_{sf}) \quad (6)$$

in which C denotes the concentration of sodium (or any other suitable constituent) in the respective components. While a reasonable estimate was obtained for the more exposed forest, an unexpectedly high fog water input was derived for the less exposed forest. Similarly, unrealistically high values for CW were obtained in this way for an exposed ridge-top cloud forest in Puerto Rico (Te Linde *et al.*, 2001; cf. Asbury *et al.*, 1994), suggesting that the approach is less than straightforward in complex mountainous terrain, possibly owing to spatial and temporal variations in dry deposition of sea salts. A similar mass balance approach uses the difference in isotopic composition of rain and fog water (fog often being enriched in the heavier isotopes ^{2}H and ^{18}O relative to rainfall in the same region; Ingraham, 1998; Scholl *et al.*, 2002). Dawson (1998) quantified the importance of CW in this way to the water use of a redwood forest in California. The method gives good results as long as contrasts in the isotope composition of fog and rain are sufficiently large (Dawson, 1998; Te Linde *et al.*, 2001; Eugster *et al.*, 2002).

Attempts have also been made to measure fog deposition using lysimeters (Trautner *et al.*, 1990; Fowler *et al.*, 1990; Cameron *et al.*, 1997). Although such a set-up approximates natural conditions as closely as possible, it is best suited for short-statured vegetation, such as, grasses and crops rather than tall, deep-rooting trees. When lysimeter-based results were compared with estimates derived with micrometeorological techniques, considerable discrepancies were sometimes obtained (Fowler *et al.*, 1990; Cameron *et al.*, 1997). Finally, Chang *et al.* (2002) estimated fog interception by a mossy montane coniferous forest in Taiwan by multiplying the average rate of fog absorption by individual moss samples times their estimated biomass at the stand scale. Although the fog "stripping" capability of individual conifer leaves was about half that of the mosses (0.30 vs. 0.63 g H_2O g^{-1} dry weight h^{-1}), the corresponding leaf biomass was about 20 times larger, giving an inferred fog interception capacity for the canopy as a whole of ca. 2 mm h^{-1} (a very high value) versus ca. 0.17 mm h^{-1} for mosses only (Chang *et al.*, 2002).

Eddy Covariance Method

Although the direct measurement of net fog deposition (i.e. the downward flux to the canopy minus the flux in the opposite direction owing to concurrent fog formation) allowed by the eddy covariance method is promising, the technique is not without problems and cannot be applied in the steep and complex topography in which many fog-affected vegetation types occur. The few studies that have

compared eddy covariance-based estimates of *CW* with traditionally derived values (using equations (4) or (5); Vermeulen *et al.*, 1997; Holwerda *et al.*, 2005) suggested much smaller (3–6 times) values for directly measured net deposition. The reasons for such discrepancies are likely to vary between sites. On the one hand, these include the sometimes large uncertainties in the estimation of P_g and P_{net} (especially at wet and windy locations; cf. Figures 5, 7, and 8), on the other hand there is the problem of vertical flux divergence, that is, the flux as measured several meters above a forest canopy is not equal to that occurring at the canopy level (Kovalski and Vong, 1999; Burkard *et al.*, 2002; Holwerda *et al.*, 2005). The current understanding is that fog formation (through condensation of ascending air) and fog interception by the vegetation are concurring and large components at sloping windy sites. This makes it difficult to directly determine the fluxes at the plant leaf reference level using eddy covariance measurements performed above the canopy, since the technique only measures the net difference between the two components (Kovalski and Vong, 1999; Holwerda *et al.*, 2005). Current fog deposition research is beginning to focus on conditions prevailing within canopies (DeFelice, 2002). So far, only "surface-normal" fluxes have been investigated, and it has been implicitly assumed that horizontal advective impacts during strong winds (Walmsley *et al.*, 1996) lead to a vertical flux that is included in the eddy covariance measurement. This assumption may need to be revised in the future.

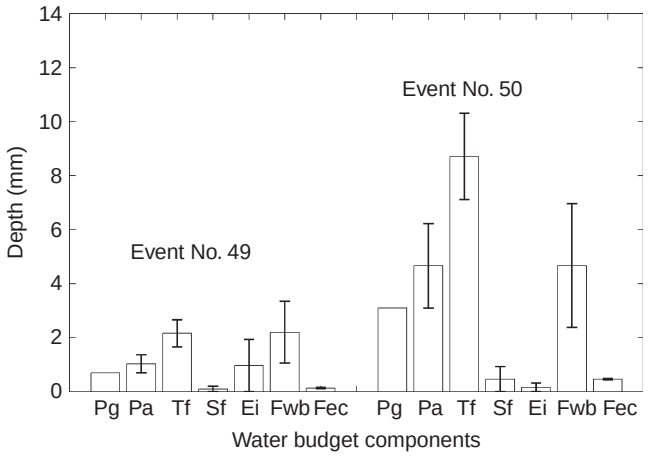

Figure 8 Wet-canopy water budget components and their (estimated) standard errors for two consecutive sampling periods (Nos. 49 and 50) in elfin cloud forest, Pico del Este, Puerto Rico (after Holwerda *et al.*, 2005). Explanation of symbols: *Pg* = gross precipitation, *Pa* = precipitation adjusted for wind- and slope effects, *Tf* = throughfall, *Sf* = stemflow, *Ei* = wet-canopy evaporation, *Fwb* = fog interception according to water budget method, *Fec* = fog deposition according to eddy covariance method

Fog as a Hydrologic Input: Selected Examples

Fog inputs are highly variable in time (Yin and Arp, 1994; Dawson, 1998; Holder, 2003; Liu *et al.*, in press) and in space, particularly in mountainous terrain (Weaver, 1972; Cavelier *et al.*, 1996; Walmsley *et al.*, 1996; cf. Figures 5 and 10). Reported figures are often difficult to compare between locations, however, because of differences in methodology (fog gauges vs. net precipitation or direct eddy covariance measurements) and duration of the measurements (short-term vs. seasonal or annual). Generally, fog deposition (interception) in an area increases with elevation within the cloud belt, mostly as a result of the concurrent

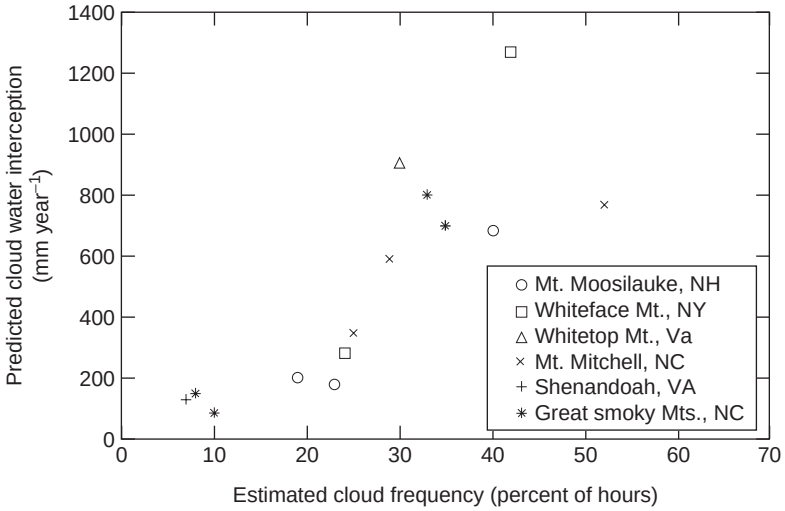

Figure 9 Comparison of fog interception and cloud frequency for several mountains in the eastern United States (drawn from tabled data in Vong *et al.*, 1991)

increases in fog frequency (immersion time) and wind speed (Figures 5, 9, and 10). The reasonably consistent relationship between fog frequency and fog deposition per region (e.g. Figure 9) indicates that the former may be used as an initial screening factor to identify areas that are likely to receive significant hydrologic (and associated chemical) inputs from fog (Vong *et al.*, 1991; Yin and Arp, 1994). Similarly, interception of advection fog in coastal areas tends to decrease with distance from the coast (Cereceda *et al.*, 2001) and Yin and Arp (1994) were able to closely predict the frequency of fog over large areas in eastern Canada as a function of distance from the coast, time of

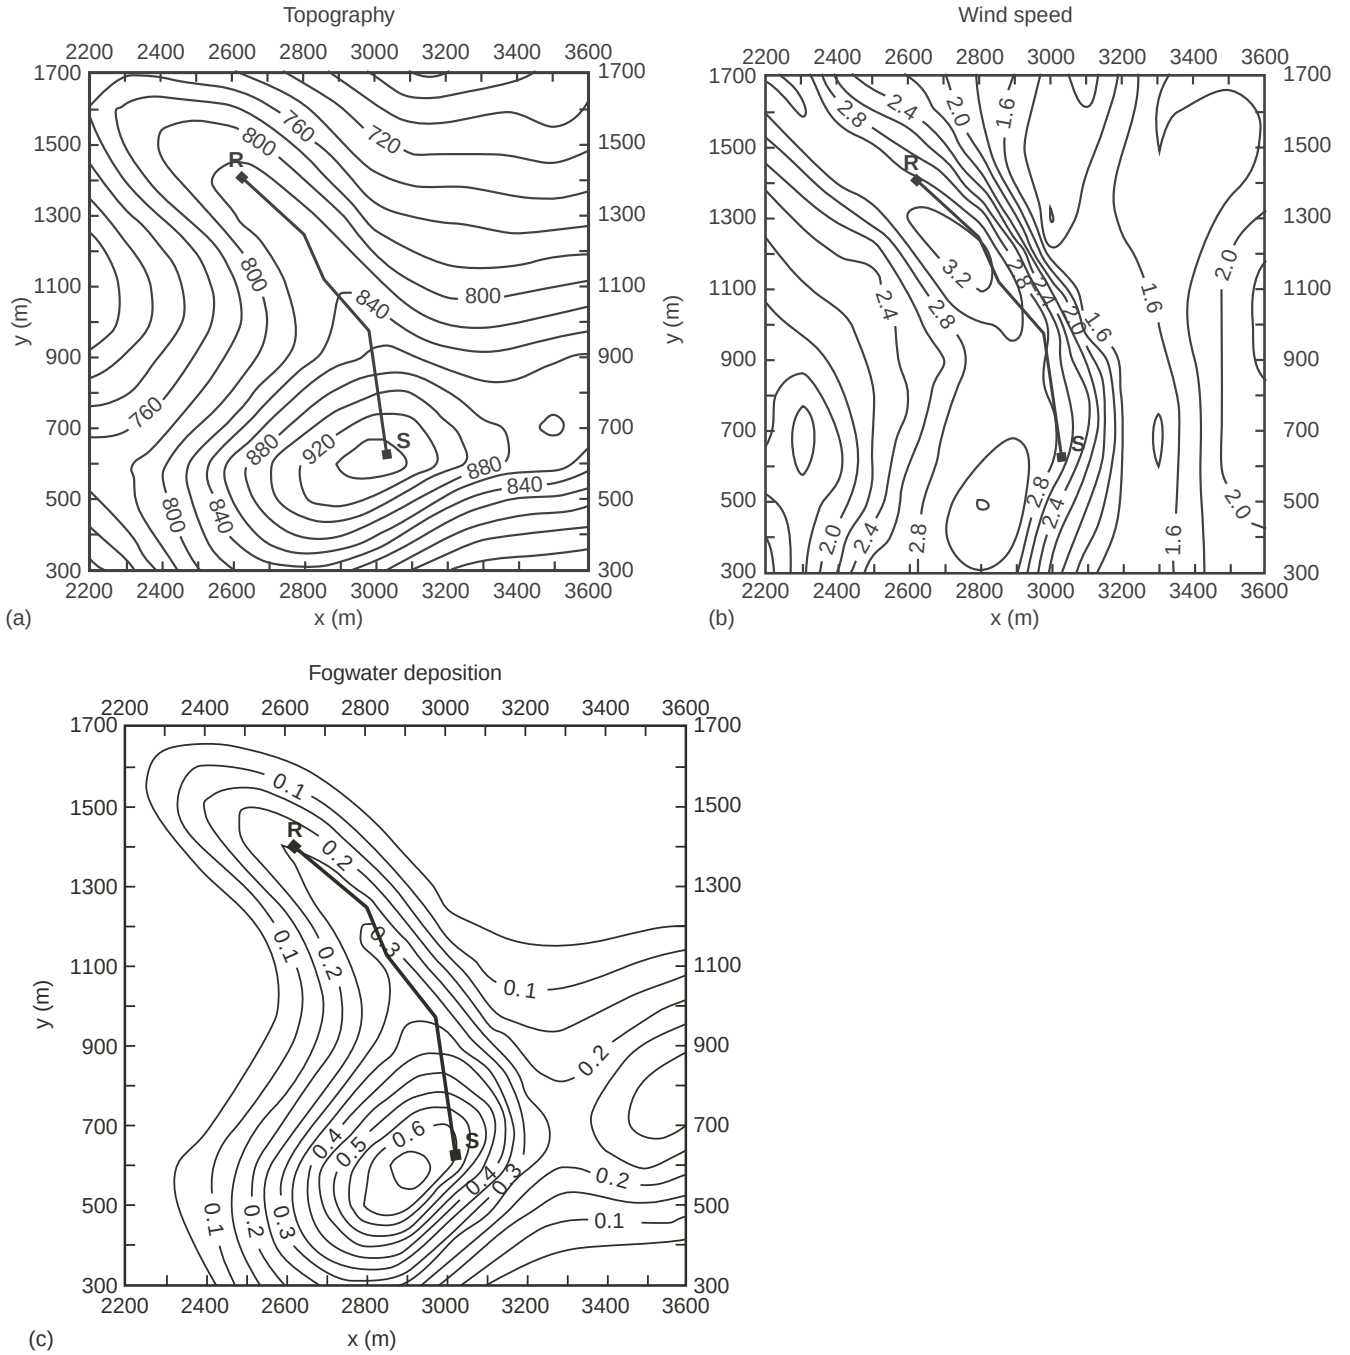

Figure 10 Spatial patterns of (a) topography (contour interval 20 m), (b) modeled wind speeds at 1.5 m above the canopy (isotach interval 0.2 m s^{-1}), and (c) modeled fog water deposition rate (isopleth interval 0.05 L m^{-2} h^{-1}) for the summit (S) and ridge (R) area on Roundtop Mountain, Quebec, Canada. year (month) and monthly temperature. Finally, owing to their close association with wind, advection fogs (both in coastal and mountain areas) are typically associated with larger depositions than radiation fogs (see below).

Table 2 lists gross and net fog interception data (i.e. CW and CW_{net} as used in equations 2–5) from selected locations around the world, representing a range of conditions in terms of climatic zone, elevation, proximity to the coast, and vegetation type. Despite the methodological limitations referred to earlier, and the caution that thus needs to be applied in their interpretation, the data in Table 2 confirm that fog is a significant hydrologic input in many coastal and montane situations, regardless of climatic zone. Leaving the very high potential deposition recorded for otherwise barren coastal northern Chile (site 1 in Table 2) aside for the moment, average CW values derived for a range of evergreen forest types across the humid tropical to subtropical and warm-temperate "maritime" climatic spectrum exhibit a fairly narrow range (0.95–2.45 mm d^{-1}), with the highest values being associated with the wettest and windiest locations (Puerto Rico, Costa Rica). Naturally, the (mostly corresponding) values of CW_{net} at these and comparable sites are somewhat lower owing to the effect of wet-canopy evaporation, but they are still considerable (range: 0.65–2.15 mm d^{-1}). Moreover, higher values than these annual means are sometimes observed during the dry season, both for mountain fog (e.g. Guatemala: 1.3 mm d^{-1} vs. 0.64 mm d^{-1} on average; Holder, 2003; cf. García-Santos *et al.*, in press) and valley (radiation) fog (e.g. South China: 0.22 vs. 0.52 mm d^{-1} during the wet and dry season, respectively; Liu *et al.*, in press). Needless to say, such increases render the extra inputs by fog even more important, both from the hydrological and the ecological perspective. Returning to the most extreme example (northern Chile), there are no measurements of fog drip underneath natural vegetation in the area but throughfall measurements made beneath ten *Caesalpina* trees in the subdesertic coastal area of southern Peru suggested an average fog drip of nearly 1 mm d^{-1} (Calamini *et al.*, 1998). In northern Chile, the fog is exploited increasingly for domestic purposes using large screen collectors (cf. Schemenauer and Joe, 1989; Cereceda *et al.*, 2001).

Except at the windiest and coldest mountain sites (cf. Figure 9), fog deposition rates under cool temperate conditions tend to be much more modest (typically $\ll$1 mm d^{-1}), particularly when tall vegetation gives way to grass or moorland (Table 2). Fowler *et al.* (1990) suggested that replacing moorland vegetation in the northern UK (site n in Table 2) by ca. 20-m tall spruce forest might increase fog deposition by a factor of 3.7. In addition, because solute concentrations in cloud water are generally much higher than in rainfall (e.g. Vong *et al.*, 1991), the associated deposition of major ions might even be increased by 50% (Fowler *et al.*, 1990).

MODELING FOG DEPOSITION

Although the measurement of fog deposition on tall vegetation is fraught with difficulty and uncertainty, even for individual sites (cf. Figures 5 and 8), there is a need for sound estimates to be made over long time periods and in regions of complex terrain, both in the context of understanding forest decline in areas with high pollution loading via cloud water deposition (e.g. Vong *et al.*, 1991) and in areas where fog constitutes an important addition to the overall water budget (Vogelmann, 1973; Dawson, 1998). Such difficulties have prompted the development and testing of predictive models of fog deposition of varying complexity. Some of the more widely used models are discussed briefly below.

The general model developed by Shuttleworth (1977) (based in turn on the pioneering work of Hori (1953) and Merriam (1973)) describes the fundamental processes of cloud water deposition to, and evaporation from, a uniform vegetation canopy. In this steady-state, single-layer model, the turbulent transfer of fog droplets to the canopy from the surrounding air is modeled by direct analogy to Ohm's law for electrical circuits, in which a current representing the flux is calculated as the ratio of a potential gradient and a resistance. In this case, the flux is that of fog water to the canopy surface, the potential gradient is the difference in fog droplet concentration between the air and the receiving surface, and the resistance that to droplet deposition (Shuttleworth, 1977). Lovett (1984) adapted the Shuttleworth model by incorporating the vertical variation in an otherwise homogenous canopy structure. A series of layers was introduced in which the vertical turbulent transport of fog droplets is controlled by the aerodynamic resistances between layers, and that between the top layer and the air above the canopy. In more detail, Lovett's model consists of two submodels, the first simulating the turbulent diffusion of fog droplets into the forest and their deposition on to foliar and branch surfaces, and the second simulating evaporation and condensation during conditions of cloud immersion within the forest. The description of the turbulent transport component is based on the similarity hypothesis, which states that momentum and droplets are exchanged between the within-canopy and above-canopy air spaces with the same efficiency, that is, the droplets are assumed to follow the turbulent airstream into the canopy. Although the interior air of large clouds is generally supersaturated, thin clouds and fogs can be slightly undersaturated. Also, net radiation, which is the chief variable controlling evaporative potential, ranges from slightly positive to slightly negative depending on the time of day and depth of the cloud (Pruppacher and Klett, 1998). Therefore, Lovett (1984) simulated evaporation and condensation using a submodel that is very similar to the cloud deposition submodel, except that it accounts for

the partition of available energy into sensible and latent heat (cf. **Chapter 45, Actual Evaporation, Volume 1**). To enable comparisons to be made between model predictions of "gross" fog water interception (deposition), and "net" fog interception derived from measurements of throughfall (cf. equations (2) and (3)), the corresponding amounts of wet-canopy evaporation need to be subtracted from predicted deposition totals (Lovett, 1984; cf. **Chapter 43, Evaporation of Intercepted Rainfall, Volume 1**).

Lovett's model was developed specifically to estimate fog deposition in subalpine balsam fir forest in the northeastern US, for which highly detailed forest structural information was available. The model was subsequently generalized for use in spruce forests (Mueller, 1991) and deciduous forests (cf. Vong *et al.*, 1991), also in the eastern US. Modifications included improvements in leaf area and droplet collection efficiency parameterization schemes, diffusivity profiles above and within the canopy, and the relationship between fog droplet size distribution and liquid water content (Vong *et al.*, 1991; Mueller, 1991). Comparative experiments have revealed that the Lovett deposition model is quite sensitive to the specification of LWC and drop size distribution. Indeed, Lovett (1984) himself concluded that uncertainty in the input data, in addition to general temporal and spatial variability aspects, made his model impractical for estimations at the landscape or seasonal scale (see also below).

Another widely used model (Beswick *et al.*, 1991; Gallagher *et al.*, 1992) is the analytical model developed by Slinn (1982). Approximated analytical equations are used to model the dry deposition of droplets to vegetation canopies. The deposition velocity of a droplet is described by the cumulative effects of its sedimentation velocity, the overall drag coefficient of the canopy, wind speeds at reference height and at the top of the canopy, a universal droplet collection efficiency, and a parameter characterizing the wind profile within the canopy. The chief drawback of this model is its dependence on a large number of parameters. Moreover, Kovalski and Vong (1999) examined the validity of the assumed analogy between momentum and fog droplet fluxes and concluded that simpler models based on droplet impaction efficiencies would be physically more robust, although requiring accurate information on within-canopy structure, wind speeds, and size-dependent droplet number concentrations. Such information is rarely available at high spatial resolutions and thus the modeling of fog water deposition in this way will remain a major challenge for some time.

For most hydrologic applications, it is not essential to know the vertical distribution of fog water flux within a canopy. Thus, Unsworth and Wilshaw (1989) proposed a simpler, aerodynamic approach in combination with droplet settling velocities to derive the rate of fog water deposition D_f (expressed in $\mathrm{g\,m^{-2}\,s^{-1}}$):

$$D_f = LWC \left\{ k^2 u(z) / \left[\ln\left(\frac{z-d}{z_0} \right) \right] + v_s \right\} \qquad (7)$$

where k = von Kármán's constant (0.4), $u(z)$ = wind speed ($\mathrm{m\,s^{-1}}$) as measured at reference height z (m), d = zero plane displacement (m), z_0 = roughness length (m), v_s = deposition velocity by sedimentation ($\mathrm{m\,s^{-1}}$), and *LWC* ($\mathrm{mg\,m^{-3}}$) as defined previously (*see* **Chapter 43, Evaporation of Intercepted Rainfall, Volume 1** and **Chapter 45, Actual Evaporation, Volume 1** for definitions of d and z_0). The Unsworth and Wilshaw model assumes that fog droplets are deposited by way of turbulent diffusion and sedimentation, and that turbulent diffusion proceeds at the maximum rate allowed by momentum transport. This alternative approach achieves a greater degree of spatial integration and its predictions match eddy-covariance flux measurements of fog deposition much better than the more mechanistic approaches discussed above. For example, incorporation of a fog deposition component as derived with equation (7) into the water budgets of six forested watersheds in the Maritime Provinces of eastern Canada effectively resolved earlier discrepancies between simulated and measured streamflow volumes (Yin and Arp, 1994). In areas with a noncontinuous forest cover, there is the added complication that fog interception is much higher at forest edges than toward the interior (Weathers *et al.*, 1995; Yin and Arp, 1994).

In recent years, increased effort has been directed toward assessing the spatial distribution of fog water deposition on forest in complex mountainous terrain. Walmsley *et al.* (1996) developed and applied a model for the estimation of spatial variations in fog water volume "stripped" by a coniferous forest canopy over areas of $2-164\,\mathrm{km^2}$ surrounding Roundtop Mountain (970 m) in Quebec, Canada. Their model acknowledges that amounts of fog water deposition are highly site dependent and largely governed by the following five factors: canopy structure, horizontal wind speed, collection efficiency of the tree crowns, fog liquid water content, and variation of fog frequency with altitude. Forest canopy structure was described as the summation of individual trees, where each tree was assumed to be a vertical cylinder topped by a cone. Spatial variations in wind speed and direction were calculated using the wind flow model of Bridgman *et al.* (1994). The fog collection efficiency of the treetops (i.e. the upper "cones") was assumed to be represented by that of an AES/ASRC passive fog collector, which has been shown to closely simulate fog water collection by similar types of coniferous trees (Joslin *et al.*, 1990). However, fog *LWC* values could not be derived directly from collector sample amounts because of the variation in collector efficiency with wind speed and droplet size referred to earlier (Mueller and Imhoff,

1989). Hence, *LWC* at different elevations was calculated from cloud-base height observations and the assumption that *LWC* above the cloud base was 38% of the value calculated for adiabatic ascent. This simple approach proved to be in "reasonable agreement" with *LWC* values measured earlier in the region (Walmsley *et al.*, 1996). Finally, the variation of fog frequency with altitude was assumed to be linearly related to height above sea level as demonstrated earlier for the area by Schemenauer (1986). Any effects of fog droplet size on deposition velocity (notably for moderate wind speeds; Gallagher *et al.*, 1988) were not considered because calculations had to be made over several tens of km^2 and detailed dropsize distribution data are not available at this scale (Walmsley *et al.*, 1996).

In the application, spatial variations in the wind velocity field just above the canopy were found to be closely related to the main terrain features (valleys, ridges, summits; Figure 10). Fog water deposition rate at the canopy top was specified as a function of topographic height above the cloud base (read: *LWC*) and wind speed. As a result, spatial patterns of fog water deposition strongly reflected the pattern of topographic contours (Figure 10). Although predicted deposition rates were not validated in the field, they were found to be typical of measured values reported in the literature (Walmsley *et al.*, 1996).

The models discussed so far were developed primarily to demonstrate the importance of fog water deposition to high elevation ecosystems. Compared to mountain and advective fog types, comparatively little effort has been put into the modeling of radiation fog, despite the fact that water and ion fluxes associated with such fog may be significant in particular cases (e.g. Liu *et al.*, in press). von Glasow and Bott (1999) presented a sophisticated one-dimensional model describing the (thermo)dynamics and microphysical structure of radiation fog, as well as the associated atmospheric radiative transfers in some detail (cf. Bott *et al.*, 1990).

This short overview has demonstrated, if anything, that prediction of both one-dimensional and spatial patterns of fog water deposition remains a major challenge. Moreover, although some deposition models (notably that of Lovett, 1984) have been applied to a variety of vegetation types, simulated deposition totals have only rarely been evaluated against credible measurements (cf. Vong *et al.*, 1991; Kovalski and Vong, 1999) whereas model applications in tropical montane cloud forests seem to be lacking entirely (Bruijnzeel, 2004; Bruijnzeel *et al.*, in press).

CONCLUDING REMARKS

Although the hydrologic importance of fog to many coastal and montane ecosystems (particularly under subhumid and arid conditions) is well-established, reliable quantitative information on fog deposition is relatively scarce (cf. Table 2). This reflects the intrinsic complexities of the processes involved as well as the large temporal and spatial variability of fog occurrence and deposition rates (Kovalski and Vong, 1999; Lovett, 1984). With the arrival of eddy-covariance equipment, direct measurements of net fog deposition (i.e. the flux to the canopy minus the flux in the opposite direction owing to concurrent fog formation) have become possible, but in the few examples in which the results have been compared with independent measurements (e.g. crown drip), eddy covariance based estimates were invariably much lower. Further comparative work at carefully selected locations is needed.

Similarly, a number of fog deposition models of varying complexity is available but the predicted rates of fog interception have rarely been validated (Vong *et al.*, 1991). In addition, the modeling of spatial patterns of fog deposition over larger areas (tens to hundreds of km^2) is still in its infancy although plausible estimates have been obtained using a topography-based approach (Walmsley *et al.*, 1996). To improve the degree of realism in predictions of spatial fog deposition, state-of-the-art knowledge of cloud physics will need to be combined with (micro)meteorological and hydrologic measurement of cloud-droplet spectra and fog water deposition. In particular, the approach of Walmsley and coworkers needs to be linked to actually measured *LWC* values and drop size spectra (for the computation of the gravitational component of deposition) at different elevations and for contrasting degrees of exposure.

Our understanding of the ecological role of fog interception and absorption by tall vegetation has increased in recent years for some (subhumid) ecosystems, including the *lomas* of northern Chile and Peru (Pinto *et al.*, 2001; Aravena *et al.*, 1989) and the redwoods of California (Dawson, 1998; Burgess *et al.*, 2001), partly through the application of stable isotopes. Much less is known about the influence of fog on the physiologic functioning of tropical montane cloud forests, be it absorption of fog by foliage (Yates and Hutley, 1995) or epiphytes (Hölscher *et al.*, 2004; Zotz and Hietz, 2001), the suppression or even reversal of tree water uptake (Cavelier, 1990; Burgess *et al.*, 2001), and photosynthesis (Jiménez *et al.*, 2003). Such information is especially relevant at "marginal" cloud forest sites where rainfall alone is not sufficient to sustain evergreen rain forest (Vogelmann, 1973; Hutley *et al.*, 1997). Similarly, fears have been expressed that the loss of the cloud-capturing capacity of cloud forests upon conversion to pasture or temperate vegetable cropping will lead to diminished streamflow, particularly during the dry season (Zadroga, 1981), although experimental evidence for this is limited (cf. Ingwersen, 1985; Bruijnzeel, 2001).

Ridge-top cloud forests are potentially under threat by lifting cloud base levels owing to global warming (Still *et al.*, 1999) or, more speculatively, lowland forest conversion to pasture (Lawton *et al.*, 2001). The plants and

animals living in cloud forests are finely adapted to the prevailing (and rather extreme) climatic conditions and a significant decline in the frequency or density of fog may have disastrous consequences for the vitality (or indeed survival) of populations of frogs, toads, and anoline lizards (cf. Pounds *et al.*, 1999) as well as epiphyte and bryophyte communities (cf. Zotz and Hietz, 2001). Under rather more marginal conditions in East Africa, cloud forests are increasingly subject to fire and Hemp (in press) has drawn attention to the potentially large volumes of water that may be missed once the fog intercepting capacity of tall vegetation is lost after fire.

Summarizing, although much is still to be learned (both qualitatively and quantitatively) about the hydrologic and ecological roles of fog in a variety of ecosystems, considerable progress has been made in recent years with the measurement and modeling of fog deposition. In addition, a considerable body of work is currently underway (cf. Schemenauer and Puxbaum, 2001; Bruijnzeel, 2004; Bruijnzeel *et al.*, in press) and the results of these new initiatives are awaited with interest.

39: Surface Radiation Balance

MICHAEL H UNSWORTH

Atmospheric Sciences Group, College of Oceanic and Atmospheric Sciences, Oregon State University, Corvallis, OR, US

The surface radiation balance is the algebraic sum of the net solar radiation and the net long-wave radiation received by a surface. It may be measured directly with a net radiometer, deduced from measurements of its upwelling and downwelling components, or modeled from climatological, geographical, and atmospheric data. Methods of modeling and measuring each of the components are discussed. Downwelling solar radiation from cloudless skies may be modeled from knowledge of atmospheric properties, but effects of clouds require more empirical approaches most suitable for monthly means. Downwelling long-wave radiation below cloudless skies is well related to temperature and humidity near the ground. An empirical method to account for clouds is given. Reflection coefficients and emissivities of natural surfaces are tabulated for use in calculating upwelling short and long-wave radiation. Net radiometer designs are reviewed, and examples are given of the surface radiation balance and its components over forest and grass. Issues of spatial variability of the surface radiation balance are discussed.

INTRODUCTION

Radiation from the sun is the initial source of the energy that drives the hydrologic cycle. But transformations of the solar radiation reaching the earth in the atmosphere and at the earth's surface result in there being several streams of upwelling and downwelling radiant energy in various wavebands at the earth's surface, and it is the net balance of these streams (just like the balance in a bank account) that provides the main resource that is partitioned at the surface into latent and sensible heating. So the surface radiation balance Q^* is a fundamental component of the surface-atmosphere energy exchange. In spite of its importance, Q^* is seldom measured as a climatological variable; more commonly it is computed from measured or modeled components. Modeling approaches may include numerically complex schemes such as those that are included in large-scale atmospheric models (e.g. (Niemela *et al.*, 2001a,b), which require vertical profiles of atmospheric properties, or they may rely on more empirical approaches on the basis of observed climatological variables at the surface. This review will therefore include discussion of the measurement and modeling of components of Q^* before considering methods and examples of direct measurements of the surface radiation balance.

DEFINITION

The surface radiation balance Q^* for a horizontal surface is

$$Q^* = K^* + L^* = K_\downarrow - K_\uparrow + L_\downarrow - L_\uparrow \qquad (1)$$

where K and L are the short- and longwave components; arrows represent the direction of the flux, and * signifies a net flux.

COMPONENTS OF THE SURFACE RADIATION BALANCE

Downwelling Shortwave Radiation

The shortwave radiation falling on a horizontal surface is the remainder after processes of scattering and absorption in the atmosphere have had their effect. At the mean distance of the earth from the sun, which is 1.50×10^8 km, the incident radiant flux density (termed the *irradiance*) on a surface held perpendicular to the solar beam is

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

known as the *Solar Constant*. The name is misleading because this quantity, with a mean value of $1366\,W\,m^{-2}$ (Crommelynck *et al.*, 1995), varies by about $\pm 1\,W\,m^{-2}$ in phase with the sunspot number (Frohlich and Lean, 1998; Willson and Mordvinov, 2003). The path length of the solar beam through the atmosphere varies with latitude, season, and time of day in ways that can be predicted from astronomical formulae (Monteith and Unsworth, 1990). As the beam passes through the atmosphere it is modified in quantity, quality, and direction by the processes of scattering and absorption.

Scattering has two main forms. Gas molecules in the atmosphere scatter light almost uniformly in all directions (Rayleigh scattering). The effectiveness is proportional to the inverse fourth power of the wavelength so that blue light (400 nm) is scattered about nine times more effectively than red light. Thus in a cloudless sky some of the direct beam radiation becomes diffuse radiation and reaches the ground from the (blue) hemisphere. Dust in the atmosphere and thin clouds scatter more dominantly forward (Mie scattering), but multiple scattering below thick clouds is more spatially uniform. The efficiency of scattering tends to become independent of wavelength as particle or droplet size increase. Consequently, overcast or very dusty (turbid) skies appear white.

Absorption of solar radiation in the cloudless atmosphere is mostly from ozone, water vapor, carbon dioxide, and oxygen. Clouds may absorb up to 20% of solar radiation.

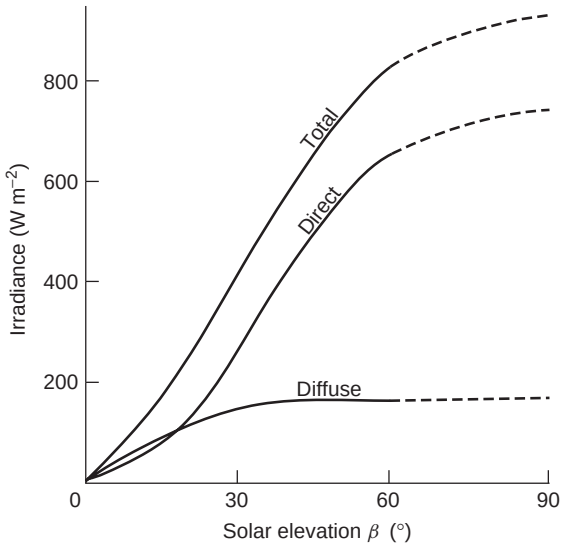

Figure 1 Variation of solar radiation components on a horizontal surface on a cloudless day at Sutton Bonington (53° N, 1° W), showing diffuse and direct irradiance and their sum, the total (global) solar irradiance. The full lines are from measurements and the dashed lines are approximate extrapolations to illustrate how the terms would vary at larger solar elevations (Reprinted from Principles of Environmental Physics, (1990) with permission from Elsevier)

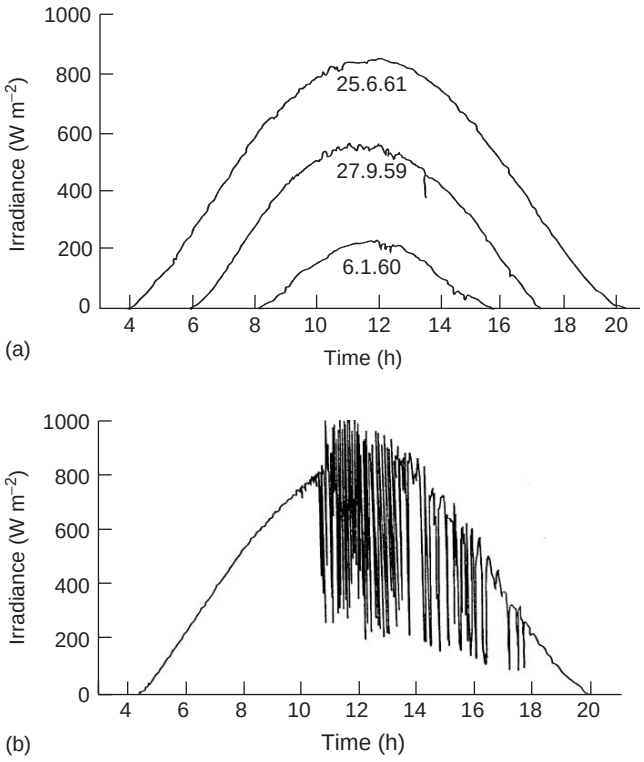

Figure 2 (a) Global solar irradiance on a horizontal surface on three cloudless days at Rothamsted, UK (52° N, 0° W). During the middle of the days, the records fluctuate more than in the morning and evenings, probably because of diurnal changes in dust loading in the atmosphere (Reprinted from Principles of Environmental Physics, (1990) with permission from Elsevier) (b) Global solar irradiance on a horizontal surface on a day of broken cloud at Rothamsted, UK (52° N, 0° W). Very high values of irradiance occurred immediately before and after the sun was occluded by clouds because radiation is scattered downwards from the cloud margins. The minimum values are the diffuse irradiance when the sun was completely obscured (Reprinted from Principles of Environmental Physics, (1990) with permission from Elsevier)

Solar Radiation at the Ground

As a consequence of scattering and absorption, solar radiation has two distinct directional properties when it reaches the ground. Direct radiation arrives from the direction of the sun; diffuse radiation includes all the other solar radiation received from the blue sky and from clouds either by scattering or transmission. The sum of the flux densities for direct and diffuse radiation on a horizontal surface is known as *global or total solar radiation* $K\downarrow$ ($W\,m^{-2}$). Figure 1 shows a typical example of the variation of each of these components with solar elevation on a cloudless day. Figure 2(a) shows the daily variation of $K\downarrow$ on three cloudless days and Figure 2(b) shows the daily variation on a day when broken clouds developed. When there is a broken cloud, the irradiance is enhanced when clouds are close to the sun and scatter radiation toward

the ground, but when clouds obscure the sun the radiation becomes entirely diffuse.

Measuring Solar Radiation

Solar radiation at the ground is in the waveband 0.3–3.0 μm, and the standard instruments for measuring it (pyranometers) should have a uniform response over this waveband so that they are equally effective for global or diffuse (blue sky) radiation. The best-known instruments are made by Eppley (**http://www.eppleylab.com/**) and Kipp and Zonen (**http://www.kippzonen.com/**) and use thermopile sensors coated with a black pigment. An alternative method for measuring global solar radiation is to use a pyranometer with a silicon photovoltaic sensor (**http://env.licor.com/Products/Sensors/rad.htm**), but these sensors detect only a small fraction of the spectral range and so should be used only in unobstructed global radiation (i.e. not for diffuse or reflected radiation unless they are specifically recalibrated for such measurements against a thermopile pyranometer).

Modeling Solar Radiation

Apart from astronomical and geographical factors (latitude, elevation), $K\downarrow$ is influenced by cloud, turbidity, absorption, and scattering. Empirical models based on these factors or other climatological variables have been developed by several investigators including Kasten (1983), Thornton and Running (1999), and Meza and Varas (2000). Methods for calculating instantaneous values of $K\downarrow$ are given by Campbell and Norman (1998). Methods using observations of sunshine hours or cloud cover can be very effective for estimating $K\downarrow$ for monthly mean or other longer period calculations. Iziomon and Mayer (2001) concluded that the Angstrom–Prescott formula agreed with observations within 2.5% for a lowland site and 3.4% for a mountain site when its empirical coefficients were calibrated for the sites. The formula is:

$$\frac{\Sigma K\downarrow}{\Sigma E_0} = A + B\left(\frac{S}{S_0}\right) \qquad (2)$$

where $\Sigma K\downarrow$ and ΣE_0 are the daily totals of global solar radiation and extraterrestrial radiation (MJ m^{-2}) respectively, and S and S_0 denote the corresponding sunshine duration and day length (hrs). Values of E_0 and S_0 can be found in List (1966). The disadvantage of equation (2) is that the coefficients A and B are somewhat site dependent. Iziomon and Mayer (2001) found mean values $A = 0.21 \pm 0.02$ and $B = 0.58 \pm 0.02$ for 12 sites in Germany.

Upwelling Shortwave Radiation $K\uparrow$

Upwelling short-wave radiation $K\uparrow$ is the product of $K\downarrow$ and the shortwave reflection coefficient of the surface ρ, also termed the *albedo*. Typical albedos for several surface types are given in Table 1, where data are taken from Campbell and Norman (1998), Monteith and Unsworth (1990), Offerle *et al.* (2003) and Gash and Nobre (1997). Values of ρ are influenced by the amount of vegetation cover, soil type, soil wetness, and solar elevation; the values in the table should be regarded as approximate for high solar elevations. In particular, tall canopies and smooth water surfaces have albedos that increase at low solar elevation. The albedo of clear, still water is almost constant at about 0.05 when the solar elevation exceeds 45°, but increases rapidly with decreasing elevation, approaching 1.0 at grazing incidence (Monteith and Unsworth, 1990) (*see* **Chapter 44, Evaporation from Lakes, Volume 1**).

Upwelling shortwave radiation can be measured with an inverted thermopile pyranometer. Special care is necessary at low sun angles to avoid measuring radiation that has been reflected and refracted in the instrument domes.

Downwelling Long-wave Radiation $L\downarrow$

Downwelling long-wave radiation $L\downarrow$ at the surface originates from radiatively active gases in the atmosphere (principally water vapor and carbon dioxide) and from clouds when present. Gaseous emission is present in specific wavebands in the range 0.3–30 μm, whereas

Table 1 Reflection coefficients (albedos) for solar radiation

Surface	Reflection coefficient	Surface	Reflection coefficient
Grass	0.24–0.26	Coniferous forest	0.05–0.15
Wheat	0.16–0.26	Tropical rainforest	0.12–0.14
Barley	0.23	Snow, fresh	0.75–0.95
Maize	0.18–0.22	Snow, old	0.40–0.70
Potato	0.19	Soil, wet dark	0.08
Sugar cane	0.15	Soil, dry dark	0.13
Cotton	0.21	Soil, wet light	0.10
Tundra	0.15–0.20	Soil, dry light	0.18
Tropical pasture	0.17–0.19	Sand, dry	0.35
Deciduous forest	0.10–0.20	Urban areas	0.10–0.27
		Water	0.05 (solar elevation >45°)

emission from clouds corresponds to black body radiation at the temperature of cloud base. From cloudless skies, more than half the long-wave flux received at the ground comes from gases in the lowest 100 m, and roughly 90% from the lowest kilometer. Consequently, $L\downarrow$ is often estimated as

$$L\downarrow = \varepsilon_a \sigma T_a^4 \tag{3}$$

where ε_a is an estimated broadband atmospheric emissivity, σ is the Stefan–Boltzmann constant ($5.67 \times 10^{-8}\,\mathrm{W\,m^{-2}\,K^{-4}}$), and T_a is a bulk atmospheric temperature (in Kelvin) usually approximated by air temperature near the ground. Formulae for estimating ε_a for cloudless skies have been reviewed by Prata (1996) and Niemela *et al.* (2001a). The Prata equation (Prata, 1996) was most successful

$$\varepsilon_a = 1 - (1 + aw)e^{-(b+cw)^{0.5}} \tag{4}$$

where w is the precipitable water content of the atmosphere, given approximately by

$$w = \frac{4.65 e_a}{T_a} \tag{5}$$

where e_a is the vapor pressure near the ground (the units of w are $\mathrm{kg\,m^{-2}}$ when e_a is in Pa and T_a is in K; the empirical constants are $a = 0.10\,\mathrm{kg^{-1}\,m^2}$, $b = 1.2$, $c = 0.30\,\mathrm{kg^{-1}\,m^2}$). By using equations (4) and (5) with equation (3), values of $L\downarrow$ from cloudless skies can be calculated. A simpler expression for $L\downarrow$ from cloudless skies was given by Monteith and Unsworth (1990)

$$L\downarrow = a + b\sigma T_a^4 \tag{6}$$

where the empirical coefficients determined in central England were $a = -119 \pm 16\,\mathrm{W\,m^{-2}}$ and $b = 1.06 \pm 0.04$. A similar expression was derived by Swinbank (1963) from measurements in Australia.

Effects of clouds on $L\downarrow$ are harder to model because cloud fraction, height, and type have radiative impacts. For climatological averages, Monteith and Unsworth (1990) suggested that the emissivity $\varepsilon_a(c)$ of sky covered with a fraction c of cloud was given by

$$\varepsilon_a(c) = (1 - 0.84c)\varepsilon_a + 0.84c \tag{7}$$

Offerle *et al.* (2003) and Sugita and Brutsaert (1993) developed more complex expressions to account for clouds.

Measuring Downwelling Long-wave Radiation

Downwelling long-wave radiation may be measured with a pyrgeometer: a thermopile instrument that uses a silicon dome with a vacuum-deposited interference filter that allows transmission of long-wave radiation while excluding shortwave radiation. Pyrgeometers (precision infrared radiometers) are made by Eppley (**http://www.eppleylab.com**) and by Kipp and Zonen (**http://www.kippzonen.com/product/cg4.pdf**). There has been concern that pyrgeometers register incorrectly large values of $L\downarrow$ when the domes are exposed to direct solar radiation, which causes heating. Correction procedures have been described (Albrecht and Cox, 1977; Weiss, 1981), and some users prefer to employ a shading disk that avoids sun striking the dome.

Table 2 Long-wave emissivities of natural and artificial surfaces

Surface	Emissivity
Vegetation leaf	0.94–0.99
Soil	0.93–0.96
Water	0.96
Concrete	0.88–0.93

Upwelling Long-wave Radiation $L\uparrow$

It is often assumed that the long-wave emissivity ε_s of most natural surfaces is unity, that is, they are perfect emitters for long-wave radiation, so that $L\uparrow$ can be estimated from knowledge of the surface temperature T_s (in Kelvin) as $L\uparrow = \varepsilon_s \sigma T_s^4$ with $\varepsilon_s = 1$. Although this is often a reasonable assumption for radiation balance estimates, Table 2 shows that the emissivities of natural surfaces are generally a few percent less than unity, and for more precise calculations this should be taken into account as follows. Since long-wave absorptivity is equal to long-wave emissivity, a small fraction of $L\downarrow$ will be reflected from the surface, augmenting the emitted flux. Thus, $L\uparrow$ is given by

$$L\uparrow = \varepsilon_s \sigma T_s^4 + (1 - \varepsilon_s)L\downarrow \tag{8}$$

Calculations using equation (8) with typical values from equations (3–7) can be used to show that the error in assuming an emissivity of unity for the surface is usually very small, particularly under cloudy skies.

Upwelling long-wave radiation may be measured with an inverted pyrgeometer, or it may be estimated using a radiation thermometer assuming that emissivity is equal to 1.0.

SURFACE RADIATION BALANCE Q^*

The surface radiation balance Q^* can be deduced from measurements or models of the separate components described above, or it may be measured directly with a net radiometer. A net radiometer is a thermopile instrument capable of detecting downwelling and upwelling solar and long-wave radiation and performing the algebraic subtraction indicated

in equation (1). The basic design of most net radiometers has changed little since the reviews by Fritschen and Gay (1979) and Woodward and Sheehy (1983). Single-structure instruments have upward and downward facing thermopiles covered with domes of thin polyethylene that transmits short and long-wave radiation. The thermopiles are connected in opposition so that they generate a signal proportional to the difference between the downward and upward radiant fluxes. The sign convention is that fluxes toward the surface are treated as positive. Halldin and Lindroth (1992) compared and evaluated six net radiometer designs, and Hodges and Smith (1997) described the intercalibration of net radiometers at 21 sites. Two commonly used commercial instruments are the REBS Q7-1 (manufactured by Radiation and Energy Systems, Seattle, Washington, and marketed by Campbell Scientific (**http://www.campbellsci.com/solarrad.html**)), and the NR-LITE net radiometer (manufactured by Kipp and Zonen (**http://www.kippzonen.com**)). Recently, an instrument consisting of four independent sensors for the components of Q^* has become available (i.e. with upward and downward facing pyranometers and pyrgeometers configured so that the individual signals and the net radiation are outputs) from Kipp and Zonen (model CNR1). Examples of measurements with this system are shown in Figures 3 and 4.

The Figures show the surface radiation balance over short grass and over an old growth Douglas fir/Western Hemlock forest in the Pacific Northwest of the United States. By day, solar radiation was the dominant influence on the radiation balance. Reflected solar radiation was much less from the forest than the grass. The upwelling long-wave radiation varied less over the forest because the tree canopy was

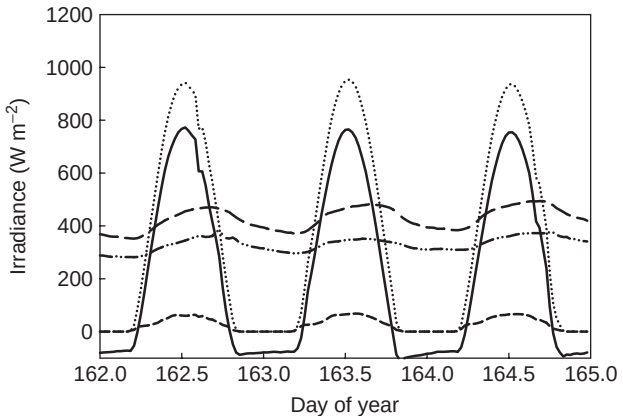

Figure 3 Net radiation and its components measured above an old growth Douglas fir/Western hemlock forest on three almost cloudless days (June 11–13, 2002) at Wind River, Washington, USA (Data courtesy of Ken Bible, University of Washington) Symbols: Q^* ——; K↓ · · · · ; K↑- - - - ; L↓—·—·—·—; L↑———

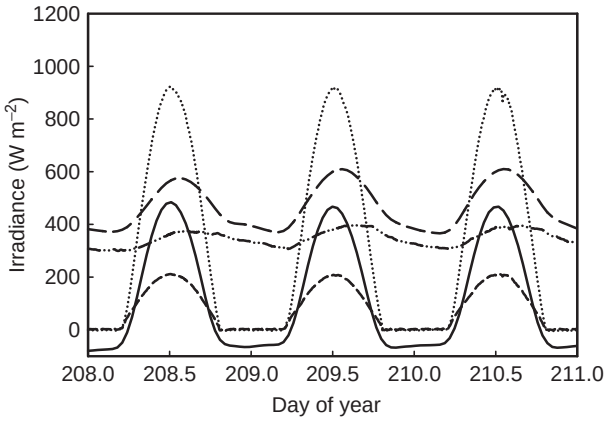

Figure 4 Net radiation and its components measured above an unirrigated field of short grass on three cloudless days (July 27–29, 2003) at Hyslop Farm, Corvallis, Oregon, USA (Data courtesy of Reina Nakamura, Oregon State University) Symbols: Q^* ——; K↓ · · · · ; K↑- - - - ; L↓—·—·—·—; L↑———

well coupled to the atmosphere in the day so that it is not heated as much by the sun as the short grass. At night, the surface radiation balances over both surfaces are similar in magnitude, suggesting that heat flow from the soil was not effective in keeping the grass canopy warmer than the more isolated forest canopy.

Figures 3 and 4 demonstrate that there is a good correlation between Q^* and $K\downarrow$ which can be used to estimate Q^* from global solar radiation records (Kaminsky and Dubayah, 1997). But the principles summarized in this article show that such an approach is not only site dependent, but also surface dependent, so that methods for estimating Q^* from its components are preferable (Offerle *et al.*, 2003).

Influences of Surface Heterogeneity and Large-Scale Averaging

Net radiation measurements are usually made with a single instrument deployed over the surface. For uniform surfaces such as agricultural crops, this single measurement may be a good representation of the spatial average surface radiation budget, suitable for use in energy balance studies. But for spatially inhomogeneous surfaces such as natural ecosystems or urban areas, a point measurement of Q^* may not be appropriate. Anthoni *et al.* (2000) used measurements and a simulation model to estimate the spatial variability of upwelling short- and long-wave radiation in a spatially heterogeneous juniper sagebrush ecosystem, and Offerle *et al.* (2003) compared three methods of estimating Q^* over urban areas. Hodges and Smith (1997) used point measurements of Q^* together with satellite measurements of K^* to produce a map of net radiation over a large part of the region where the BOREAS experiment (*see* **Chapter 177,**

The Role of Large-Scale Field Experiments in Water and Energy Balance Studies, Volume 5) was conducted (50° N–60° N, 110° W–95° W). They found that clouds had a greater influence on the surface radiation budget than ecosystem variability at this scale.

Acknowledgments

I am grateful to Ken Bible, University of Washington, and Reina Nakamura, Oregon State University, for providing the data for Figures 3 and 4 respectively.

40: Evaporation Measurement

ANNE VERHOEF[1] AND CLAIRE L CAMPBELL[2]

[1]*Department of Soil Science, The University of Reading, Reading, UK*
[2]*Centre for Ecology and Hydrology, Edinburgh, UK*

This chapter summarises the practical methods available to estimate evaporation, E. It describes the background of methods based on soil physical, micrometeorological and plant physiological concepts. The most appropriate method will mainly depend on required spatial and temporal scales of E, accuracy needed, and the available resources (financial and manpower). These issues are taken into account during the discussion.

INTRODUCTION

The aim of this chapter is to provide an overview of the techniques available for measurement of land surface evaporation. This review will focus on obtaining high-frequency evaporation estimates based on scientific methods and relatively sophisticated instrumentation. The methods used to measure evaporation are based on the concepts of micrometeorology, plant physiology, or the soil water balance (SWB, see equation 1). The most appropriate method(s) will be determined by the scientific research question or the practical purpose for which the evaporation data are required.

Scientific research will generally need values of evaporation at small time steps (e.g. half-hours), and at a variety of spatial scales (leaf, plant, plot, and field). Often, knowledge of the separate components of evaporation (soil and plant) may be required to provide a full understanding of the atmosphere-vegetation-soil interactions related to the evaporation process. Micrometeorological methods are generally the most expensive, but they have the advantage of providing field-scale area-average estimates of evaporation at a fine time resolution. The SWB-based and plant physiological methods will supply small-scale spatial estimates at a range of timescales (half-hourly to weekly). These can be scaled up to provide field-scale evaporation, using estimates of leaf area index (LAI), and soil/vegetation coverage fractions.

We will discuss the methods most commonly used to measure evaporation. For each method, the underlying principles will be described, and the method will be evaluated against relevant experimental design criteria. These criteria include the spatial scale, temporal frequency and accuracy of the data, labor intensity, sources of error, and the relative cost.

The alternative method of estimating evaporation is by modeling. Models range from those calculating actual evaporation by multiplication of the potential evaporation (*see* **Chapter 41, Evaporation Modeling: Potential, Volume 1**) by a factor depending on crop type, development stage, and soil water status (see Allen *et al.*, 1998), to detailed mechanistic Soil Vegetation Atmosphere Transfer models (*see* **Chapter 45, Actual Evaporation, Volume 1**).

We will begin by describing the two key equations used in measurement of evaporation. First, the water balance for a soil profile, which is given by (see Hillel, 1998):

$$\Delta S_M = P + I_R + C_R - E - D - R \qquad (1)$$

where ΔS_M is the change in soil moisture content during a given period, P is the precipitation, I_R the amount of irrigation, C_R the capillary rise, E the amount of water evaporated, D the deep drainage, and R the run off or run on. P, I_R, and C_R are gain terms, E and D are loss terms, whereas R can be either a gain or a loss. In equation 1, the terms have units of depth of water per unit of time, typically mm H_2O day^{-1}.

Secondly, the surface energy balance (SEB), which is given by:

$$Q^* - G = H + \lambda E \qquad (2)$$

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

where λ is the latent heat of vaporization ($\sim$2.45 MJ kg^{-1}). Equation 2 is an important boundary condition for energy exchange processes at the land surface, determining how available energy (net radiation flux density, Q^*, minus soil heat-flux density, G) is partitioned between sensible heat-flux density, H and latent heat-flux density, λE. The SEB is directly related to the SWB through the evaporation term, λE (see Brutsaert, 1982; Hillel, 1998).

In the SEB, we are dealing with energy fluxes in units of W m^{-2}. E in mm day^{-1} can be converted to λE in W m^{-2} given that 1 kg m^{-2} H_2O = 1 mm H_2O.

METHODS BASED ON THE SOIL WATER BALANCE

Weighing lysimetry and soil physical methods use the SWB to determine evaporation. These methods depend on being able to either ignore (e.g. drainage, D), successfully measure, or estimate the various gain and loss terms in equation 1, so that we can estimate E.

Weighing Lysimetry

The first and most direct method is weighing lysimetry, which involves monitoring weight changes of an extracted, undisturbed soil column. Evaporation is calculated from differences between regularly measured masses corrected for precipitation, irrigation, and often drainage. The top of the lysimeter is mounted flush with the soil surface, and it is assumed that the water loss from the lysimeter is representative of that of the surrounding area.

Lysimeters vary in size and depth, mainly depending on the type of evaporation of interest (total, plant, or soil) and the type of vegetation. Large (surface area of approximately 2–10 m^2 and depths ranging between 2 to 4 m) to medium-sized (usually $<$1 m^2 and maximum depths of 1.5 m) lysimeters are mainly used to measure total evaporation, that is, vegetation plus soil (e.g. Dugas and Bland, 1989; Allen and Fisher, 1990). Additionally, they can measure transpiration if the bare soil under the crop is covered to prevent soil evaporation (see Klocke *et al.*, 1985), or provide estimates of soil evaporation if the spacing between the canopy elements (e.g. trees or crop rows) is large enough. The smallest lysimeters, the microlysimeters (see Boast and Robertson, 1982), are used for measurements of soil evaporation below canopies. These consist of cores, which weigh typically 1–3 kg, with diameters ranging between about 5 and 20 cm, and depths of between 5 and 30 cm.

Lysimeters vary in their weighing method. Large lysimeters will use either balance beam and counterweight mechanisms, or the hydraulic principle (see Allen and Fisher, 1990). Generally, the medium types are completely supported by load-cells. Microlysimeters are usually weighed manually (see Allen, 1990; Daamen *et al.*, 1993).

The spatial scale of the measurement is equal to the lysimeter surface area. Concerning the measurement frequency, most lysimeters will allow continuous weighing, yielding half-hourly estimates of E, whereas microlysimeters are often weighed only once a day, although increased scale accuracy allows a higher frequency, if manpower is available. Most lysimeters are intended for long-term use, for example, to determine interannual variation of seasonal E.

Crucial practical details to consider with lysimetry are the depth of the lysimeter, minimization of soil and plant disturbance during extraction, the boundary to water flow often imposed at the base of the lysimeter (e.g. D and C_R are zero for closed-bottom microlysimeters), minimization of edge effects, and choice of lysimeter wall material. The lysimeter material, particularly if made of metal, can have a significant effect on the soil heat-flux and evaporation regime. If used below a vegetated surface, the depth of the lysimeter should be below the expected maximum root depth. The LAI of the plants in the lysimeter should be representative of the study site (see Dugas and Bland, 1989).

The resolution of lysimeters depends on the weighing equipment and on the resolution of the dataloggers. Lysimeters of the balance beam and hydraulic type have a typical resolution of 0.02 mm. The smaller, load-cell based lysimeters usually have a reduced resolution of about 0.05 mm (Allen and Fisher, 1990). Wind, temperature, and hysteresis effects can influence the accuracy of the method (Allen and Fisher, 1990). For microlysimeters, the magnitude of the errors depends on the width and depth of the microlysimeter and on the time since the core was extracted from the soil profile. Daamen *et al.* (1993) proposed a protocol for the use of microlysimeters in water balance studies.

Finally, the cost and manpower requirements of the facility should be considered. A large-sized lysimeter set up, including datalogging equipment, has a similar cost to the mid-to-high range micrometeorological methods. Manpower requirements are relatively low after installation; the installation of the larger type lysimeters is not straightforward (see Howell *et al.*, 1985). Microlysimeters, often made in-house, are extremely cheap and use standard laboratory scales. However, they put a considerable demand on manpower because of their requirement for manual weighing.

Soil Physical Methods

Another way to determine evaporation on the basis of the SWB is by estimating its other terms separately for an *in situ* soil profile, and inverting the equation to obtain E. This method can be used to measure total evaporation or soil evaporation where the spacing is such that the soil moisture regime between canopy elements is unaffected by root water uptake.

It is relatively easy to quantify P, by employing raingauges. Also, if the surface is relatively flat, R can be ignored. Very often, capillary rise, C_R, is assumed to be negligible, which is a reasonable assumption if the soil is coarse-textured and groundwater levels are deep. Detailed measurements of soil moisture content, θ, over time, are required to derive ΔS_M, the change in profile soil water content during a given period. There are various ways to measure θ, as will be discussed below. However, to get reliable estimates of E, it is crucial to know the partitioning between E and D and there are three methods to achieve this.

1. The simplest method is based on the assumption that the soil moisture content is equivalent to or less than field capacity (*see* **Chapter 72, Measuring Soil Water Content, Volume 2**). Thus, drainage below the root zone is assumed to be negligible, and E can be calculated directly from ΔS_M. This is a reasonable assumption in some cases (e.g. a deep, sandy soil), but generally (slow) drainage will continue for weeks after a considerable rainfall or irrigation event at levels comparable to the water loss by evaporation. Using this method can lead to errors in the estimation of E of up to 30% (Van Bavel *et al.*, 1968). In some cases D is approximated as a certain percentage of rainfall or as a function of soil moisture content (Klay and Vachaud, 1992).
2. In this method, D is found by employing a time-integrated form of Darcy's law:

$$D = \int F \, \mathrm{d}t = \int -k(\theta)\frac{\Delta \Psi_h}{\Delta z} \, \mathrm{d}t \qquad (3)$$

   F is the downward flux of soil water through the bottom of the soil profile, $k(\theta)$ is the hydraulic conductivity as a function of θ, and $\Delta \Psi_h / \Delta z$ is the change of hydraulic potential with depth. This technique requires additional vertical measurements of the matric potential, Ψ_m, using tensiometers, from which Ψ_h can be easily obtained (see Figure 1), as well as estimates of the $k(\theta)$ function. For details of methods for determination of k and Ψ_h, see Rowell (1994). Klay and Vachaud (1992) propose a simplified method, based on equation 3, for use with sandy soils in semiarid conditions.
3. This method is based on the determination of the zero-flux plane, ZFP (see McGowan and Williams, 1980). The zero-flux plane (ZFP) is the level above which upward water flux, that is, evaporation takes place, and below which downward flow due to drainage takes place. It can be located as the depth at which the hydraulic potential gradient, $\Delta \Psi_h / \Delta z$, equals zero (see Figure 1). Once the position of the ZFP has been found, the changes in soil water stored above the ZFP can be attributed to evaporation, and those below the ZFP attributed to drainage.

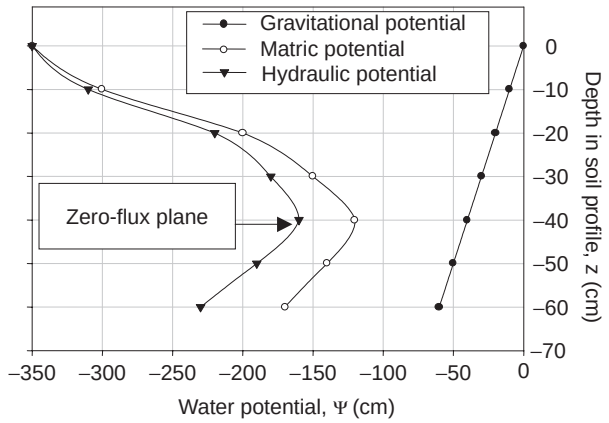

Figure 1 This diagram shows values of the soil hydraulic potential, Ψ_h, against depth in the soil profile. Ψ_h is the sum of Ψ_g (the gravitational potential) and Ψ_m (the matric potential). Ψ_m can be measured using tensiometers or derived from the soil water retentivity curve if values of soil moisture content are known. Ψ_g equals the depth in the profile, if, as in this case, the potential are expressed in length units. This diagram illustrates the concept of the ZFP, that is, the point where the gradient of hydraulic potential with depth, $\Delta \Psi_h / \Delta z$, is zero. Soil water movement above this plane will be upwards, below it the water will flow downwards

Using the ZFP concept to divide between E and D assumes that plant roots are not extracting water from below the ZFP, which is not always realistic. Also, it is very hard to accurately determine the ZFP as root water uptake may be too small to perturb the hydraulic gradient enough to enable unequivocal detection of the ZFP.

A time series of the θ profile (for derivation of ΔS) may be achieved using neutron probes, γ-ray scanners (Hillel, 1998), Time Domain Reflectometry (Topp *et al.*, 1980; Roth *et al.*, 1990), Profile probes or a profile of single Thetaprobes (Delta-T Devices, 1999; 2001, for example). Excepting the Thetaprobe and Time Domain Reflectometry sensors, these instruments require the installation of access tubes. In the first two techniques, the probe is lowered manually and operated at various depths, typically every 7–10 days. The Profile probe estimates θ from the dielectric constant of soil, and is essentially a further development of the widely used Thetaprobes. These may be connected to a data logger to provide continuous records of θ. The 1-m long Profile probe can be installed permanently to provide continuous concurrent measurements at six depths. Each of the soil moisture instruments described has a small sphere of influence (thereby limiting representativity), ranging from about two centimeters maximum diameter for the Profile probes to about 30 cm for the neutron probe or γ-ray scanners. The spatial scale of the evaporation

estimate is given by the diameter of the sphere of influence of the soil moisture measurement. To obtain a representative plot or field average ΔS_M, several access tubes should be distributed over the area of interest.

Temporal frequency of E estimates depends on the frequency of θ measurements, or may be determined by their reliability at short time steps. We recommend that Profile and Thetaprobe soil moisture measurements should not be used for time steps of less than 24 hours, since they can be sensitive to daily temperature variation. Soil type and soil moisture content appear to determine the magnitude of the temperature effect.

Unless the soil is very gravelly or has a high clay content, access tubes and tensiometers are relatively easy to install. Use of the neutron probe or γ-ray scanners is labor intensive, and requires supplementary gravimetric measurements, as these instruments are unreliable within 30 cm of the soil surface. Furthermore, these two instruments can pose a health hazard if handled incorrectly. All methods mentioned above are not valid during times when rainfall or irrigation occurs.

The accuracy of the method depends largely on the errors related to the installation and calibration of the soil moisture equipment and the tensiometers (*see* **Chapter 73, Soil Water Potential Measurement, Volume 2**). Locating the ZFP can be a significant problem. However, measurement of the $k(\theta)$ curve also poses challenges.

MICROMETEOROLOGICAL METHODS

Two types of micrometeorological methods can be defined: direct and indirect methods. The direct method, the Eddy Covariance (EC) method, is based on turbulence theory. The indirect methods include the Flux-Profile method and Bowen ratio energy balance (BREB) method, both of which infer the fluxes from the relationship between gradients of scalar concentration and the vertical scalar flux. The Variance method and Scintillometry use experimental techniques, as explained below, to estimate sensible heat-flux, H. To obtain latent heat-flux (i.e. evaporation), λE, over the scintillometer or Variance method footprint, requires back-calculation from equation 2 using additional estimates of equivalent area-average Q^* and G.

First, a brief introduction on a few important micrometeorological concepts is given. For further reading, see Brutsaert (1982), Stull (1988), Monteith and Unsworth (1990), and Garratt (1992). As the procedures and equations related to determination of H and momentum flux, τ, are very much intertwined with those related to λE, these fluxes will be addressed as well, as this will facilitate the explanation.

The vertical exchange of atmospheric fluxes at the Earth's surface is a result of turbulence, because of forced and free convection. Forced convection is a consequence of airflow experiencing friction with the Earth's surface; its strength is given by a velocity scale called the *friction velocity*, u_* ($\mathrm{m\,s^{-1}}$), which is related to τ by: $u_*^2 = |\tau|/\rho_a$, where ρ_a is the density of air ($\mathrm{kg\,m^{-3}}$). Free convection gives rise to vertical motions in the atmosphere, as a result of differences in air density caused by solar heating of the ground. The relative influence of these two processes will determine the stability of the atmosphere (neutral, stable, or unstable), that is, its propensity to mix atmospheric constituents. This may be expressed by a stability parameter, for example, the ratio of the measurement height, $z(m)$ to the Obukhov length, $L(m)$, see equation 7.

All micrometeorological techniques require extensive homogeneous upwind areas and steady state conditions. The upwind distance from the mast to the nearest change in underlying surface type or roughness is referred to as the available fetch (Gash, 1986). The flux recorded by micrometeorological methods is an integration of sources and sinks of a scalar, for example, water vapor, within a shifting, dynamic source area, upwind of the sensor. The flux source area varies in magnitude with surface roughness, atmospheric stability, and sensor height, and in location with wind direction. Models are available to estimate the upwind fetch and crosswind dimensions of the flux source area (see Schmid, 2002, for a review). Typically, fetches measure a few hundred to a few thousand meters upwind, and a few tens of meters crosswind of a measuring point.

It is important to choose the sensor height such that the flux source area remains within the available fetch, but to also ensure that the sensors are within the inertial sub layer, typically taken to begin at twice the canopy height (see Brutsaert, 1982). The exception is the BREB method which may be applied below the inertial sub layer, as it is independent of turbulence (Moncrieff *et al.*, 1997b).

Eddy Covariance (EC) Method

The random nature of turbulence has resulted in meteorologists using statistical, rather than deterministic, approaches. By application of Reynolds averaging an atmospheric variable A may be separated into its turbulent part, A', and its nonturbulent, average part, $\overline{A}$, ($A = \overline{A} + A'$) (see Stull, 1988, for details of Reynolds averaging rules). Furthermore, the covariance between two variables is defined as $(1/N)\sum_{i=0}^{N-1}(A_i - \overline{A})(B_i - \overline{B})$ where A_i and B_i are instantaneous values of A and B, and N is the number of observations within the period of interest. Using Reynolds averaging, this can also be written as $(1/N)\sum_{i=0}^{N-1} A_i' B_i'$ and hence as $\overline{A'B'}$. For the surface fluxes λE and H, we are interested in the covariance between the vertical wind speed, $w(\mathrm{m\,s^{-1}})$ and the specific humidity, $q(\mathrm{kg_{water}\,kg_{air}^{-1}})$, on the one hand, and w and air temperature, T on the other.

These are also called the *eddy fluxes* and with appropriate multiplication factors ($\rho_a\lambda$ and $\rho_a c_p$) we obtain:

$$\lambda E = \rho_a \lambda \overline{w'q'} + C \quad H = \rho_a c_p \overline{w'T'} + C \qquad (4)$$

Here, c_p is the specific heat capacity of air ($\mathrm{J\,kg^{-1}\,K^{-1}}$). C is a correction term as discussed later. The above explains why this method is called the Eddy Covariance method. It is also often referred to as the Eddy Correlation method, as the covariance normalised by the product of the standard deviations of the two variables (e.g. σ_w and σ_T) equals a correlation coefficient. Generally, the term Eddy Covariance is now preferred over Eddy Correlation, as the first more accurately captures the essence of the method.

By obtaining fast-response measurements of state variables such as w and q or T, we can generate time series for which we can find the perturbation values of the data points (i.e. the fluctuations around the mean, as indicated by the primes). For example, if we subtract the mean air temperature, as averaged over, for example, 30 minutes, from each data point (within that half-hour period) to yield a time series of T' and similarly of w', we can find a time series of $w'T'$ by multiplying the two. The average of this series, $\overline{w'T'}$, is the vertical turbulent (eddy) heat flux (see Stull, 1988).

The EC method therefore requires high-frequency measurements of the three components of wind speed (u, v, and w) and scalars relevant to the fluxes of interest (e.g. temperature, water vapor or carbon dioxide concentration). Fast-response sensors, capable of measuring at 10–20 Hz, are essential to detect the flux carried by high frequency eddies. Typically, a three-axis sonic anemometer and an adjacent Infra Red Gas Analyzer (IRGA) are used to provide the required data for H, λE and carbon dioxide flux estimates (Moncrieff *et al.*, 1997a) (see Figure 2).

Three-axis sonic anemometers measure u, v, and w, and the speed of sound. The "sonic temperature" is derived from variations in the speed of sound, and has been found to be similar to the virtual temperature (Kaimal and Gaynor, 1991). Typically, the sonic temperature (with some corrections) is used to calculate the sensible heat-flux.

IRGAs calculate the concentration of H_2O and CO_2 in the optical path from the difference due to absorption of infrared (*IR*) radiation between the source and the detector (alternatively, fast-response humidity meters, Lyman-α or Krypton hygrometers, can be used to measure the H_2O concentration). IRGAs are available in either a closed path (e.g. Licor 6262) or an open path (e.g. Licor 7500) set up. Open path IRGAs have fewer associated errors, although comparisons have shown that the results can be similar after appropriate corrections are applied (Leuning and Judd, 1996). They do not work in rain, however, and the aerodynamic effects of their presence close to the sensor volume of the sonic anemometer needs to be carefully scrutinized.

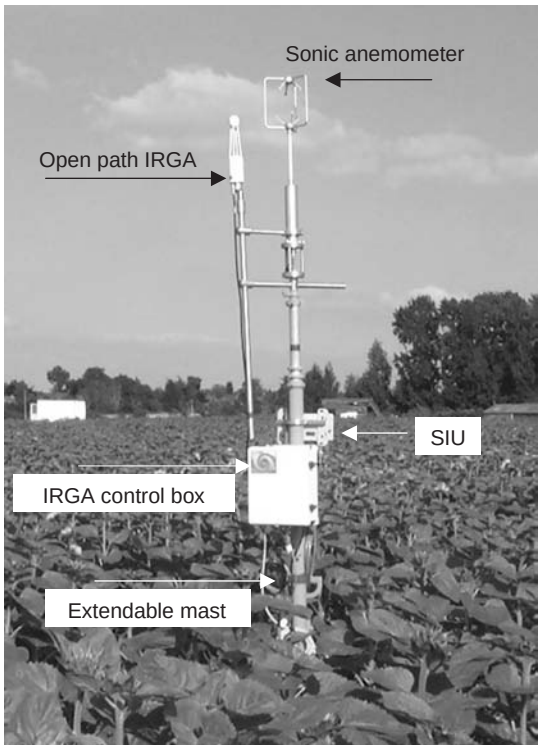

Figure 2 This photograph shows an example of an Eddy Covariance system in use in the field. In this example, the open path Licor 7500 Infra Red Gas Analyzer, and the Gill Solent R3 sonic anemometer were used. With this equipment, the sonic anemometer and IRGA sensor cables are connected to the Gill Sensor Input Unit (SIU) to transmit data to the logging PC. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Acquisition and postprocessing software are required to obtain and record the raw data (about 20 MB a day), to generate the covariances and to apply the corrections. Two Windows programs, *Edisol*, acquisition software, and *Edire*, for postprocessing, were developed at the University of Edinburgh, and may be downloaded from the Web at **`http://www.geos.ed.ac.uk/abs/research/micromet/EdiRe`**.

Eddy Covariance Corrections

The correction terms in equation 4 are due to both physical effects and system artifacts. The physical corrections account for the use of sonic virtual temperature instead of air temperature in calculation of H (Kaimal and Gaynor, 1991; Liu, 2001), and the fact that $\overline{w\rho_a} \neq 0$ due to atmospheric buoyancy (Webb *et al.*, 1980; Paw *et al.*, 2000). The system corrections remove any time lag between instruments, apply a coordinate rotation of the wind velocities (McMillen, 1988; Wilczak *et al.*, 2001; Finnigan *et al.*, 2003; Paw *et al.*, 2000; Finnigan *et al.*, 2003), and correct for frequency loss due to instrumentation effects (Moore, 1986; Laubach and McNaughton, 1998; Massman, 2000).

Standard correction procedures can be found in Moncrieff *et al.* (1997a) and Aubinet *et al.* (2000), and within the recent review by Massman and Lee (2002).

Finally, cosine errors in the sonic anemometer due to flow sheltering by the instrument frame may lead to significant underestimation of fluxes (Gash and Dolman, 2003). Van der Molen *et al.* (2004) have proposed a polynomial correction for Solent sonic anemometers.

Flux-Profile Method

The Flux-Profile method is based on K-theory (see Stull, 1988), which assumes that vertical transport of quantities (such as water vapor) is proportional to the concentration gradient of the quantity. The constant of proportionality is known as the *eddy diffusivity* (much larger than the molecular diffusivity as found in, for example, a laminar sublayer), and given the symbol K.

$$\lambda E = -\lambda \rho_a K_e \frac{\partial \overline{q}}{\partial z}; \quad H = -\rho_a c_p K_h \frac{\partial \overline{T}}{\partial z}; \quad \tau = \rho_a K_m \frac{\partial \overline{u}}{\partial z} \tag{5}$$

where K_x (with $x = e, h$, and m for λE, H, and momentum, respectively) is the turbulent exchange coefficient or eddy diffusivity (with units of $m^2\,s^{-1}$). It is assumed that the turbulent Ks are related to wind shear (through friction velocity, u_*) and buoyancy, via a stability function ϕ. Using dimensional analysis and similarity theory (see Stull, 1988), we find for K:

$$K_x = \frac{\kappa u_* (z - d)}{\phi_x} \tag{6}$$

where κ is the von Kármán constant ($= 0.4$) and $d(m)$ the zero-plane displacement height, a parameter that is introduced to correct the shape of the logarithmic wind profile close to the surface (Tennekes, 1973). ϕ_x is a function of the stability term, the Obukhov length, L:

$$L = \frac{-\overline{T}}{g\kappa} \frac{u_*^3}{\overline{w'T'}(1 + 0.61\overline{w'q'})} \tag{7}$$

with g ($m\,s^{-2}$) being the acceleration due to gravity. Several functions for ϕ_x are in use; however, the most commonly used are those of Dyer (1974) and Paulson (1970).

In practice, the derivatives in equation 5 are difficult to measure. Therefore, discrete differences are used, for example, Δq, ΔT, and Δu. One possibility is to employ a profile above the crop, of at least three levels of colocated, continuous T, q, and u measurements, and to calculate $u_*(= \kappa z \phi_m \Delta\overline{u}/\Delta z)$, H and λE simultaneously. In this case, the set of equations given above are applied in an iterative procedure, as L contains the unknown quantities u_*, $\overline{w'T'}(= H/\rho_a c_p)$ and $\overline{w'q'}(= \lambda E/\rho_a \lambda)$.

Alternatively, the Flux-Profile equations can be written as (see Thom, 1975), in analogous form to Ohm's law:

$$\lambda E = -\rho_a \lambda \frac{\overline{q}(z_2) - \overline{q}(z_1)}{r_e}, \quad H = -\rho_a c_p \frac{\overline{T}(z_2) - \overline{T}(z_1)}{r_h} \tag{8}$$

that is, the flux is proportional to the driving gradient and inversely proportional to the resistance to transport in the atmosphere ($r_x = \int_{z_1}^{z_2} (\,dz/K_x)$, an aerodynamic resistance). Equation 8 is the resistance analog of equation 5 and it indicates that K_x, and thus ϕ_x, has to be integrated from z_1 to z_2. The integrated stability functions, usually denoted with Φ_x, are given by Paulson (1970).

In practice, z_2 is taken as the reference level (often taken as at least two times the canopy height), whereas z_1 refers to the surface (i.e. $z = 0$). This leads to the bulk transfer equations for latent heat and sensible heat transfer, often used for remote sensing applications as it is relatively easy to determine T_s remotely (see Kustas *et al.*, 1989):

$$\lambda E = \rho_a \lambda \frac{q_s - q_r}{r_e}, \quad H = \rho_a c_p \frac{T_s - T_r}{r_h} \tag{9}$$

with the subscripts s and r referring to the value of the atmospheric variable at surface and reference level, z_r, respectively. For λE, a problem is the determination of q_s, the surface humidity, that is, the air's specific humidity at the humidity roughness height, $z_{0,q}$. For unsaturated or drying soil surfaces, and for the canopy surface in particular, q_s is not readily determined (see Garratt, 1992). To remedy this problem, the Penman–Monteith equation has been developed (Monteith, 1965); evaporation is calculated using single-level environmental variables (radiation, vapor-pressure deficit, temperature, and wind speed), and estimates of aerodynamic and surface resistances. For a detailed discussion of this method, (*see* **Chapter 45, Actual Evaporation, Volume 1**).

To describe the aerodynamic resistances r_e and r_h required in equation 9, we use the theoretical vertical profiles of u, T, and q in the atmospheric surface layer. We denote the heights, above d, where the downward extrapolated profiles yield the surface values by $z_{0,m}$, $z_{0,T}$ and $z_{0,q}$ (and usually assume $z_{0,T} = z_{0,q}$). These are known as the surface roughness lengths for momentum, heat and evaporation, respectively. The logarithmic wind profile (Tennekes, 1973) is given by

$$u_* = \kappa u \left[\ln\left(\frac{z_r - d}{z_{0,m}}\right) - \Phi_m\left(\frac{z_r - d}{L}\right) \right]^{-1} \tag{10}$$

The aerodynamic resistance between $(z_{0,m} + d)$ and z_r is then calculated as

$$r_{ax} = \frac{1}{\kappa u_*} \left[\ln\left(\frac{z_r - d}{z_{0,m}}\right) - \Phi_x\left(\frac{z_r - d}{L}\right) \right] \tag{11}$$

However, the total scalar resistance, r_x (with $x = h$ or e) is composed of $r_x = r_{ax} + r_r$, where r_r is often called the *excess resistance*, that is, the resistance for an air layer between $(z_{0,T/q} + d)$ and $(z_{0,m} + d)$. In practice (for remote sensing purposes, for example), the value of r_r is not known and instead relatively simple formulae are used that employ readily available parameters to derive r_r. To achieve this, r_r is related to the dimensionless quantity $\kappa B^{-1} : \kappa B^{-1} = \ln(z_{0,m}/z_{0,T}) = \kappa r_r u_*$ and Brutsaert (1982) and, Verhoef *et al.* (1997a) for example, describe several formulae for the estimation of κB^{-1}. Often, for simplicity, the following very general rules are used: $\kappa B^{-1} = 2.0$ for closed crops, 0 for bare soils and κB^{-1} has values between about 5 and 15 for sparse canopies. Momentum roughness parameters $z_{0,m}$ and d can be found from profile measurements of u (Robinson, 1962) or from empirical relations related to canopy geometry (e.g. Raupach, 1992, Verhoef *et al.*, 1997b).

Bowen Ratio Energy Balance Method (BREB)

The BREB method assumes that $\Phi_h = \Phi_e$ and therefore $r_h = r_e$, eliminating the effect of atmospheric stability and turbulence. This method combines measurements of air temperature and humidity profiles with the SEB. It employs the Bowen Ratio, β, which is defined by $H/\lambda E$. β is derived from air temperature and vapor pressure (e in mbar) differences between the measurement levels:

$$\beta = \gamma \frac{\Delta \overline{T}}{\Delta \overline{e}} \tag{12}$$

where γ is the psychrometric constant in mbar K^{-1} (see Perez *et al.*, 1999). Combining the SEB and β gives

$$\lambda E = \frac{Q^* - G}{1 + \beta} \quad H = \beta \frac{Q^* - G}{1 + \beta} \tag{13}$$

To use the BREB technique, two atmospheric humidity and temperature sensors, a net radiometer and an estimate of soil heat-flux are required.

The accuracy of the BREB method depends on the ability of the instrumentation to measure small gradients of temperature and humidity (and this can be very difficult over rough surfaces such as forests), plus good measurements of Q^* and G. The soil heat-flux can be estimated with a variety of methods, involving soil heat-flux plates or a profile of soil temperature and θ (see Smith and Mullins, 1991). Even more important are reliable estimates of Q^*; relatively large differences can exist between simultaneous recordings with different sensors as a result of poor levelling, lack of recalibration, wind and water drop effects (see Field *et al.*, 1992). At night $(Q^* - G)$ is small, and β can be difficult to determine. The BREB method has mainly been used to measure total λE, although Wallace and Holwill (1997) used it to measure soil λE between strips of sparse vegetation.

Variance Method

Both the Variance method and the scintillometry method are based on Monin–Obukhov similarity theory. Similarity theory is a technique often used by meteorologists when the knowledge of the governing physics is insufficient to derive laws based on first principles. It is based on the organization of meteorological variables into dimensionless groups. A proper choice of groups will allow empirical relationships between these groups that are universally applicable. Monin–Obukhov similarity theory is usually applied to the surface layer and uses variables or groups such as the friction velocity, u_*, and the Obukhov length, L (see Stull, 1988).

Monin–Obukhov similarity theory predicts a universal relationship between the variance of temperature, humidity, and wind speed (σ_T, σ_q, and σ_u), and the dimensionless stability parameter $(z - d)/L$ (Panofsky and Dutton, 1984). Relationships describing sensible and latent heat-flux transfer can be derived using this theory, such that (see de Bruin *et al.*, 1993):

$$H = \rho_a c_p \left[\left(\frac{\sigma_T}{c_{T1}} \right)^3 \left(\frac{\kappa g (z-d)}{T} \right) \left(\frac{1 - c_{T2}(z-d)/L}{-(z-d)/L} \right) \right]^{1/2} \tag{14}$$

$$\lambda E = \lambda \rho_a \left(\frac{\sigma_q}{c_{T1}^{3/2}} \right) \left[\sigma_T \left(\frac{\kappa g (z-d)}{T} \right) \left(\frac{1 - c_{T2}(z-d)/L}{-(z-d)/L} \right) \right]^{1/2} \tag{15}$$

where c_{T1} and c_{T2} are constants. In order to estimate L, an additional profile of anemometers is required to calculate u_* (see Monteith and Unsworth, 1990). Measurement of σ_T can be made with fast-response thermocouples, whereas σ_q can be obtained from an IRGA or a Lyman-α hygrometer, raising the cost significantly. de Bruin *et al.* (1993) showed that estimates of λE using σ_q did not correspond well with EC data, whereas estimates of H using the Variance method did compare well with the EC method (see also Lloyd *et al.*, 1991). Therefore, most researchers would use σ_T to find H and then calculate λE using equation 2 with area-average estimates of Q^* and G.

Scintillometry Method

Monin–Obukhov similarity theory also predicts that the temperature structure parameter C_T^2, which scales directly with H, can be defined as a unique function of $(z - d)/L$:

$$\frac{C_T^2 (z-d)^{2/3}}{(\overline{w'T'}/u_*)^2} = C_{TT1} \left(1 - C_{TT2} \left(\frac{z-d}{L} \right) \right)^{-2/3} \tag{16}$$

with $c_{TT1} = 4.9$ and $c_{TT2} = 9$ (de Bruin *et al.*, 1993).

Once H has been determined, as with the Variance method, λE can be found from $Q^* - H - G$.

C_T^2 can be measured using scintillometry. Temperature fluctuations cause fluctuations of the refractive index of air. By measurement of the fluctuation of the light intensity of a beam transmitted over a horizontal path with known length, this refractive index can be determined. In general, both temperature and humidity fluctuations will cause fluctuations of the refractive index. For operations in the visible or near-infrared range, and at large Bowen ratios, this humidity prediction can be neglected. The light intensity fluctuations are then directly proportional to C_T^2 (Kohsiek, 1982; Green *et al.*, 1994; de bruin *et al.*, 1995).

PLANT-PHYSIOLOGICAL METHODS: MEASUREMENT OF TRANSPIRATION

The main factors determining transpiration are described in **Chapter 42, Transpiration, Volume 1**. Plant physiological methods used for measurement of transpiration comprise sap flow measurements (Allen and Grime, 1995; Smith and Allen, 1996), plant chambers (Goulden and Field, 1994), deuterium tracing (Calder *et al.*, 1992), or a combination of porometry (see Jones, 1992) and calculations (Roberts *et al.*, 1990; Dugas *et al.*, 1993). In some cases, destructive methods have been used to directly obtain transpiration (Calder *et al.*, 1992). The sap flow method has become the standard in estimating whole plant transpiration. This technique is usually automated, so continuous records of plant water use with high time resolution can be obtained. In contrast, the other methods are labor intensive, provide a considerably poorer time resolution, influence the microclimate of the plant or leaf, or are often difficult to interpret (see Smith and Allen, 1996). Therefore, only the sap flow method will be described in detail below.

Sap Flow

The sap flow method measures the rate at which sap ascends stems, by using heat as a tracer for sap movement. These methods can use the heat balance principle (stem heat balance and trunk sector heat balance method), which involves applying continuous heating, or the heat-pulse technique where short pulses of heat are applied. Also, rates of sap flow can be determined empirically, using the thermal dissipation technique, from the temperature of sapwood near a continuously-powered heater implanted in the stem (Granier, 1985).

The stem heat balance method can be used to measure sap flow in both woody (Steinberg *et al.*, 1989) and herbaceous stems, with stem diameters ranging between 2 and 125 mm. The other methods can only be used on woody trunks with diameters larger than 120 mm (trunk sector heat balance), >30 mm (heat-pulse method), or >40 mm (thermal dissipation technique). Such gauges are commercially available (see, Smith and Allen, 1996 for more details) and can be connected to dedicated loggers.

In the stem heat balance method, the gauge comprises a flexible heater, typically a few centimeters in width, which is wrapped around the stem, insulated and weather-shielded. Thermopiles are used to measure the radial temperature gradient away from the heater (ΔT_r), and a set of thermocouples is used to measure temperature gradients ΔT_a and ΔT_b (see Figure 3). These temperature gradients are required to calculate components in the heat balance of the stem (see equation 17). Heat is applied to the entire circumference of the stem encircled by the heater, and the mass flow of sap is obtained from the balance of the fluxes of heat into and out of the stem (see also Figure 3, reprinted from Smith and Allen, 1996), as summarized by:

$$P = q_v + q_r + q_f \tag{17}$$

where P is the electrical power supplied to the heater, q_v is the rate of vertical heat loss by conduction, q_r is the radial heat loss by conduction and q_f is the heat uptake by the moving sap stream. If P, q_v, and q_r are known, q_f can be determined by difference and the mass flow rate of sap (F_m) calculated using

$$F_m = \frac{2q_f}{c_s(\Delta T_a + \Delta T_b)} \tag{18}$$

where c_s is the specific heat capacity of sap, whereas q_v is found from

$$q_v = A_{\mathrm{st}} k_{\mathrm{st}} \left(\frac{\Delta T_b - \Delta T_a}{x} \right) \tag{19}$$

where A_{st} is the cross-sectional area of the heated stem section, k_{st} is the thermal conductivity of the stem and x is the distance between the two thermocouple junctions on each side of the heater. Standard values of k_{st} are $0.42\,\mathrm{Wm^{-1}\,K^{-1}}$ for woody stems and 0.54 for herbaceous stems (Smith and Allen, 1996).

The radial component of the stem heat balance, q_r, is determined from ΔT_r using

$$q_r = K_{\mathrm{sh}} \Delta T_r \tag{20}$$

K_{sh} is the effective thermal conductance of the sheath of materials surrounding the heater.

Gauges should be installed on straight sections of stem without swellings or lumps since they could cause poor contact between the stem surface and the heater or thermocouples. Also, it is important that water ingress between the probe and the stem is prevented. Accurate determination of sap flow rate using this technique depends critically on the correct value of K_{sh}, which can be obtained when sap

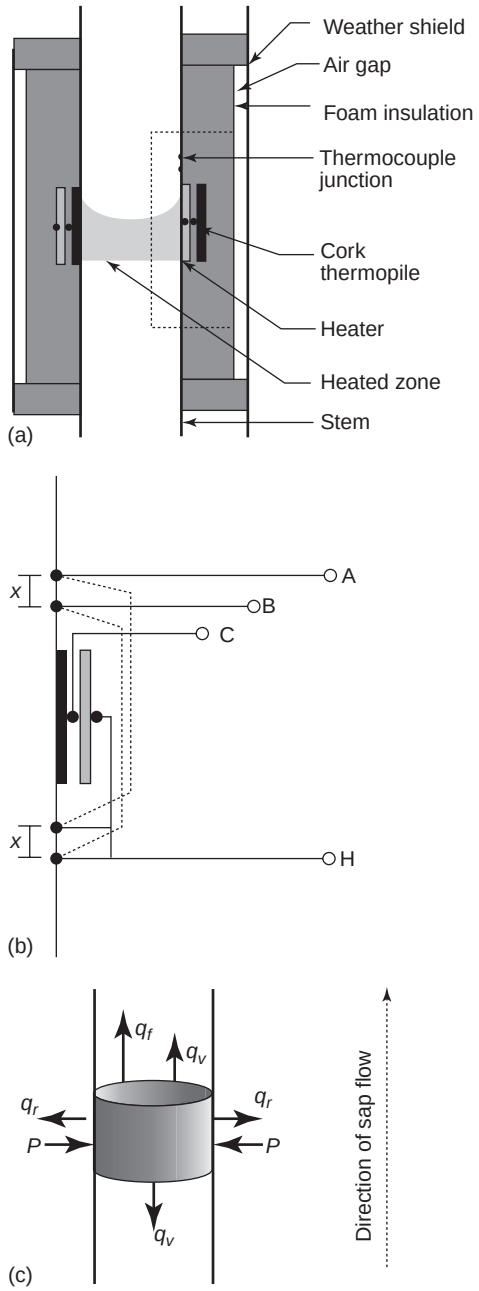

Figure 3 (a) Vertical cross-section through a stem heat balance gauge. The dashed box in (a) is expanded in (b) to show wiring details of thermocouples in the gauge; copper wires are shown as solid lines and constantan wires as dotted lines. For the determination of sap flow, the temperature differentials ΔT_a, ΔT_b, and ΔT_r are obtained from measurements of the voltages across AH, BH, and CH, respectively. (c) The heat balance of the length of stem heated by the gauge, where P is heat-applied to the stem, q_v is the rate of vertical heat loss by conduction, q_r is radial heat loss by conduction and q_f is heat uptake by the sap stream. (Smith DM and Allen SJ, Measurement of sap flow in plant stems. *Journal of Experimental Botany* (1996), **47**(305): 1833–1844, by permission of Oxford University Press)

flow is zero, for example, using data from the hours before dawn (Steinberg *et al.*, 1989), after heavy rainfall (Allen and Grime, 1995), or by wrapping all foliage in plastic to prevent transpiration (Steinberg *et al.*, 1989).

In the heat-pulse method, the mass flow of sap is determined from the velocity of the short heat pulses, v_h, moving along the stem. Each set of heat-pulse probes consists of one heater probe and two sensor probes containing thermistors. Usually, four sets of heat-pulse probes are used, one in each quadrant of the stem. Heater and sensor probes (about 2 mm in diameter) must be installed in parallel holes drilled radially into the sapwood, with one sensor probe placed at a distance of x_d (~5 mm) below the heater and the other probe placed at x_u (~10 mm) above the heater. Short (1–2 s) pulses of heat are periodically released from the heater probe and the sensor probes are monitored continuously to measure the velocity of each pulse as it moves with the sap stream. The volumetric sap flux density per unit cross-sectional area of sapwood, u_v, is given by:

$$u_v = \frac{\rho_{\mathrm{sm}} c_{\mathrm{sm}}}{\rho_s c_s} v_h \quad \text{with} \quad v_h = \frac{(x_d - x_u)}{2t_{\mathrm{e}}} \tag{21}$$

where ρ and c are density and specific heat capacity, with the subscripts s and sm referring to sap and sap plus woody matrix, respectively. Furthermore, t_e is the time at which the temperatures of the upstream and downstream sensor probes are equal after the release of a heat pulse. Mass flow rates of sap through the stem (F_m) are then calculated from the integral of the sap flux-profile over the cross-sectional area of the sapwood. For more details on these methods, see Smith and Allen (1996).

Scaling up from Plant to Stand

Each gauge provides a measure of the transpiration of an individual plant or tree, but to get area-average estimates of transpiration it is necessary to extrapolate to the field scale. Various methods have been used (see Smith and Allen, 1996). Where members of a stand are of similar size, stand transpiration can be calculated from plant density; where size is variable within a stand, individual plants can be scaled up by determining relationships between sap flow rates and stem diameter, stem basal area, sapwood area, or leaf area, and then extrapolating transpiration rates to unit area of land on the basis of surveys of tree size or measurements of LAI.

LAI can be measured destructively, by removing the plant leaves and using either a leaf area meter, a planimeter, or a scanner to measure the area of each leaf. Alternatively, the gap fraction analysis method (see Welles and Cohen, 1996, for details of the method and comparison of available sensors), or digital photography (White *et al.*, 2000) can be used. Finally, it is possible to derive LAI from remote sensing, by use of the Lidar (Laser

altimetry ranging) technique (White *et al.*, 2000). Refer to section **Chapter 51, Spatially Resolved Measurements of Evapotranspiration by Lidar, Volume 2** for details of the use of Lidar to estimate vegetation structure. Further discussion of the statistical and modeling approaches to upscaling in general can be found in sections **Chapter 9, Statistical Upscaling and Downscaling in Hydrology, Volume 1** and **Chapter 11, Upscaling and Downscaling – Dynamic Models, Volume 1** respectively.

SUMMARY

We have described the principles of each of the commonly used evaporation measurement methods. For any given experiment, the most appropriate method(s) will be determined by the spatial and temporal scales of interest, accuracy, restrictions on applicability, labor intensity, equipment required, and the cost. The methods are summarized with respect to these criteria, below.

The Eddy Covariance, Variance, and Flux-Profile methods have similar footprint dimensions (Horst, 1999; Lloyd *et al.*, 1991), such that the effective fetch is typically of the order of 10's to 100's of meters upwind. Scintillometry may be used to supply H measurements at the regional scale, using path lengths of several kilometers (see de Bruin *et al.*, 1996). Lysimetry may provide λE averaged over an area from $0.002\,m^2$ to $10\,m^2$. The methods based on the water balance can also supply long-term, continuous estimates of evaporation (generally, total or soil evaporation) but they have problems with representativity as they supply small-scale estimates; maximum averaging areas of about $0.3\,m^2$. Sap flow gauges provide transpiration for an individual branch, tiller, or plant.

Half-hourly averaging periods are generally used for the described micrometeorological techniques, plus lysimetry, and the use of sap flow gauges. The BREB method may be applied with shorter averaging periods (Steduto and Hsiao, 1998). Microlysimetry often provides daily averages, whereas soil physical methods provide daily or weekly averages.

EC estimates of H and λE are usually validated by examining the closure of the SEB (equation 2). Typically, the sum of H and λE estimated by eddy covariance underestimates $Q^* - G$ (see Wilson *et al.*, 2002, for a review). Fluxes measured by the EC method are considered to be accurate to 5–20% (Goulden *et al.*, 1996). Micrometeorological methods are typically compared with EC data as proof of accuracy: Scintillometry (Beyrich *et al.*, 2002) and the variance method (Lloyd *et al.*, 1991) all compared reasonably well with the EC method. Transpiration obtained using the sap flow technique appears very accurate and it can be scaled up to provide field-scale estimates of λE, which has been shown to compare well with EC estimates (see Allen and Grime, 1995).

Eddy covariance measurements of some trace gases can become unreliable, particularly at night when wind speeds are low and katabatic drainage is suspected. The Flux-Profile method collapses when gradients become small, for example, close to rough canopies. Furthermore, errors of up to 30% may occur, due to uncertainties in the stability corrections and in the equivalence of the exchange coefficients (Steduto and Hsiao, 1998). The BREB method fails when sensible and latent heat fluxes are equal and opposite (e.g. at sunset and sunrise), during irrigation or precipitation and when the available energy is low (see Perez *et al.*, (1999), for BREB quality control criteria and model). The variance method breaks down during stable conditions when H becomes negative. Sources of error in scintillometry include obstacles within the optical path, and misalignment of the transmitter and receiver. Soil physical methods fail during periods of rainfall or irrigation.

All micrometeorological methods require a medium amount of labor and user intervention. When using the EC method, regular field calibration of the IRGA is recommended. The corrections applied to the covariances must be understood, and applied correctly. Lysimetry requires little manual intervention after installation, except microlysimeters, which require manual weighing. The soil physical methods require little labor, with the exception of the use of the neutron probe or γ-ray scanner for soil moisture measurements. Sap flow gauges may be fully automated, and require relatively little maintenance.

For Eddy Covariance, the total equipment cost is quite substantially larger than that of any other method described. The Flux-Profile method equipment cost is that of the three sets of temperature, wind speed, and humidity instruments, plus data logging. For the Variance method, the equipment required is one fast-response thermocouple and a profile of anemometers, and as such, is inexpensive. The BREB method requires a minimum of two psychrometers, two anemometers, a net radiometer and soil heat-flux plates. A medium-to-large lysimeter is quite costly, but smaller varieties are not. The soil physical methods are also economical.

Acknowledgments

We thank Dr. Jesús Fernández Gálvez for his assistance with Section 2.2 and Dr. Antonio Díaz Espejo for his literature search on lysimetry.

41: Evaporation Modeling: Potential

RICHARD G ALLEN

Department of Civil Engineering and Department of Biological and Agricultural Engineering, University of Idaho, Kimberly, ID, US

Potential evaporation (E_p) has had a relatively broad range of definition over the past century. It is defined here as the quantity of water evaporated per unit area per unit time from an idealized extensive free-water surface under existing atmospheric conditions. Three primary, common means to estimate E_p have been used during the past century. These are (i) pan evaporation measurement, (ii) an estimate of potential evapotranspiration based on weather data, and (iii) a reference evapotranspiration. Of these three, reference evapotranspiration (ET_{ref}) has the more practical application. "Potential evapotranspiration" (ET_p) had widespread usage from the 1940s through the 1970s, when the term was used to represent a maximum evaporative index from which to derive estimates of actual ET from vegetation. However, there are several major, contrasting definitions for ET_p and several challenges associated with its usage. One of the primary definitions used for ET_p is the rate of evaporation and transpiration from a saturated (free-water) vegetated surface so that the evaporation process occurs at the potential level. Challenges in sustaining a saturated surface and in measuring weather data that are coincident with such a surface make this definition for ET_p theoretically attractive, but practically difficult. Standardized parameterizations of the Penman–Monteith equation are described for calculating ET for grass and alfalfa references. The reference evapotranspiration, despite some shortcomings, can be a consistent and reproducible index for a weather-based potential evaporation.

INTRODUCTION

Evaporation is the process whereby liquid water is converted to water vapor (vaporization) and removed from the evaporating surface (vapor removal). Water evaporates from a variety of surfaces, such as lakes, rivers, pavements, soils, and vegetation. The evaporation of liquid water at the Earth's surface and its consequent flux into the atmosphere is a major component of the hydrologic cycle and an essential ingredient in sustaining biological systems of the earth. Evaporation through plants drives the transpiration process for transport of minerals from soil to plant parts and provides evaporative cooling (*see* **Chapter 42, Transpiration, Volume 1**). Evaporation from soil dries the upper soil profile, thereby impacting strength of the soil surface and infiltration rates during precipitation. Globally, the annual volume of evaporation in essence equals the annual volume of precipitation, with relatively small differences caused by storage changes in ice fields, soil water, and groundwater recharge or extraction. Evaporation has high spatial variability similar to that of precipitation, but is dampened by rainfall runoff, surface energy limitations and availability of water stored in soil and water bodies.

Relatively large quantities of energy are required to change the state of water molecules from liquid to vapor. Solar radiation, and long-wave radiation (*see* **Chapter 39, Surface Radiation Balance, Volume 1**) and, to a lesser extent, heat from beneath the surface and from the lower atmosphere provide this energy. The driving force to remove vapor from the evaporating surface is the gradient between the vapor pressure at the surface and that of the overlying atmosphere. As evaporation proceeds, the surrounding air becomes more humid and the evaporation process will slow down if the humid air is not transferred to the atmosphere. The replacement of the saturated air with drier air is a strong function of wind speed. Hence, solar radiation, air temperature, air humidity, and wind speed are climatological parameters to consider when assessing the evaporation process.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

There is an inverse relation between actual evaporation and evaporative demand, as discussed from various perspectives in (**Chapter 42, Transpiration, Volume 1**; **Chapter 43, Evaporation of Intercepted Rainfall, Volume 1**; **Chapter 44, Evaporation from Lakes, Volume 1**; **Chapter 45, Actual Evaporation, Volume 1**). The relation occurs because the evaporation "demand" or "potential" varies with the heat energy stored in, and transported from, the lower atmosphere and the relative dryness (thirst) of the lower atmosphere (in addition to radiation energy), and because atmospheric characteristics depend on the "history" of the air mass as it is influenced by upwind evaporation processes. By definition, potential evaporation is rarely reached over a region, owing to lack of an extensive free-water surface, but is a useful index by which to characterize the atmospheric environment and by which to set limits when quantifying water fluxes.

Definition of Potential Evaporation

Potential evaporation (E_p) has had a broad range of definitions over the past century. E_p is defined here (and in **Chapter 45, Actual Evaporation, Volume 1**) as the quantity of water evaporated per unit area per unit time from an idealized extensive free-water surface under existing atmospheric conditions (Shuttleworth, 1992). This definition can in principle be applied to any surface, including vegetation, having a free-water (saturated) surface. However, owing to the influence of stomatal resistance (*see* **Chapter 42, Transpiration, Volume 1**), the saturated condition for vegetation only occurs during and briefly following rain or sprinkle irrigation events. This creates a problem befalling the use and measurement of E_p (or *potential evapotranspiration* as the process has sometimes been termed when applied to potential evaporation from vegetation).

Impact of Surface Characteristics

Most hydrologic process applications focus on areas having vegetated surfaces. Therefore, it is important that the definition of E_p, if it is used as an index, applies to those surfaces as well as to water bodies. This creates a challenge in defining a standardized E_p index to characterize climatic demand because the potential vapor flux from a saturated surface is influenced by the aerodynamic and radiation properties of the surface. Thus, E_p from an aerodynamically rough surface, such as a forest, will generally be greater than that from an aerodynamically smooth surface, such as short clipped grass (*see* **Chapter 42, Transpiration, Volume 1** and **Chapter 43, Evaporation of Intercepted Rainfall, Volume 1**) which is, inturn, more rough than an aerodynamically smooth water surface. E_p from a short clipped grass can also be greater than that from a deep, clear water body that absorbs much of the solar radiation beneath the free-water surface and thus makes it unavailable in real time for conversion to latent heat (i.e. E_p) (*see* **Chapter 44, Evaporation from Lakes, Volume 1**). Consequently, a range of E_p indices are needed to represent the maximum evaporation physically possible for specific surface conditions, even given the same atmospheric conditions.

Feedback to the Atmosphere

In addition to the impact of surface roughness on E_p rate, there are effects of negative feedback between the "demands" of the atmospheric boundary layer and the E_p rate. The negative feedback is caused by the humidification of the boundary layer and reduction of sensible heat content (*see* **Chapter 43, Evaporation of Intercepted Rainfall, Volume 1** and **Chapter 44, Evaporation from Lakes, Volume 1**). These effects are not immediate over a small stretch of free-water surface, owing to the large storage content of the lower boundary layer for both heat and vapor. However, the effects become pronounced as the fetch of free-water surface increases to distances on the order of thousands of meters. Both of these modifications to the boundary layer (heat and vapor storage) reduce E_p. Therefore, to be strictly true to the definition of E_p given previously, E_p should be estimated (if from weather-based equations) only when the weather data are measured over the same saturated surface from which E_p is occurring. Otherwise, the weather data will not truthfully reflect the feedback that would occur under conditions of E_p. The exception to this is when one is estimating E or evapotranspiration from small stands of vegetation that have different aerodynamic, surface conductance, or wetness conditions to their surroundings. In this case, the E_p and current weather should not be expected to reach an equilibrium.

Another type of feedback concerns the wind velocity profile immediately above vegetation. Generally, as vegetation roughness increases, especially for dense vegetation, the wind velocity profile becomes less "steep" (smaller change in velocity with height) for several meters above the vegetation and the average velocity decreases. Allen and Wright (1997) found wind speed 3 m above 2-m tall corn (i.e. measured at 5 m above ground surface) to be 30% lower than wind speed 3 m above clipped grass. Differences between wind speed from standard weather stations located over short vegetation and wind speed over tall, dense forest can be even greater. Allen and Wright developed roughness-based translation equations to adjust for the impact of roughness on wind speed. This effect should be considered when estimating potential evaporation for specific vegetation.

Because E_p for vegetation only occurs during and for a few hours following wetting events, in principle, one can only calculate or estimate E_p using weather data collected during those times. This is, of course, not very useful for hydrologic process models that are operated

over long, continuous time periods and that need relatively continuous measures of an evaporative index to serve as a boundary condition. Therefore, concessions must be made, since most weather data are collected over nonsaturated terrain or nonsaturated vegetation and, although techniques are now well developed (*see* **Chapter 40, Evaporation Measurement, Volume 1**), evaporation is still challenging and costly to measure.

METHODS TO APPROXIMATE POTENTIAL EVAPORATION

Three primary, common means to estimate E_p have been used during the past century. These are (i) pan evaporation measurement, (ii) an estimate of potential evapotranspiration based on weather data, and (iii) a reference evapotranspiration. Of these three, reference evapotranspiration (ET_{ref}) has the more practical application. The term *evapotranspiration* (ET), developed over the last half-century (Thornthwaite, 1948), is used as a simplifying concession to describe the combined vapor fluxes from soil and vegetation. Some scientists argue that evaporation from soil and evaporation from plants via transpiration both constitute evaporation, so that only the term evaporation is necessary, and the use of the term transpiration is redundant. However, the term ET is useful for efficiency of communication and visualization, since the use of only the term evaporation generally requires qualification as "evaporation from soil" or "evaporation from vegetation leaf surfaces" or "evaporation of transpired water within leaves", or the sum of all these processes. For communication efficiency, the sum of all three of these evaporation components, which constitutes the total flux of vapor from a vegetated surface, is commonly referred to as ET (if one wishes, one can think of the term ET as representing "evaporation total").

Pan Evaporation

Evaporation from an evaporation pan has been used for several centuries as an approximate measure of E_p. However, research over the last several decades points to the need for caution in the use of general pan evaporation data to estimate lake evaporation or evapotranspiration (ET) from land. The standard evaporation pan in much of the world is the USA Class A Pan, which is 1.21 m in diameter and 254 mm deep, constructed of stainless steel, and placed above a 0.15-m tall open timber framework such that the top of the pan is about 0.4 m above the surrounding ground level. Two other commonly used pans are the Russian (Soviet) GGI-3000 (0.3 m^2) pan and the GGI-20 m^2 tank, both placed in the soil with only 0.075 to 0.1 m of rim above the soil surface. Details are given by the World Meteorological Organization (1970). Daily pan evaporation (E_{pan}) is computed from the change in water storage in the pan, inputs of precipitation and water added to maintain an adequate supply.

Owing to differing thermal characteristics between the pan and large water bodies, E_{pan} tends to overestimate the total amount of evaporation and distort the seasonal distribution (*see* **Chapter 44, Evaporation from Lakes, Volume 1**). Thus, on a seasonal basis, E_p usually peaks several months before the peak evaporation of deep lakes. Early studies in the United States in semiarid to arid climates revealed a very significant response in E_{pan} to pan size, but now it is clear that this was primarily the result of a decreasing effect of local advection with increasing size of the water surface area. Pruitt and Doorenbos (1977b) reported almost no difference (4%) between evaporation from a 0.62-m diameter Russian pan and a 5-m diameter Russian pan when both were located in a 5-ha irrigated grass field. On the other hand, at a dry site in Nevada, evaporation from the smaller Russian pan averaged some 1.6 times that of the larger pan, although when corrected for the net heat transfer from soil to the pans, a factor of 1.45 resulted (Hounam, 1973).

Young (1947) presented a good discussion of the problem of local pan environment in relation to estimating lake evaporation. Later studies in India by Ramdas (1957) and studies at Prosser, Washington and in California (Pruitt, 1960, 1966; State of California DWR, 1975, 1979) provided clear evidence that unless the local environment of a pan was taken into account, the estimation of ET (or of lake evaporation) was subject to errors of up to 35%. Pruitt and Doorenbos (1977a) introduced pan factors (k_p) to multiply by E_{pan} for estimating ET from a clipped grass reference surface and evaporation from shallow water bodies. These coefficients take into account the effects on pan evaporation of upwind fetch (both dry and moist), mean relative humidity, and total daily wind (Doorenbos and Pruitt, 1977; Jensen *et al.*, 1990; Shuttleworth, 1992; Allen *et al.*, 1996; FAO, 1998).

Pan maintenance can be challenging. The water level for a Class A pan must be kept within a range of 0.05 to 0.075 m below the top of the pan. If the pan is protected from birds, for example, with 12.5-mm (0.5-inch) mesh screen, k_p should be increased 5 to 10 percent (Stanhill, 1962). Pans made of monel metal, or those older galvanized metal pans, which have lost their original reflectance characteristics, may need a reduction to k_p of up to five percent. In general, the water should be kept clean, although turbidity differences appear to produce little difference in evaporation from Class A pans. There is an obvious need to avoid contamination by oil-related products. Pans are generally inoperable during winter when water can freeze. In some cases, pans are heated; however, the heat addition increases the E_{pan} above ambient conditions. Another complicated situation arises when pans are placed in a small enclosure surrounded by tall crops. The reduced

aerodynamic turbulence over the pan can dramatically reduce the E_{pan} measurement (Jensen *et al.*, 1990).

With the challenges in pan operation and maintenance, and the inability to precisely convert E_{pan} into E_p or even into a reference ET, and due to expense and difficulties in automation of pan measurements for electronic data recording and communication, pans are falling out of common usage. Use of E_{pan} is generally being replaced by the use of reference evaporation or reference ET calculated from weather data.

Potential Evapotranspiration

The term "potential evapotranspiration" (ET_p) had widespread usage from the 1940s through the 1970s (Thornthwaite, 1948; Jensen, 1974), when the term was used to represent a maximum evaporative index from which to derive estimates of actual ET (ET_a) from vegetation (Penman, 1963). However, there are several major, contrasting definitions for ET_p and several challenges associated with its usage. One of the primary definitions used for ET_p is as the rate of evaporation and transpiration from a saturated (free-water) vegetated surface so that the evaporation process occurs at the potential level. In this definition, ET_p is similar to E_p, but applied only to vegetation. As for E_p, the challenge with the saturated surface definition for ET_p is that the magnitude, although depending primarily on atmospheric conditions and surface albedo, varies with the surface characteristics including aerodynamic roughness (*see* **Chapter 42, Transpiration, Volume 1** and **Chapter 43, Evaporation of Intercepted Rainfall, Volume 1**). Thus, the definition for ET_p should be tied to specific vegetation in regard to height, leaf area, and roughness. This is done using a predictive equation such as the Penman–Monteith (introduced as equation (1) *see* **Chapter 45, Actual Evaporation, Volume 1**) with very small or zero surface resistance and aerodynamic and radiative properties that fit the vegetation. Also, because conditions of saturated vegetation occur only for short periods during and following dewfall, rainfall, or irrigation by sprinkler, it is difficult to obtain the measurements of ET_p for free-water surface conditions by which to develop predictive equations.

A second definition for ET_p is to relax the requirement of a free-water surface (i.e. saturated vegetation surface) and to set ET_p equal to the rate of ET expected from relatively tall, dense, leafy vegetation having dry leaf surface, but that has relatively high soil-water content, is disease and stress free, and is therefore transpiring at a rate governed by nearly maximum leaf and boundary-layer conductances in conjunction with energy availability. The advantage of this definition for ET_p is that it follows more closely an upper bound on ET expected from vegetation on nonrainy days. It is this second definition that was used in papers and equation developments by Penman (1948, 1963) where ET_p was associated with ET measured from a clipped, cool-season grass. A challenge with this definition, however, is again the need to define the specific characteristics and aerodynamic structure of the vegetation representing ET_p. Associated with the definition of the upper bound for ET_p for a specific type of vegetation is the challenge of defining the value to use for the surface (leaf and canopy) conductances, which can be shown to vary with environmental factors of solar radiation, relative humidity at the leaf surface, leaf temperature, soil-water potential and carbon dioxide concentration (*see* **Chapter 42, Transpiration, Volume 1** and **Chapter 45, Actual Evaporation, Volume 1**). In some ways, this second definition of ET_p is the best one to use in hydrologic science, with estimates based on the Penman–Monteith or multilayer approaches. However, use of ET_{ref}, as discussed later, may be more consistent and convenient. Also, the feedback between the defined potential surface and its characteristics and the associated weather measurements should be considered. One should not "mix and match" ET_p from tall forest vegetation, for example, with weather data collected over a short grassed surface.

A third definition for ET_p, and perhaps the best one for process modeling, is as the potential ET to expect from any specific type and condition of vegetation or other terrestrial surface under conditions of sufficient soil-water to not inhibit transpiration. This definition, as applied to vegetation, applies even to conditions of low leaf area, for example, during initial plant development, and is therefore synonymous with what is often termed, in agricultural applications, as "potential crop ET" (FAO, 1998). The value for ET_p is strongly governed by the relative leaf area over the surface and leaf conductance properties. Some definitions for this type of ET_p assume a relatively dry soil surface between plants so that the soil evaporation component is small. Other definitions (as in FAO usage FAO, 1998) include a soil evaporation component that can change daily as soil dries. Actual evaporation (or actual ET) is modeled as equal to ET_p until a point when soil-water availability in the effective root-zone falls to a level that can no longer supply water to the plant at the ET_p rate (Hatfield and Allen, 1996).

Reference Evapotranspiration

The definition and use of the term "reference evapotranspiration" (ET_{ref}) was developed in the 1970s (Wright and Jensen, 1972; Pruitt and Doorenbos, 1977) to resolve ambiguities involved in the definition and interpretation of "potential evapotranspiration" as noted in the previous section. The "reference" descriptor points to the use of a specific type of vegetation or specific definition of vegetation properties to represent the evaporative index. Wright and Jensen suggested that maximum ET for nonsaturated conditions may be approximated by ET from a

well-watered reference crop of alfalfa (also called Lucerne) of a height of at least 0.2 m. Doorenbos and Pruitt described their ET_{ref} (termed ET_o) as "*the rate of evapotranspiration from an extensive surface of 8–15 cm tall, green grass cover of uniform height, actively growing, completely shading the ground and not short of water*". Subsequently, this definition specified the grass cover to be a cool-season grass having roughness, density, leaf area, and canopy resistance characteristics similar to perennial ryegrass (*Lolium perenne*) or alta fescue (*Festuca arundinacea* Schreb. "Alta"), since warm-season grass varieties, such as Bermuda (*Cynodon dactylon*), exercise considerable control over transpiration and can have lower ET_{ref} rates.

The benefit of using the reference concept is the ability to readily measure and validate reference ET using living, standardized vegetation. In addition, because stomatal control of the reference surface is intended to approximate that of most agricultural vegetation, ET_{ref} is generally more similar to actual ET than is E_p. An advantage of using ET_{ref} is that weather data are commonly measured above "standardized" weather surfaces that are usually grass or other short growing vegetation. Hence, the predicted ET flux is synchronized with the temperature, humidity, and wind measurements taken over the weather station surface and reflects the impact of feedback mechanisms between the vegetation and overlying boundary layer.

DEFINITION OF REFERENCE *ET*

For general prediction purposes, the complex aerodynamic (turbulent) structures within and above vegetation canopies and the effects of partitioning of net radiation and energy within the canopies can be described in terms of simple resistances (*see* **Chapter 40, Evaporation Measurement, Volume 1**; **Chapter 42, Transpiration, Volume 1** and **Chapter 45, Actual Evaporation, Volume 1**). In the most simple form, this is accomplished using the linear "big leaf" model of Monteith (1965, 1985) where two resistances, surface and aerodynamic, are assumed to operate in series between leaf interiors and some reference height above the vegetation. Bulk surface resistance (r_s) is related to the resistance of vapor flow through individual stomatal openings (r_l) and total leaf area (*see* **Chapter 42, Transpiration, Volume 1**). Aerodynamic resistance (r_a) describes the resistance to the random, turbulent transfer of vapor from the vegetation upward to the weather measurement height, and the corresponding vertical transfer of sensible heat away from or toward the vegetation. The r_a term (and to some degree, the r_s term) includes the effects of diffusive resistance through thin molecular layers along leaf surfaces, momentum transfer through pressure forces within the plant canopy, and turbulent transfer among canopy leaves and above the canopy. The r_a is affected by boundary-layer stability (*see* **Chapter 40, Evaporation Measurement, Volume 1**). The location of the r_s and r_a terms as used in the Monteith model are shown in Figure (1) of **Chapter 45, Actual Evaporation, Volume 1**.

Assuming that eddy diffusion transfer factors for latent heat and sensible heat are the same and that differences between transfer factors for momentum and those for heat can be quantified through a simple ratio (*see* **Chapter 40, Evaporation Measurement, Volume 1**), the Penman–Monteith (PM) form of the combination equation (Monteith, 1965) takes the form:

$$\lambda E = \frac{\Delta(R_n - G) + \rho_a c_p (e_s - e_a)/r_a}{\left(\Delta + \gamma\left(1 + \frac{r_s}{r_a}\right)\right)} \qquad (1)$$

where R_n and G are net radiation and soil heat-flux densities, Δ is the slope of the saturation vapor pressure–temperature relationship, ρ_a is mean air density, c_p is specific heat of air at constant pressure, $e_s - e_a$ is the vapor pressure deficit of air at the reference (weather measurement) height, and γ is the psychrometric constant. λE in (1) represents evaporation or ET expressed as a latent energy flux density, for example as $W\,m^{-2}$. λE is converted to units of water depth per unit time by dividing by the latent heat of vaporization, λ, and by the density of liquid water.

The Penman–Monteith equation as formulated in equation (1) includes all significant parameters governing energy exchange and the corresponding latent heat-flux (evapotranspiration) from a uniform expanse of vegetation. Most of the parameters in equation (1) can be readily measured or calculated from weather measurements on an hourly or shorter time basis. Equation (1) is generally capable of responding to changes in weather and climate in a manner similar to nonstressed, forage, or annual vegetation, so that it is reasonable to use this equation to represent ET_{ref} conditions.

The ET_{ref} value is typically transformed into an estimate of E_{act} during modeling by applying a cover coefficient, crop coefficient, or crop factor (K_c) that is defined as the ratio of E_{act} to ET_{ref}. The value for K_c when the soil surface is dry is strongly related to the fraction of ground covered by vegetation. K_c is further influenced by the height (roughness) and leaf structure of vegetation as well as surface conductance properties. Although the concept and use of K_c can be unappealing to users who desire a more theoretical and analytical structure to the ET estimate, for example, one that applies equation (1) directly to a specific surface using aerodynamic and surface properties that are defined and calibrated for example, as described in (*see* **Chapter 45, Actual Evaporation, Volume 1**), the consistent and reproducible behavior of the K_c

and the ability to set upper and lower limits and to estimate general values, based only on visual observation of vegetation, is appealing. The specific and direct application of equation (1) to vegetation without K_c and definition of ET_{ref} requires detail of roughness and leaf area properties over time as vegetation develops, the need to account for impacts of feedback between surface and boundary layer, the need to dynamically estimate r_s for the soil component as a function of water content and cover, and the need for a net radiation model specific to the canopy architecture. These needs require relatively complicated, well tested, and data-populated models such as those by Shuttleworth and Wallace (1985), Shuttleworth and Gurney (1990), Dolman (1993), and Huntingford *et al.* (1995). While these models, if sufficiently calibrated, are capable of producing more accurate estimates of ET_a (*see* **Chapter 42, Transpiration, Volume 1** and **Chapter 45, Actual Evaporation, Volume 1**) often, hydrologic model applications do not warrant the application intensity or time requirements, and the simple $K_c\,ET_{ref}$ method provides sufficiently accurate estimates. The $K_c\,ET_{ref}$ approach has greatly simplified the complexity and amount of information required to predict ET_a and has enabled the transfer of values for K_c between locations and between climates. This has been a primary reason for the wide acceptance and application of the $K_c\,ET_{ref}$ approach as a working model that can be used until more sophisticated methods become available for direct estimation of actual crop ET. FAO (1998) summarized K_c values for a wide range of agricultural crops and described means for estimating K_c based on visual descriptions of vegetation.

Basis for Reference *ET*

Reference ET is defined as the evapotranspiration from an extensive surface of reference vegetation having a standardized, uniform height and that is actively growing, completely shading the ground, has a dry, but healthy and dense leaf surface, and is not short of water. This definition has typically been applied to two common and standardized reference vegetation types: clipped, cool-season grass and full-cover alfalfa.

Standardized Definitions

It is generally accepted that the grass reference crop is a "cool-season", C-3 type of grass with roughness, density, leaf area, and bulk surface resistance characteristics similar to perennial ryegrass (*Lolium perenne* L.) or alta fescue (*Festuca arundinacea* Schreb. "Alta"). Alfalfa reference ET, typically abbreviated ET_r, was defined by Wright and Jensen (1972) as: "*... ET from well-watered, actively growing alfalfa with 8 in. (20 cm) or more of growth...*" and by Wright (1982) as "*...when the alfalfa crop was well-watered, actively growing, and at least 30-cm tall; so that measured ET was essentially at the maximum expected level for the existing climatic conditions"*. The height of alfalfa (*Medicago sativa* L., vs ranger) in the data set used to develop surface resistance algorithms for the ASCE Penman–Monteith application (Jensen *et al.*, 1990) to ET_r ranged from about 0.15 to 0.80 m in height and averaged 0.47 m (Allen *et al.*, 1989).

Generally, alfalfa ET_r is about 1.1 to 1.4 times that of grass ET, typically abbreviated ET_o, due to the increased roughness and leaf area of alfalfa. The higher value (1.4) represents the ratio of ET_r to ET_o under extremely arid and windy conditions (minimum daytime relative humidity (RH) $<20\%$ and wind speed $>5\,m\,s^{-1}$ (11 mph)) and the lower value (1.1) represents the ratio of ET_r to ET_o under humid, calm conditions (Pereira *et al.*, 1999; Wright *et al.*, 2000). ET_r is sometimes preferred over ET_o because its larger roughness and leafiness cause it to better approximate the upper limit of ET expected from all types of vegetation (Pereira *et al.*, 1999). However, alfalfa does not grow well under some tropical conditions and at elevations above about 2000 m. However, ET_r is now defined by ASCE-EWRI (2005) as a virtual reference crop that can be applied at all locations. Cool-season grasses can be cultivated over a wide range of climates, seasons and elevations, for example, at 4000 m in Bolivia (Garcia *et al.*, 2004).

ET Equations to Define ET_{ref}

Because of the challenges in growing and maintaining living reference vegetation, where the LAI and thus the value for r_s can vary between clippings for grass by nearly a factor of 2, a calibrated ET_{ref} equation is now generally used to represent the "hypothetical" or "virtual" reference. The FAO (Smith *et al.*, 1991, 1996; FAO, 1998) has adopted the PM equation as a standardized definition for ET_o where values for r_s, surface albedo, and aerodynamic roughness are fixed. FAO Irrigation and Drainage Paper No. 56 defined ET_o in terms of the PM equation as the rate of evapotranspiration from "*a hypothetical reference crop with an assumed crop height of 0.12 m, a fixed surface resistance of* $70\,s\,m^{-1}$ *and an albedo of 0.23"*, and where the reference surface "*closely resembles an extensive surface of green grass of uniform height, actively growing, completely shading the ground and with adequate water"*.

Penman–Monteith as a Definition

The Penman–Monteith (PM) equation was introduced in its full form as equation (1). The PM formulation of the combination equation incorporates aerodynamic and surface resistance terms that represent physical characteristics of the particular reference crop. Aerodynamic resistance in equation (1) is generally calculated as

$$r_a \frac{\left(\ln\left(\frac{z_u - d}{z_{om}}\right) - \Psi_m\right)\left(\ln\left(\frac{z_{T,e} - d}{z_{oh}}\right) - \Psi_h\right)}{k^2\,u_z} \qquad (2)$$

where z_u is the measurement height for wind speed, $z_{T,e}$ is the measurement height for temperature and vapor pressure, d is the zero-plane displacement height for the weather measurement surface, z_{om} is the roughness height for momentum transfer, z_{oh} is the roughness height for vapor and sensible heat transfer, k is the von Karman constant (0.41), u_z is the wind speed at the z_u height and Ψ_m and Ψ_h are integrated stability functions for momentum and sensible heat transfer (more theory on stability is given in **Chapter 40, Evaporation Measurement, Volume 1**). Definitions and procedures for calculating stability parameters Ψ_m and Ψ_h are available from Brutsaert (1982), Katul and Parlange (1992) and Allen *et al.* (1996). Normally, Ψ_m and Ψ_h can be assumed zero for ET_{ref} calculations because the reference surface is well watered so that boundary-layer stability is close to neutral or only mildly unstable or stable and values for Ψ_m and Ψ_h are small. This simplifies the calculation process.

Standardized parameterizations of equations (1) and (2) have been proposed by ASCE-EWRI (2005) for both ET_o and ET_r following the format adopted by FAO. When the supporting parameter equations for r_a, ρ_a and λ are reduced and combined into equation (1), the FAO styled, reduced equation used by ASCE-EWRI results

$$ET_{ref} = \frac{0.408\Delta(R_n - G) + \gamma \dfrac{C_n}{T + 273} u_2 (e_s - e_a)}{\Delta + \gamma(1 + C_d u_2)} \quad (3)$$

where ET_{ref} applies to both clipped grass and alfalfa reference surfaces. ET_{ref} has units of mm d^{-1} for 24-h time steps and mm h^{-1} for hourly time steps, R_n and G are in MJ $m^{-2} d^{-1}$ or MJ m^{-2} h^{-1}, T is mean daily or hourly air temperature (°C), u_2 is mean daily or hourly wind speed at 2-m height (m s^{-1}), e_s and e_a are in kPa, Δ and γ are in kPa $°C^{-1}$, and C_n and C_d are coefficients that change with calculation time step, reference type (grass ET_o or alfalfa ET_r), and, in some cases, with time of day. Values for C_n and C_d are given in Table 1. The values for hourly C_d for ET_o by ASCE-EWRI stem from the use of $r_s = 50$ s m^{-1} during daytime and $r_s = 200$ s m^{-1} during nighttime and the 24-h time-step value for C_d for ET_o stems from $r_s = 70$ s m^{-1}. For additional reading on r_s for ET_o, see Allen *et al.* (2005b). For ET_r, the values for hourly C_d stem from the use of $r_s = 30$ s m^{-1} during daytime and $r_s = 200$ s m^{-1} during nighttime and the 24-h time-step value for C_d stems from $r_s = 45$ s m^{-1}. The standardized definitions imply vegetation heights for the ET_o and ET_r surfaces of 0.12 and 0.5 m. R_n can be measured or estimated. If R_n is estimated, FAO (1998) and ASCE-EWRI provide standardized estimation procedures that use a fixed albedo of 0.23. The widely used FAO-56 Penman-Monteith equation (FAO, 1998) uses $C_n = 900$ and $C_d = 0.34$ for daily timesteps. For hourly timesteps, Allen *et al.* (2005b) recommend the use of values shown for ET_o in Table 1 for the FAO method.

The use of the standardized definitions for ET_o and ET_r provide for a consistent index of evapotranspiration that is readily compared between climates, locations, and time periods. The definition, although standardized, is tied to measurable surfaces, so that the predictive equation (3) can be compared to local measurements when desired or necessary.

Limitations of ET_{ref}

Although useful as a standardized climatic evaporation index, ET_o tends to underpredict maximum ET expected from tall vegetation such as trees, brush, and tall grasses like corn and sugar cane when the taller vegetation has unrestricted access to soil-water. Underprediction can be as much as 40% in arid climates and is caused by the close coupling of tall vegetation to the boundary layer. Some of the underprediction is moderated, however, by the fact that temperature and humidity of the lower boundary layer over rough vegetation will be cooler and more humid under conditions of maximum ET, owing to the more efficient scalar transport. Unfortunately, this feedback is generally not taken into account in models when weather data collected over grass are used to predict ET from taller vegetation. The taller alfalfa reference overcomes many of the shortcomings of grass in terms of aerodynamic roughness, but its use is less common in some parts of the globe.

Both definitions for ET_{ref} (clipped grass and alfalfa) assume an extensive, well-watered fetch for the evaporating surface as well as for the weather measurement. In arid settings, air temperature and relative humidity are substantially impacted by absence of an evaporating surface. When

Table 1 Values for C_n and C_d in equation (3) (after ASCE-EWRI, 2004)

	Short reference, ET_o		Tall reference, ET_r		Units for ET_o, ET_r	Units for R_n, G
Calculation time step	C_n	C_d	C_n	C_d		
Daily	900	0.34	1600	0.38	mm d^{-1}	MJ m^{-2} d^{-1}
Hourly during daytime	37	0.24	66	0.25	mm h^{-1}	MJ m^{-2} h^{-1}
Hourly during nighttime	37	0.96	66	1.7	mm h^{-1}	MJ m^{-2} h^{-1}

placed into the reference equation (3), data collected over a dry surface will cause as much as 30% overprediction of ET_{ref}. For further reading, see Allen *et al.* (1983), Ley *et al.* (1996), Jensen *et al.* (1997), FAO (1998), Temesgen *et al.* (1999) and ASCE-EWRI (2005).

One last limitation in the standardized definition for ET_{ref} is that it assumes constant surface resistance and albedo, regardless of environmental conditions or sun angle. When net radiation is measured over the reference surface, sun angle impacts on albedo are taken into account. This poses a challenge when converting the ET_{ref} into actual ET using some type of K_c under conditions where the stomatal behavior of the vegetation being modeled may vary substantially during the day.

Use of ET_{ref} as an Index

ET_o as defined by equation (3) has been applied within a global weather database by the International Water Management Institute that is published in the form of a World Climate Atlas (URL = `http://www.iwmi.cgiar.org/WAtlas/atlas.htm`). This database contains monthly mean weather and ET_o data for the 1961–1990 period and is useful for providing general ET_{ref} inputs for hydrological modeling of river basins and for extracting climate inputs for vegetation modeling. Droogers and Allen (2002) investigated the overall quality and populational behavior of the World Climate Atlas ET_o database. A similar, but independent, compilation of mean monthly weather data including ET_o by equation (3) was published by FAO (1993) as the CLIMWAT database (URL = `http://www.fao.org/ag/agl/aglw/climwat.stm`).

The alfalfa ET_r has been used as a calibration means within the METRIC energy balance model (Tasumi *et al.*, 2005; Allen *et al.*, 2005a) to improve the accuracy of the ET surface derived from satellite images. ET_{ref} is used to interpolate ET maps between satellite image dates within the remote sensing surface energy balance algorithm for land (SEBAL) (Bastiaanssen *et al.*, 1998) and METRIC, and other satellite-based energy balance procedures for deriving actual ET.

PENMAN VERSUS PENMAN–MONTEITH

The Penman–Monteith equation (1) was an extension to the original Penman (1948, 1963) equations where a wind function (w_f) in the aerodynamic term of the numerator was replaced with r_a and the $(1 + r_s/r_a)$ term was added to the denominator. Under free-water surface conditions, r_s tends toward zero, and equation (1) reverts to the Penman equation, with the exception that r_a is used in the numerator rather than the w_f, where generally, $w_f = a + b\,u$, where a and b are empirical coefficients and u is wind speed at some height above the surface (*see* **Chapter 44, Evaporation from Lakes, Volume 1**). In some regards, a distinct advantage of the w_f of the Penman equation is that it has a lower value (parameter a) when u decreases to zero or nearly zero. This is not the case for the classical equations used for r_a in the definition for ET_{ref}, (for example, equation (2) when the instability functions, Ψ, are set to zero), so that r_a tends toward infinity as u decreases toward zero. This behavior for r_a is unrealistic, as under conditions of low wind speed, for example, less than $0.5\,m\,s^{-1}$ at 2-m height, and $R_n - G > 0$, buoyancy forces caused by surface heating will play a significant role in transport of air away from the surface, thereby sustaining some aerodynamic transport. Thus, there should be some maximum value for r_a (conversely a minimum value for u in equation (3)) when the PM equation is applied for ET_{ref}. FAO (1998) and ASCE-EWRI (2005) have recommended limiting wind speed at 2-m height to $0.5\,m\,s^{-1}$ or greater when calculating ET_{ref}.

With the limitation imposed on wind speed in equation (3) for ET_{ref} or with the use of stability correction in equation (2) when used in equation (1) for E_p or ET_p, the Penman–Monteith method is recommended over the Penman, because the explicit definition for r_a via equation (2) allows users to easily modify r_a for changing vegetation roughness. This modification is not very straightforward with the w_f in the Penman equation.

QUALITY OF WEATHER DATA

The accuracy and quality of the E_p, ET_p, or ET_{ref} estimation is only as accurate as the weather data on which it is based. All E and ET equations require weather or climate data that reflect the environment of the area for which ET is estimated. Weather data should be screened before use. This is especially important with electronically collected data, since human oversight and maintenance may be limited. When weather measurements are determined to be faulty, they can be adjusted or corrected using a justifiable and defensible procedure, or the user may elect to replace perceived faulty data with estimates. Simple, visual procedures for qualifying weather data for use in ET estimation were described by Allen (1996), FAO (1998) and ASCE-EWRI (2005).

USE OF SIMPLIFIED EMPIRICAL EQUATIONS

A large number of empirical methods have been developed over the last century by scientists and specialists worldwide to estimate E or ET using a variety of climatic variables. Relationships were often subject to rigorous local calibrations, but proved to have limited global validity. The application of equations (1) and (3) requires data for air

temperature (T), vapor pressure (e_a), net radiation (R_n) or solar radiation (R_s) and wind speed (u). If some of the required weather data are missing or cannot be calculated, one must make a choice. Either equation (1) or (3) can be retained and the missing data estimated using a reliable technique that keys off other data or historical information, or an empirical equation is used that does not call for the missing data. Smith *et al.* (1991), FAO (1998) and ASCE-EWRI (2005) made strong arguments for utilizing the same (theoretically valid) ET_{ref} equation, regardless of data availability, and with estimation of missing data. The basis for the arguments is that one should obtain a more accurate estimate of E or ET using a theoretically correct method that considers all major factors, even when one or more factors are best estimates, than one will find when using an empirical method that essentially "closes its eyes" to many facets of the missing factor. FAO (1998) and ASCE-EWRI proposed general, relatively simple procedures for estimating missing parameters. These include estimating dewpoint temperature from daily minimum air temperature (less some fixed offset that is a function of climatic aridity), estimating R_s as a function of daily maximum and minimum air temperature and extraterrestrial radiation, and estimating missing wind speed using long-term monthly values characteristic of the area. More sophisticated weather generation models are available for estimating missing weather data that preserve some of the correlation between weather parameters and that preserve natural random variation (Richardson and Wright, 1984; Johnson *et al.*, 1996; Nelson, 2004; Meyer *et al.*, 2004).

If empirical methods for ET are to be applied, the four more popular and perhaps dependable methods are the Hargreaves *et al.* (1985), the Priestley and Taylor (1972), and the Makkink (1957) methods. The 1985 Hargreaves equation, which requires only daily maximum and minimum air temperature data along with calculated extraterrestrial radiation, generally provides relatively dependable estimates (Droogers and Allen, 2002; Hargreaves and Allen, 2003). FAO (1998) recommended calibrating the Hargreaves equation against the PM at regional sites, especially if the climate is subhumid to humid. Garcia *et al.* (2004) found the Hargreaves method performed relatively well at two arid locations near 3800-m elevation in Bolivia, but there was worse performance at two more humid locations.

As discussed in (*see* **Chapter 44, Evaporation from Lakes, Volume 1** and **Chapter 45, Actual Evaporation, Volume 1**), the Priestley–Taylor method, requiring only R_s and T, defines an equilibrium E or ET for large regions having adequate water supply. This implies it should be used under subhumid to humid conditions. The multiplier for the Priestley–Taylor method generally requires enhancement under arid conditions (Jury and Tanner, 1975; Jones and Kiniry, 1986; Steiner *et al.*, 1991). The Makkink method, also requiring only R_s and T, can be used if humidity data are considered to be of poor quality. Otherwise, one should trust the PM method (equations (1) and (3)) to produce a more accurate estimate, even in humid climates where the vapor pressure deficit ($e_s - e_a$ in the PM equation) is at times small. When humidity data are judged to be poor, one can replace the data with estimates based on daily minimum air temperature or can retreat to the empirical methods.

CONCLUSIONS

The theoretical concepts of potential evaporation, E_p, and potential evapotranspiration, ET_p, make them useful indices and definitions. However, the conditions behind the terms are generally difficult to sustain within hydrologic systems for measurement and are difficult to sustain even for weather data collection, owing to the importance of collecting temperature and humidity data that are coincident to the evaporating surface being modeled. The reference ET surfaces and definitions, ET_o and ET_r, for grass and alfalfa (i.e. short and tall references), are associated with a different set of problems and challenges when used for hydrologic modeling. However, the ET_{ref} is useful as a consistent and reproducible climatic index and is generally synchronized with weather data collected over well-watered grassed surfaces. The collection and use of pan evaporation data is losing popularity as improvements in the ET_{ref} definitions become accepted, and owing to the expense and the difficulty in making accurate automated measurements of evaporation from pans.

42: Transpiration

JOHN ROBERTS

Centre for Ecology and Hydrology, Wallingford, Oxfordshire, UK

The transpiration process is the uptake of water by plant roots, transport through the plant and evaporation from the leaf through pores called stomata. Evaporation of water from the leaf is determined by atmospheric conditions such as radiation, temperature and humidity deficit but the plant can limit transpiration by partial or complete stomatal closure. Generally stomata open in response to increasing radiation but tend to close with increasing air humidity deficit and reduced availability of soil moisture. Because the stomata have to be open in daylight for the entry of carbon dioxide into the leaf for the photosynthesis process, water loss is an inevitable consequence. Nevertheless transpiration itself has important roles. Nutrients are brought into the plant when water is taken up from the soil and evaporation of transpired water prevents leaf temperature reaching supra-optimal levels. There are numerous ways that transpiration might be measured. These include measurements of soil water changes below vegetation or changes in atmospheric humidity above vegetation. Alternatively measurements can be made on individual plants or leaves. In most circumstances the source of water for transpiration is the soil and principally the surface soil layers where most roots are found. In the future, increased levels of atmospheric CO_2 are expected to reduce transpiration through reduction in stomatal aperture.

WHAT IS TRANSPIRATION?

Transpiration is the process by which water is evaporated from within a plant. Essentially, water is evaporated through small holes (known as *stomata*) in the leaves, and this draws water up through the plant (in microscopic tubes termed *xylem*) from the soil. This "transpiration stream" brings water to the plant to be used in photosynthesis, to produce carbohydrates, and to maintain turgidity (rigidness) in the cells and tissues. However, very little of the water is actually used in photosynthesis and to maintain turgidity. Most of the water sucked up from the soil is evaporated through the stomata. A primary purpose of the stomata is to exchange carbon dioxide and oxygen with the atmosphere in addition to regulating the loss of water from the leaves. The movement of water up from the soil through the plant plays a key role in bringing minerals from the soil into and through the plant. In situations where leaves experience a high radiation loading, leaf temperatures can be critically high. Cooling of the leaf by the dissipation of heat during the evaporation of transpired water is another important role for transpiration.

There is a continuous stream of water from within the leaves of plants down through the plant to the roots and soil. Water molecules bind together and these bonds have substantial strength. There is a continuous column of water from within the leaf drawing up water from the soil. The cohesive forces of water molecules mean that water columns down through the plant can be maintained under significant tensions. In very tall trees, these tensions can be considerable. Suctions equivalent to 5 MPa (50 bars) have commonly been reported for actively transpiring tall trees.

Transpiration from vegetation is usually reported as a depth of water (mm), in the same way that rainfall and evaporation are reported. Transpiration might range from very low or zero in completely water-stressed vegetation, sparse crops, or vegetation in winter. The highest values of transpiration might be up to rates estimated as the potential transpiration rate (*see* **Chapter 41, Evaporation Modeling: Potential, Volume 1**). In this case, it would be expected that the vegetation completely covered the ground, there was no shortage of soil water and climatic conditions are optimal, for example, high summer or tropical conditions. Transpiration can exceed the potential rate if extra energy is available as advection.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Table 1 Annual transpiration of global forest types

Vegetation	Location	Annual transpiration (mm)	Reference
Tropical rainforest	Manaus, Brazil (2°57′S: 59° 57′W)	1030	Shuttleworth (1988)
Southern European evergreen oak	Evora, Portugal (38° 32′N: 8° 01′W	207	David *et al.* (2004)
Temperate coniferous forest	Thetford, UK(52° 25′N: 0° 39′E)	352	Gash and Stewart (1977)
Boreal coniferous forest	Saskatchewan, Canada (53° 55′N: 104° 41′W	204	Saugier *et al.* (1997)

In summer conditions in the United Kingdom, maximum transpiration rates of up to 4 mm day^{-1} have been measured routinely in forests although much higher rates ~8 mm day^{-1} have been observed in fast-growing short rotation coppice plantations. In forests with 750 trees ha^{-1}, a transpiration rate of 4 mm day^{-1} would mean that 50 kg of water per day would be lost on average from each tree. In a wheat or barley field with around 250 stems m^{-2}, transpiration loss through each stem would be of the order of 150 gm.

An insight into the range of annual forest transpiration that might be encountered can be achieved by comparing values from various studies carried out in a range of forest types occurring from boreal to tropical regions. The annual transpiration (with associated information) of forest types occurring in different global regions are given in Table 1. As expected the highest annual total is found in tropical rainforest in Brazil. The high annual total is largely a consequence of the evergreen canopy and therefore year-round transpiration with no limitations of solar radiation, air temperature, or available soil moisture. Potential evaporation rates in this area of the Amazon basin would enable much higher transpiration, but the reduction of canopy conductance in response to an increased air vapor pressure deficit (see Figure 1) means that daily transpiration is often around 3.5 mm, barely different from transpiration of Scots pine *(Pinus sylvestris)* measured at Thetford Forest on summer days.

Annual transpiration from the evergreen oak *(Quercus rotundifolia)* woodland in Portugal is 207 mm. Although this estimate does not include losses from ground vegetation beneath the trees, the low transpiration rate is largely a consequence of the sparse open canopy of the woodland. Shortage of water is probably not an issue as the trees had access to groundwater. The annual transpiration from the boreal forest is also low. Although the growing season is short (~140 days), a major constraint on transpiration is probably soil temperature, which will still be cold enough to limit root water uptake, and probably also mineral nutrients throughout the growing season. This was considered as a major factor in producing low stomatal conductances in the jack pine *(Pinus banksiana)* in the boreal forest.

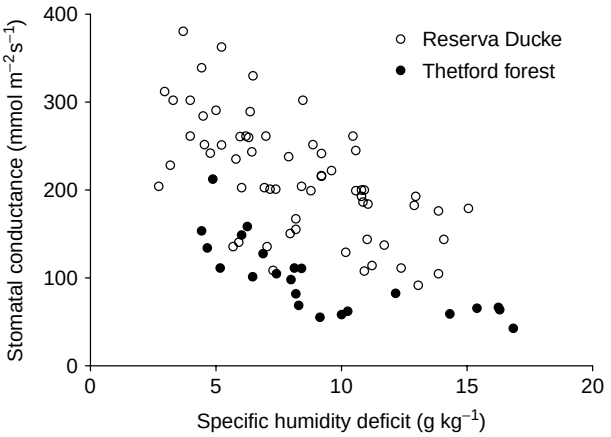

Figure 1 The decline in leaf stomatal conductance with air humidity deficit in *Piptadenia suaveolens*, an upper canopy tree species at the Reserva Florestal Ducke, Manaus, Brazil (unpublished data from John Roberts) and the upper canopy of Scots pine (*Pinus sylvestris* L.) at Thetford Forest, UK (Redrawn from Beadle *et al.*, 1985, *Journal of Applied Ecology* **22**, 557–571, by permission of British Ecological Society)

Transpiration from the temperate coniferous forest is higher than both the southern European and boreal forests. Although not constrained by water stress, daily transpiration is likely to be limited by a strong decline in stomatal conductance with increasing vapor pressure deficit (Figure 1). The annual transpiration of around 325–350 mm year^{-1} shown for Thetford Forest was shown to be very similar for many woodlands (both broadleaf and coniferous) in Europe by Roberts (1983). Roberts identified a number of factors that might contribute to this similar transpiration. Few forests are limited by water stress, and daily transpiration is constrained by probable links between stomatal/surface conductance and air humidity deficit. Furthermore, the presence of understory vegetation below an open tree cover will have a significant role in eliminating tree transpiration differences between dense and open forests. One factor that has been shown to be important in determining transpiration from forests and woodlands is the age of the trees. There is now substantial evidence from studies both on trees and catchments that as trees age their transpiration declines.

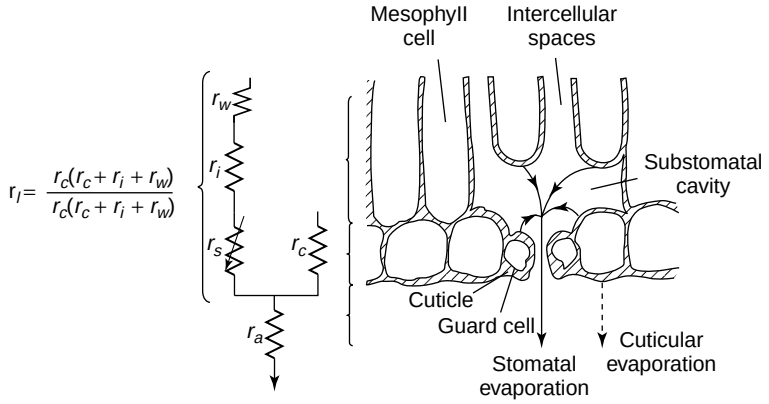

Figure 2 Pathways for water loss from one surface of a leaf showing the boundary layer (r_a), cuticular (r_c), variable stomatal (r_s), intercellular space (r_i), wall (r_w), and leaf (r_l) resistances. The total leaf resistance is the parallel sum r_l for upper and lower surfaces (Redrawn from Jones (1992), Plants and Microclimate, Second Edition, Cambridge University Press)

Practically all of the water lost from vegetation will have been taken from the soil. The amount of water taken up from the soil and used in metabolic processes, for example photosynthesis, is trivial. Some water is lost from plants as transpiration does not come directly from the soil but from storage in the body of the plant. Generally, this stored water is a smaller fraction of the total daily transpiration than water coming directly from the soil. In any case, water lost from storage in the plant tissues will be replaced with water from the soil, and this may occur in the following night, or in the case of some forests, in the following winter.

CONTROLS OF TRANSPIRATION

The evaporation of water from leaf surfaces is influenced by all the factors involved in evaporation from free water surfaces; evaporation is increased as energy inputs increase, and as the vapor pressure gradient from the leaf surface into the atmosphere increases. Evaporation can also be enhanced by increases in wind speed. Nevertheless, there is a particularly important control in the leaf surface. The apertures (stomata) in the leaf surface are able to regulate the loss of water vapor as transpiration. Closure of the stomata also means that the entry of carbon dioxide into the leaf for fixation by photosynthesis will be limited.

A comprehensive discussion of stomata, their structure, occurrence, function, and factors in the control of stomatal opening will be found in Willmer and Fricker (1996). Stomata may occur in small numbers on stems and leaf stalks but are much more common on one or more leaf surface. Stomata occur in more or less equal numbers over the surfaces of grass and cereal leaves, and also in some conifers for example. The most common situation, however, is for stomata to be found on the undersides of leaves, and this is the situation for tropical and temperate broad-leaved trees, and herbaceous plants. Figure 2 shows a cross-section through a stomatal apparatus, with the stomatal opening occurring on the underside of the leaf. Figure 2 shows the resistances met as water vapor is transpired from one surface of the leaf. Evaporation of water from cell walls is regarded by some to be the site of the first resistance (r_w) in the water loss pathway. The transfer resistance within the intercellular spaces (r_i) is followed by the stomatal resistance (r_s), and the boundary-layer resistance (r_b). The pathway of water transfer through the cuticle is very high and is in parallel with the stomatal resistance (r_s). All of these resistances may be expressed as a conductance which is the reciprocal value of the resistance. The stomatal resistance or conductance is variable, depending on the degree of stomatal opening. Figure 2 shows that the whole leaf resistance for one surface of the leaf is r_l, with the total leaf resistance being the parallel sum for the upper and lower surfaces. The dominance of the stomata as the major sites for the transfer of water vapor from the inside of leaves to the outside is reinforced, because the rest of the leaf is covered with the cuticle which has a very high resistance to vapor transfer, unless the leaf surface (and therefore the cuticle) is damaged in some way. The low permeability of the cuticle is reflected in a very high cuticular resistance.

The boundary layer of a leaf refers to the air layer next to the leaf surface, where the surface friction reduces the wind speed in comparison to the bulk airflow. The air layer immediately adjacent to the leaf surface effectively remains static, and the transfer of molecules such as water vapor, occurs by diffusion only. In still air, the low boundary-layer conductance will have a major influence on the flux of water vapor out of a leaf unless the stomata are practically closed. In moving air, on the other hand, the exit of water vapor from the vicinity of the leaf is regulated more by the stomata (Figure 3).

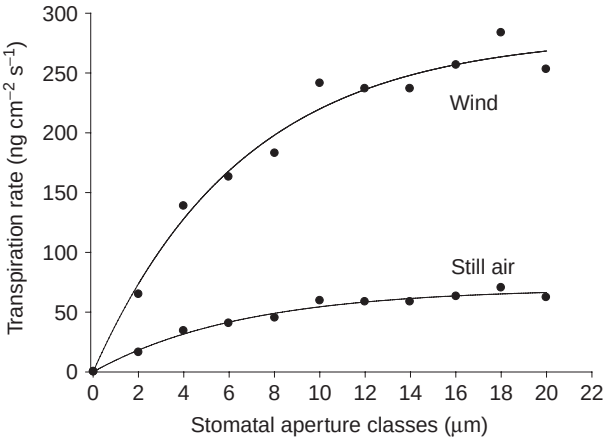

Figure 3 The regulation of transpiration by stomatal aperture in Zebrina pendula leaves under moving and still air conditions (Redrawn from Bange, 1953)

A number of factors, both environmental and within the plant, can influence stomatal aperture. Stomata open in response to increases in solar radiation and show an asymptotic relationship with radiation up to full midday illumination conditions. There is an increase in stomatal opening in response to temperature. Stomatal opening increases up to an optimum value of temperature which is species dependent but can be as much as 30 °C. In many species, particularly trees, stomata close in response to increases in the air atmospheric humidity deficit. The exact mechanism by which plants might sense humidity and reduce stomatal opening remains to be revealed. Nevertheless, strong negative relationships have been observed between stomatal conductance (g_s) and air humidity deficit (D) in a wide variety of vegetation types, particularly those including woody plants (see Figure 1). An important consequence of the negative relationship between g_s and D is that from day to day transpiration remains fairly similar, and never reaches the high values expected from considerations of radiation input. There is a high covariance between D, solar radiation, and air temperature. Therefore on bright, hot days with high D, stomata may be no more open than on a duller, cooler day with smaller D.

It could be postulated that the relationship between g_s and D in plants acts as a form of daily rationing of water, and might delay the development of severe soil water deficits which might lead to a more long-term state of stomatal closure. The reduction in the availability of soil moisture has a fundamental control of stomatal opening, usually operating through the leaf water status and turgidity of the leaf. Plants operate as integrated systems with signals to a leaf coming from all parts of the plant resulting in a net response. As well, the hydraulic signal to the foliage from the roots indicating the development of reduced availability of water in the soil chemical signals can also be transmitted. Stressed roots produce substances that are transported to the guard cells of the stomata via the transpiration stream. There is good evidence the plant hormone, abscisic acid (ABA), is an important hormonal factor which is transported from the roots (Davies and Zhang, 1991). ABA has a strong inhibitory influence on stomatal opening. There is still a need to research particular aspects of ABA and the control of stomata, and therefore transpiration. For example, up until now there has not been a convincing demonstration of the transport of ABA from the roots of mature trees into their canopies, during the development of soil water stress.

Much understanding about the controls of stomatal opening by environmental factors came from detailed studies involving individual plants in controlled conditions. In these studies, the convention was to modify one environmental factor whilst all others were held constant. In real field situations, especially in a complex canopy, the degree to which stomata are open depends on the interplay of a range of environmental conditions. Transpiration from an individual leaf will depend on (1) the degree of stomatal opening (stomatal conductance) determined by environmental conditions, (2) the leaf-boundary conductance which is usually strongly influenced by the size and shape of the leaf, and (3) environmental conditions that force transpiration particularly temperature, available energy, and air vapor pressure deficit. Wind speed around the leaf will have an influence on boundary-layer conductance.

At any one time during the day, the transpiration of a vegetation canopy reflects the environmental influences on the stomata of individual leaves, depending on their position in the canopy. In plant canopies, particularly the more complex ones, for example temperate and tropical forests, there is usually significant systematic variation in leaf stomatal and leaf-boundary conductance down through the canopy. This variation in the conductances coupled with systematic microclimatic variation also down towards the base of the canopy means a major influence on levels of transpiration from different zones in the canopy. Light levels decline with depth in plant canopies. These reduced light levels mean that stomatal opening is reduced, and also that less energy is available to force transpiration. Humidity levels are also usually higher within canopies. This means that the leaf to atmosphere vapor pressure gradient is reduced which limits transpiration. Wind speeds are also lower within canopies. This will mean that leaf boundary-layer conductances might become critically low in canopies where the air is less agitated.

The modification of microclimate within complex canopies means that although the leaf area index (leaf area per unit of ground area, $m^2\,m^{-2}$) might be high, that is, six or more, transpiration in the lower levels of the canopy might be very much reduced. Roberts *et al.*, (1996), working in the tropical rainforest in the central Amazon, Brazil,

examined the interaction of microclimate and leaf conductances in controlling transpiration using a five layer formulation canopy layer and total transpiration estimation routine (CLATTER) of the Monteith–Penman equation (*see* **Chapter 45, Actual Evaporation, Volume 1**). They showed that because of reduced light levels, leaf conductances fall systematically down through the forest canopy. Leaf boundary-layer conductances fell because of the reduced wind speeds towards the forest floor, and humidity deficits also declined systematically towards the forest floor. CLATTER showed that although there is a substantial fraction of the total leaf area index (forest LAI ~6) in the lower layers of the canopy, the fraction of the total forest transpiration from the lower layers is much less than layers in the upper canopy that contain a lower foliage density (Figure 4).

As well as the possession of stomata which can regulate water loss, land plants living in regions of water shortage avoid desiccation, and may possess a large number of structural and life history adaptations that are considered to contribute to conserving water. Some of these adaptations are as follows:

- highly reflective leaf surfaces brought about by wax deposits or reflective hairs;
- stomata sunk into pits in the leaf surfaces;
- reductions in leaf area per mass of plant;
- leaves reduced in size;
- deep roots, or a large mass of root per mass of shoot;
- modifications of stem or root to form water storage organs;
- ability to shed leaves during the driest periods to avoid water deficits;

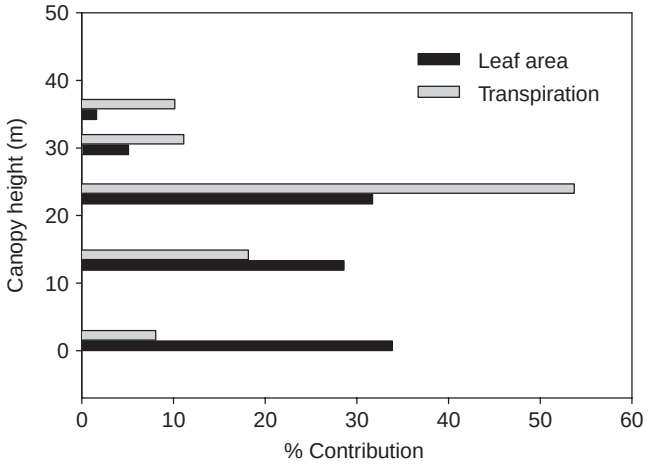

Figure 4 Leaf area in each of five canopy layers as a percentage of total leaf area and transpiration from each layer as a percentage of total transpiration. Reserva Florestal Ducke, Manaus (After Roberts *et al.,* 1996. Reproduced with permission from CEH)

- in dry zones there is a prevalence of annual plants where the plant survives dry periods as a seed, or if a perennial, the plant survives as a subterranean or otherwise much-reduced structure.

WHAT ARE THE ROLES FOR TRANSPIRATION ?

The foliage of plants with a large surface area relative to its volume, constantly exposed to sun and wind, will lose water very rapidly. This does not occur with leaves, because the entire surface is covered with a thin, waterproof layer, the cuticle. Although there may be some microscopic cracks and fissures in the cuticle, largely the cuticle provides a very effective means of restricting the loss of water from the leaf. However, the leaf must be able to take up the gas, carbon dioxide (CO_2), for photosynthesis, and to lose the excess oxygen (O_2) not required for respiration. The leaf must also take up oxygen for respiration when photosynthesis is not taking place, such as during the night and in low sunlight. The stomata in the leaf surfaces control both the entry of CO_2, and the exit of O_2. The diffusion outwards of water vapor is regarded by some as an unnecessary consequence of the stomata being open for the uptake of CO_2. Nevertheless, there are important roles for transpiration and the need for stomata to function as they do in the leaf surface.

Transpiration and Leaf Temperature

A key feature of transpiration for plants is the cooling effect that prevents leaf temperatures from exceeding lethal limits and to be maintained close to the optimum for the functioning of a range of physiological processes which occur inside leaves. Particularly in regions such as deserts, with high radiation inputs, the need for leaves to be cooled is of paramount importance. Figure 5 (Lange, 1959) shows that the temperatures of freely transpiring leaves of the desert cucumber *(Citrullus colocynthis)* are maintained at around or below air temperature, and well below lethal limits. When transpiration is interrupted, leaf temperature rises to beyond critical limits within the next hour.

Evaporation, and especially transpiration, from plant and vegetation surfaces, is particularly important to the land surface energy balance. Therefore, changes in vegetation cover which modify levels of radiant energy used to drive transpiration flux have a large influence on temperatures at the vegetation surface.

Transpiration and Nutrient Uptake

A crucial aspect of transpiration is the associated uptake of certain nutrient ions and their transport and distribution through the plant, to support plant growth and development.

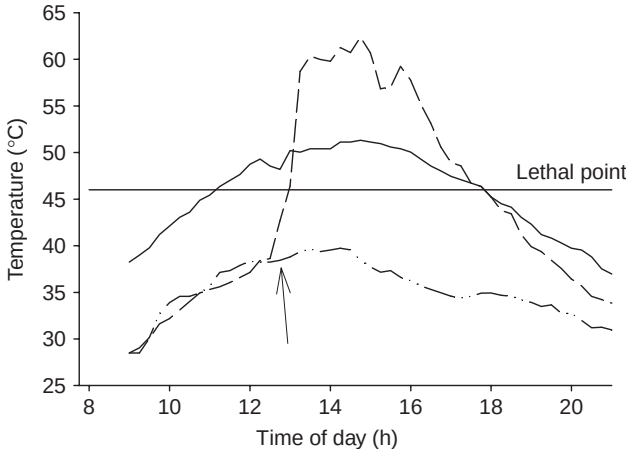

Figure 5 Transpirational cooling in the desert plant (*Citrullus colocynthis*). Graph shows air temperature (___), leaf temperature (-··- ··-) and temperature of another leaf which was cut off (arrow shows time of detachment) to stop transpiration (- - - -). (After Lange, 1959. Figure 6 Schematic presentation of the movement of mineral elements to the root of a tree. (1) Root interception: soil volume displaced by root volume. (2) Mass flow: transport of bulk soil solution along the water potential gradient, driven by transpiration. (3) Diffusion nutrient transport along the concentration gradient. • = available nutrients. (After Marschner, 1995)

Barber (1995) discusses three mechanisms by which plants obtain nutrients from soil and the influence of soil moisture conditions and transpiration in these mechanisms. The three methods are shown schematically in Figure 6. All three methods may be in use at the same time but the uptake of certain nutrients may be exclusively by one method.

Root growth can mean that roots encounter unexploited zones of available nutrients, this is regarded as nutrient uptake by interception. Diffusion is the movement of certain nutrient ions along a concentration gradient, usually towards the root surface where concentration is lowest, from the bulk soil where the concentration is highest.

Root interception is used to describe the acquisition of soil nutrients at the interface of the soil and the root. These nutrients are acquired by virtue of the growth of roots in the soil. Because soil moisture status will determine the amount and distribution of root growth, the level of soil moisture will influence nutrient uptake by root interception. Nutrients move in soil in two ways. First, nutrients are transported to the roots by mass flow along with the water taken up as part of transpiration. Therefore, the uptake of nutrients will be directly influenced by the transpiration rate and the nutrient concentrations in the soil from where the water is taken up. Transpiration by the plants has a fundamental role in the mass flow of nutrients through and from the soil, and into the plants via the roots. Mass flow is the process by which plants usually acquire at least three of their most important nutrient requirements, nitrogen, calcium, and magnesium, and considerable nutrient quantities enter the vegetation as part of the water uptake process. It was estimated that $80\,\mathrm{kg\,ha^{-1}\,year^{-1}}$ of nitrogen is taken up by the broadleaf woodland on the Hubbard Brook catchment, USA (Likens and Bormann, 1995). Nutrient uptake will fluctuate with soil water availability. In many circumstances, nutrient availability in the topsoil declines steeply during the growing season because low soil moisture becomes a limiting factor for nutrient delivery to the root surface. The second process by which nutrients move through soil, is by diffusion along a concentration gradient. Rate of ion diffusion is directly related to the water content of the soil (θ). Increases in θ reduce the tortuosity of the diffusion path, and increases the diffusion flux. There is often a linear relation between θ and the diffusion coefficient. Diffusion is particularly important for nutrients such as potassium and phosphorus. Table 2 shows the relative importance of

Table 2 Nutrient demand of a maize crop and estimates of nutrient supply from the soil by root interception, mass flow, and diffusion (After Barber, 1995 by permission of John Wiley & Sons Inc.)

		Estimates of amounts (kg ha^{-1}) supplied by

the different mechanisms of nutrient uptake in the case of several key elements.

HOW IS TRANSPIRATION MEASURED?

Because there are a wide range of questions relating to transpiration from plants and vegetation, a wide range of techniques have been used to measure the process. The most appropriate technique to be used depends largely on the temporal and spatial scale over which estimates are needed. There are approaches, because they are capable of measuring total transpiration from stands of vegetation, for example, micrometeorological or soil depletion studies, that are not able to provide detailed information about the contribution of individuals that comprise the vegetation. They are not appropriate for isolated individual plants. Nor can the contribution of different vertical layers in complex vegetation be separated by techniques that measure total vegetation transpiration. Sometimes detailed information is required about the contribution of fragments of the vegetation to total transpiration and the factors that control their transpiration. In this case, approaches such as porometry or sap flow will have to be used.

Soil Water Depletion

Studies of rates of soil water depletion are usually used to estimate transpiration over timescales of at least a few days, and they cannot distinguish water taken up by different species when they are growing in close proximity. Sufficient measurements of soil water content need to be made to account for spatial variation in water storage in the soil. In addition, the amount of drainage needs to be measured, or it must be insignificant. Provided drainage from and recharge to the soil is quantified or insignificant, changes in soil water storage allow evaporation to be calculated when rainfall is absent or measured separately. Soil moisture depletion techniques require repeated *in situ* measurements of soil water content, which may be with a neutron probe (Bell, 1987; Dean *et al.*, 1987), the impedance "ThetaProbe" technique (Gaskin and Miller, 1996), or by using time domain reflectometry (Topp *et al.*, 1980, 1984).

Micrometeorological Methods

A revealing approach to measuring evaporation, where it is possible to discriminate between evaporation from wet canopies and transpiration from dry canopies, exploits some of the micrometeorological methods that are available. These approaches are covered elsewhere in this volume (*see* **Chapter 40, Evaporation Measurement, Volume 1**). Following rain events, there will be a significant contribution to the vapor flux from partially wetted leaves and damp soil and litter surfaces. The values from micrometeorological approaches to determine transpiration flux under these circumstances need to be interpreted with care.

Lysimeters

A lysimeter is a device in which a volume of soil with associated vegetation is isolated hydrologically from the surrounding soil. Drainage is measured or is zero, and in the case of lysimeters that are weighed, changes in water storage are determined by weight difference. The application of weighing lysimeters to studies in mature or semimature trees has been very limited. A single large Douglas fir tree was installed in a weighing lysimeter by Fritschen *et al.* (1973). Reyenga *et al.* (1988) installed a lysimeter in a regenerating eucalyptus forest in New South Wales, Australia. Large potted trees capable of being weighed (up to 500 kg) have proved useful for calibrating other techniques such as isotopic tracers (e.g. Dugas *et al.*, 1993). Another form of lysimeter is the drainage lysimeter, which has been used very commonly in short crops but rarely in forests. Calder (1976) described a drainage lysimeter constructed in a Norway spruce plantation in mid-Wales, UK. The lysimeter was sealed at the base by a soil layer of impermeable clay. Data from the lysimeter associated with nearby net rainfall measurements enabled calculation of three separate years of transpiration loss (Calder, 1977).

The Cut-tree Technique

Excising the bases of plants, even large trees (Ladefoged, 1963) under water and measuring water uptake, can be used to estimate transpiration. However Roberts (1977, 1978), showed that removal of soil and root resistances can improve the leaf water status of cut-trees compared to controls, leading to differences in stomatal conductance and transpiration between normal trees, and those with excised roots. Nevertheless, the tree-cutting technique has proved useful in examining the water relations of mature trees (Roberts, 1977), and the amount of water stored in trees that can contribute to transpiration (Roberts, 1976). The technique has also proved particularly valuable as a means of calibrating other techniques such as isotopic tracers (Waring and Roberts, 1979). Because in the cut-tree technique water is drawn up through the tree in a natural way and conditions around the canopy are not modified, the method offers the best option for the calibration of sap flow techniques.

Sap Flow Techniques

Sap flow techniques provide a means of continuously monitoring rates of sap flow. Information about sapwood cross-sectional area of sampled trees, or the leaf area of the sampled tree in relation to the leaf area of the forest, enables transpiration to be estimated on a land area basis. The range of techniques for measuring sap flow and the limitations of different approaches have been reviewed by Swanson (1994) and Smith and Allen (1996).

HEAT-PULSE VELOCITY

The heat-pulse velocity (HPV) method determines rates of sap flow by determining the velocity of a short pulse of heat removed by the upward-moving sap stream. The technique is only really useful on woody stems, and the depth of sapwood must not be so deep that the sensor probe cannot sample it adequately.

Each set of heat-pulse probes consists of one heater probe and two sensor probes containing miniature thermistors. Typically, four sets of probes are installed at equal distances around the circumference of the stem. The heat-pulse technique is based on a compensation principle; the velocity of sap ascending the stem is determined by correcting the measured velocity of a heat-pulse for the dissipation of heat by conduction through the wood matrix. In practice, this is achieved by installing the sensor probes at unequal distances upstream and downstream of the heater probe. The upstream sensor is usually nearer the heater than the downstream one. Heat-pulse velocity (v_h) is calculated from

$$v_h = \frac{\chi_d - \chi_u}{2t_0} \tag{1}$$

where χ_d and χ_u are the distances between the heater and the upstream and downstream sensors, respectively, and t_0 is the time taken after the heat pulse for the temperature of the two sensors to become equal again.

STEM HEAT BALANCE

The stem heat balance (SHB) method can be used to measure sap flow in both woody and herbaceous stems, and these can be very small in diameter. The approach has been used on branches, small trees, and even roots (Smith *et al.*, 1997). A full description of a SHB gauge is given by Smith and Allen (1996). Heat is applied to the outside of the segment of stem enclosed by the heater, and the sap flow derived from the fluxes of heat into and out of the heated section. Sap flow (F) is related to the different heat losses from the stem section (Swanson, 1994) by

$$F = \frac{Q_h - Q_t - Q_v - Q_s}{C_s \Delta T} \text{g s}^{-1} \tag{2}$$

where Q_h is heater power, Q_v is vertical heat loss, Q_r is radial heat conduction, Q_s is heat storage, C_s is the heat capacity of the sap, and ΔT is the temperature difference between the top and bottom of the heated section. The stem sector heat balance method, as described by Cermák *et al.* (1984), requires stainless steel electrode plates to be inserted in a tree stem. If there is substantial variation in sap flux around a large tree trunk, installations would be made at more than one point.

THERMAL DISSIPATION

Granier (1985, 1987) proposed an alternative sap flow technique. Each probe consists of a pair of needles, which are inserted into the sapwood. The upper needle contains a heating probe and a thermocouple, which is referenced to a second needle inserted in the sapwood lower down in the stem. Continuous heating of the upper needle sets up a temperature difference (ΔT) between the two needles. ΔT is at a maximum when the sap flow is at a minimum and decreases as the sap flow increases. Granier (1985) found that for two conifer species and oak, volumetric sap flux density (u_v, $\text{m}^3\text{m}^{-2}\text{s}^{-1}$) is related to ΔT by the following relationship:

$$u_v = 0.000119\text{Z}^{1.231} \tag{3}$$

where

$$\text{Z} = \frac{\Delta T_0 - \Delta T}{\Delta T} \tag{4}$$

when ΔT_0 is the value of ΔT when there is no sap flow. The mass sap flow rate (F_m) is then

$$F_m = \rho_s u_v A_{sw} \tag{5}$$

where ρ_s is the sap density and A_{sw} is the sapwood cross-sectional area. Granier *et al.* (1990) suggest that the parameters in the equation above are not dependent on wood properties or tree species and that the technique may possibly be used without calibration. However, this possibility needs testing for a wider range of species than has been the case thus far because Granier type gauges are commercially available and now very widely used. A calibration rig in which heat dissipation can be measured in a large beech log while water is passed through at different rates is shown in Figure 7.

Porometers and Infrared Gas Analyzers (IRGAs)

Porometers enable measurements of stomatal conductance, g_s, of individual leaves to be measured *in situ*. An Infrared Gas Analyzer (IRGA) can also be used to determine CO_2 exchange from the leaf as well as g_s. Additional useful information that can be acquired or calculated are leaf transpiration rates, leaf temperatures, and the internal CO_2 concentration of the leaves. g_s determined with a porometer or IRGA gives the most detailed information in both temporal or spatial scales about the environmental and internal controls of g_s, and hence transpiration.

g_s measured with porometers and IRGAs has also been used to estimate transpiration from plant canopies. This involves multiplying g_s by the leaf area index to produce a surface or canopy conductance (g_c) $\cdot$ g_c can be used with a canopy boundary-layer conductance, g_a, to estimate transpiration using the Penman–Monteith equation

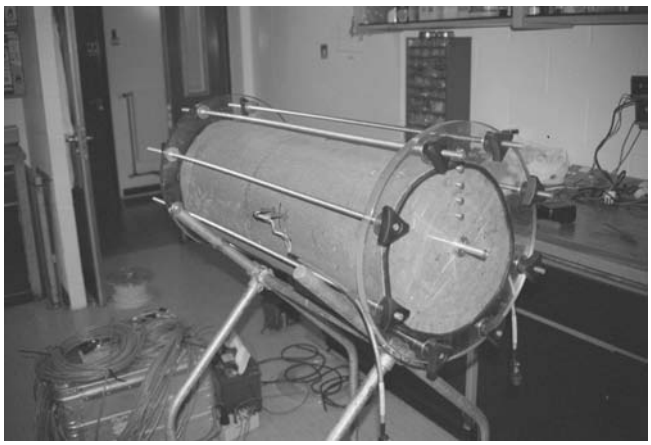

Figure 7 Calibration of the output from a thermal dissipation probe in a large beech (*Fagus sylvatica*) log. In the rig water can be passed through the log at different rates (Photo by John Roberts). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

(*see* **Chapter 45, Actual Evaporation, Volume 1**; Monteith, 1965). This type of approach has been used successfully even in very complex tropical rain forest canopy (Roberts *et al.*, 1993), although detailed information of the vertical distribution of leaf area density and the vertical changes in canopy microclimate are required, which imposes a severe logistical constraint.

Radioactive and Stable Isotope Tracers

A number of tracers have been used to measure transpiration from branches and individual trees. These values can then be scaled up to give stand transpiration. Waring and Roberts (1979) used P^{32} and tritium to measure the transpiration of Scots pine trees. Calder *et al.* (1992) described an approach using deuterium oxide (D_2O) which was injected into eucalyptus trees in plantations. Transpired water was collected in polythene bags tied on to selected branches. From the information of the D_2O injected (M), and the concentration of the transpirate produced over a known time interval ($C\,dt$), transpiration (F) can be calculated.

$$M = F \int_0^\infty C\,dt \tag{6}$$

The time resolution for tracing techniques is relatively low. Transpiration values can only be resolved over a few days. It is, therefore, difficult to use the techniques to understand the influence of short-term environmental fluctuations on transpiration.

SOURCES OF WATER FOR TRANSPIRATION

In the vast majority of cases for land plants, the source of water transpired by plants comes from water stored in the upper layers of soil. Measurements of drying patterns in the few meters of soil below vegetation usually show the largest reduction in soil moisture in the soil surface layer with reduced changes in deeper zones.

Jackson *et al.* (1996) reviewed the pattern of root mass and vertical distribution that had been previously reported for different terrestial biomes. The relationship proposed by Gale and Grigal (1987) was used by Jackson *et al.* to describe the vertical distribution of roots.

$$Y = 1 - \beta^d \tag{7}$$

Y is the cumulative fraction of root mass ($0 < Y < 1$) from the soil surface to a depth of d cm. β is a fitted parameter and has larger values for relatively deeply rooted vegetation. For example, β for temperate coniferous forests is 0.976, but 0.943 for temperate grassland.

The concentration of roots in the soil surface is probably related to a number of factors; the ready availability of plant nutrients from litter deposition and decomposition in the soil surface, and the ease with which surface roots can exploit small frequent inputs of rainfall from storms after soil drying has progressed from a saturated condition. Roots in the soil surface offer the shortest pathway, that is, the lowest resistance for water movement into the plant, and the association of a large population of fine roots that are associated with large structural roots that are in the soil surface for stability against wind blow.

Nevertheless, the small amount of deep roots (constituting a relatively small fraction of total root biomass) have crucial roles in acquiring water for growth and survival during drought. The tropical rainforest in the eastern part of the Amazon basin in Brazil remains evergreen even though the dry season may extend to 4 to 5 months. In this forest Nepstad *et al.* (1994), founds roots to a depth of 18 m. The water stored below 2 m in the soil and available to the trees provided more than 75% of the water extracted from the entire profile during the dry season.

HOW WILL GLOBAL CHANGES INFLUENCE TRANSPIRATION?

Vegetation affects the amount of evaporation from a catchment through transpiration and interception (*see* **Chapter 43, Evaporation of Intercepted Rainfall, Volume 1**). Both vary with vegetation type, so a change in vegetation due to a change in climate would have an effect on (catchment) evaporation, with the effect of course depending on the extent of the change in vegetation. The rate of transpiration for a given plant, however, will also be influenced by climate change. Plants absorb CO_2 from the atmosphere as part of the process of photosynthesis, and this CO_2 is absorbed through stomata.

An increasing concentration of CO_2 in the atmosphere has two main (hydrologically relevant) effects on plants, which have been demonstrated through experiments at the leaf and plant scale. These influences are likely to have opposing effects on water use by vegetation. First, net photosynthesis increases with increasing carbon dioxide concentrations in the atmosphere. This is expected to increase plant growth and leaf area index. This should be expected to increase vegetation transpiration (e.g. Long, 1999).

On the other hand, a second effect of CO_2 enrichment is to make stomata smaller, which has the effect of reducing the stomatal conductance to evaporation. The largest reduction in stomatal conductance, as much as 40%, has been found in grasses and herbaceous species, with a lower reduction (~20%) being more typical in woody vegetation (Saxe *et al.*, 1998). The reductions in stomatal conductance lowers the rate of transpiration for a given set of meteorological inputs, and the water use efficiency (WUE: ratio of carbon uptake (i.e. biomass growth) to transpiration) of plants increases. This has frequently been taken to mean that increased CO_2 concentrations will lead to a reduction in catchment scale evaporation, but this is not necessarily so. In fact, many of the few studies that have looked at scales larger than the plant have shown that evaporation per unit area does not decrease as CO_2 concentrations rise, largely because the increased WUE is offset by additional plant growth. Kruijt *et al.* (1999), for example, estimated that increasing CO_2 concentrations would have little net effect on transpiration over forest. In a study using a dynamic vegetation model coupled with a climate model to simulate the effects of both CO_2 increase and associated climate change Betts *et al.* 2000, found that, at the global scale, the effects of CO_2 – enrichment and temperature – increase on plant growth offset reduced stomatal conductance. Also, catchments contain a mix of land uses – including bare soil – which will be affected differently by increasing concentrations of CO_2. The higher proportion of total evaporation derived from intercepted water, the less the direct effect of increasing CO_2 on catchment evaporation. There is clearly considerable uncertainty over the effect of CO_2 enrichment on plant transpiration (Amthor, 1995; Jarvis *et al.*, 1999), and hence catchment evaporation (Field *et al.*, 1995), and it is not possible to draw any general conclusions.

43: Evaporation of Intercepted Rainfall

JORGE SOARES DAVID[1], FERNANDA VALENTE[1] AND JOHN HC GASH[2]

[1] *Instituto Superior de Agronomia, Tapada da Ajuda, Lisboa, Portugal*
[2] *Centre for Ecology and Hydrology, Wallingford, Oxfordshire, UK*

When rain falls on to a vegetated surface (gross rainfall), a part is intercepted by the canopy and evaporated directly back into the atmosphere (interception loss). The remainder of the rainfall reaches the ground (net rainfall) either through gaps and by dripping from the canopy (throughfall), or by running down the main stem (stemflow). The canopy storage capacity is the minimum amount of water necessary to completely saturate the canopy surface. Interception loss is conventionally measured as the difference between the incident gross rainfall, and the sum of throughfall and stemflow. It is usually a significant component of the overall evaporation and may play an important role in watershed water balance. The total amount of interception loss depends on the rate of evaporation from the wet canopy, the canopy storage capacity, and the distribution and intensity of rainfall. Interception loss is particularly high in forests due to their high aerodynamic roughnesses. Available models range from empirical relationships to physically based conceptual models. Within the latter, the Rutter-type models are those that have been taken up as the more generally applicable technique. Most of the models rely on the use of the Penman–Monteith equation to estimate the evaporation rate. Current research is largely directed at modeling in horizontally heterogeneous vegetation, where the Penman–Monteith equation may not be valid.

INTRODUCTION

When rain falls on to a vegetated surface (gross rainfall, P_g), a part is intercepted by the canopy and evaporated directly back into the atmosphere. This is termed the *interception loss* (I). The remainder of the rainfall reaches the ground surface either directly through gaps in the canopy and by dripping from the canopy (throughfall, T_f), or by running down the main stem or trunk (stemflow, S_f). Figure 1 shows these main components of the interception process. The actual amount of water that reaches the ground is termed *net precipitation*, and is the sum of throughfall and stemflow. Unless there is fog or cloud interception (*see* **Chapter 38, Fog as a Hydrologic Input, Volume 1**), the net rainfall is less than the incident gross rainfall, which falls on the top of the canopy.

The concept of a canopy storage capacity was first introduced by Horton (1919). Water is retained on the surface of leaves, twigs, and branches by surface tension until the surface tension forces are in balance with the gravitational forces (Leonard, 1967). The canopy then reaches its storage capacity (S) and dripping starts (canopy drainage). S is then defined as the minimum amount of water necessary to completely cover the canopy surface in still air.

The interception process may play an important role both in the water balance of watersheds and in the ecology of the vegetation. Interception occurs with all vegetation types: a forest canopy, understorey or litter layer, or for crops and other short vegetation (Zinke, 1967; Calder, 1990; Ward and Robinson, 2000). However most research, both theoretical and experimental, has been focused on rainfall interception by forests.

The interception loss from forests is usually a significant component (25%–75%) of overall evaporation (Gash and Stewart, 1977; McNaughton and Jarvis, 1983; Shuttleworth, 1988). Expressed as a percentage of gross rainfall, interception loss may vary from 9% in Amazonia (Lloyd *et al.*, 1988) to values as high as 60% in *Picea sitchensis* and *Picea abies* stands in Brittany (Forgeard *et al.*, 1980). This wide variation is mainly due to differences in time distribution patterns of rainfall between regions. The largest

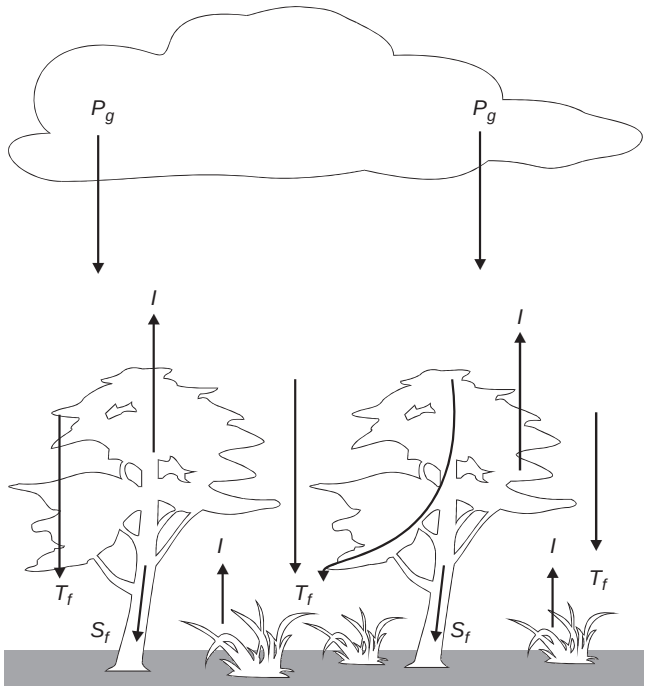

Figure 1 The main components of the rainfall interception process: Gross rainfall (P_g), Interception loss (I), Throughfall (T_f), and Stemflow (S_f)

evaporation losses occur in climates with a well-distributed rainfall of frequent, small storms; rather than in those with a few large ones (Rutter, 1975).

The redistribution of rainfall at the ground surface may also be quite important for the ecology and water relations of the vegetation. Typically, throughfall has a high spatial variability with dripping concentrated mainly at the edges of trees crowns (Eschner, 1967; Shuttleworth, 1988; Lloyd and Marques, 1988; Ward and Robinson, 2000). Additionally, and in spite of being a minor component of net rainfall, stemflow can concentrate a significant amount of water in the soil near the stem base (Eschner, 1967; Rutter, 1975; Herwitz, 1982). The ecological importance of this nonuniform distribution of net rainfall is further increased considering that this incoming water is enriched in nutrients (Chamberlain, 1975; Miller, 1984). The spatial variability of throughfall is particularly acute, and clearly nonrandom, under forests with prominent trees (Herwitz and Slye, 1995), at forest edges (Darnhofer *et al.*, 1989) and under isolated trees (King and Harrison, 1998; Gómez *et al.*, 2002), particularly during rainfall events with high wind speeds.

MEASURING INTERCEPTION

Conventionally, interception loss is measured as the difference between the incident gross rainfall, and the sum of throughfall and stemflow (net rainfall) measured at ground-level. Gross rainfall may be measured above the forest canopy or in a nearby clearing. Measurement of gross rainfall in forest clearings may be prone to errors because of the possible variability of rainfall in space, particularly during convective storms. Gross rainfall is probably best measured above the forest canopy in the same location as the net rainfall measurements. However, measurements of rainfall above the canopy are liable to undercatch as a result of turbulence around the gauge. According to Roberts *et al.* (2004), these errors are minimized if measurements are made just above the canopy.

To overcome the great spatial variability of throughfall, it is usually measured by intensive sampling using an array of funnel or trough gauges, placed randomly beneath the forest canopy. Typically, 20 to 30 funnel gauges would be needed to sample an approximately 1500-m^2 forest plot, with 50 to 90 trees (e.g. Valente *et al.*, 1997). A better long-term statistical sample is obtained by moving the gauges to new random positions after each reading. In heterogeneous forest, such as tropical forests, throughfall variation in space is even greater, and particularly large gauging samples are then needed (Lloyd and Marques, 1988; Bruijnzeel, 1990; Loescher *et al.*, 2002).

Stemflow is usually measured using gutters sealed around the trunk leading to a collecting/measuring device. Stemflow is also very variable from tree to tree. The sampling problems referred to above for throughfall also apply to stemflow, but are not so acute because stemflow is usually a small component of the canopy water balance (e.g. Lloyd *et al.*, 1988; Hutjes *et al.*, 1990; Valente *et al.*, 1997).

Some workers (e.g. Calder and Rosier, 1976; Calder *et al.*, 1986, 1996) prefer to use large plastic sheet gauges to measure the net rainfall. These gauges collect 100% of both throughfall and stemflow over an area of approximately 20 m^2. Although this method overcomes the problem of sampling small-scale variability, it misses any information on the variation of net rainfall in space. Also, while sheet gauges seem to work well in plantation forests, they are problematic when there is a dense understorey, in the case of widely spaced trees (Ward and Robinson, 2000) or in heterogeneous tropical forest (Roberts *et al.*, 2004). Furthermore, it can be difficult to maintain the plastic sheets free from leaks frequently caused by insects and rodents.

As aforementioned, interception loss is conventionally indirectly estimated as the difference between gross rainfall and net rainfall, that is, a small difference between two large numbers. Therefore, both gross rainfall and net rainfall need to be measured with precision to provide an accurate assessment of the interception loss.

Alternative, more direct methods of measuring the evaporation from wet canopies have been attempted, such as the micrometeorological Bowen ratio method (Stewart,

1977) (*see* **Chapter 40, Evaporation Measurement, Volume 1**). Techniques have also been developed to measure the change of water stored on the canopy, either by weighing cut branches (Rutter, 1967) or trees (Teklehaimanot and Jarvis, 1991), by applying straingauges to branches *in situ* (Hancock and Crowther, 1979), or through γ-ray (Calder and Wright, 1986) and microwave (Bouten *et al.*, 1991) attenuation. However, none of these methods have been accepted as a generally applicable technique. More recently, Mizutani *et al.* (1997) and Gash *et al.* (1999) have shown that fast-response ultrasonic anemometers, with good water shedding properties and spike-suppressing software, can function normally during rainfall. The eddy correlation method (*see* **Chapter 40, Evaporation Measurement, Volume 1**) can thus be used to measure evaporation from wet canopies in the turbulent boundary layer above the vegetation. Gash *et al.* (1999) have used this method to measure sensible heat-flux and then derive the evaporation from a wet pine canopy as the residual in the energy balance equation.

FACTORS AFFECTING INTERCEPTION

The total amount of interception loss from a particular vegetation cover depends on the rate of evaporation from the wet canopy as well as on the duration of canopy wetness (Rutter, 1975; Ward and Robinson, 2000). The latter is influenced both by the canopy storage capacity and by the distribution and intensity of rainfall.

Evaporation Rate from Wet Canopies

The most realistic description of evaporation from canopies is given by the Penman–Monteith equation (Monteith, 1965). When the canopy is dry, the flux of water vapor from the canopy surface (transpiration, λE_T) can be expressed (*see* **Chapter 41, Evaporation Modeling: Potential, Volume 1**, **Chapter 45, Actual Evaporation, Volume 1**) as:

$$\lambda E_T = \frac{sA + \rho\, c_p D/r_a}{s + \gamma(1 + r_c/r_a)} \tag{1}$$

where E_T is the transpiration rate, A the available radiative energy, c_p the specific heat capacity of air at constant pressure, D the vapor pressure deficit, γ the psychrometric constant, s the slope of the saturation vapor pressure curve, λ the latent heat of vaporization of water, and ρ the density of air. r_a is the aerodynamic resistance that constitutes the control of vapor transfer from the foliage surfaces into the atmosphere and r_c is the surface (or canopy) resistance that represents the combined influence of stomata from all leaves.

When the canopy is wetted by rain, evaporation of intercepted rainfall is largely a physical process that does not depend on the functioning of stomata. The evaporation rate from a wet canopy (interception loss, λE_I) may therefore be expressed by equation (1), with $r_c = 0$:

$$\lambda E_I = \frac{sA + \rho\, c_p D/r_a}{s + \gamma} \tag{2}$$

Thus, for a given temperature, the rate of evaporation of intercepted water mainly depends on: the available energy (A), the vapor pressure deficit of surrounding air (D), and the aerodynamic resistance (r_a). The aerodynamic resistance to water vapor transfer is a function of the roughness characteristics of the evaporative surface and of wind speed (Monteith and Unsworth, 1990). With increasing height of vegetation, there is usually an increase in roughness length (z_0) and therefore, a decrease in the aerodynamic resistance (Rutter, 1975).

For many years there was a controversy between some authors who argued that evaporation from wet canopies was a net loss for the water balance and others who supported the view that it was just balanced by a corresponding reduction in transpiration during rainy periods (Ward and Robinson, 2000). These contradictory arguments can be easily clarified by defining a "relative interception rate", dividing equations (2 and 1) (Monteith, 1965; Rutter, 1975):

$$\frac{E_I}{E_T} = 1 + \frac{\gamma}{s + \gamma}\left(\frac{r_c}{r_a}\right) \tag{3}$$

The graph of the relationship between E_I/E_T and r_c/r_a is shown in Figure 2. From this it can be seen that when r_c and r_a are of similar size ($r_c/r_a \approx 1$), as happens with short vegetation, the rate of evaporation of intercepted water will be about the same as the transpiration rate would be in similar weather conditions. However, when r_a is an order of magnitude lower than r_c ($r_c/r_a \approx 10$), as it is for forests (Stewart and Thom, 1973; Thom, 1975; McNaughton and Jarvis, 1983), intercepted water evaporates at 3 to 5 times the transpiration rate (Stewart and Thom, 1973; Rutter,

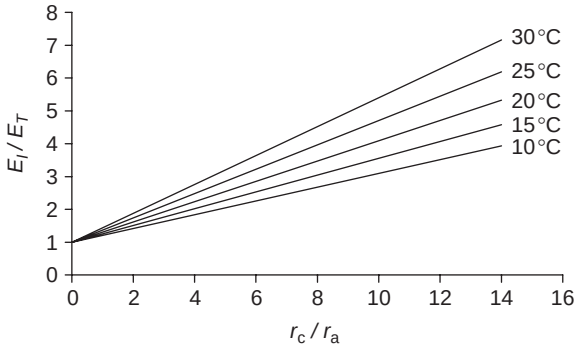

Figure 2 Change of relative interception rate (E_I/E_T) with the ratio r_c/r_a and temperature

1975). The evaporation from wet canopies is thus clearly a net water loss for forests, but not so for short vegetation. This explains the use of the term "interception loss" for forest ecosystems.

The main reason for the high evaporation rate of intercepted rainfall from forests is their high aerodynamic roughnesses and, therefore, correspondingly very low values of r_a. An additional consequence for aerodynamically rough vegetation, such as forests, is that the aerodynamic (right-hand) term of equation (2) is often much larger than the radiation term (Calder, 1990). Under these circumstances, it is the supply of advected energy, via the cooling of the above air mass that is able to support the high rates of evaporation from wet forests (Stewart, 1977; Pearce *et al.*, 1980; Calder, 1990). High evaporation rates are possible even at night when net radiation is close to zero (Pearce *et al.*, 1980; Calder, 1990). Dry-air advection, heat added to the air or removal of water from it may be responsible for the maintenance of a significant air vapor pressure deficit during rainfall events (McNaughton and Jarvis, 1983).

Reviewing the existing literature, Roberts *et al.* (2004) found that the average evaporation rate for wet forest canopies is a very conservative parameter. Values from forests in Great Britain (Gash *et al.*, 1980), in France (Gash *et al.*, 1995), in Portugal (Valente *et al.*, 1997), in Amazonia (Lloyd *et al.*, 1988), in West Africa (Hutjes *et al.*, 1990), and in West Java (Calder *et al.*, 1986) are remarkably similar (varying between 0.17 and 0.34 mm h^{-1}). As such, it would seem that the driving meteorological variables during rainfall usually do not vary much from tropical to temperate latitude forests: radiation is low, vapor pressure deficit is small, and wind speeds are similar.

Canopy Storage Capacity

The canopy storage capacity (S) is usually considered as a constant parameter for a given vegetation cover. However, some authors consider that it may vary with drop size and therefore with rainfall intensity (Calder, 1986; Hall, 1992).

Canopy storage may be evaluated both by indirect or direct methods. Leyton *et al.* (1967) developed the most commonly applied indirect method, whereby S is estimated as the negative intercept of the envelope line between throughfall and gross rainfall, with a preestablished slope (close to 1). By this method, S is considered equal to the total interception loss for those events when the evaporation during rain is negligible.

The alternative direct methods usually rely on weighing after artificial wetting (Aston, 1979; Herwitz, 1985; Teklehaimanot and Jarvis, 1991; Liu, 1998; Llorens and Gallart, 2000) or on γ-ray (Calder and Wright, 1986) and microwave (Bouten *et al.*, 1991; Klaassen *et al.*, 1998) attenuation.

Canopy storage values can range from 0.2 to 3.8 mm depending on species, leaf area index, canopy cover, vegetation structure, and density (Table 1). There is no evidence of a systematic difference between forest and short vegetation. Within forests, S tends to be higher in conifers than in broadleaves. Canopy storage is particularly low in deciduous forests during the leafless (winter) period.

Rainfall Distribution and Intensity

The interception loss is usually greater from intermittent than from continuous rain, when the intensity and total duration are the same (Rutter, 1975). This is due to the significance of the frequency of rewetting cycles, which

seems more important than either the duration or the amount of rainfall (Ward and Robinson, 2000). In some particular situations, the rate of interception loss may be limited by rainfall intensity when the latter is lower than the potential evaporative rate (Rutter, 1975).

It is helpful to consider the evaporation of intercepted water on a rainfall event basis, assuming that each individual storm is preceded by a rainless period long enough to allow the canopy and stems to dry out completely. Making this simplifying assumption, each rainfall event may be divided into three main distinct phases (Gash, 1979): (1) a wetting phase, from the onset of rain until the canopy is saturated; (2) a saturation phase, and (3) a drying phase, lasting from the end of rainfall until the canopy and trunks are completely dry. The total interception loss during the storm can then be considered as the sum of total evaporation loss during phases (1) and (2) plus the evaporation during phase (3) which is equal to the canopy storage (S). From this, it is clear that (1) interception loss of long lasting rainfall events will mainly depend on the rate of evaporation, and (2) interception loss of short-duration events will be mainly determined by the canopy storage. These two extreme situations are typified by the contrasting climatic conditions of New Zealand (Pearce and Rowe, 1981; Rowe, 1983) and tropical rainforests (Lloyd *et al.*, 1988; Herwitz, 1985), respectively. Temperate climatic conditions will lie between these two extremes.

MODELING INTERCEPTION

Interception models allow experimental results to be extrapolated both in time and in space, and they are required as a component of hydrological and meteorological forecasting models. However, models can also provide insight into the functioning of the process.

Despite the pioneering work of Horton (1919), who pointed out that rainfall duration was the key variable, most of the early modeling studies attempted to express the interception loss in relation to gross rainfall, either as a percentage or through simple empirical relationships (Zinke, 1967). However, these relationships are site specific and extrapolation to areas with different rainfall regimes is likely to result in erroneous predictions.

Rutter *et al.* (1971, 1975) were the first to model forest rainfall interception recognizing that the process was primarily driven by evaporation from the wetted canopy. The Rutter model calculates a running water balance of the water stored on the canopy and trunks, relating it to rates of rainfall, drainage, and evaporation. It requires both above canopy rainfall and meteorological data (in short time-steps) as well as four parameters describing the structure of vegetation (among which are the canopy storage capacity and the trunk storage capacity). Trunk storage (S_t) is usually very small compared to canopy storage (S). The evaporation is calculated from the Penman–Monteith equation (2). The main practical problem is the high data requirements of the model. Gash (1979) proposed a simpler storm-based model, known as *Gash's analytical model*. This model incorporates some simple features of the linear regression models, but keeps the fundamental physical background of the Rutter model. The analytical model is less demanding in driving data. It requires the same four structural parameters, as the Rutter model, but applies a single constant value for both the average rainfall intensity and the average evaporation rate during the whole simulation period. This model has been used with considerable success in a wide range of conditions, from temperate forests (Gash *et al.*, 1980; Pearce and Rowe, 1981; Dolman, 1987) to tropical rainforests (Lloyd *et al.*, 1988; Hutjes *et al.*, 1990).

However, when both the Rutter model and Gash's analytical model were used in sparse forests, they were found to overestimate the interception loss (Lankreijer *et al.*, 1993; Gash *et al.*, 1995; Valente *et al.*, 1997). This led to reformulations of both Gash's model (Gash *et al.*, 1995) and the Rutter model (Valente *et al.*, 1997) to take into account the forest sparseness and to improve boundary conditions. In these sparse canopy versions of the models, the wet canopy evaporation is considered linearly dependent on the canopy cover fraction (c). Figure 3 shows the conceptual framework of the sparse forest Rutter model. The reformulated versions of these models are able to simulate well the interception loss both in sparse and closed canopies since, when canopy cover tends to 100%, the sparse model versions reduce to the original ones. Recent applications of the revised Gash's model confirm that model predictions are good in a wide range of conditions, from closed to very sparse canopies (Gash *et al.*, 1995; Valente *et al.*, 1997; Dykes, 1997; Asdak *et al.*, 1998; Carlyle-Moses and Price, 1999; Jackson, 2000). Van Dijk and Bruijnzeel (2001a, 2001b) have further modified the revised version of Gash's model to allow it to be applied to rapidly growing vegetation where the leaf area index is changing through time.

As an alternative to these Rutter-type models, Calder (1986) developed a stochastic model in which the canopy storage varies with drop size, and therefore with rainfall intensity. In a subsequent two-layer version of the stochastic model (Calder, 1996), the size of the primary raindrops is related to rainfall intensity, but the size of the secondary drops, dripping from the upper to the lower levels, is species-dependent. However, at present only the Rutter and Gash models or their derivatives have been taken up as a generally applicable technique (Roberts *et al.*, 2004).

Although the controversy over whether the canopy storage capacity should be treated as a variable or a fixed parameter (Roberts *et al.*, 2004) has not been solved, the above-mentioned models offer a range of reliable modeling tools of different complexity. However, all these models are

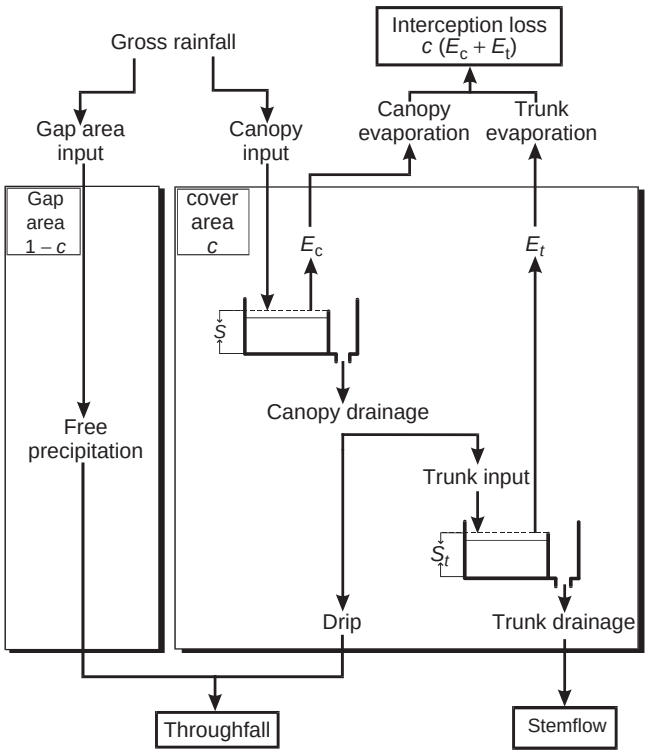

Figure 3 The conceptual framework of the sparse Rutter model (Adapted from Valente *et al.*, 1997)

based on the assumption of horizontally uniform conditions. Such conditions do not always occur and current research is largely directed at modeling interception under these circumstances, where the application of the Penman–Monteith equation may not be valid. For example, small tropical islands and tropical coastal sites have particularly high rates of interception loss, which are poorly simulated by the existing models (Schellekens *et al.*, 1999, 2000; Roberts *et al.*, 2004). Forests with prominent trees and savannah-type ecosystems with isolated trees are another example. In some of these cases, it may also be important to consider the influence of the incident angle of wind-driven rainfall on the high, and nonrandom, spatial variation of throughfall. Three-dimensional models (e.g. Herwitz and Slye, 1995; Xiao *et al.*, 2000), coupled with improved estimates of evaporation, can probably constitute a good basis for the development of new modeling solutions to apply in spatially heterogeneous forests.

44: Evaporation from Lakes

JONATHAN W FINCH AND ROBIN L HALL

Centre for Ecology and Hydrology, Wallingford, Oxfordshire, UK

Lakes are an important part of the hydrological cycle, but quantifying the evaporation rates from them is not a trivial task. The amount of radiant energy captured by a lake is generally the dominant control on the annual evaporation rate. At shorter time periods, the major factors affecting lake evaporation are: the albedo, the heat-storage term of the energy budget, and the atmospheric diffusion processes. The albedo is a function of the solar elevation angle and the proportion of downward diffuse radiation, and can be predicted from empirical relationships. The heat-storage term can decouple the evaporation rates from the net radiation, but can be estimated simply in the case of well-mixed water. However, in the situation where the lake becomes thermally stratified, more complex, hydrodynamic models are required. The three commonly used methods of estimating lake evaporation are: mass transfer, energy balance, and combination equations. There are strengths and limitations to each of these methods.

INTRODUCTION

A lake is defined as a large inland body of water. Globally, lakes cover an area of about 1.5 million km^2 and store approximately 0.8% of the nonfrozen freshwater (Shihklmonaov, 1993). Although this may seem a small percentage of the world's freshwater, lakes are an important part of the hydrological cycle because they act as storage that can have a significant effect on the flows in rivers. They also provide a range of aquatic habitats. From the human perspective they can be vital sources of water supply, in which case they may be natural or manmade. Forecasting the evaporative losses from these water bodies is important for a number of activities, such as reservoir catchment management operations, wetland habitat conservation, and so on. However, quantifying the evaporation from lakes is not a trivial task because there are a number of factors that can affect the evaporation: the climatology and the physiography of the lake and its surroundings. Unlike other land surfaces, the water in a lake is liquid and thus has the potential to transport stored heat within the lake itself and into and out of the lake.

The evaporation rate is controlled by the energy available at the water surface, and the ease with which water vapor diffuses into the atmosphere. This section begins by considering the energy balance of lakes, and the factors affecting it. The factors affecting the processes of diffusion into the atmosphere are then considered. Finally, the three methods most commonly used to estimate the evaporation from lakes are described.

THE ENERGY BALANCE

The amount of radiant energy captured by the lake (net radiation) is generally the dominant control on the annual evaporation rate. The net radiation, Q^*, is the difference between the downward and reflected solar radiation, plus the difference between the downward and upward longwave radiation (*see* **Chapter 39, Surface Radiation Balance, Volume 1**).

Net Short-wave Radiation

The net short-wave radiation, K^*, is that portion of the downward solar radiation captured by the lake, taking into account losses due to reflection. A portion, $K_{\downarrow,d}$, of the solar radiation incident at the top of the atmosphere, K_0, reaches the lake surface as the direct beam; see Figure 1. Some solar radiation also reaches the lake surface as the diffuse component, $K_{\downarrow,f}$, after scattering by atmospheric particles and clouds. Part of the solar radiation reaching

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

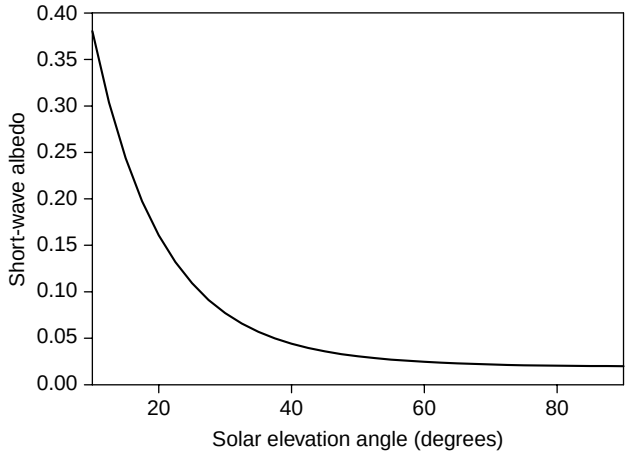

Figure 2 Theoretical variation of the albedo of a water surface with the solar elevation angle

the lake is reflected so that the net short-wave radiation is:

$$Q^* = (1 - \alpha_{sw})(K_{\downarrow,d} + K_{\downarrow,f}) \quad (1)$$

Where α_{sw} is the short-wave albedo, or reflection coefficient, of the downward global solar radiation, that is, the sum of the diffuse and direct beam. The albedo may be affected by a number of factors, such as the turbidity and the reflection coefficient of the lake bottom. There is a considerable literature on the albedo of water, albeit mainly relating to oceanography; Jerlov (1976); Kirk (1994); Mobley (1994) discuss the subject in detail.

The albedo will vary, both over the course of a day and over a year because it is a function of the solar elevation angle. For an infinitely deep body of pure water with no suspended particles and a perfectly smooth surface, the albedo can be calculated from a combination of Snell's law and Fresnel's equation, Figure 2. The albedo has a very low value, about 0.02, at high elevation solar elevation angles. However, as the elevation angle decreases, the albedo steadily increases until, at an angle of 37°, it has doubled from a value of 0.02 to 0.04. At lower elevation angles it rises rapidly. Davies (1972) found that this curve was in good agreement with observations for cloudless skies, that is, when the direct beam can be expected to be significantly greater than the diffuse radiation. However, he noted systematic differences from the theoretical model. At high solar elevation angles, the measured albedo exceeded the model values, which he attributed to the effect of waves on the water surface; whereas at a solar elevation angles less than 30°, the measured values were less than theoretical values, which he attributed to the increasing proportion of diffuse radiation. The minimum albedo, corresponding to high solar elevation angles, will be a function of both the latitude of the site and the time of year. Since the periods of high albedo are associated with low downward solar radiation, the impact of the variations in albedo on the annual evaporation rate is diminished.

For cloudy conditions, the situation is complicated by the fact that a larger proportion of the downward solar radiation is in the form of diffuse radiation, with a tendency to increase the albedo. Thus, the albedo will include a component that is a function of the amount and angular distribution of the downward diffuse solar radiation.

Predicting the albedo of water is thus not a trivial issue. Although physically rigorous numerical models of albedo have been constructed, for example Mobley (1995), they are demanding both computationally and in terms of the input parameters. These models are usually regarded as research tools, and empirical models have tended to be used in practice. Anderson (1954) measured albedo at Lake Hefner, in the southwest of the USA, and produced a series of regression equations relating the albedo to the solar elevation angle and the cloud type, for example, low overcast, high broken, and so on. In practice, this method is difficult to use because the information on the clouds is not readily available. Payne (1972) made measurements of albedo from platforms at two sites (the Sargasso Sea and coastal waters off Massachusetts) to produce a look up table, reproduced graphically in Figure 3, that related the albedo of water to the solar elevation and the transmissivity of the atmosphere (defined as the ratio of the downward solar radiation at the Earth's surface to that at the top of the atmosphere).

Although it is uncertain to what extent Payne's model can be applied to inland waters, the optical characteristics of large, deep lakes are probably not too different to those of oceanic waters. However, for smaller, shallower water lakes, this is not necessarily true because of the possibility of reflectance from the bottom, differences in the waves on the surface, and differences in the amount and type of suspended particles; all of which will tend to increase the albedo.

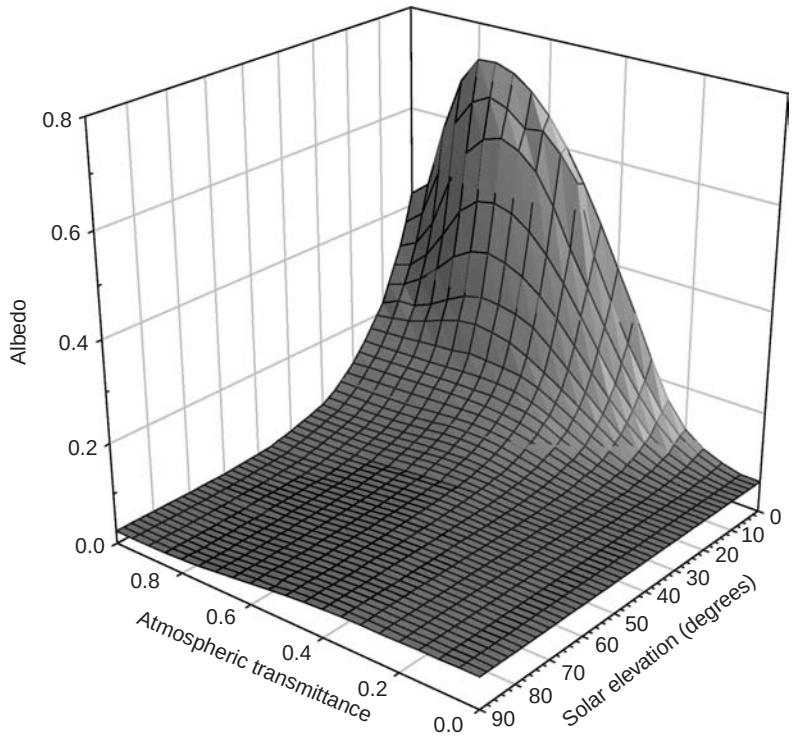

Figure 3 Variation of the albedo of a water surface as a function of solar elevation angle and atmospheric transmittance (Using the data of Payne, 1972)

The surface of the water will rarely be perfectly flat, because of wind-induced waves. The size and orientation of these waves will be a function of the strength and direction of the wind, and the fetch and depth of the lake. The effect of waves on the water surface will be to change the distribution of elevation angles of the incident radiation. However, Richter (1988) failed to detect any correlation between albedo and wind speed in four years of measurements of the radiation balance at a lake in Germany, so it would seem that this factor may not be significant.

Suspended particles in the lake will tend to increase the albedo, mainly by backscattering the radiation that has penetrated into the lake. This effect will be a function of the size and number of the suspended particles that will depend on the type of lake; the phytoplankton abundance in the upper layers will have an effect, as will the amount of suspended sediments. Floating aquatic vegetation can also have an impact on the albedo. Finally, reflectance from the bottom will be a function of the albedo of the bottom materials, the depth and turbidity of the water, and the angle of the incident radiation. Reflectance from the bottom can generally be neglected for lakes over 5 m deep.

Net Long-wave Radiation

There is a significant exchange of radiant energy between the lake surface and the atmosphere in the form of long-wave (thermal) radiation. Net long-wave radiation can be expressed as the difference between the downward radiation, $L_{\downarrow}$, and upward radiation, $L_{\uparrow}$. The downward radiation is related to the temperature and humidity structure of the atmosphere and the cloud cover, because its dominant source is the water vapor molecules in the atmosphere. The reflectivity of the water surface is normally around 0.02; however, it is often taken to have a value of zero, which does not introduce any significant error. The upward radiation emitted from the surface of the lake and can be calculated from the Stefan–Boltzman law:

$$L_{\downarrow} = \varepsilon_a \sigma (T_s + 273.13)^4 \qquad (2)$$

where ε_a is the effective emissivity, σ is the Stefan–Boltzman constant (4.9×10^{-9} MJ m^{-2} K^{-4} d^{-1}) and T_s is the temperature of the water, at the surface, in degrees Celsius.

Both Anderson (1954) and Davies (1972), on the basis of numerous measurements, concluded that the average value of the effective emissivity is 0.97. However, Richter (1988), also on the basis of measurements, found a value of 0.983 was more appropriate. This latter value is supported by more recent work, for example Ogawa *et al.* (2002).

Available Energy

When time-steps of less than a year are of interest, it is generally more convenient to consider the available energy,

A, rather than the net radiation, as this takes into account the change in the heat stored in the lake, W, and the advected energy, A_q, due to inflows and outflows of water.

$$A = Q^* + W + A_q \tag{3}$$

The seasonal distribution of evaporation can be significantly affected by the heat-storage capacity of the lake; which is, to a large extent, determined by its depth. In tropical regions, the temperature of large lakes is generally remarkably uniform, for example, Sene *et al.* (1991). However, at higher latitudes, where there is a strong seasonal variation in the solar radiation input, the stored energy in the lake introduces a time lag with the result that the evaporation rate is decoupled from the net radiation. This is illustrated in Figure 4, which shows the calculated energy balance for two theoretical, well-mixed lakes, at a latitude of 51°36'N in southern England, with water depths of (a) 5 and (b) 15 m. The radiation components were calculated using the model of Finch and Gash (2002), using a daily time-step, for the period 1972 to 2002 inclusive, and then aggregated to 10-day period 30-year averages. The net radiation closely follows the noon solar elevation for both depths, but for a depth of 5 m, there is a lag, of about a month, before the maximum latent heat-flux occurs whilst, for a depth of 15 m, the lag is about two months.

The situation becomes more complicated if a lake becomes thermally stratified. Detailed discussions are given by Imberger and Patterson (1989) and Henderson–Sellers (1984). The temperature dependence of the density of water is a key factor (the maximum density occurs at a temperature of 4 °C). Stratification occurs in large, deep lakes (at mid and high latitudes), and may accentuate the time lag between the net radiation and the evaporation rate. During the early spring, most of the large, temperate lakes exhibit a nearly uniform temperature distribution with depth (homothermal conditions). As the year progresses and the weather warms up, the lake receives heat at an increasingly rapid rate. Initially, the lake remains homothermal because the heat received at the surface layers is transported to deeper layers by wind-induced currents and turbulence. As the rate of heating continues to increase, it begins to exceed the rate of transfer to deeper layers with the result that the temperature of the surface layers increases faster than those of the deeper layers. As the heating continues, a point of inflection develops in the temperature depth profile forming a well-mixed upper layer (the epilimnion) is formed, with relatively intense gradients at its bottom boundary. The plane of maximum temperature gradient is known as the *thermocline*. During the remainder of the heating period, the epilimnion deepens and the thermocline slowly descends into the lake. Once a thermocline has formed, the deeper regions of the lake are relatively uninfluenced by changes in surface conditions.

In the fall, after the lake has attained its maximum heat content, the wind mixing is augmented by convective mixing as a result of surface cooling. The resultant increase in density causes the water to sink and the thermocline moves down rapidly into the deeper layers of the lake, often referred to as turnover. The thermocline continues to move down rapidly as the well-mixed upper layers cool further, until the whole lake again attains homothermal conditions.

A "reverse" stratification can be created in winter, especially in continental climates where the average temperature falls below 4 °C, but the cool layer is much thinner than the epilimnion of summer. Sufficient cooling may permit the lake to freeze over, whilst retaining the temperature of the deeper water in the range of 2–4 °C. If the minimum (winter) temperature of the lake is greater than 4 °C, then there is only one turnover (in the fall).

The net result of the heat storage is that water temperatures are lower than air temperatures during the summer and vice versa during the winter. Thus, the evaporation rates from large deep lakes may be higher in winter than in summer (Blanken *et al.*, 2000).

Change in Heat Storage

It is simple to measure the change in lake heat storage, for example, by deploying thermistors at a range of depths and at a number of locations. However, estimating the change in heat storage using a model can prove a challenge. Predicting the development of thermal stratification requires a comprehensive numerical hydrothermal model. Suitable models are described by Ahsan and Blumberg (1999), Hamilton and Schladow (1997), Hostetler and Bartlein (1990), and Henderson-Sellers (1984). These models are a major topic in themselves and so will not be described here. The problem can be significantly simplified if it is assumed that: the lake is horizontally uniform (so that a one-dimensional model can be used), the heat flux at the bottom of the lake is negligible, the time-step is daily or greater, and the water is well mixed. An analytical solution, using commonly available meteorological data, is provided by the concept of equilibrium temperature. Edinger *et al.* (1968) introduced this concept (and an associated time constant) as the temperature towards which the water temperature is driven by the net heat exchange, that is, when the water is at equilibrium temperature, the net rate of heat exchange is zero. From this, he was able to derive an expression for the temperature of a well-mixed lake as a function of time and water depth, and hence the change in heat stored. Similar approaches have been taken by Keijman (1974), de Bruin (1982), and Finch (2001). The concept was extended by Fraedrich *et al.* (1977) to include the effect of energy advected to a reservoir by inflow and outflow.

Recently, Finch and Gash (2002) have developed a simple finite difference model, where the water temperature is derived by iteration. The model successfully estimated

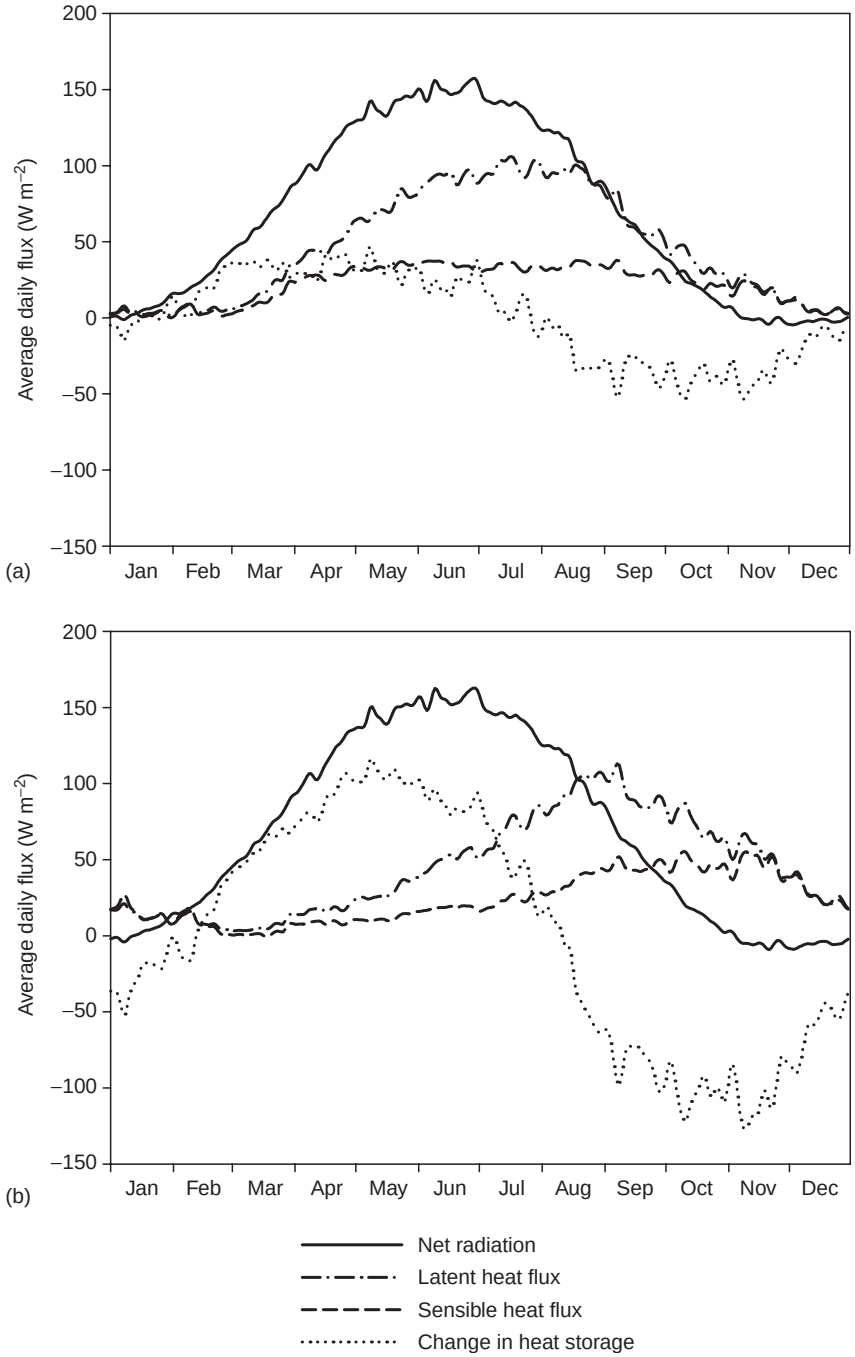

Figure 4 The modeled 28-year average energy-budget components for lake depths of (a) 5 m and (b) 15 m

the annual evaporation rates, from a reservoir with an area of 17.2 ha in southeast England, to an accuracy of 2%, and the monthly evaporation rates to an accuracy of 10%.

Advected Energy

The heat transferred into a lake by precipitation, and inflows and outflows of water may be a significant factor in the energy budget of the whole lake. Inflow includes rivers and land surface run off, bank storage, and seepage from groundwater. Outflow includes rivers, controlled withdrawals (reservoirs), and leakage to groundwater. If the advected energy is a significant component of the energy budget, then it must be estimated. It can be approximated by:

$$A_Q = \rho_w c_w (Q_i T_i - Q_o T_w + P T_p) \qquad (4)$$

where A_Q is the advected energy per unit area of lake, Q_i and Q_o are the rates of inflow and outflow per unit area of lake, P is the rate of precipitation, and T_i, T_w, and T_p are the temperatures (°C) of the inflow, the outflow (i.e. the lake), and the precipitation; ρ_w and c_w are the density and specific heat of water respectively.

Diffusion into the Atmosphere

A number of factors can affect the diffusion processes. With constant wind speed, the evaporation rate is related to the size of the lake surface and to the relative humidity of the air. As a parcel of air moves across a lake, its water vapor content increases, resulting in a decrease in the rate of evaporation, as the layer of air that overlies the lake and, due to its proximity to the water, approaches saturation. The larger the lake, the greater will be the total reduction in the depth of water evaporated. If the lake is large enough, the humidity of the air will be largely independent of the distance it has traveled from the edge and hence the evaporation will be closely related to the amount of energy available. On the other hand, small lakes exert little influence on the temperature or humidity of the overlying air. Some observations indicate, however, that evaporation can be enhanced over large lakes in situations where the effect of increased wind speed more than compensates for the increased humidity of the air associated with the larger distance traveled by the air over water, for example, Venalainen *et al.* (1998). They also noted that evaporation from lakes fringed with forest would be reduced through sheltering: apparently the reduction in turbulence associated with the reduced wind speeds more than compensates for the increased aerodynamic roughness of the forest.

Empirical and theoretical studies have been made of the evaporation from small areas (the oasis effect). As an airstream moves over a homogeneous land cover, the energy exchange with the land surface will tend to reach an equilibrium condition, principally by changes to the humidity of the air immediately above the surface. If the land cover changes, then the energy exchange will also change to establish a new equilibrium. Various studies (e.g. Brutsaert and Yeh, 1969; Brutsaert and Yeh, 1970; Brutsaert and Yu, 1968; and Rao *et al.*, 1974) have shown that, although the effect of a change in surface cover propagates slowly up into the atmosphere, the adjustment of the surface evaporation rate into a moving airstream occurs quickly as the air passes on to a different type of evaporative surface (generally, within 5 to 10 m of the boundary between the two surfaces). This suggests that for lakes, it is the surface characteristics of the lake itself which will dominate. In addition, lakes of a significant size, many kilometers across, can modify the wind direction as well as the strength, for example, Samuelsson and Tjernstrom (2001); Taylor *et al.* (1998).

The preceding discussions apply to a freshwater lake. However, for saline water, the evaporation rate decreases by about 1% for each 1% increase in salinity because of the reduced vapor pressure of the saline water. This effect is normally small enough to be discounted when estimating evaporation rates from "fresh" lakes although methods for quantifying the effect are available, for example, Calder *et al.* (1984); Ali *et al.* (2001), which may be important in semiarid and arid areas.

QUANTIFYING THE EVAPORATION

The three main methods used to estimate the evaporation from lakes are: the bulk transfer; energy balance, and combination equations. The reader is referred to key texts for other methods which are either mainly of historic interest or are rarely used: evaporation pans (Gangopaghaya *et al.*, 1966), mass balance (Harbeck *et al.*, 1954; Lapworth, 1965), and empirical factors (Finch, 2003). Micrometeorological measurement techniques are not included here as they are described elsewhere (*see* **Chapter 40, Evaporation Measurement, Volume 1**).

Bulk (Mass) Transfer

A simple derivation of the bulk transfer equation is given by Sene *et al.* (1991), which has the form

$$E = Cu(e_w^* - e) \tag{5}$$

where E is the evaporation and u is the wind speed, e is the vapor pressure of the air and e_w^* the saturated vapor pressure. The wind speed and the vapor pressures are measured at a reference height above the water surface, typically 2 m. C is the mass-transfer coefficient, which can be thought of as the total drag coefficient; the combination of skin friction and a force resulting from the deceleration of the wind in the direction of flow. Over a uniform surface, C can be calculated from theory as a function of the atmospheric stability and the roughness of the surface which itself is affected by the wind speed (Brutsaert, 1982; see p. 117). This coefficient has often been determined for sea surfaces, although there is considerable scatter in the results (Brutsaert, 1982 see Table 3). For most lakes, the conditions of surface uniformity are not met and it is necessary to make more restrictive assumptions to obtain a theoretical solution to the evaporation and heat transfer equations (Brutsaert, 1982; pp. 167–171). The value of C reflects the transfer characteristics of the particular lake, which are determined by its geometry, plant cover, and the topography, land use and climate of the surrounding land. Moreover, the value of the coefficient is specific for the characteristics of the site used to record the meteorological data; for example, a value derived for wind speed measured at 2 m

will not be correct for use with wind speeds measured at 10 m, even at the same site. Over the years, meteorological data have been inconsistently measured using a variety of different standards, resulting, according to Singh and Xu (1997), in over 100 such evaporation formulae. It is therefore not possible to find a value of C that is applicable to all lakes. Rather, it is best to determine it empirically for a particular lake from the ratio of the mean evaporation rate, measured using a standard method, for example, eddy correlation (*see* **Chapter 40, Evaporation Measurement, Volume 1**) or the energy budget, to the mean vapor pressure gradient. Nevertheless, attempts have been made to produce a generally applicable value. Based on an extensive measurement program on reservoirs in the western USA, Harbeck (1962) suggested an expression for C that incorporated the area of the lake. The transfer equation is

$$E = 2.909 D_w^{-0.05} u_2 (e_w^* - e) \tag{6}$$

where the evaporation rate, E, is in mm day^{-1}, the vapor pressures, e_w^* and e, are in kPa, D_w is the area of the water surface in m^2, and u_2 is the wind speed at 2 m (m s^{-1}) above the water surface. This is suitable for lakes in the range of 50 m $< D_w^{0.5} <$ 100 km that are in a relatively arid environment.

An alternative form for the mass-transfer equation, dating from the nineteenth century, has also been widely used. This takes the form

$$E = f(u)(e_w^* - e) \tag{7}$$

where $f(u)$ is a function of the wind speed that allows for free convection, that is, evaporation when there is no wind. The wind speed function takes the form:

$$f(u) = a + bu \tag{8}$$

where a and b are empirical constants. Sweers (1976) reviewed wind speed functions and concluded that, for a temperate climate, best results were obtained using the wind function of McMillan (1973) adjusted for the area of the lake in relation to the lake studied by McMillan. This function is,

$$f(u) = \left(\frac{5 \times 10^6}{D_w}\right)^{0.05} (3.6 + 2.5u_3) \tag{9}$$

where u_3 is the wind speed measured over the water at 3 m above the surface.

Simon and Mero (1985) gave up trying to use the mass-transfer method to estimate evaporation from Lake Kinneret in Israel because of inconsistent results and large scatter in estimates of the transfer coefficient. In contrast, Sacks *et al.* (1994) found good agreement (generally within 8%) between the energy-budget evaporation and monthly mass-transfer evaporation for a shallow lake in Florida, but larger discrepancies (mean monthly difference of 24%) for a similar but deeper lake, also in Florida. Correcting the mass-transfer coefficient for stability effects (Stauffer, 1991; Harbeck *et al.*, 1958) did not improve matters. Sacks *et al.* suggested that the differences might be a smoothing effect caused by using long-term mean vapor pressure gradients; one of the main problems with this method is that it is sensitive to the errors in the vapor pressure gradient. They also found that using the Harbeck (1962) form for the mass-transfer coefficient produced lower values that resulted in underestimates of the evaporation from the shallow lake by 14% and from the deep lake by 27%. This was in contrast to Sturrock *et al.* (1992) who found that the Harbeck prescription gave higher values than those based upon energy-budget estimates. The reasons for these discrepancies remain unclear.

Energy Budget

The energy-budget method is generally accepted as the most accurate method of measuring the evaporation from a lake (Winter, 1981). As its name implies, the evaporation from a lake is estimated as the energy component required to close the energy budget when all the remaining components of the budget of the lake are known, that is, it is the residual of:

$$\lambda E + c_w(T_w - T_b)E = Q^* - H + W + F_{\text{in}} - F_{\text{out}} + F_p - G \tag{10}$$

where λ is the latent heat of vaporization, c is the specific heat of water, T_w and T_b are the temperature of the evaporated water (generally the water surface) and an arbitrary base temperature respectively, W is the change in heat storage, F_{in} and F_{out} are the heat-fluxes associated with water flows in and out of the lake, F_P is the heat inflow associated with precipitation, and G is the heat conduction occurring between the water and its substrate. All the energy components are in units of energy per unit surface area of the water.

Usually the sensible heat, H, (the amount of energy directly warming the air) cannot be readily determined and it is eliminated through use of the Bowen ratio, β, defined as the ratio between the sensible and latent heat-fluxes (*see* **Chapter 40, Evaporation Measurement, Volume 1**):

$$\beta = \frac{H}{\lambda E} = \frac{\gamma(T_s - T_a)}{(e_s^* - e)} \tag{11}$$

where γ is the psychrometric parameter, T_s and T_a are the temperatures of the water surface and the air at a reference height and e_s^* and e are the saturated vapor pressure of

the air at the water surface temperature and the vapor pressure of the air at the reference height. $H = \beta\lambda E$ can be substituted into the energy balance equation to give the evaporation rate,

$$E = \frac{Q^* + W + F_{\text{in}} - F_{\text{out}} + F_p - G}{\lambda(1+\beta) + c_w(T_s - T_b)} \tag{12}$$

The second term in the denominator represents a correction term for the difference between the temperature of the evaporated water and an arbitrary base temperature.

By suitable selection of averaging period it is sometimes possible to neglect the F_{in}, F_{out}, and G terms. Indeed, it is usually the case that the energy content of a lake is chiefly governed by the exchange of energy through the surface, rather than the inflows, including precipitation, and outflows and the water-substrate interface (Henderson-Sellers, 1986). This would certainly be the case if the volumes of water flowing in and out of the lake are small compared to the volume, or the temperatures are close to the temperature of the lake. Under these conditions, $T_b = T_s$ and the last four terms in the numerator can be neglected. The energy budget is then given by

$$E = \frac{Q^* + W}{\lambda(1+\beta)} \tag{13}$$

This is sometimes referred to as the reduced energy budget equation (Simon and Mero, 1985; Assouline and Mahrer, 1993; dos Reis and Dias, 1998).

The accuracy of the reduced energy balance equation depends upon the timescale and size of the lake. Because of the heat storage, the deeper the lake, the longer the time interval required between measurements of the temperature profile to attain acceptable accuracy in the temperature differences. In the classic study at Lake Hefner (Anderson, 1954), an accuracy of 5% in the evaporation estimate was achieved for periods of a week or more but the accuracy decreased for shorter periods. For a shallow (average depth 0.6 m) lake, Stewart and Rouse (1976) assumed that daily values were sufficiently accurate to use them as a standard against which an alternative method was validated.

The disadvantages of the energy balance method are the large number and frequency of measurements needed and the difficulties inherent in making some of them. Consequently, it is expensive and has not often been used in the more complete form. Exceptions being the Lake Hefner study (Anderson, 1954), the work by Stauffer (1991) on Lake Mendota, Wisnonsin, and Sturrock *et al.* (1992) on Williams Lake, north central Minnesota, and more recently a comparative study of evaporation from two lakes in Florida (Sacks *et al.*, 1994).

For accuracy, measurements of surface and profile water temperatures and the micrometeorology should be made at a representative point or points over the lake. This has often been achieved using an anchored instrumented raft (e.g. Anderson, 1954; Assouline and Mahrer, 1993; Sturrock *et al.*, 1992) but also for ease of maintenance and cost, measurements have been made over land – sometimes with data being used from distant weather stations. Work has been done to determine the effect on the accuracy of the evaporation estimates of using land-based and distant data sources (e.g. Keijman, 1974; Rosenberry *et al.*, 1993; Winter and Rosenberry, 1995).

Estimation of the Bowen ratio, β, requires measurement of air temperature and vapor pressure above the water and the water temperature to derive the saturated vapor pressure at the temperature of the water surface. This is usually achieved using wet and dry bulb thermometers at a reference height on a raft and a thermometer just below the surface of the water.

The change in heat storage, W, per unit surface area is calculated from the following:

$$W = \rho_w c_w h \frac{\Delta T_w}{\Delta t} \tag{14}$$

where ΔT_w is the change in spatially averaged temperature of the lake in time step Δt. For shallow lakes that are well mixed, T_w can be approximated by the surface temperature (Keijman, 1974). This, however, begs the question as to a suitable average value for the surface temperature; in calm conditions and high solar radiation, spatial variation in surface temperature can be large over short timescales. For deep lakes it is necessary to conduct thermal surveys consisting of temperature profiles with depth, ideally measured at a sufficient number of stations to produce a good average. For example, in the exceptional Lake Hefner study, weekly surveys were made at 16 stations and daily at one of two stations (Anderson, 1954), while at Williams Lake, surveys were made fortnightly at 16 stations (Sturrock *et al.*, 1992). Selection of the appropriate time interval, which will depend upon the size of the lake, can result in the value of the change in heat storage being small enough to be neglected.

Estimation of the energy advected in and out of the lake requires that the inflow and outflow are gauged accurately and the water temperature measured. Where inflow or outflow are large relative to the volume of the lake, and cannot be accurately gauged, the energy balance method may become unusable. However, in many lakes the inflow and outflow are relatively small (e.g. Williams Lake, Sturrock *et al.*, 1992). Sturrock *et al.* (1992) calculated the groundwater volumes using the Darcy equation (see Ward and Robinson, 2000, pages 157–159), and used water temperature from wells for inflow, and surface temperature for leakage. The energy advected by rainfall is usually determined from the recorded rainfall and the wet-bulb temperature recorded during rainfall. Sacks *et al.* (1994); Stauffer (1991); Sturrock *et al.* (1992) concluded that for

the lakes that they studied, the advected energy was trivial compared to the other terms; for example, 1% of the radiation terms. However, Sacks *et al.* (1994) and Stauffer (1991) found that the largest of the advected terms was that due to precipitation. In nonnatural or seminatural lakes, for example, reservoirs and cooling ponds, other advective components may be large but easy to measure.

In some circumstances, the heat conduction into the substrate can be significant, Sturrock *et al.* (1992) found that in the summer neglecting it made a 7% difference to the estimated evaporation from Williams Lake (average depth 5.2 m) in Minnesota. Stauffer (1991) states that ignoring sediment heat exchange can be a major source of error in estimation of evaporation and implies that the Lake Hefner results may be flawed through ignoring this component. He used annual sine-wave functions to model the sediment-water heat exchange (Likens and Johnson, 1969).

Combination Equations

Over the last fifty years the most widely used formula to estimate evaporation from water, or vegetation, has been the Penman equation (Penman, 1948) (*see* **Chapter 41, Evaporation Modeling: Potential, Volume 1**). Its successful application in many different locations is attributable to its physical basis. Linacre (1993) presents a table comparing monthly or annual measured evaporation with Penman estimates for a wide range of lakes from around the world. The median value of the ratio of measured to estimated evaporation is 0.99 with a standard deviation of 0.12.

Penman combined the mass transfer and energy-budget approaches and eliminated the requirement for surface temperature to obtain his expression for the evaporation in mm per day from open water:

$$E = \frac{\Delta A}{\Delta + \gamma} + \frac{\gamma f(u)(e_a^* - e)}{\Delta + \gamma} \tag{15}$$

where A, the available energy, is in units of equivalent depth of water ($\mathrm{mm\,day^{-1}}$), e_a^* and e are the saturation vapor pressure and the actual vapor pressure of the air respectively, at a reference height above the lake surface. Δ and γ are the rate of change of the saturation vapor pressure with temperature and the psychrometric parameter respectively. The psychrometric parameter is calculated as:

$$\gamma = \frac{c_p P}{0.622\lambda} \tag{16}$$

where c_p is the specific heat of the air, P is the atmospheric pressure and λ is the latent heat of vaporization (which is a function of temperature).

The Penman–Monteith equation (Monteith, 1965) (*see* **Chapter 41, Evaporation Modeling: Potential, Volume 1** and **Chapter 45, Actual Evaporation, Volume 1**) is a more general form of combination equation. Essentially, the evaporation rate is obtained from the simultaneous solution of diffusion equations for heat and water vapor, and the energy balance equation. When applied to a lake it takes the form

$$E = \frac{1}{\lambda}\left[\frac{\Delta A + \rho c_p (e_a^* - e)/r_a}{\Delta + \gamma}\right] \tag{17}$$

where the aerodynamic resistance r_a is the resistance that the water molecules encounter in moving from the water surface to a reference height in the atmosphere and is inversely proportional to the wind speed. Accurate estimates require that the value of the aerodynamic resistance, r_a, accounts for the effects of surface roughness, size of the lake, and atmospheric stability.

When air travels a long distance over a wet surface, it will tend to saturation so that the second term tends to zero. The first term represents the lower limit of evaporation and is referred to as the *equilibrium rate*. However, in practice, equilibrium evaporation is rarely found; because the atmosphere near the surface is never truly homogeneous and, even over oceans, atmospheric humidity deficits develop. Priestley and Taylor (1972) (*see* **Chapter 41, Evaporation Modeling: Potential, Volume 1**) analyzed data collected over oceans and extensive saturated land surfaces, and found that the evaporation values were fitted using:

$$E = \alpha \frac{\Delta A}{\Delta + \gamma} \tag{18}$$

where the constant α accounts for the evaporation arising from the humidity deficit in addition to the equilibrium term. The equation is now known as the *Priestley–Taylor* equation. Priestley and Taylor found that the average value of α was 1.26 from the data they examined and there has been subsequent corroboration of this value by other studies. de Bruin and Keijman (1979) used the Priestley–Taylor equation to estimate the evaporation from a large shallow lake (Lake Flevo; 460 $\mathrm{km^2}$, mean depth 3 m) in The Netherlands and found very good agreement with daily evaporation measured by the energy-budget and water-budget methods during the summer and early fall with $\alpha = 1.25$. However, they also found diurnal variation in the value of α which they attributed to the variation of the difference between air and water temperatures and suggested that the conditions producing such variation would be expected from many lakes. They also found evidence of seasonality in the value of α, of at least the same magnitude as the diurnal variation in evaporation. This variation is the result of some evaporation occurring when the available energy was zero.

A further simplification is given by Stewart and Rouse (1976), who derived a variation of the Priestley–Taylor equation by using a linear function of downward solar

radiation to replace the net radiation and heat storage. The resulting equation is identical to the formula of Makkink (1957), who used it to estimate the evaporation from well-watered grass and is:

$$E = a\frac{\Delta}{\Delta+\gamma}K_{\downarrow} + b \qquad (19)$$

where $K_{\downarrow}$ is the downward global solar radiation. As with other methods, the disadvantage of the Priestley–Taylor equation is the requirement for measuring the available energy; it is often not possible or too expensive to make adequate measurements of change in the heat stored in the water for a large lake. de Bruin (1978) overcame this difficulty by combining the Penman and Priestley–Taylor equations, thus eliminating the energy term to give the relationship

$$E = \left(\frac{\alpha}{\alpha-1}\right)\left(\frac{\gamma}{\Delta+\gamma}\right) f(u)(e_a^* - e) \qquad (20)$$

This formula requires only measurements of air temperature, humidity deficit, and wind speed at 2 m. de Bruin tested the method by using a form of the wind function given by Sweers (1976) with time-averaged input data measured at the center of Lake Flevo to calculate evaporation for varying time intervals. He found good agreement with estimates from the energy-budget method for intervals of 10 days or more. He also found that the Priestley–Taylor coefficient was not constant for intervals of a day or less.

CONCLUSIONS

The literature on evaporation from lakes tends to be dominated by measurements of specific lakes; which is probably not surprising, given the large number of factors that can affect the evaporation rates. Nevertheless, it is possible to make reliable predictions of the evaporation to an acceptable accuracy for most purposes. Other than limitations in the measurements, there are three major sources of uncertainty.

The first is the albedo of lakes. For conditions of deep, low turbidity water, there is probably sufficient knowledge to give reasonably accurate information from readily available data (such as Payne, 1972). However, when factors, such as bottom reflectance; turbidity and aquatic vegetation, cannot be ignored, the only reliable methods, currently available, are computationally intensive, for example, radiative transfer models, but the effort required to use these methods is seldom justified for operational purposes, in terms of the "value" of the improved accuracy.

The second major source of uncertainty is the heat-storage term of the energy budget. Although it is possible to make measurements to quantify this term, the effort may be significant for many lakes, and there are models available that can quantify this term. The analytical solution provided by the equilibrium temperature model (Edinger *et al.*, 1968) or the numerical solution of Finch and Gash (2002) can be used if the lake water is well mixed. Models are also available for the case when thermal stratification occurs (e.g. Hostetler and Bartlein, 1990; Hamilton and Schladow, 1997). However, these models are essentially one-dimensional and so using them for a three-dimensional situation requires care, or a more complex model.

The final major cause of uncertainty is in the wind function. The literature is dominated by, what are essentially, empirical descriptions of the wind function and it is unclear what the uncertainty is when these functions are applied to locations other than those for which they were determined.

45: Actual Evaporation

ALBERTUS JOHANNES DOLMAN

Department of Hydrology and Geo-Environmental Sciences, Faculty of Earth and Life Sciences, Vrije Universiteit, Amsterdam, The Netherlands

Actual evaporation concerns the evaporation from natural surfaces. Globally actual evaporation from the land amounts to around 71 10^3 km^3 $year^{-1}$. Measurement of evaporation occurs by water balance techniques or directly through micrometeorological techniques. Actual evaporation depends on land cover and meteorological conditions. Evaporation can be predicted by various equations, amongst the Penman-Monteith equation which takes into account both the vegetation properties as well as the meteorological conditions. In the case of sparsely vegetated areas soil evaporation and plant evaporation need to be treated separately. Estimating the correct value of surface conductance is a critical issue in applying the Penman-Monteith equation, but models exists. Evaporation from bare soil can be treated as a two stage process, with rapid evaporation at potential rates after rain, and subsequent drying. At larger than catchment scales, feedbacks with the atmospheric boundary layer make it possible to apply evaporation equations based on equilibrium concepts, such as the Priestley-Taylor equation. There has been substantial progress in evaporation modeling and measurements over the last 25 years. This knowledge can be used much more in assessing changes in evaporation of catchments that may result from perturbations in land use and climate.

INTRODUCTION

Evaporation refers to the transfer of moisture from a particular surface to the overlying atmosphere. The physical process of evaporation consists of the exchange of water molecules between a free water surface and the air. The evaporation rate is expressed as the quantity of water evaporated per unit area per unit time from a (water) surface under existing atmospheric conditions. The surface can be any of the following nonexhaustive list: a lake (*see* **Chapter 44, Evaporation from Lakes, Volume 1**), the inside of the plant leaves (*see* **Chapter 42, Transpiration, Volume 1**, the water surface adhering to a soil conglomerate, or the surface of a soil (*see* **Chapter 40, Evaporation Measurement, Volume 1**) or canopy just after rain (*see* **Chapter 43, Evaporation of Intercepted Rainfall, Volume 1**. It is important to distinguish actual evaporation from potential evaporation. Potential evaporation is the quantity of water evaporated per unit area per unit time from an idealized extensive free water surface under existing atmospheric conditions (*see* **Chapter 41, Evaporation Modeling: Potential, Volume 1**, Shuttleworth, 1992). Actual evaporation is the evaporation that occurs in reality from a natural, nonidealized surface. Globally, evaporation from the land surface to the atmosphere amounts to 71 10^3 km^3 $year^{-1}$. The evaporation from the oceans is much larger, 42 810^3 km^3 $year^{-1}$ (German Advisory Council on Global Change, 1999).

Traditionally, actual evaporation has been estimated as the residual of the catchment water balance (e.g. Bosch and Hewlett, 1982). These studies are very useful to estimate annual evaporation (Zhang *et al.*, 2001, 2004), but suffer from accumulated errors in the residual term that represents evaporation. In contrast, micrometeorological techniques can measure the fluxes of evaporation directly, but these techniques need considerable maintenance, and often are biased towards producing good weather data. However, since 1995, a global network of flux towers (*see* **Chapter 40, Evaporation Measurement, Volume 1**) has emerged that can now be used to estimate evaporation from a variety of land-cover types (Baldocchi *et al.*, 2001).

Zhang *et al.* (2001, 2004) present an elegant analysis of data from 250 catchments worldwide with a "rational function" analysis of the main factors driving evaporation. They

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

suggest that the total evaporation of a catchment can be approximated by considering two factors only, atmospheric demand and water availability. Atmospheric demand is given by the maximum possible evaporation, that is, potential evaporation; water availability can be represented by precipitation. Under dry conditions, potential evaporation exceeds precipitation, and the actual evaporation of a catchment will approach the precipitation amount. Conversely, under wet conditions, water availability exceeds potential evaporation and actual evaporation will approach asymptotically potential evaporation. This approach builds on Budyko (1974) and Milly (1994) who suggested that the long-term water balance of a catchment is determined by the interaction of supply (precipitation) and demand (potential evaporation), mediated by soil moisture storage. Figure 1 shows results of Zhang *et al.* (2001), both from a simple model based on the above considerations for grass and forested catchments, and with catchment data. These results suggest that the scale of catchments such a simple approach works remarkably well, with a linear (1 : 1) relation between rainfall and evaporation for catchments that receive up to 500 mm year^{-1}, and an asymptotic relation (driven by evaporative demand and not by water availability) for catchments receiving more than 500 mm year^{-1}. The difference between forest and grassland originates in the high interception losses of forest that make up a considerable part of the total evaporative loss. Total evaporation from forest saturates at about 1400 mm year, while for grasslands this value is around 900 mm year^{-1}.

These values could in principle be compared to the direct measurements of evaporation such as quoted in Law *et al.* (2002). However, the values of evaporation measured by micrometeorological techniques usually refer to dry-canopy evaporation only (transpiration) and contain little evaporation during wet-canopy evaporation (interception). Consequently, total evaporation values as given in Law *et al.* (2002); Valentini (2003) should be treated with care, when interception losses are not explicitly treated. When this is taken into account, the annual evaporation from Fluxnet data for coniferous forests is 397 ($\pm$31) mm year^{-1}; for mixed evergreen and deciduous forest 386 ($\pm$18) mm year^{-1}; for deciduous broadleaf 512 ($\pm$69) mm year^{-1}; for grassland 494 ($\pm$104) mm year^{-1}, and for crops 666 ($\pm$67) mm year^{-1}. The values for forests are very close to the average of 350 mm that was suggested by Roberts (1983) as a good annual average estimate for transpiration of European forests. This indicates that the FLUXNET values indeed are closer to the annual transpiration rates, than to the total evaporation (transpiration plus interception). Grassland and crops have a higher dry-canopy evaporation than forest, because they are less coupled to the atmosphere and thus show less stomatal control (e.g. Shuttleworth and Calder, 1979).

The Fluxnet data can also be used to identify the main controls on evaporation. Wilson *et al.* (2002) show how the partitioning of energy, as expressed by the ratio of sensible heat to latent heat (Figure 2), the Bowen ratio (β), can be used to group different vegetation types in climate space. The graph shows the position of the individual sites with respect to the magnitude of the latent heat (evaporation) and sensible heat fluxes. In contrast to the

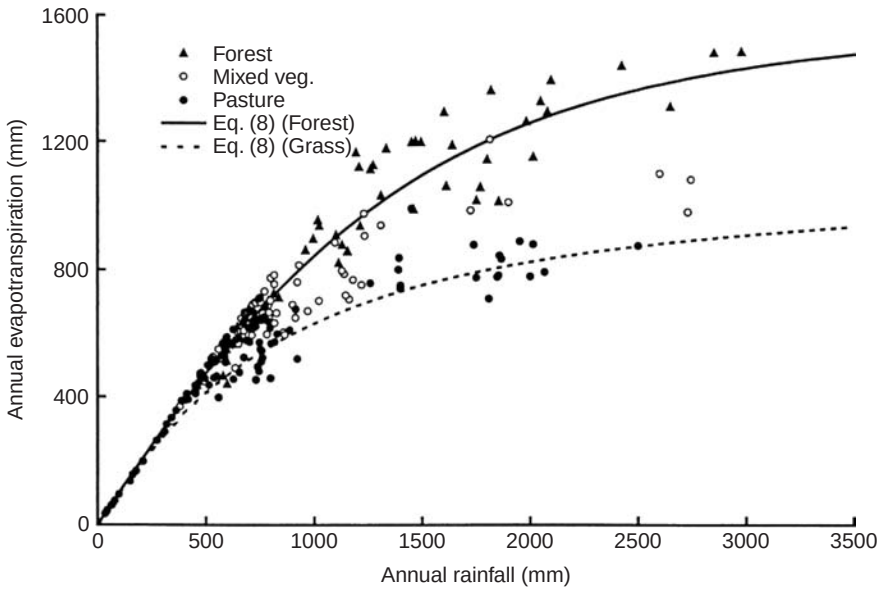

Figure 1 Relationship between annual precipitation and evaporation. The dashed line represents the best fit of a theoretical model for grass-only catchments, the solid line the best fit for forests (Reproduced from Zhang *et al.*, 2001 by permission of American Geophysical Union)

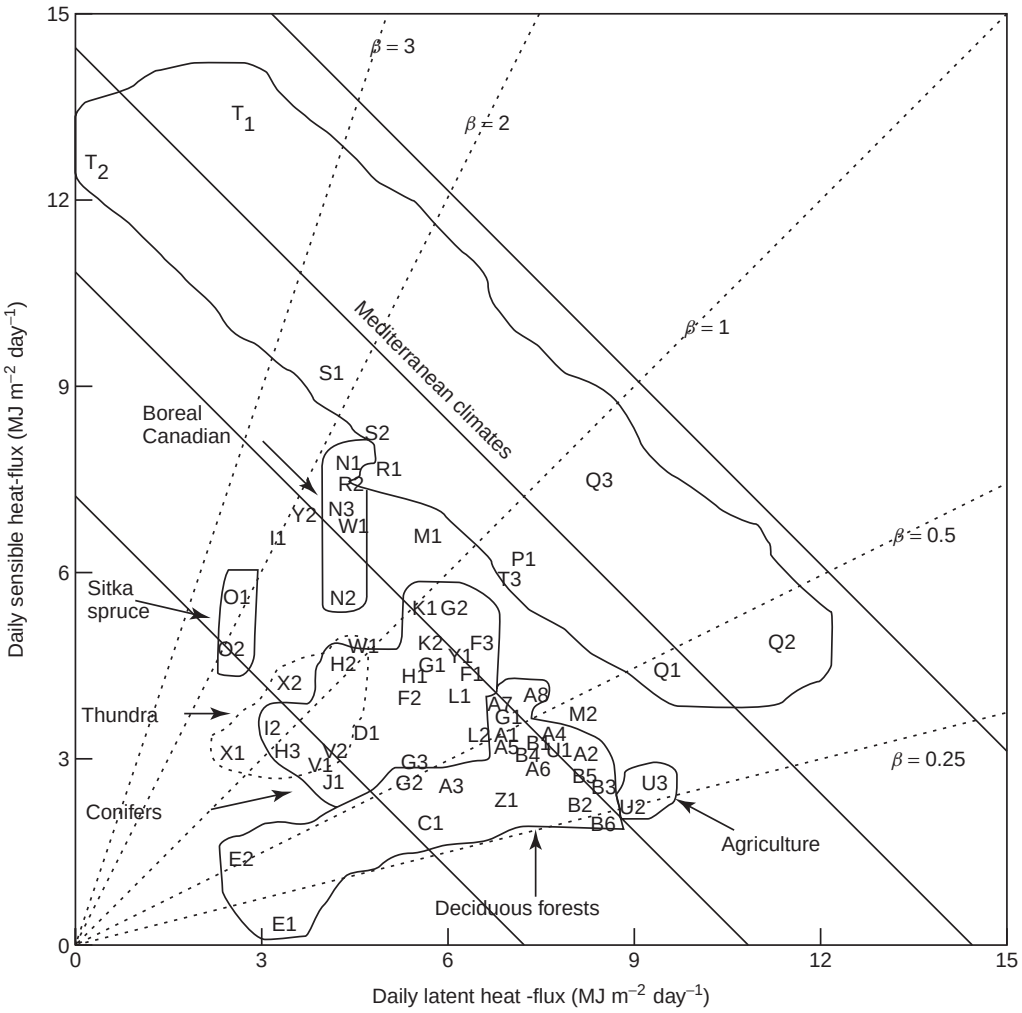

Figure 2 The daily cumulative sensible heat flux *versus* the daily cumulative latent heat flux between days 165 and 235 for the FLUXNET sites analyzed in Wilson *et al.* (2002). The letter and number codes refer to the sites in Table 1 (letter) and year of study at that site (number) of Wilson *et al.* (2002). Also shown are lines of constant Bowen ratio (dashed lines) and lines of constant total turbulent energy fluxes (solid diagonal lines). Enclosed circles denote subjective delineations between different vegetation types and climates (Reproduced from Wilson *et al.* (2002), by permission of American Geophysical Union)

annual rates discussed earlier, these data refer to the growing season only. Also shown are lines of constant available energy (the sum of latent and sensible heat) and lines of constant β-ratio. Moving from the lower left corner of the diagram to the upper right, the available energy increases, whereas moving from the lower right to the upper left, the value of the β-ratio increases. Low evaporation rates are found in Sitka spruce, tundras and boreal forest, high evaporation rates in deciduous forests and agriculture. Most of the forests have low β-ratios implying that most of the energy received is transmitted back to the atmosphere as sensible heat. Deciduous forests tend to have lower β-ratios and higher evaporation rates than coniferous forest. The average β-ratio at tundra sites appears to be close to one.

PREDICTING EVAPORATION

Evaporation at the earth's surface is constrained by the energy available to turn liquid water into its vapor form and by the capability of the surrounding air to transfer moisture away from the saturated surface. At the surface these constraints are best expressed through the energy balance equation and the transfer equations of latent and sensible heat:

$$K_{\downarrow}(1-\varsigma) + L_{\downarrow} - L_{\uparrow} = \lambda E + H + G + \Delta S \quad (1)$$

$$\lambda E = -K_{\nu}\frac{\delta q}{\delta z} \quad (2)$$

$$H = -\rho c_p K_h \frac{\delta T}{\delta z} \tag{3}$$

with $K_\downarrow$ the incoming short-wave radiation ($W\,m^{-2}$), ζ the short-wave albedo, $L_\downarrow$ and $L_\uparrow$ the incoming and outgoing long-wave radiation ($W\,m^{-2}$), λE the evaporation (latent heat flux, $W\,m^{-2}$), λ is the latent heat of evaporation, H the sensible heat flux ($W\,m^{-2}$), G the soil heat flux ($W\,m^{-2}$), ΔS the change in heat storage in biomass and atmosphere ($W\,m^{-2}$), K_v and K_h the transfer coefficients for water vapor and heat respectively, $\delta q/\delta z$ the vertical gradient in specific humidity from the evaporating surface to a reference height above the surface ($g\,kg^{-1}$), and similarly $\delta T/\delta z$ is the vertical gradient in temperature (°K), ρ is the density of air ($kg\,m^{-3}$) and c_p the specific heat of air ($J\,kg^{-1}K^{-1}$).

Penman (1948) was among the first to achieve the crucial combination of the energy balance equation with the transfer equations to arrive at an expression for actual evaporation. His original equation, however, contained an empirical wind function that replaced the transfer coefficients in equations 2 and 3. This wind function was difficult to generalize, and subsequently, Thom and Oliver (1977) provided a more physical basis based on considerations of aerodynamic transfer over rough surfaces by introducing an aerodynamic resistance. To eliminate the surface temperature from the equation combining the bulk discrete versions of equations 1a and 1c, Penman introduced the slope of the saturated specific humidity *versus* temperature curve evaluated at air temperature given by

$$s = \frac{q^*(T_s) - q^*(T_a)}{T_s - T_a} \tag{4}$$

where $q^*(T_s)$ is the saturated specific humidity at surface temperature T_s(°K), and $q^*(T_a)$ is the saturated specific humidity at air temperature T_a. (Penman used the slope of the saturated vapor pressure *versus* temperature curve, but in this paper specific humidity is used throughout.)

Predicting Evaporation from Vegetated Sources

Monteith (1965) took into account the control of vegetation on evaporation and described the transfer of water from the collective saturated surfaces in the plant stomatal cavities in the plant stomata to the air outside the leaves by a canopy scale resistance r_s. The resulting equation, carrying now both an aerodynamic and canopy resistance, is known as the *Penman–Monteith equation* and is arguably still the most advanced resistance model of evaporation used in hydrological practice today (Shuttleworth, 1992). For a mathematically precise and exact definition and brief historical overview of its development, see Raupach (2001). The most common form of the Penman–Monteith (PM) equation reads:

$$\lambda E = \frac{\Delta(Q_* - G) + \dfrac{\rho c_p D}{r_a}}{s + \dfrac{c_p}{\lambda}\left(1 + \dfrac{r_a}{r_s}\right)} \tag{5}$$

with Q_* the net radiation, consisting of the left-hand term of energy balance equation ($W\,m^{-2}$), D the specific humidity deficit (Note the difference between D, the specific humidity deficit and δq, the gradient in specific humidity, in equation 2.) of the air ($g\,kg^{-1}$) equal to q_* (T_a)-q_a, λ the latent heat of vaporization ($J\,kg^{-1}$). Two important variables appear in this equation that replace the transfer coefficients of the transfer equations of heat and moisture, the aerodynamic and surface resistance: r_a and r_s ($s\,m^{-1}$). (Only in the case of a full canopy cover, can the surface resistance be equal to the canopy resistance (e.g. Shuttleworth, 1978). For the derivation of the "big leaf" version of the PM model as presented here, this is not important. When the canopy cover is not full, and there is bare ground directly in contact with the overlying atmosphere, the surface resistance is not equal to the canopy resistance and approaches the reciprocal sum of the canopy and an assumed soil resistance.) A schematic showing the flux of latent heat encountering first the surface resistance and subsequently the aerodynamic resistance r_a, is given in Figure 1. The PM equation assumes that evaporation and sensible heat originate from the same source in the canopy. The main advantage of the Penman–Monteith equation is that the meteorological driving variables, wind speed, specific humidity deficit, and temperature are required only at a single level above the surface, obliterating the need for the notoriously difficult observation of surface values. The main stumbling block for the practical application of this equation is the estimation of the values for aerodynamic and surface resistance. When there is unlimited supply of water, the PM equation can be used to calculate potential evaporation (*see* **Chapter 41, Evaporation Modeling: Potential, Volume 1**). When the canopy is wet, the surface resistance equals zero and the PM equation can be used to calculate evaporation of intercepted rainfall (*see* **Chapter 43, Evaporation of Intercepted Rainfall, Volume 1**). Although there is a wide range of empirical evaporation equations of which some are particular cases of the PM equation (see Brutsaert, 1982; Shuttleworth, 1992), the use of the PM equation is recommended because of its clear physical interpretation.

Aerodynamic Resistance

The aerodynamic resistance controls the rate of water vapor transfer away from the surface and is intuitively inversely proportional to the wind speed. It can be expressed for conditions of neutral stability as:

$$r_a = \frac{\ln^2\left[\dfrac{(z-d)}{z_0}\right]}{k^2 u(z)} \tag{6}$$

where d is the displacement height (m) and z_0 the aerodynamic roughness length (m), k von Karman's constant ($= 0.41$) and $u(z)$ the wind speed measured at height z ($\mathrm{m\,s^{-1}}$) (the aerodynamic resistance is mathematically the integral with height of the reciprocal of the transfer coefficients of equations 2 and 3 (with $K_v = K_h$) and is obtained by using the logarithmic wind profile). Corrections for non-neutral stability are given by Verma (1989). Typical values for forest are $5\,\mathrm{s\,m^{-1}}$, the values are generally an order of magnitude larger and for grassland approach $50\,\mathrm{s\,m^{-1}}$ (Shuttleworth, 1992; Verma, 1989; Stewart, 1988).

More detailed descriptions of turbulent transport can be used to replace the aerodynamic resistance. Raupach (1989), and subsequently Dolman and Wallace (1991); Finkele *et al.* (2003) applied this Lagrangian theory with success in evaporation models.

Canopy or Surface Resistance

The estimation of the surface resistance is more complicated. The surface resistance is not necessarily the collected reciprocal sum of the individual stomatal resistances ($1/r_s = \Sigma r_{stom}$), although Shuttleworth (1978) argues on theoretical grounds that the difference is negligibly small for most practical applications. Typical unstressed values for surface resistance are $50\,\mathrm{m\,s^{-1}}$. The surface resistance of vegetation shows a marked diurnal and seasonal variation (Dolman *et al.*, 1998) and requires careful estimation. Straightforward sensitivity analysis of the PM equation shows that for low crops, that is, grasslands, the estimation of the radiation part of the PM equation is important and that the estimation of the surface resistance is less important For tall crops such as forest, the estimation of surface resistance is more important as in that case the evaporation is dominated by the humidity deficit and surface resistance. It is thus important to develop adequate models of surface resistance.

In the absence of a full physiological understanding of stomatal behavior, two type of models have been developed. These models have more in common than might appear at first sight. The first is generally referred to as the stress function model and was first developed by Jarvis (1976) to describe leaf level stomatal behavior. It expresses the actual resistance as a minimum resistance (maximum conductance) that is being increased by a number of stress functions that describe the empirically observed collective behavior of the stomata in the form of the canopy resistance (Stewart, 1988) and it is important to note that the version given in equation 7 is the canopy scale version:

$$\frac{1}{r_c} = \frac{1}{r_{min}} f(K_\downarrow) f(D) f(T) f(\theta) \tag{7}$$

where f(i) is the stress function with reference to the variable i, θ the soil moisture deficit, that is, the relative amount of soil moisture compared to field capacity and r_{min} the minimum canopy resistance ($\mathrm{s\,m^{-1}}$) (this equation is often given in the form of conductances where $r_{min} = 1/g_{s,max}$ and g is the conductance). The form of these functions is given by Jarvis (1976) and Stewart (1988). For each vegetation type or application, these functions require derivation from measurements at canopy level or some way of scaling measurements of stomatal resistance to the canopy (Dolman *et al.*, 1991). Maximum canopy conductances for a number of vegetation types are given in Table 1. For comparison, the stomatal conductance is also shown. A slightly wider range of maximum conductances, obtained from eddy correlation data is given in Buchmann and Schulze (1999). Their values range from $7.1\,\mathrm{mm\,s^{-1}}$ for tundra, through $35\,\mathrm{mm\,s^{-1}}$ for temperate grassland to values of 20 to $25\,\mathrm{mm\,s^{-1}}$ for deciduous and evergreen broadleaf forests. Evergreen needleleaf forest have generally lower resistances (e.g. Buchmann and Schulze, 1999). The canopy conductance is to first order, ignoring radiation divergence within the canopy, equal to the amount of leaf area times the stomatal conductance. When radiation absorption in the canopy is taken into account the relationship becomes nonlinear as shown by Dolman *et al.* (1991). It is important to appreciate the difference between values of maximum conductance (minimum resistance) that are observed in the field and given by Kelliher *et al.* (1995) and Buchmann

Table 1 Maximum stomatal (leaf level $g_{s,max}$) and surface conductances (G^3_{max}) for a number of global vegetation types (from Kelliher *et al.,* 1995). Sample standard deviations are also given. The stomatal and surface resistance values are also given

Vegetation type	$g_{s,max}$ ($\mathrm{m\,ms^{-1}}$)	$r_{s,min}$ ($\mathrm{s\,m^{-1}}$)	$G_{s,max}$ ($\mathrm{mm\,s^{-1}}$)	$R_{s,min}$ ($\mathrm{s\,m^{-1}}$)
Temperate grassland	8.0 ± 4.0	125	17.0 ± 4.7	58
Coniferous forest	5.7 ± 2.4	175	21.2 ± 7.1	47
Eucalypt forests	5.3 ± 3.0	189	17.0	58.8
Temperate deciduous forest	4.7 ± 1.7	213	20.7 ± 6.5	48.3
Tropical rainforest	6.1 ± 3.2	164	13.0	76.9
Cereals	11.0	91	32.5 ± 10.9	30.8
Broadleaved herbaceous crops	12.2	82	30.8 ± 10.2	32.5

and Schulze (1999) and those that are obtained by using equation 7 and obtained by mathematically optimizing a maximum conductance against a set of observations. These latter values are theoretical maxima that are never attained, the observed values represent the highest possible value, given the fact that almost always some constraint is reducing the conductance and are thus generally lower than the optimized values.

More recently, a canopy resistance model was developed that is based on the observed linear relation between photosynthesis and conductance at leaf level (Ball *et al.*, 1987). Expressed here as a resistance this relation reads

$$\frac{1}{r_c} = a + \frac{bAh_s}{c_i} \tag{8}$$

where A is the carbon assimilation rate (μmol C m^{-2} s^{-1}) of the leaf, h_s the surface relative humidity just outside the leaf, c_i the internal CO_2 concentration in the stomatal cavities (μmol m^{-3}) and a and b are constants.

This equation needs to be scaled up through the canopy (if the stomatal scale version of equation 7 is used, this would equally apply to the Jarvis model). It is important to stress that the relation between assimilation rate and conductance, though intuitively appealing, is as empirical as the stress function approach in its use of the surface relative humidity to increase the resistance. In fact, this is exemplified in the approach of Leuning (1995) where the relative humidity is replaced by a stress function involving the vapor pressure deficit. In practice, this function has remarkably similar performance to the one used in the Jarvis–Stewart approach. The real appeal of using this A-g_s relation is twofold. First, the calculation of the assimilation rate can be based on purely biogeochemical reasoning. This, in principle, would avoid the necessity of recalibrating the model for each vegetation cover. Second, by linking the water exchange with the exchange of carbon, a more realistic description of the relation between growth and water use is obtained. However, the advantage of using of the A-g_s equation for practical hydrological purposes is still marginal, whereas in contrast, in climate models its use is increasing (Sellers *et al.*, 1992; Jacobs *et al.*, 1994; Cox *et al.*, 1998; Calvet *et al.*, 1998; Ronda *et al.*, 2001).

Evaporation from Bare Soil

Evaporation from bare soil can be a significant component of the water balance, particularly in semiarid environments (Wallace and Holwill, 1997). Soil evaporation can be described as a "two-stage process". The first stage is under the conditions where the available soil moisture is sufficient to meet the atmospheric demand. This happens immediately after rainfall or irrigation events. Soil evaporation under these conditions equals potential evaporation. Typically this stage last 1 to 2 days, although in some cases when evaporative demand is low and the soil contains a high amount of clay, this stage may last for 5 days. In the second stage, the amount of soil moisture has dropped and soil evaporation is no longer only restricted by evaporative demand but also by availability of moisture. In these conditions, the time change of soil moisture can be described as a desorption process with evaporation proportional to the square root of the time since the start of the process:

$$\lambda E_s = \tfrac{1}{2} D (t - t_0)^{-\frac{1}{2}} \tag{9}$$

with λE_s the soil evaporation, t the time and t_0 the time since the start of stage 2, D is a desorptivity (in units of W m^{-2} day^{-1} when evaporation is expressed as a heat flux or in mm day^{-1} when evaporation is expressed as water flux). The desorptivity is assumed constant for a particular soil type. It varies from a value of 2.1 for sandy loam with gravel, to a value of 5 mm day^{-1} for a clay loam soil (Kustas, 2002). Although the two-stage process describes soil evaporation at diurnal timescales, extension of the theory to (sub) hourly timescales is straightforward (Brutsaert and Chen, 1995; Porté-Agel *et al.*, 2000). The determination of the desorptivity coefficient is not without problems, as is the identification of the switch from stage 1 to 2 (Kustas, 2002).

The observed dependence of soil evaporation on available soil moisture suggests that a resistance approach may also be feasible that incorporates a dependence of soil surface resistance on soil moisture. Mahfouf and Noilhan (1991) review several such formulations. These approaches can be divided into so-called α and β approaches. In the α-approach, the saturated humidity in the soil pore space (compare equation 2) is adjusted by a factor α that may be related to soil matrix potential and takes into account that, averaged over a certain depth, the evaporation takes place from a nonsaturated surface. In the β-approach, the humidity in the pore space at the evaporation front is assumed to be saturated, and β is the ratio of an aerodynamic resistance and the sum of the aerodyamic and soil surface resistance. In general, the β-approach appears to yield better results. Relations that try to define the soil resistance as a function of soil moisture (e.g. van de Griend and Owe, 1994) range from linear to exponential (Kustas, 2002). A particular problem in defining these relations is the depth of the soil profile that needs to be considered. Also, approaches that relate the resistance to the depth of the soil surface to an evaporation front suffer from similar problems (Camillo and Gurney, 1986).

Evaporation from Mixed Surfaces

Most natural vegetation, perhaps with the sole exception of tropical rainforests, consists of a mixture of surfaces and soils. Particular pronounced examples can be found in

the semi-arid natural vegetation of savannahs and in the case of developing agricultural crops. In these cases, the sources and sinks of evaporation (the leaves) and sensible heat (mostly the dry soil) are different. A dry soil in such a case transforms the temperature and thereby the specific humidity deficit around the leaves by an extra sensible heat input from the soil. This increases the evaporation from the leaves compared to a situation where the soil releases no additional heat. The reverse, dampening of the evaporation, occurs when the soil is wet and releases latent heat through soil evaporation. Shuttleworth and Wallace (1985) and subsequently Dolman (1993), Huntingford (1995), and Daamen (1997) developed models to take this into account. They take the general form of

$$\lambda E_{\text{tot}} = C_{\text{c}} P M_{\text{c}} + C_{\text{s}} P M_{\text{s}} \tag{10}$$

where the total evaporation λE_{tot} is expressed as a linear sum of the contribution from the canopy and soil. The factors C_c and C_s are functions of the canopy and aerodynamic resistances in the pathways from soil and vegetation to the atmosphere. PM_c and PM_s represent the equivalent Penman–Monteith equations, which would apply to evaporation from a closed canopy and bare soil respectively. The solution to the coupled system involves the definition of a within canopy humidity deficit D_0 (Shuttleworth and Wallace, 1995) that determines the evaporation from the leaves and soil.

Models that go beyond the two-source approach and allow more than two components are described by, for example Verhoef and Allen (2000). Such a situation may occur, for instance, in a savannah where small trees are surrounded by a mixture of grasses and bare soil. Daamen and McNaughton (2000) compare the performance of three types of resistance configurations (Figure 3) to predict evaporation from six land surface types. They conclude that the two-source model (interactive model) is generally superior, but that the differences between the three versions are within $50\,\text{W}\,\text{m}^{-2}$, when the component surface resistances are approximately equal or both very large. When the ratio of the two resistances describing transport from the canopy air to the reference height to that from the component surface to the canopy air, is large, the component evaporation is closely coupled to the canopy air, and an interactive model performs better than either a patch or single surface model (PM model). Such conditions may occur for low overstory canopies (steppe, pasture), sheltered canopies such as orchards, or canopies with large leaf area index but narrow leaves (Daamen and McNaughton, 2000).

Actual Evaporation Based on Crop Factors

It has long been common practice to express actual evaporation as the product of a potential rate (reference crop evaporation, *see* **Chapter 41, Evaporation Modeling: Potential,**

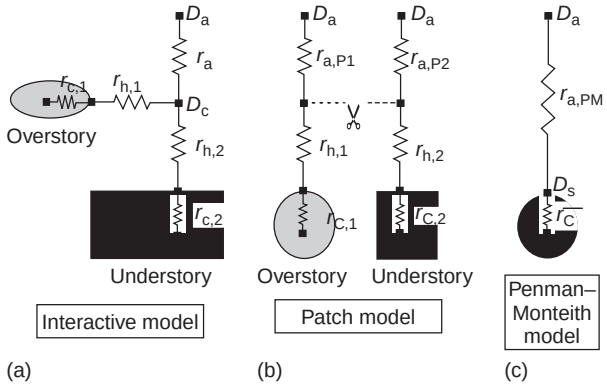

Figure 3 Evaporation (latent heat flux) and sensible heat flux from a vegetated surface to the atmosphere encounters a canopy resistance r_c and subsequently an aerodynamic resistance r_h (between a surface and the within canopy air) and r_a (from the canopy air to the reference height). Shown are three possible configurations of resistance networks to deal with mixtures of canopies and soil. Only in the interactive model (a) is the air ''sensed'' by the canopy dependent on the fluxes from the lower surface. In the two other configurations, they are either separated (b) or aggregated (c) (Reproduced from Daamen and McNaughton (2000), by permission of American Society of Agronomy)

Volume 1) and a reduction factor, which depends on the time of year and vegetation type (Doorenbos and Pruit, 1977). This can be expressed as

$$E_{\text{a}} = kE_{\text{p}} \tag{11}$$

where E_a and E_p are the actual and potential rates of evaporation ($\text{mm}\,\text{day}^{-1}$) and k a reduction or crop factor. It is easily shown (e.g. Wallace, 1995) that the crop factor is not a constant, but a complicated function of the surface (canopy) and aerodynamic properties of the crop and the climate in which they are derived. Wallace (1995) showed the crop factor to be a function of temperature, wind speed, crop height, and cover and rainfall. Although thus in appearance simple, and recently again recommended by the FAO (e.g. Allen *et al.*, 1998), the crop factor approach is conceptually not without its problems.

Actual Evaporation Based on Equilibrium Evaporation Concepts

It is useful at this stage again to define the Bowen ratio $\beta = \text{H}/\lambda\text{E}$. When air moves over a moist surface and gradients of temperature and specific humidity with height are small or become saturated with respect to moisture, Priestley showed that the Bowen ratio should approach a constant value of $\beta = s/\lambda$. Raupach (2001) defines equilibrium evaporation as when the ratio λE/A takes the value $\varepsilon/(1+\varepsilon)$ and $\beta = 1/\varepsilon$ with $\varepsilon = (\lambda/c_{\text{p}})\,\text{dq}_{\text{sat}}/\,\text{dT}$, with A the available energy ($\text{A} = \text{H} + \lambda\text{E}$) the ratio $\text{dq}_*/\,\text{dT}$ contains the

variations in latent and sensible heat content of saturated air and is similar to the more familiar s as used in the simplified analysis above (see also Brutsaert, 1982)) (Brutsaert, 1982). Combining this insight with the Penman–Monteith equation, with the second term above the nominator set to zero and with zero surface or canopy resistance ($r_s = 0$) as appropriate for a moist surface, yields the "equilibrium evaporation" (see also Brutsaert, 1982; Raupach, 2001):

$$\lambda E = \frac{s}{s + \frac{c_p}{\lambda}} Q_* \tag{12}$$

Equilibrium evaporation as defined by these authors refers to the lower limit of evaporation from a moist surface where the specific humidity deficit of the second term in the nominator of the PM equation has become zero as a result of contact of air with a moist surface over a very long fetch.

The second term in the nominator of the PM equation is seen to represent the departure from this equilibrium. Priestley and Taylor (1972) termed this departure from equilibrium evaporation α, and it is easily seen that α is only unity when the specific humidity deficit in the PM equation is zero, in other words when advection is negligible. That this is hardly ever the case proves the fact that most empirical values of α for short crops are of the order 1.2–1.3 (e.g. Brutsaert, 1982). For tall crops, Shuttleworth and Calder (1979) show convincingly that the equilibrium approach is not appropriate because the physiological control of the forest transpiration reduces α below a value of 1 in dry canopy conditions, while in wet canopy conditions large-scale advection and negative sensible heat fluxes (Stewart, 1977) may form an additional supply of energy and force α to be well above the value for short crops. This emphasizes the important point that for tall crops in particular, it is important to estimate dry and wet canopy evaporation separately.

Faith in the equilibrium evaporation concept by hydrologists is largely based on the belief that at larger regional scale, the atmospheric conditions override the surface control. A number of concepts have been derived that use the perceived dampening power of the atmosphere to estimate regional-scale evaporation (e.g. Bouchet, 1963; Morton, 1983). Although McNaughton and Jarvis (1991) show that at larger scale the feedback of the atmospheric boundary layer dampens the effects of surface controls – and thus makes precise estimation of the surface resistance less important – the physical basis of the Bouchet and Morton schemes remains doubtful (see de Bruin, 1983; McNaughton and Spriggs, 1989). Nevertheless, de Bruin showed that the feedback of the increasing atmospheric boundary-layer humidity during the day causes the regional surface conductance to vary less than if the feedback were neglected. When the surface resistance is moderately influenced by soil moisture stress, surface conditions are again important, whereas in the case of a completely dry surface, the boundary layer overrides surface control and a crude estimation of the surface resistance is sufficient. However, the de Bruin (1983) and McNaughton and Spriggs (1989) studies were restricted to a few clear days, with no cloud development or rainfall and require rather detailed observational input from the boundary layer, and clearly have no general practical application as yet. At the annual timescale, there may be promise in extending the complementary relationship along the lines discussed earlier in this paper (Zhang *et al.*, 2001) and incorporate not only the evaporation-potential evaporation feedback, but also the precipitation feedback on evaporation.

CONCLUSIONS

There has been remarkable progress in our understanding of actual evaporation in the last two decades, at least partly due to our increased ability to measure directly the fluxes of latent and sensible heat by micrometeorological techniques (*see* **Chapter 40, Evaporation Measurement, Volume 1**). At the same time, progress in modeling has generated a suite of evaporation models that can now be applied under various circumstances. To a large extent, the choice of a particular model will depend on the data availability and purpose. For simple applications, the crop factor approach may still work best; in hydrological and meteorological models, the more physically and physiologically based models are a more suitable option. These allow predictions to be made under various changing environmental factors, which the more empirical approaches can never realistically attain to predict.

At large scales, the relationships between evaporation, rainfall and available energy appear to be more straightforward than at smaller scales (Wilson *et al.*, 2002) and water use by vegetation in different climates more conservative (Law *et al.*, 2002). This feature can be exploited when predicting the effects of land-cover change on the hydrological balance (e.g. Zhang *et al.*, 2001, 2004). The challenge in the next few years for hydrometeorologists still is to match our micrometeorological estimates with the catchment scale observations. Only then, can process understanding at short time and spatial scales be used to explain the larger integral constraints we observe of catchment scale behavior.

Remote Sensing

46: Principles of Radiative Transfer

MATTHIAS DRUSCH[1] AND SUSANNE CREWELL[2]

[1]*European Centre for Medium-Range Weather Forecasts, Reading, UK*
[2]*Munich University, Munich, Germany*

The article gives an introduction to classical vector radiative transfer theory (RTT). It comprises a brief summary of the fundamental quantities in RTT and the corresponding definitions. Based on these quantities, the transfer equation for radiation will be introduced in its basic form for a plane-parallel, horizontally homogeneous atmosphere. Polarization and the Stokes vector are introduced, which extend the scalar radiative transfer equation to the more general form of the vector radiative transfer equation. Scattering processes and interactions with the surface are discussed within the mathematical framework given in the first part of the paper. As an example, the theoretical concept presented is then applied to passive microwave remote sensing. A solution for the radiative transfer equation, which is commonly used for the retrieval of atmospheric quantities (e.g. water vapor) and land surface properties (e.g. soil moisture), is derived based on approximations and simplifications. More general approaches to solve the radiative transfer equation including multiple scattering are described and discussed in a separate section.

INTRODUCTION

Radiative transfer theory (RTT) describes the interaction between matter and electromagnetic radiation. Electromagnetic waves travel in vacuum and air at the speed of light at $\sim 3 \times 108\,\mathrm{ms}^{-1}$. The electromagnetic spectrum covers gamma rays, X rays, ultraviolet, visible, infrared, microwaves, television signals, and radio waves as shown in Figure 1. Following Planck's law, solar radiation can be described as radiation emitted from a black body at a temperature of about 6000 K. Consequently, the solar component comprises radiation from the Gamma rays to the infrared spectral range. Only ~0.4% of the energy of solar radiation is emitted at wavelengths above 5 μm. The irradiance at the top of the atmosphere (solar constant S_0) is $1366\,\mathrm{Wm}^{-2} \pm 3\,\mathrm{Wm}^{-2}$ depending on the solar-earth distance and natural fluctuations of the sun's activity (Lean and Rind, 1998). Consequently, the energy available for the earth-atmosphere system is:

$$E_{\mathrm{sol},\downarrow} = \pi r_E^2 (1-\alpha) S_0 \tag{1}$$

with the planetary albedo α. This energy is absorbed by the system and reemitted following Stefan–Boltzmann's law:

$$E_{\mathrm{ter},\uparrow} = 4\pi r_E^2 \sigma_B T_E^4 \tag{2}$$

with the blackbody temperature of the earth T_E, the radius of the Earth r_E and the Stefan–Boltzmann constant σ_B. Using equations (1) and (2), a blackbody temperature for the atmosphere-earth system of ~255 K is obtained. At this temperature, a blackbody emits only 0.4% of its radiation at wavelengths below 5 μm (Goody and Yung, 1961). As a consequence, solar and terrestrial radiation can be treated independently. In equations (1) and (2) radiation has been integrated over all wavelengths and angles. In addition, T_E and α are "mean" quantities, which comprise the atmosphere (clouds, gaseous profiles, etc.), ocean (ice, foam, algae, etc.), and land surfaces (vegetation, soil texture, snow, etc.). For a comprehensive description of the interaction of electromagnetic waves and the earth-atmosphere system in hydrological applications and numerical modelling (including climate models, numerical weather prediction (NWP) models, soil-vegetation-atmosphere transfer

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

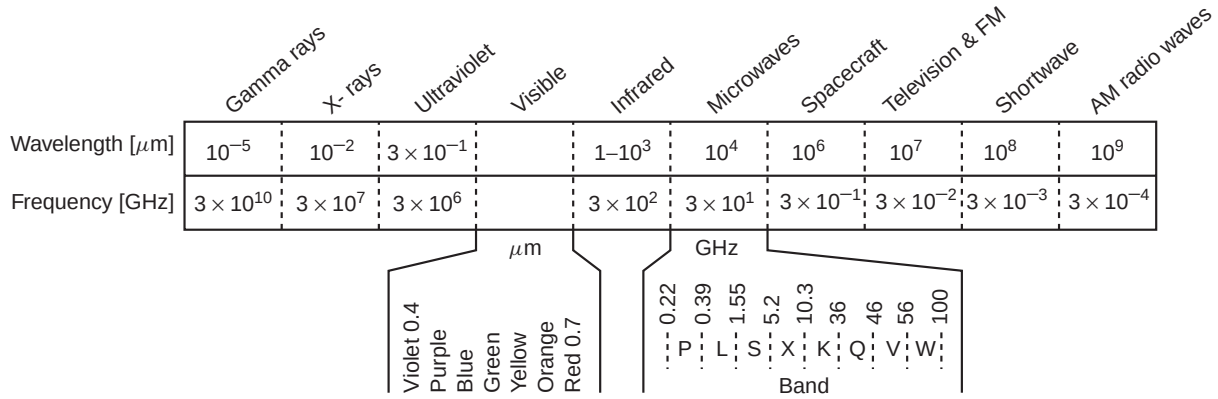

Figure 1 The electromagnetic spectrum (after Liou, 2002; Ulaby *et al.*, 1982)

(SVAT) models, physical and chemical cloud models, vegetation growth models, etc.), the RTT has to be much more complex.

Remote sensing is a second field of research, which is strongly related to RTT. Passive remote sensing techniques make use of the interaction of natural radiation with the variable of interest while active methods employ artificial sources of radiation such as lasers or radio wave sources. Retrieving geophysical parameters from radiation measurements requires RTT unless purely statistical methods are used.

In general, the theoretical and computational work on RTT can be divided in forward (or direct) and backward (or inverse) applications. In forward modelling studies, the geophysical parameters characterizing the earth-atmosphere system and the boundary conditions for the radiation sources are prescribed and the radiation field is computed for the given environment. Numerical climate or NWP modelling are typical examples of forward applications. For the inverse problem, the radiation field is known and it is aimed to retrieve the parameters characterizing the atmosphere and/or the surface. Many of the remote sensing applications have to address the inverse problem. Since analytical solutions for the inverse problem do not exist, a large number of statistical and physical retrieval methods have been developed. Often, variational methods assume a certain set of geophysical parameters and the computed radiances are compared with the observations. In the consecutive iteration steps, the parameters are modified to match the observations taking into account the observation and model errors.

Even if we limit ourselves to forward applications, it is impossible to provide a complete introduction to RTT for the most relevant physical processes at the visible to microwave spectral range within the framework of an article. For the basic laws in RTT, for example, Planck's law, Wien's law, Stefan–Boltzmann law and Kirchhoff's law, the reader is referred to more general textbooks, for example, Salby (1996). The focus of this paper is the classical vector RTT, since it has found extensive applications in research and operations. An overview of radiative transfer theory requires the use of mathematical expressions. The mathematics presented in this article partly exceeds the formalism presented in more general textbooks, for example, Salby (1996). Compared to specific books on radiative transfer (e.g. Chandrasekhar (1960), Liou (2002)) the number of equations is small and the corresponding level of complexity is low. However, the basic equations and theory presented in this article allow the reader to cope with more specific scientific articles addressing radiative transfer, remote sensing, engineering, and biophysical applications. A further reduction of the number of equations would not lead to a better understanding of the topic.

The first two sections comprise a brief summary of the fundamental quantities in RTT and the corresponding definitions. Based on these quantities, the transfer equation for radiation will be introduced in its basic form for a plane parallel, horizontally homogeneous atmosphere. This derivation can be found in many articles and textbooks on remote sensing and radiative transfer (e.g. Ulaby *et al.*, 1982; Liou, 2002; Chandrasekhar, 1960). In the section "Polarization and vector radiative transfer equation", polarization and the Stokes vector will be introduced, which extends the scalar radiative transfer equation to the general form of the vector radiative transfer equation. The sections "Scattering and phase functions" and "Boundary conditions – the surface" address scattering processes and interactions with the surface, respectively. Based on the theoretical framework presented in the first six sections, the radiative transfer equation is simplified and solved for passive microwave applications. More general approaches to solve the radiative transfer equation are presented in the section "Solutions".

DEFINITIONS

In a medium that interacts with radiation at a specific frequency ν, the specific intensity I_ν can vary from point to point and with the direction of propagation at each point. Following Chandrasekhar (1960), the specific (or monochromatic) intensity can be defined as:

$$I_\nu \equiv I_\nu(x, y, z; l, m, n; t) \tag{3}$$

where (x,y,z) and (l,m,n) define the point and the direction cosines and t indicates the temporal dependence of intensity. The specific intensity is given in units of $\mathrm{Wm^{-2}\,sr^{-1}\,Hz^{-1}}$ and is often referred to just as intensity (or radiance) for simplicity. The integration over the entire hemisphere gives the flux density F_ν also called *irradiance*, which is used in energetical studies. Integration over an infinitesimal frequency range $\mathrm{d}\nu$, the directions defining an element of the solid angle $\mathrm{d}\omega$ ($\mathrm{d}\omega = \mathrm{d}\sigma/r^2 = \sin\theta\,\mathrm{d}\theta\,\mathrm{d}\phi$) and a time interval $\mathrm{d}t$, leads to the amount of energy dE_ν transported through the cross-section $\mathrm{d}\sigma$ (Figure 2):

$$\mathrm{d}E_\nu = I_\nu \cos\theta\,\mathrm{d}\nu\,\mathrm{d}\sigma\,\mathrm{d}\omega\,\mathrm{d}t \tag{4}$$

If the intensity I_ν at a given point is independent of direction, the radiation field is called *isotropic*. In this case, the relation $F_\nu = \pi I_\nu$ holds. Such a radiation field, which is characterized by constant intensities at each point, is said to be homogeneous. For practical applications in hydrology and atmospheric sciences, the medium (e.g. atmosphere, vegetation canopy, or the soil) that interacts with the radiation is often characterized by stratified plane-parallel layers with invariant physical properties. In a spherical coordinate system where z is the height and θ and ϕ the polar and azimuthal angles, the corresponding specific intensity can be written as:

$$I_\nu \equiv I_\nu(z, \theta, \phi; t) \tag{5}$$

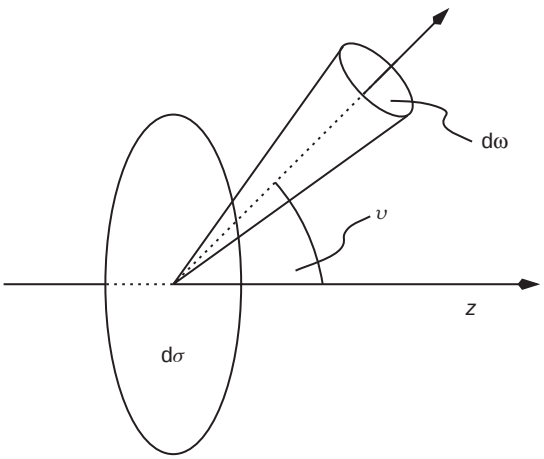

Figure 2 Definition of the specific intensity

SCALAR RADIATIVE TRANSFER EQUATION

Radiation characterized by a specific intensity I_ν passing a volume, defined by its thickness $\mathrm{d}s$ and a unit cross-section, will be weakened by an amount $\mathrm{d}I_\nu$. This extinction is caused by interaction with matter, namely *absorption and/or scattering*. Introducing the mass extinction, absorption, and scattering coefficients σ_e', σ_a', and σ_s' we can write:

$$\sigma_e' = \sigma_a' + \sigma_s' \tag{6}$$

The corresponding volume coefficients σ_e, σ_a, and σ_s can be obtained by multiplication with the density of the medium. Consequently, the amount of radiation absorbed and/or scattered by the matter in a volume $\mathrm{d}\sigma\,\mathrm{d}s$ for a solid angle element $\mathrm{d}\omega$ in a given time interval $\mathrm{d}t$ can be formulated as:

$$\sigma_e\,\mathrm{d}s\,I_\nu\,\mathrm{d}\nu\,\mathrm{d}\sigma\,\mathrm{d}\omega\,\mathrm{d}t \tag{7}$$

On the other hand, radiation intensity can be increased within the volume by contributions from scattering and emission. This source term can be described by introducing the volume emission coefficient j_ν

$$j_\nu\,\mathrm{d}s\,\mathrm{d}\nu\,\mathrm{d}\sigma\,\mathrm{d}\omega\,\mathrm{d}t \tag{8}$$

The change of the radiation intensity propagating along a path $\mathrm{d}s$ caused by extinction (7) and sources (8) expressed in specific intensity is therefore:

$$\frac{\mathrm{d}I_\nu}{\mathrm{d}s}\,\mathrm{d}s\,\mathrm{d}\nu\,\mathrm{d}\sigma\,\mathrm{d}\omega\,\mathrm{d}t = -\sigma_e\,\mathrm{d}s\,I_\nu\,\mathrm{d}\nu\,\mathrm{d}\sigma\,\mathrm{d}\omega\,\mathrm{d}t + j_\nu\,\mathrm{d}s\,\mathrm{d}\nu\,\mathrm{d}\sigma\,\mathrm{d}\omega\,\mathrm{d}t \text{ or}$$

$$\frac{\mathrm{d}I_\nu}{\sigma_e\,\mathrm{d}s} = -I_\nu + \frac{j_\nu}{\sigma_e} \tag{9}$$

The emission coefficient j_ν can be written as the sum of two source terms. Radiation in the direction defined through the angles θ and ϕ is due to scattering processes $j_{\nu s}$ and emission from the medium in local thermodynamic equilibrium, $j_{\nu a,}$. The first term may be expressed as:

$$j_{\nu s}(\theta, \phi) = \sigma_s \frac{1}{4\pi} \int_0^\pi \int_0^{2\pi} p(\theta, \phi; \theta', \phi') I_\nu(\theta', \phi') \sin\theta'\,\mathrm{d}\theta'\,\mathrm{d}\phi' \tag{10}$$

In equation (10) the normalized phase function $p(\theta, \phi, \theta', \phi')$ is introduced. It describes how much radiation is scattered from incidence direction characterized by angles (θ',ϕ') into observation direction given by (θ,ϕ). Perfect scattering in the absence of any absorption requires:

$$\frac{1}{4\pi} \int_0^\pi \int_0^{2\pi} p(\theta, \phi; \theta', \phi')\,\mathrm{d}\theta'\,\mathrm{d}\phi' = 1 \tag{11}$$

Under the assumption of local thermodynamic equilibrium the thermal emission is given through Kirchhoff's law and the Planck function:

$$j_{va} = \sigma_a B_\nu(T) \tag{12}$$

$$B_\nu(T) = \frac{2h\nu^3}{c^2}\frac{1}{e^{h\nu/k_B T} - 1} \tag{13}$$

where h and k_B are the Planck and Boltzmann constants and T the temperature. Combining equations (10) and (12) in (9) gives the scalar radiative transfer equation:

$$\frac{\mathrm{d}I_\nu}{\sigma_e\,\mathrm{d}s} = -I_\nu + \omega_0\frac{1}{4\pi}\int_0^\pi\int_0^{2\pi} p(\theta,\phi;\theta',\phi')I_\nu(\theta',\phi') \sin\theta'\,\mathrm{d}\theta'\,\mathrm{d}\phi' + (1-\omega_0)B_\nu(T) \tag{14}$$

with ω_0 the single scattering albedo defined as:

$$\omega_0 = \frac{\sigma_s}{\sigma_s + \sigma_a} \tag{15}$$

It has to be noted that equation (14) is valid for a specific frequency only. Therefore, the properties of the medium may be frequency dependent as well. RTT in which the radiation directly depends on frequency and where conversion of radiation between different frequencies takes place will not be discussed. Active remote sensing techniques such as, Raman lidar may need other forms of the radiative transfer equation. Methods to solve equation (14) are discussed in the section "Solutions".

POLARIZATION AND VECTOR RADIATIVE TRANSFER EQUATION

Equation (14) describes the radiative transfer for the specific intensity I_ν. Another source of information in remote sensing is the polarization of radiation. In order to model polarization effects due to particle scattering and/or rough surface reflection, we have to extend equation (14) to the full vector equation.

Wave Formalism

Elliptically polarized electromagnetic waves are described by the time-dependent electric field $\boldsymbol{E}$. Following Chandrasekhar (1960), Liou (1992) the field components can be projected to two perpendicular vectors in the plane orthogonal to the direction of propagation:

$$\boldsymbol{E}(t) = \boldsymbol{E}_l(t) + \boldsymbol{E}_r(t) = a_l(t)\cdot\boldsymbol{e}_l + a_r(t)\cdot\boldsymbol{e}_r \tag{16}$$

$\boldsymbol{e}_l$ and $\boldsymbol{e}_r$ are orthogonal unit vectors parallel and perpendicular to the scattering/reflection plane and define the local coordinate system as shown in Figure 3. In this system, the amplitudes and the complex electric field components can be expressed using the circular frequency ω_c, the wave number k, four constants (a_l, a_r, ε_l, ε_r), and the phase lag $\rho = \varepsilon_l - \varepsilon_r$ between both components of the wave:

$$\begin{aligned} a_l &= a_l^0 \sin(\omega_c t - \varepsilon_l) \\ a_r &= a_r^0 \sin(\omega_c t - \varepsilon_r) \\ E_l &= a_l^0 e^{-i\rho} e^{-kz+i\omega_c t} \\ E_r &= a_r^0 e^{-i\rho} e^{-kz+i\omega_c t} \end{aligned} \tag{17}$$

Intensity Formalism

The Stokes vector $\boldsymbol{I} = (I, Q, U, V)$ is defined by the components of the electromagnetic field (e.g. Chandrasekhar, 1960; Liou, 2002). It can be expressed with the real amplitudes, the phase difference and the angles β and χ (Figure 3):

$$\begin{aligned} I &= a_l^2 + a_r^2 = I_l + I_r \\ Q &= a_l^2 - a_r^2 = I_l - I_r = I\cos 2\beta\cos 2\chi \\ U &= 2a_l a_r\cos\rho = I\cos 2\beta\sin 2\chi \\ V &= 2a_l a_r\sin\rho = I\sin 2\beta \end{aligned} \tag{18}$$

The first Stokes parameter gives the total intensity, Q indicates the degree of linear polarization, U describes the plane of polarization and the ellipticity is given by V. For a

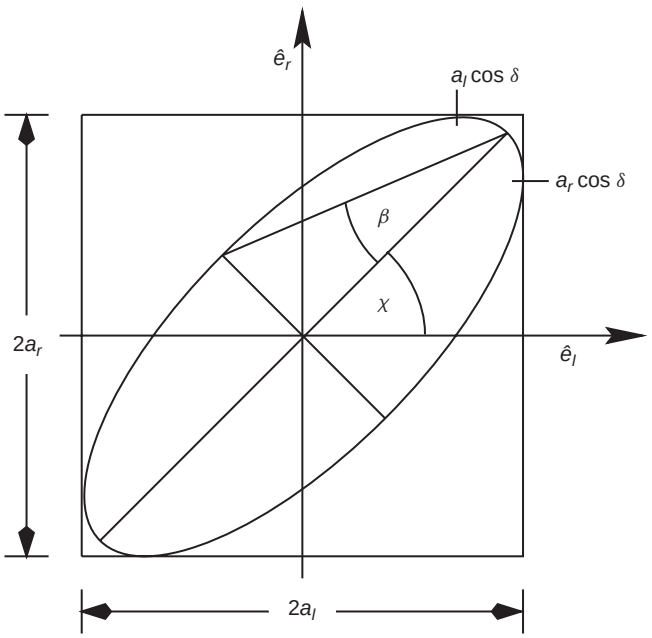

Figure 3 Illustration of an elliptically polarized electromagnetic wave

single wave and fully polarized light $I^2 = Q^2 + U^2 + V^2$ is valid. Natural radiation consists of the superposition of many different waves and contains a mixture of polarized and unpolarized light. In this case, the relation

$$I^2 \geq Q^2 + U^2 + V^2 \tag{19}$$

is valid. The degree of polarization is then given through:

$$P = \frac{\sqrt{Q^2 + U^2 + V^2}}{I} \tag{20}$$

Transformation of Stokes Vectors and Global Coordinates

Equations (18) describe the Stokes vector in local coordinates, which are used to describe single scattering processes. The radiative transfer equation refers to a Cartesian grid for the position and spherical coordinates for directions. Scattering processes change the direction of propagation and therefore a transformation between the local system, in which the scattering process is described, and the global coordinate system for the radiative transfer calculations is required. The geometry is illustrated in Figure 4. Assuming that the incident beam P_1 is scattered at the origin O to P_2, the local coordinate system is defined in the plane $P_1\ OP_2$. Let $\boldsymbol{R}(\Theta)$ be the phase function and Θ the scattering angle in the local system. In order to apply the phase function the Stokes vector of the incident light has to be transformed from the directions to which the polarization refers in global coordinates (plane $P_1 OZ$) to the local coordinates ($P_1 OP_2$). After performing the scattering process, a transformation from $P_1 OP_2$ to $P_2 OZ$ is necessary. The clockwise rotation angles for both rotations are $(-\iota_1)$ and $(\pi - \iota_2)$, respectively. The rotation transformation matrix for the Stokes vector reads:

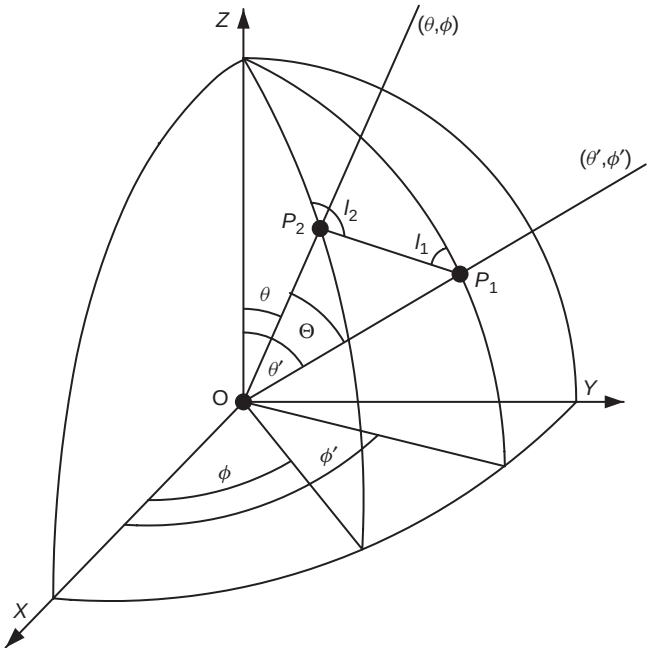

Figure 4 Directions of incoming and outgoing radiation with notation of angles

$$\boldsymbol{L}(\phi) = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & \cos^2\phi & \sin^2\phi & 0 \\ 0 & \sin^2\phi & \cos^2\phi & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \tag{21}$$

The scattered beam is computed from:

$$\boldsymbol{I}(\theta, \phi) = \boldsymbol{L}(\pi - \iota_2)\boldsymbol{R}(\cos\Theta)\boldsymbol{L}(-\iota_1)\boldsymbol{I}(\theta', \phi') \tag{22}$$

The phase function $\boldsymbol{P}(\theta,\phi;\theta',\phi')$ is transformed from the local system to the global system by:

$$\boldsymbol{P}(\theta, \phi; \theta', \phi') = \boldsymbol{L}(\pi - \iota_2)\boldsymbol{R}(\cos\Theta)\boldsymbol{L}(-\iota_1) \tag{23}$$

For a set of discrete angles $(\theta,\phi;\theta',\phi')$, the angles ι_1 and ι_2 can be calculated with $\mu = \cos\theta$ and $\mu' = \cos\theta'$:

$$\cos\iota_1 = \frac{-\mu + \mu'\cos\Theta}{\pm(1 - \cos^2\Theta)^{1/2}(1 - \mu'^2)^{1/2}} \tag{24}$$

and

$$\cos\iota_2 = \frac{-\mu' + \mu\cos\Theta}{\pm(1 - \cos^2\Theta)^{1/2}(1 - \mu^2)^{1/2}} \tag{25}$$

The plus and minus signs in equations (24) and (25) are used for $\pi < \phi - \phi' < 2\pi$ and $0 < \phi - \phi' < \pi$, respectively. The scattering angle Θ, which is given in local coordinates, transforms to the global system through:

$$\begin{aligned} \cos\Theta &= \mu\mu' + (1 - \mu^2)^{1/2}(1 - \mu'^2)^{1/2}\cos(\phi - \phi') \\ &= \cos\theta\cos\theta' + \sin\theta\sin\theta'\cos(\phi - \phi') \end{aligned} \tag{26}$$

Vector Radiative Transfer Equation

Replacing the intensities in equation (14) by Stokes vectors leads to the Vector Radiative Transfer Equation (VRTE). As a consequence, scattering and extinction coefficients and the phase function become matrices. Following equation (14) the VRTE can be written in the general form:

$$\begin{aligned} \frac{\mathrm{d}^3\boldsymbol{I}(x, y, z, \theta, \phi)}{\frac{1}{\eta}\mathrm{d}x\frac{1}{\delta}\mathrm{d}y\frac{1}{\mu}\mathrm{d}z} &= -\boldsymbol{\sigma_e}(x, y, z, \theta, \phi)\boldsymbol{I}(x, y, z, \theta, \phi) \\ &\quad + \boldsymbol{\sigma_a}(x, y, z, \theta, \phi)\boldsymbol{B}(T(x, y, z)) \\ &\quad + \int_0^{2\pi}\int_0^{\pi} \boldsymbol{P}(x, y, z, \theta, \phi, \theta', \phi') \\ &\quad \boldsymbol{I}(x, y, z, \theta', \phi')\sin\theta'\,\mathrm{d}\theta'\,\mathrm{d}\phi' \end{aligned} \tag{27}$$

In general, the phase matrix $\boldsymbol{P}$ and the extinction matrix σ_e are nondiagonal and couple the four components of the Stokes vector. Therefore, the differential equations do not decouple and have to be solved simultaneously. In the scattering phase matrix $\boldsymbol{P}$, three dimensions for position and space and four for the propagation directions of the incident and scattered radiation have to be considered. Therefore, $\boldsymbol{P}$ cannot be normalized and a volume scattering coefficient cannot be defined. As a consequence, the single scattering albedo ω_0 as defined by equation (15) does not exist.

Another interesting fact to note is that there is no well-defined optical thickness for the four component Stokes vector. The exponential attenuation law (Bouguer–Lambert-Beer's law) for the transmission is not applicable and the transmission along path length ds cannot be calculated using:

$$I(s + \mathrm{d}s) = I(s)e^{-\sigma_e \mathrm{d}s} \tag{28}$$

The differences in the Stokes vector components have to be computed at a series of small enough intervals ds to ensure that the change in intensity is linear in the path length coordinate:

$$\mathrm{d}\boldsymbol{I} = \boldsymbol{\sigma}_e \boldsymbol{I}\, \mathrm{d}s \tag{29}$$

SCATTERING AND PHASE FUNCTIONS

It is one objective of scattering theory to quantify the scattering phase matrix, single scattering albedo, and the scattering cross sections for the individual scatterers, which can comprise molecules, aerosols, ice crystals, leafs, stems, and so on. The size parameter $\alpha_{size} = 2\pi r/\lambda$, which defines the relation between particle radius r and wavelength λ, the complex refraction index and the particle shape are often used to determine the appropriate solution method.

In case of isotropic scattering, the phase function is given by $p(\cos\Theta) = 1$. For many atmospheric applications, Rayleigh scattering is of particular interest. Lord Rayleigh first characterized it in 1871 in the context of the explanation for the blue sky. Although its original application focused on sunlight and atmospheric molecules, it was found that Rayleigh scattering theory could be applied to processes where the particle size is much smaller than the wavelength. As a rule of thumb, α_{size} should be smaller than 0.1. The phase function describing Rayleigh scattering can be formulated as:

$$p(\cos\Theta) = \tfrac{3}{4}(1 + \cos^2\Theta) \tag{30}$$

with the corresponding phase matrix:

$$\boldsymbol{R} = \frac{3}{2}\begin{pmatrix} \cos^2\Theta & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & \cos\Theta & 0 \\ 0 & 0 & 0 & \cos\Theta \end{pmatrix} \tag{31}$$

Following Chandrasekhar (1960), the scattered intensity I^{scat} can be written as:

$$I^{\text{scat}} = \frac{128\pi^5}{3\lambda^4}\alpha_p^2 I\, \mathrm{d}\omega \frac{3}{4}\left(1 + \cos^2\Theta\right)\frac{\mathrm{d}\omega'}{4\pi} \tag{32}$$

with α_p being the polarizability. The scattering coefficient per particle can be introduced as:

$$\sigma_{s,p} = \frac{128\pi^5}{3\lambda^4}\alpha_p^2 \tag{33}$$

Figure 5 shows a Rayleigh scattering diagram in polar coordinates and a scattering angle versus scattering phase function representation. The three curves describe I_l, I_r, and $I_l + I_r$ (the scale is not identical in each case). Rayleigh scattering theory cannot be applied if the particle size is not small compared to the wavelength, for example, for interactions of natural light with cloud and rain droplets, aerosols, ice crystals, or vegetation canopies. For particles that are large compared to the wavelength, the geometric optics approach (or ray tracing technique) can be applied (e.g. Macke *et al.*, 1996). For cases with particles sizes, which are comparable in size with the wavelength, exact solutions for single scattering problems exist only for highly symmetrical particle shapes if the surface of a particle is an iso-plane of a coordinate system, in which the vector wave equations can be derived. Under these conditions, the wave equation can be separated into a set of differential equations, which can be solved. Mie (1908) analyzed the problem for spheres in a spherical coordinate system using spherical harmonics. The solution for the scattering matrix and the scattering cross sections are obtained from an infinite series of Mie-coefficients, which are determined from the corresponding Legendre polynomials and spherical Bessel functions (Liou, 1992). A selection of Mie type phase functions is presented in Figure 6. The calculations are based on standard gamma drop size distributions (Hansen and Travis, 1974) characterized by effective radii of 10 μm and 100 μm for cloud water and rain, respectively. The wavelengths referred to in Figure 6 are 0.55 μm, 10 μm, and 1 mm for the visible, infrared, and microwave, respectively. For the visible and infrared wavelengths, the rain and water drops are comparably large and a strong forward peak characterizes the Mie scattering phase functions. In the infrared spectral region, the scattering phase function decreases monotonously with scattering angle. For the visible, a minimum around 105° is obtained. Since the microwave wavelength is much larger than the cloud water droplet, Rayleigh scattering occurs. For nonspherical particles, which are rotationally symmetrical, numerical methods have been developed to extend the applicability of Mie theory (e.g. Mishchenko *et al.*, 1996; Rother and Schmidt, 1996; Mishchenko *et al.*, 2000).

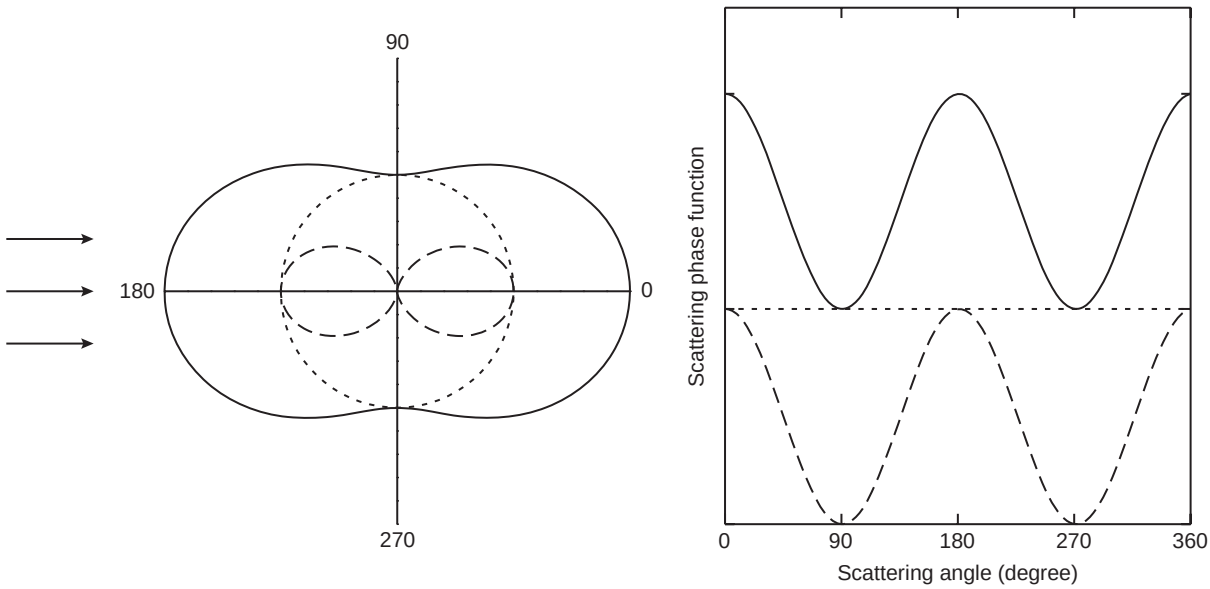

Figure 5 Schematic view of the Rayleigh phase function (after Goody and Yung, 1961)

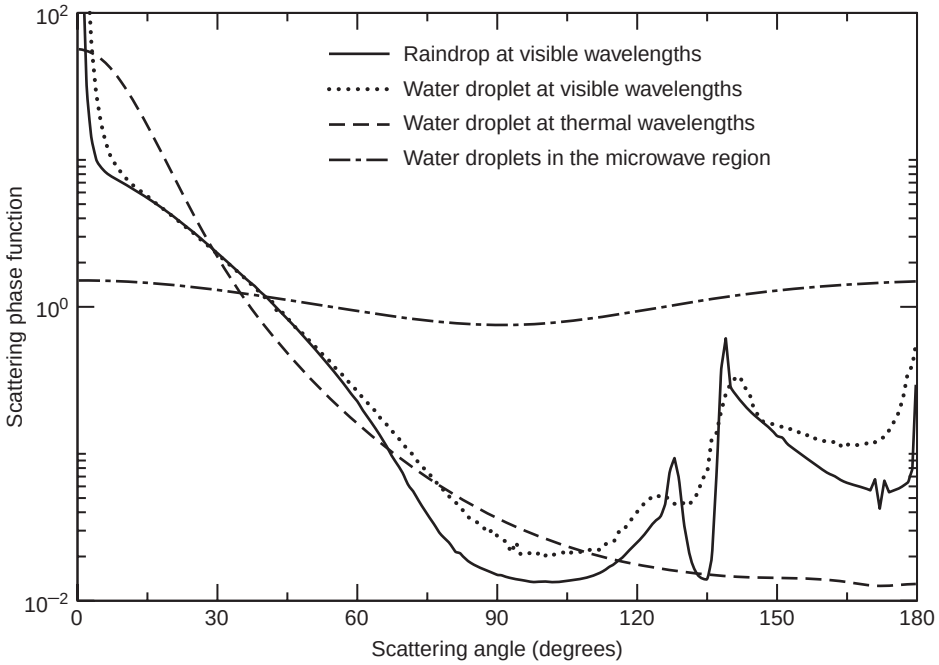

Figure 6 Scattering phase functions for visible (0.55 μm), infrared (10 μm), and microwave (1 mm) wavelengths. Effective radii of 10 μm and 100 μm for cloud water and rain characterize the drop size distributions

In order to model scattering of microwave radiation from vegetation canopies, randomly oriented nonspherical scatterers of finite size can be used. Circular discs are used to model deciduous vegetation (e.g. Tsang *et al.*, 1981). Coniferous vegetation is described by needles (e.g. Eom and Fung, 1986) and stems and branches, which are represented as circular cylinders of finite size (e.g. Cohen *et al.*, 1983; Karam and Fung, 1988). However, it has to be noted that in classical vector radiative transfer theory it is assumed that discrete particles scatter independently. This assumption is valid if the particles are distributed randomly and if the randomness of relative positions is comparable to or larger than the wavelength (Tsang *et al.*, 1985). In dense and/or discontinuous media, which are

characterized by clusters of scattering particles, collective scattering effects have to be included. Numerous models for the different wavelengths exist in the reviewed literature. Tsang *et al.* (1995) provide a brief review on different approaches and an application to passive microwave remote sensing.

BOUNDARY CONDITIONS – THE SURFACE

In general, natural surfaces reflect radiation anisotropically. The reflection at the surface can be described by the bidirectional reflectance function γ. "Bidirectional" refers to the fact that the reflection function depends on the direction of the incident radiation and the direction of the observation or outgoing radiation. The formal representation for γ is (e.g. Mishchenko *et al.*, 1999; Tsang *et al.*, 1985):

$$I(\theta, \phi) = \mu' \gamma(\theta, \phi; \theta', \phi') F \tag{34}$$

with πF the incident flux per unit area perpendicular to the incident beam (indices for polarization and frequency dependency are omitted). $\mu' \gamma_{r,t}(\theta, \phi; \theta', \phi')$ defines the bistatic scattering coefficient $\sigma^o{}_{r,t}$ (r and t indicate the polarization), which satisfies the principle of reciprocity:

$$\sigma^o{}_{r,t}(\theta, \phi; \theta', \phi') = \sigma^o{}_{t,r}(\theta', \phi'; \theta, \phi) \tag{35}$$

The emissivity ε_r and reflectivity Γ_r are given by:

$$\varepsilon_r(\theta', \phi') = 1 - \Gamma_r(\theta', \phi') \tag{36}$$

and

$$\Gamma_r(\theta', \phi') = \frac{1}{4\pi\mu} \int_0^{2\pi} \left(\sigma^o_{rr}(\theta, \phi, \theta', \phi') + \sigma^o_{tr}(\theta, \phi, \theta', \phi') \right) \sin\theta d\theta d\phi. \tag{37}$$

The reflected intensity I^S at polarization r can be expressed as:

$$I^s_r(\theta', \phi') = \frac{1}{4\pi\mu} \int_0^{2\pi} \left(\sigma^o_{rr}(\theta, \phi, \theta', \phi') I_r(\theta, \phi) + \sigma^o_{tr}(\theta, \phi, \theta', \phi') I_t(\theta, \phi) \right) \sin\theta \, \mathrm{d}\theta \, \mathrm{d}\phi \tag{38}$$

Since many remote sensing, engineering, and biophysical applications rely on an accurate description of the bidirectional reflection function or the bistatic scattering coefficient the number of models, which relate geophysical surface parameters to both quantities, is large. The concepts and complexities vary depending on the application, for which they were designed. A number of review articles or overviews on the different models and frequency ranges exist, for example, Myneni *et al.* (1989), Goel (1988), Snyder and Wan (1998), Kerr and Wigneron (1995).

APPLICATION TO PASSIVE MICROWAVE RADIOMETRY

Equation (27) is the most general form for vector RTT. For many applications simplifications can be made to obtain analytical solutions. As an example, we will derive a solution for equation (27) for passive microwave applications. The number of geophysical parameters, which can be derived from passive microwave observations, is large and covers a wide range of applications (Ulaby *et al.*, 1982): (1) oceans (surface wind speed, temperature, salinity, and oil spills; sea ice extent and age), (2) meteorology (temperature profile, water vapor profile, liquid water (clouds and rain), and integrated water vapor), and (3) agriculture and hydrology (soil moisture distribution, flood mapping, delineation of freeze-thaw boundaries, snow cover extent, snow water equivalent, snow wetness, and continental ice sheets). The derivation outlined in the following paragraphs has been used as the basis for a number of applications, especially for the land surface (e.g. Drusch *et al.*, 2001; Kerr and Njoku, 1990; Mo *et al.*, 1982).

For plane parallel azimuthally isotropic and horizontally homogeneous atmospheres, the radiances become a function of z and θ. Owing to the azimuthally symmetry, there is no interaction between the first two components and the last two components of the Stokes vector and total intensity and linear polarization can be derived without considering the U and V components of the Stokes vector. From equation 27, one obtains (Tsang *et al.*, 1985):

$$\mu \frac{\mathrm{d}\boldsymbol{I}(z, \theta)}{\mathrm{d}z} = -\boldsymbol{\sigma}_{\mathbf{e}}(z, \theta)\boldsymbol{I}(z, \theta) + \boldsymbol{\sigma}_{\mathbf{a}}(z, \theta)\boldsymbol{B}(T(z)) + \int_0^{\pi} \boldsymbol{P}(z, \theta, \theta')\boldsymbol{I}(z, \theta') \sin\theta' \, \mathrm{d}\theta' \tag{39}$$

which is equivalent to:

$$\cos\theta \frac{d}{\mathrm{d}z} \begin{bmatrix} I_v(z, \theta) \\ I_h(z, \theta) \end{bmatrix} = -\sigma_e(z) \begin{bmatrix} I_v(z, \theta) \\ I_h(z, \theta) \end{bmatrix} + \sigma_a(z) \begin{bmatrix} \frac{B(T)}{2} \\ \frac{B(T)}{2} \end{bmatrix} + \int_0^{\pi} \begin{bmatrix} P_{vv}(z, \theta, \theta') & P_{vh}(z, \theta, \theta') \\ P_{hv}(z, \theta, \theta') & P_{hh}(z, \theta, \theta') \end{bmatrix} \begin{bmatrix} I_v(z, \theta) \\ I_h(z, \theta) \end{bmatrix} \sin\theta' \, \mathrm{d}\theta' \tag{40}$$

The sources of radiation can be summarized as:

$$J(z,\mu)=\frac{\sigma_a}{\sigma_e}\frac{B(T(z))}{2}+\omega_0(z)\int_{-1}^{1}(p_{rv}(z,\mu,\mu')I_v(z,\mu')+p_{rh}(z,\mu,\mu')I_h(z,\mu'))d\mu' \quad (41)$$

with the normalized phase functions p, which are obtained through:

$$p_{r,t}=\frac{1}{\sigma_s}P_{r,t} \quad (42)$$

Introducing the height of the atmosphere z_A and the atmospheric optical depth δ:

$$\delta(z)=\int_z^{z_A}\sigma_e(z')\,\mathrm{d}z'$$
$$\mathrm{d}\delta=-\sigma_e\,\mathrm{d}z \quad (43)$$

the radiative transfer equation for polarized radiation can be written as:

$$\mu\frac{d}{\mathrm{d}\delta}I_r(\delta,\mu)=I_r(\delta,\mu)-J_r(\delta,\mu) \quad (44)$$

which is equivalent to equation (14). A formal solution for this expression can be obtained by separating the upward and downward intensities $I^+(\mu>0)$ and $I^-(\mu<0)$:

$$I_r^+(\delta,\mu)=I_r^+(\delta_A,\mu)\exp\left[-\frac{\delta_A-\delta}{\mu}\right]+\int_\delta^{\delta_A}J_r(\delta',\mu)\exp\left[-\frac{\delta'-\delta}{\mu}\right]\frac{\mathrm{d}\delta'}{\mu} \quad (45)$$

and

$$I_r^-(\delta,\mu)=I_r^-(0,\mu)\exp\left[-\frac{\delta}{|\mu|}\right]+\int_0^{\delta}J_r(\delta',\mu)\exp\left[-\frac{\delta-\delta'}{|\mu|}\right]\frac{\mathrm{d}\delta'}{|\mu|} \quad (46)$$

If we assume a nonscattering atmosphere ($\omega_0=0$ and $\sigma_a/\sigma_e=1$) and apply the Rayleigh–Jeans-Approximation (long wavelength limit, the emission by the earth's atmosphere is directly proportional to the temperature) equations (45) and (46) can be written as:

$$T_{\mathrm{Br}}^+(\delta,\mu)=T_{\mathrm{Br}}^+(\delta_A,\mu)\exp\left[-\frac{\delta_A-\delta}{\mu}\right]+\int_\delta^{\delta_A}T(\delta')\exp\left[-\frac{\delta'-\delta}{\mu}\right]\frac{\mathrm{d}\delta'}{\mu} \quad (47)$$

and

$$T_{\mathrm{Br}}^-(\delta,\mu)=T_{\mathrm{Br}}^-(0,\mu)\exp\left[-\frac{\delta}{|\mu|}\right]+\int_0^{\delta}T(\delta')\exp\left[-\frac{\delta-\delta'}{|\mu|}\right]\frac{\mathrm{d}\delta'}{|\mu|} \quad (48)$$

with T_{Br} being the equivalent Rayleigh–Jeans brightness temperature defined as:

$$I=I_v+I_h=k_B\nu^2c^2(T_{Bv}+T_{Bh}) \quad (49)$$

It should be noted that for several applications it is necessary to calculate the brightness temperatures by inversion of the Planck function to avoid systematic errors. For the sake of simplicity, we focus on the downward radiation at the bottom of the atmosphere ($\delta=\delta_A$, e.g. the total optical depth of the atmosphere), and on the upward radiation at the top of the atmosphere ($\delta=0$) as observed from a satellite. From equation (47) and (48), we obtain:

$$T_{\mathrm{Br}}^+(0,\mu)=T_{\mathrm{Br}}^+(\delta_A,\mu)\exp\left[-\frac{\delta_A}{\mu}\right]+\int_0^{\delta_A}T(\delta)\exp\left[-\frac{\delta}{\mu}\right]\frac{\mathrm{d}\delta}{\mu}$$
$$=T_{\mathrm{Br}}^+(\delta_A,\mu)\exp\left[-\frac{\delta_A}{\mu}\right]+\mathrm{T_{BAup}} \quad (50)$$

and

$$T_{\mathrm{Br}}^-(\delta_A,\mu)=T_{\mathrm{Br}}^-(0,\mu)\exp\left[-\frac{\delta_A}{|\mu|}\right]+\int_0^{\delta_A}T(\delta)\exp\left[-\frac{\delta_A-\delta}{|\mu|}\right]\frac{\mathrm{d}\delta}{|\mu|}$$
$$=T_{\mathrm{BSp}}\exp\left[-\frac{\delta_A}{|\mu|}\right]+T_{\mathrm{Badw}} \quad (51)$$

with T_{BAup}, T_{Badw}, and T_{BSp} being the atmospheric upward, atmospheric downward, and space contribution, respectively. Since scattering in the atmosphere is neglected these contributions are not polarized. The upward radiation at the bottom of the atmosphere/top of the vegetation, $T_{\mathrm{Br}}{}^+(\delta_A,\mu)$, needs further consideration, since this part contains the contribution from the surface. In order to determine $T_{\mathrm{Br}}{}^+(\delta_A,\mu)$ the radiative transfer equation has to be solved for the canopy layer. One way to obtain $T_{\mathrm{Br}}{}^+(\delta_A,\mu)$ is to replace the corresponding atmospheric parameters by the canopy optical depth δ_c and single scattering albedo ω_c in equation (44). Let the phase function describing scattering in the canopy layer being normalized as:

$$\frac{1}{2}\int_{-1}^{1}P(\delta_c,\mu,\mu')\,\mathrm{d}\mu'=1 \quad (52)$$

For vegetation fields with long cylindrical structures the scattering in the forward direction is the dominant part (Chuang *et al.*, 1980). Consequently, the forward scattering can be expressed as the sum of a Dirac- δ-function and a phase function $P^*(\mu,\mu')$, which is not peaked in the forward direction (Joseph *et al.*, 1976):

$$P(\delta_c, \mu, \mu') = 2\alpha\boldsymbol{\delta}(\mu - \mu') + (1-\alpha)P^*(\mu, \mu') \quad (53)$$

It should be noted that it is assumed that the phase function and the single scattering albedo are independent of δ_c in this approach. Different radiative transfer models for vegetation layers are available. An overview can be found in Kerr and Wigneron (1995). However, Joseph *et al.* (1976) showed that equation (44) is invariant in form when the phase function as defined in equation (53) is used. δ_c, ω_c and $P(\delta_c, \mu, \mu')$ have to be replaced by $\delta_c{}^*$, $\omega_c{}^*$ and $P^*(\mu, \mu')$ with:

$$\begin{aligned}\delta_c^* &= (1-\alpha\omega_c)\delta \\ \omega_c^* &= \frac{(1-\alpha)\omega_c}{1-\alpha\omega}\end{aligned} \quad (54)$$

Under the assumption that forward scattering is the dominant process, and since $P^*(\mu, \mu')$ is not well known, this quantity is set to 0. Little calculus yields the upward and downward contributions for the radiation at the top and the bottom of the canopy layer, respectively (Mo *et al.*, 1982):

$$\begin{aligned}T^+_{\mathrm{CBr}}(0,\mu) = T^+_{\mathrm{CBr}}(\delta_c^*,\mu)\exp\left[-\frac{\delta_c^*}{\mu}\right] \\ + (1-\omega_c^*)T_c\left(1-\exp\left[-\frac{\delta_c^*}{\mu}\right]\right)\end{aligned} \quad (55)$$

and

$$\begin{aligned}T^-_{\mathrm{CBr}}(\delta_c^*,\mu) = T^-_{\mathrm{CBr}}(0,\mu)\exp\left[-\frac{\delta_c^*}{\mu}\right] \\ + (1-\omega_c^*)T_c\left(1-\exp\left[-\frac{\delta_c^*}{\mu}\right]\right)\end{aligned} \quad (56)$$

with the canopy temperature T_c. The downward radiation at the top of the canopy $T_{\mathrm{CBr}}{}^-(0,\mu)$ is identical to the downward radiation at the bottom of the atmosphere $T_{\mathrm{Br}}{}^-$ $(\delta_A,\ \mu)$ as given in equation (51). The upward radiation at the bottom of the atmosphere $T_{\mathrm{Br}}{}^+$ $(\delta_A,\ \mu)$ is given by equation (55). Combining (56) with (51) and (55) with (50) gives the upward radiation at the top of the atmosphere $T_{\mathrm{Br}}{}^+(0,\mu)$ and the downward radiation at the bottom of the vegetation layer $T_{\mathrm{CBr}}{}^-(\delta_c{}^*,\mu)$:

$$\begin{aligned}T^-_{\mathrm{CBr}}(\delta_c^*,\mu) = \left(T_{\mathrm{BSp}}\exp\left[-\frac{\delta_A}{|\mu|}\right] + T_{\mathrm{Badw}}\right) \\ \exp\left[-\frac{\delta_c^*}{|\mu|}\right] + (1-\omega_c^*)T_c\left(1-\exp\left[-\frac{\delta_c^*}{|\mu|}\right]\right)\end{aligned} \quad (57)$$

$$\begin{aligned}T^+_{\mathrm{Br}}(0,\mu) = \left(T^+_{\mathrm{CBr}}(\delta_c^*,\mu)\exp\left[-\frac{\delta_c^*}{\mu}\right] + (1-\omega_c^*)\right. \\ \left. T_c\left(1-\exp\left[-\frac{\delta_c^*}{\mu}\right]\right)\right)\exp\left[-\frac{\delta_A}{\mu}\right] + T_{\mathrm{BAup}}\end{aligned} \quad (58)$$

Equations (57) and (58) are coupled through the surface interaction where a portion of the downward radiation at the bottom of the canopy layer is reflected. $T_{\mathrm{CBr}}{}^+(\delta_c{}^*,\mu)$ can be written as:

$$\begin{aligned}T^+_{\mathrm{CBr}}(\delta_c^*,\mu) = (1-\Gamma(\mu))T_S \\ + \frac{1}{2\mu}\int_{-1}^{0}[\sigma^*_{rr}(\mu,\mu')T^-_{\mathrm{CBr}}(\delta_c^*,\mu') \\ + \sigma^*_{rt}(\mu,\mu')T^-_{\mathrm{CBt}}(\delta_c^*,\mu')]\,\mathrm{d}\mu'\end{aligned} \quad (59)$$

with T_S the surface temperature and

$$\Gamma_r(\mu) = \frac{1}{2\mu}\int_0^1 [\sigma^*_{rr}(\mu',\mu) + \sigma^*_{tr}(\mu',\mu)]\,\mathrm{d}\mu' \quad (60)$$

$$\sigma^*_{tr}(\mu',\mu) = \frac{1}{2\pi}\int_0^{2\pi}\sigma^o_{tr}(\mu',\mu,\phi-\phi')\,\mathrm{d}\phi \quad (61)$$

In the case of specular reflection, the bistatic scattering coefficients for cross polarization (subscripts *rt* or *tr*) are 0. For $r = t$, $\sigma*$ is given as:

$$\sigma^*_{rt}(\mu',\mu) = 2\mu\sigma_r^{Spec}\boldsymbol{\delta}(\mu_s - \mu) \quad (62)$$

The reflected radiation can then be written as:

$$T^+_{\mathrm{CBr}}(\delta_c^*,\mu) = (1-\Gamma(\mu))\,T_S + \Gamma(\mu)T^-_{\mathrm{CBr}}(\delta_c^*,\mu) \quad (63)$$

For the computation of $\Gamma(\mu)$, which is based on the dielectric properties of the soil, various methods do exist (e.g. Kerr and Njoku, 1990; Wilheit, 1978). Generally, the reflection of the land surface is not specular. To take into account roughness effects, the specular reflectivities can be modified, for example, according to Choudhury *et al.* (1979) or Wegmüller and Mätzler (1999). A comprehensive and detailed discussion on passive microwave remote sensing of land surfaces can be found in Choudhury *et al.* (1995).

SOLUTIONS

The radiative transfer problem as outlined above is rather complex, and general analytic solutions of the vector radiative transfer equation, which provide the spatial distribution of intensities, do not exist. Depending on the application several approximations may apply and a number of methods to numerically solve the RTT have been developed. Often the approximations cannot resolve the full angular dependence and/or the full polarization information. Furthermore, most solutions are achieved for the one-dimensional problem where only vertical variations are considered and the atmosphere/surface is assumed to be horizontally homogeneous. Additional geometrical complications arise from the sphericity of the Earth's atmosphere. In the case of a nonscattering and horizontally homogeneous atmosphere, the RTT reduces to a relatively simple form (47) and (48), which can easily be solved by numerical integration when the vertical distribution of the absorption coefficient and temperature is known. Because the ratio between the size of the scattering particle and the wavelength determines the scattering efficiency, the neglect of scattering is well justified at microwave wavelengths, except when (large) precipitation drops are present. At short wavelengths, for example, solar radiation, scattering by atmospheric gases needs to be considered. Detailed descriptions of methods to solve the RTT can be found in many text books and publications. Following Lenoble (1985), the different methods have been separated in three groups: (1) exact analytical methods, (2) computational methods, and (3) approximate methods. This section briefly introduces and discusses some of the different concepts. According to Lenoble (1985), the primary usefulness of exact analytical methods is the understanding of the mathematical structure and of the general behavior of solutions of the radiative transfer equation. We focus on computational and approximate methods, which are most common in hydrological and meteorological applications.

Computational methods can take into account the real characteristics of the atmosphere. The accuracy of the results depends on the computer and the computation time. *Monte Carlo* methods simulate the path of individual photons, which experience absorption and scattering according to any given phase matrix within the medium of interest. All radiation variables including polarization can be derived at any point by averaging many photons propagating statistically within the considered domain. Although the computational cost is relatively high, one of the benefits of the Monte Carlo method is the ability to consider complex 3D geometries including broken clouds. The Monte Carlo technique offers a straightforward interpretation of the radiation field, which allows controlling the accuracy by the number of photons considered. Therefore, the Monte Carlo method is often used as a reference to evaluate other models. The Monte Carlo method can be formulated either as a forward or backward problem depending on the application. For example, if remote sensing applications are considered it is useful to consider the photons arriving at the detector and trace their origin backwards. The main disadvantages are (1) the statistical fluctuation in the results and (2) the limitation to optical depths below 100.

In the *Discrete Ordinate Method* (DOM, Chandrasekhar, 1960), the angular dependency of the radiative transfer equation is discretized and the solution consists of a set of first-order differential equations. DISORT (Stamnes *et al.*, 1988) is a numerically implemented solution for vertically inhomogeneous, layered media. It solves the RTT for a scattering, absorbing, and emitting medium with an arbitrarily specified bidirectional reflectivity at the lower boundary. Primary advantages of the DOM are: (1) the solution of the radiative transfer equation can be derived explicitly and the intensity calculations do not depend on the total optical depth of cloud or aerosol layers. (2) Analytic two-stream and four-stream solutions can be derived in closed forms. (3) Computational times are relatively small compared to other techniques. Polarization effects are not included in the calculations.

The Spherical Harmonical Discrete Ordinate Method (SHDOM) calculates nonpolarized monochromatic or spectral band radiative transfer in a one, two, or three-dimensional medium for either collimated solar and/or thermal emission sources of radiation (Evans, 1998). The program package is freely available from **`http://nit.colorado.edu/~evans/shdom.html`**. In contrast to the standard DOM, the angular part of the source function is represented with a spherical harmonic expansion, which allows a more efficient calculation of the scattering integral.

Within the *Successive Order of Scattering* (SOS) method, multiple scattering is treated as a sequence of single scattering events. In order to fulfill this approximation, the medium has to be divided into optically thin layers, which is appropriate in most microwave applications. SOS gives a better understanding of the problem than many of the other methods, because the photon is followed at each scattering process. Again, polarization effects cannot be taken into account. Another disadvantage is the high computational cost for situations with very weak absorption and high optical depths.

The adding, doubling, and matrix operator methods (Plass, 1973) are closely related. The reflection and transmission functions of an initial, optically thin sub layer are obtained by single scattering calculations for all incident and emergent angles at once. This layer is successively doubled until the given optical thickness of the homogeneous layer is reached. Then the homogeneous layers are added to an inhomogenous atmosphere. Polarization can be included in this approach.

Approximate methods include either an approximation of the real atmosphere or of the radiative transfer problem.

The applicability of approximate methods depends primarily on the required accuracy. The *two-stream-approximation* is commonly implemented in numerical weather prediction and climate models to calculate heating rates in the atmosphere and the Earth surface. For this purpose, it is sufficient to derive radiant fluxes rather than intensities, which reduces the computational effort. Since radiative fluxes are angular averaged properties, details of the angular intensity variation can be neglected. The strategy is to introduce an effective angular averaged intensity (stream) and determine an effective scattering angle. It is equivalent to the lowest order ($N = 1$) of the Discrete Ordinate Method. Considering the upward and downward components (two streams) leads to a pair of coupled, first-order differential equations, the *two-stream equations*. The coupling between the differential equations depends on the way the intensity and phase function are approximated (e.g. Liou, 2002). Within a homogeneous medium, the two-stream equations can be solved analytically using standard methods; for anisotropic scattering, a number of methods have been proposed. The two-stream-approximation is most accurate under isotropic conditions when the mean inclination (average cosine) is the same in both directions but works reasonable at the boundaries, too. The *Eddington-approximation* originally developed for studying the radiative equilibrium in stellar atmospheres has a similar application range as the two-stream-approximation. Here the angular dependence is approximated by a polynom resulting in a similar set of equations as for the two-stream approximation. Both approximations can be improved by implementing the Dirac function for a better representation of the forward scattering peak in the phase function and are then referred to as δ-two-stream or δ-Eddington. Differences between the Eddington- and two-stream method can be only due to the choice of the mean inclination, the boundary conditions and the choice of the phase function (Thomas and Stamnes, 1999).

Acknowledgments

The authors would like to thank Dr. H. Czekala (Radiometer Physics GmbH) for many helpful discussions and providing Figures 2, 3, and 4. Prof. A. Macke (Institute for Marine Sciences Kiel) provided Figure 6 and suggestions on the original manuscript. The paper benefited from many comments from Prof. Simmer and Dr. J. Schulz (both Meteorological Institute Bonn), Dr. P. Bauer and Dr. R. Engelen (both ECMWF), and an anonymous reviewer. We would like to thank R. Hine (ECMWF) for his help with the final preparation of the figures.

47: Sensor Principles and Remote Sensing Techniques

ANTHONY W ENGLAND

Professor of Electrical Engineering and Computer Science, Professor of Atmospheric, Oceanic, and Space Sciences, University of Michigan, Ann Arbor, MI, US

Model-derived estimates of water stored in the upper few meters of soil, in vegetation, and in snow packs are the objectives of a new satellite microwave remote sensing technology. The most mature of the alternatives, this technology will use a combination of longer wavelength satellite microwave brightness observations and Soil Vegetation Atmosphere Transfer (SVAT) models, forced by solar and thermal radiation and by weather, to produce a near-daily global field of stored water. While the near-daily temporal resolution is a unique strength for hydrometeorology, its likely spatial resolution of tens of kilometers is a serious weakness for land-surface hydrology. This article is intended as a review of the concept and the investigations that have contributed to it. It also includes brief surveys of some technologies, like aperture synthesis radiometry and combined active passive sensing, that are being explored to improve spatial resolution.

BACKGROUND

Among Earth science disciplines in the middle of the twentieth century, hydrology was notably constrained by the limitations of *in situ* sampling. The handicap was most severe for hydrometeorology because relevant processes extend over spatial and temporal scales that are difficult to characterize with a limited number of point measurements. The handicap was less severe for land-surface hydrology because much of importance occurs at the spatial scale of the watershed and the temporal scale of weather, scales that are more amenable to point measurements. The point sampling constraint discouraged investigations of linkages between land-surface hydrology and global hydrologic processes as depicted for an arctic terrain in Figure 1. Effectively, the global hydrologic cycle was understood in concept, but experimentally tracking moisture through atmospheric and land-surface elements of the water cycle using presatellite technologies required heroic effort.

Recent convergence of coupled ocean–atmosphere circulation models, satellite remote sensing technologies, and the political imperative to distinguish between human-induced climate change and natural climate variability have stimulated investigations that place land-surface hydrology in the context of the global water cycle (e.g. NRC, 1991; Lettenmaier and Rind, 1992; NRC, 1998; Vörösmarty *et al.*, 2000). Satellite remote sensing technologies have enabled these investigations and, among these technologies, three have become central to satellite sensing of land-surface hydrology. These are (i) model-based estimation of water stored in soil, vegetation, and snow, (ii) satellite sensing of soil moisture, and (iii) higher spatial resolution sensors.

Satellite sensors can be characterized by their spatial, temporal, or spectral resolutions. These attributes become part of the decision space where sensors are matched with applications. Features of the land surface might be heterogeneous at the scale of tens of meters but change occurs slowly relative to a day. For example, satellite sensors for agriculture or land-use mapping typically have spatial resolutions of <100 m but temporal resolutions of weeks (see Table 1). We can estimate the temporal resolution for the sensors in Table 2 from the swath width. If the whole earth is to be covered by an ascending orbital pass, then temporal resolution in days is approximately the circumference of the Earth divided by the product of swath width and number of orbits per day, $\approx 40\,000\ (\mathrm{SW} \times 15)^{-1}$ where swath width (SW) is in kilometers and 15 is the approximate number of orbits completed per day for satellites in

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

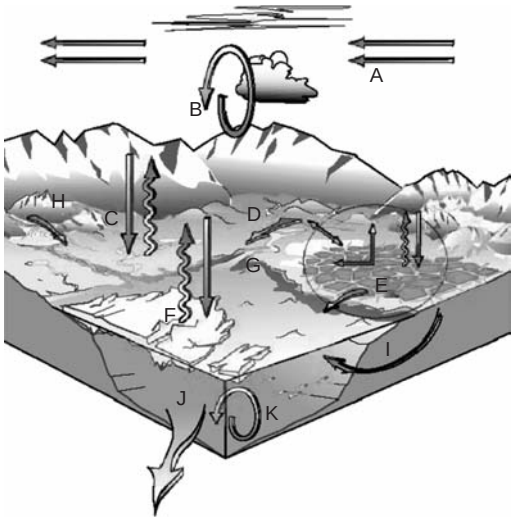

Figure 1 Conceptual model of the hydrologic cycle for the Arctic. Processes include: A – atmospheric boundary fluxes; B – atmospheric dynamics; C – land-surface atmosphere exchanges; D – discharge through well-defined flow networks; E – runoff from poorly organized lowland flow systems; F – sea ice mass balance and dynamics; G – estuarine controls on terrestrial/shelf interactions; H – changes in glacial mass balance and associated runoff; I – direct groundwater discharge to ocean; J – Arctic Ocean dynamics and deep water formation; and K – biological dynamics and oceanic food chains. Hydrometeorology includes process C – land-surface atmosphere exchange. Land-surface hydrology includes processes D – discharge through well-defined flow networks; E – runoff from poorly organized lowland flow systems; and H – changes in glacial mass balance and associated runoff. Low Earth Orbit (LEO). For example, we might estimate that the repeat time for Radarsat and ERS-1 and -2 would be approximately 27 days. In practice this temporal resolution can be shortened by using both ascending and descending passes if power and bandwidth are available, or by relaxing the requirement for global coverage, particularly at the equator. Nevertheless, none of these sensors can be thought of as providing near-daily global coverage.

Hydrometeorology required a different remote sensing strategy. Atmospheric elements of the water cycle have relevant spatial scales near the cell size of atmospheric circulation models, typically tens of kilometers, but temporal scales near a day. Operational sensors in LEO intended for hydrometeorology have had spatial resolutions as poor as 50 km but temporal resolutions of a day at higher latitudes, or twice per day if data from both ascending and descending orbital passes are used. Microwave radiometry has been well suited to high temporal resolution hydrometeorology (see Table 2). Atmospheric temperature profiles are estimated from the 60 and 118 GHz spectral features of oxygen, and water vapor profiles are estimated from the 22 and 183 GHz spectral features of water vapor (e.g. Janssen, 1993). Sea surface winds can be inferred from polarimetric brightness (e.g. Chreny and Raizer, 1998). Near-daily global coverage is readily achieved with wide swaths of conically scanning radiometers (see Figure 2). For example, the Special Sensor Microwave/Imager (SSM/I) with its 1400 km swath width would have a repeat interval of approximately 2 days and, considering both ascending and descending passes, daily global coverage at mid and high latitudes. These applications are aided by the relatively low cost and high reliability of satellite radiometers. An excellent, but somewhat dated, overview of microwave radiometry for environmental remote sensing can be found in the three-volume set by Ulaby *et al.* (1981, 1982, 1986).

Land-surface hydrology is tied to the water cycle and, like hydrometeorology, requires near-daily observations. Under relatively static and spatially homogeneous conditions, the combination of microwave brightness and empirical algorithms yields a reliable estimate of liquid water stored in a shallow soil under a significant vegetation canopy (e.g. Schmugge *et al.*, 1974; Schmugge, 1978; Newton and Rouse, 1980; Wang *et al.*, 1980a; Wang *et al.*, 1980b; Mo *et al.*, 1982; Jackson *et al.*, 1982; Ulaby *et al.*, 1983; Wang *et al.*, 1984; Schmugge *et al.*, 1986; Jackson and Schmugge, 1989; Jackson and O'Neill, 1990; Wang *et al.*, 1990; England *et al.*, 1992; Jackson, 1993; O'Neill *et al.*, 1996; Galantowicz *et al.*, 2000; Crow *et al.*, 2001; Jackson, 2001; Jackson and Lakshmi, 2001; Kerr *et al.*, 2001; Wigneron *et al.*, 2001; Shi *et al.*, 2002; Pellarin

Table 1 Examples of high spatial resolution satellite sensors and their swath widths[a]

Sensor	Description	Spatial resolution (m)	Swath width (km)
Landsat Multispectral Scanner (MSS)	Visible to near-infrared	79	185
Landsat Thematic Mapper (TM)	Visible to thermal infrared	30	185
Radarsat	5.3 GHz SAR	25	100
ERS-1 -2 Active Microwave Instrument (AMI)	5.3 GHz SAR	30	100
Japanese Earth Resources Satellite (JERS-1)	1.275 GHz SAR	18	75
Envisat Advanced SAR (ASAR)	5.3 GHz SAR	30	100

[a]Visible and near-infrared sensors collect data only during sunlit portions of an orbit. Radar sensors typically collect data only during 12–30% of an orbit because of power or data storage limitations. The swath width of radar sensors is often variable as a trade-off with spatial resolution. Listed swath widths correspond to the highest spatial resolution.

Table 2 High temporal resolution satellite microwave radiometers and their swath widths

Sensor[a]	Frequencies	Spatial resolution at lowest frequency (km)	Swath width (km)
Scanning Multichannel Microwave Radiometer (SMMR) (1978–1988)	6.6, 10.7, 18.0, 21.0. 37.0 GHz	~70	800
Special Sensor Microwave/Imager (SSM/I) (1987–present)	19.35, 22.235, 37.00, 85.50 GHz	~55	1400
TRMM Microwave Imager (TMI) (1997–present)	10.7, 19.35, 22.235, 37.00, 85.50 GHz	~40	570
Conically Scanning Microwave Imager/Sounder (CMIS) (to be launched in 2009)	6, 10, 18, 23, 36, 60, 89, 166, 183 GHz	~50	1700
ESA's Soil Moisture Ocean Salinity (SMOS) Mission (to be launched in 2007)	1.4 GHz	~50	800
NASA's Hydrosphere State Mission (HYDROS) (to be launched in 2010)	1.4 GHz active and passive	Radiometry ~40 Radar ~3	1000

[a]Kramer, 1996

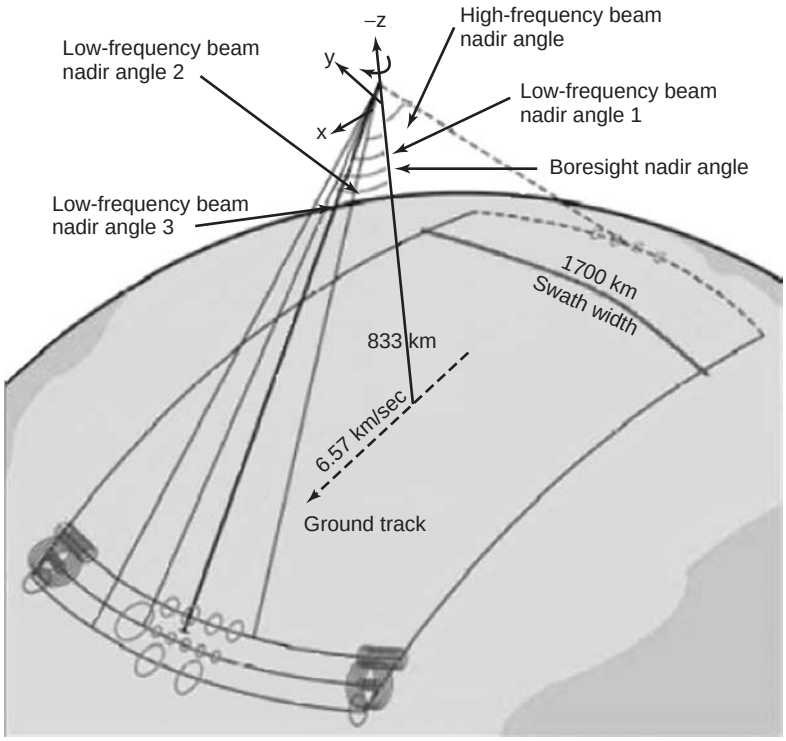

Figure 2 Scan geometry of the National Polar Orbiting Satellite System (NPOESS) Conically Scanning Microwave Imager/Sounder (CMIS) (from **`http://www.ipo.noaa.gov/Technology/cmis_summary.html`**). Like the Special Sensor Microwave/Imager (SSM/I) that preceded it (Hollinger *et al.,* 1987), CMIS scans about its vertical axis to observe swaths on the ground that are at a constant incidence angle —~55° for CMIS and 53° for SSM/I. CMIS is scheduled to be launched in 2009. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

et al., 2003; Hornbuckle and England, 2004). Such combinations of microwave brightness and an empirical algorithm can also be used to estimate the characteristics of a vegetation canopy (Ferrazzoli *et al.*, 1992; Wigneron *et al.*, 1993; Wigneron *et al.*, 1996; Karam, 1997; Njoku and Li, 1999; Ferrazzoli *et al.*, 2000; Owe *et al.*, 2001; Liu *et al.*, 2002; Hornbuckle *et al.*, 2003), whether soils are frozen or thawed (Zuerndorfer *et al.*, 1990; Zuerndorfer and England, 1992; Judge *et al.*, 1997; and Schwank *et al.*, 2004), and Snow Water Equivalent (SWE) (Chang *et al.*, 1982; Hall *et al.*, 1984; Hallikainen and Jolma, 1986; Davis *et al.*, 1987; McFarland *et al.*, 1987; Chang *et al.*, 1991; Foster *et al.*, 1991; Srivastav and Singh, 1991; Chang and Tsang, 1992; Chang *et al.*, 1992; Hallikainen, 1992; Goodison *et al.*, 1993; Koike and Suhama, 1993; Jin, 1997; Pulliainen *et al.*, 1999; Wilson *et al.*, 1999; Derksen *et al.*, 2000; Kharuk *et al.*, 2000; Rosenfeld and Grody, 2000; Macelloni *et al.*, 2001; Pulliainen and Hallikainen,

2001; Derksen *et al.*, 2003; Guo *et al.*, 2003; and Kelly *et al.*, 2003).

Static algorithms have limited value when the moisture content of the upper few centimeters of soil, the depth sensed by microwave techniques, varies significantly throughout the diurnal cycle and rapidly during the initial dry-down after a precipitation event. We usually want to know the moisture content in the root zone or at the freeze/thaw boundary of a permafrost active layer, but the relationship between near-surface water content and the water content in the root zone or deeper is dynamic. Static SWE algorithms fail when snow packs begin to melt and metamorphose, or when snow packs are laterally heterogeneous within the footprint of the sensor. Heterogeneity can be caused by topography or by variations in soil type or vegetation cover. Whatever the cause, stored water should be viewed as a dynamical parameter of a land-surface model. Water stored within the large footprint of a satellite radiometer becomes an area-weighted average of the dynamical processes within the more homogeneous subregions of the footprint.

Technologies that address these challenges – relating near-surface soil moisture to deeper soil moisture, sensing near-surface soil moisture, and achieving acceptable spatial resolutions with satellite sensors – are the themes of this review. The article is organized as (i) *Stored Water as a Modeled Product*, (ii) *Satellite Radiometers for Sensing of Shallow Soil Moisture and Snow Water Equivalent (SWE)*, and (iii) *Improved Spatial Resolution*. Although progress has been made toward retrieval of soil moisture from radar backscatter and from combinations of microwave brightness and radar backscatter, these techniques are not nearly as mature as are retrievals from microwave brightness alone. Only a cursory overview of these approaches is presented because the techniques are in rapid flux and it is unclear how successful they will be.

STORED WATER AS A MODELED PRODUCT

Data from the next generation of satellite radiometers will allow reliable detection of seasonal to decadal changes in the hydrologic cycle as expressed in temporal and spatial patterns of moisture stored in soil and snow. A schematic representation summarizing the concept as it has evolved within the remote sensing land-surface hydrology community is shown in Figure 3. Realization of the approach will yield a model-derived dynamical field of land-surface stored water, that is, the water stored in the upper few meters soil, in vegetation, and in snow. This stored water field and its state govern runoff of precipitation and snow-melt through the saturation and freeze/thaw conditions of soil, and influence the weather through land–atmosphere latent energy exchanges. A temporal record of the stored water field will also serve as a climatic record of changes in the regional moisture regime.

The approach uses the combination of a (i) Soil Vegetation Atmosphere Transfer (SVAT) model for terrain and the corresponding (ii) Radiobrightness (R) model of the microwave brightness of the terrain, to obtain a model-based estimate of stored water. The linked SVAT/R models are forced by weather and downwelling radiance to predict microwave brightness at frequencies that are sensitive to soil moisture. The models are validated and calibrated as

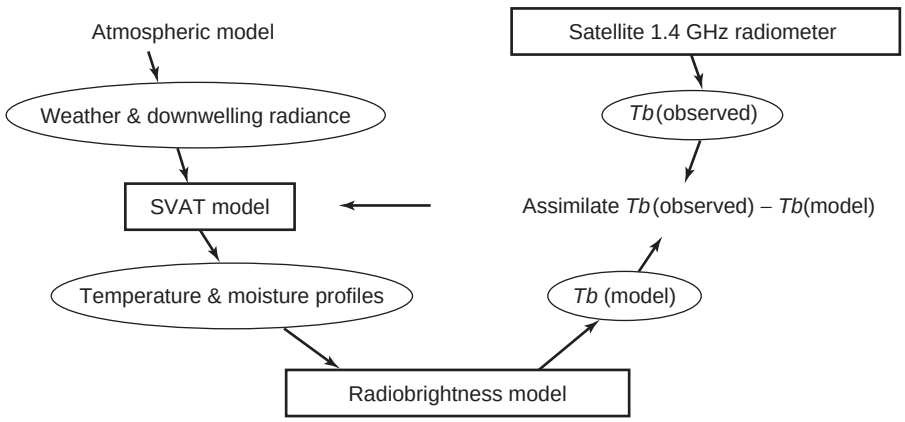

Figure 3 A strategy for remotely monitoring water stored in soil. The Atmospheric Model (or observed weather) provides weather and downwelling short- and long-wavelength radiation as forcing to the SVAT Model. The SVAT Model provides soil and vegetation temperature and moisture profiles to the Radiobrightness Model, which then predicts microwave brightness temperature, *Tb*. At low microwave frequencies, for example 1.4 GHz, a difference between observed brightness from a satellite and predicted brightness represents an error in the model's estimate of the liquid water content of near-surface soil. The error is assimilated by the SVAT Model to improve the current estimate. Over several assimilation cycles, the SVAT model converges to an accurate moisture profile at depths below those sensed by microwave radiometry

forward models, but then inverted to assimilate microwave brightness. Assimilation of an observation that is sensitive to the water content of shallow soils causes modeled soil temperature and moisture profiles to converge to actual profiles (e.g. Entekhabi *et al.*, 1994; Houser *et al.*, 1998; Davis *et al.*, 1995; Galantowicz *et al.*, 1999; Wigneron *et al.*, 1999; Lakshmi, 2000; Reichle *et al.*, 2001; Reichle and McLaughlin, 2001; Walker and Houser, 2001; Burke *et al.*, 2001). For convergence of a model to a realistic state, the SVAT/R model must accurately reflect both the physics of coupled temperature and moisture transport processes, and the emitted radiation field of the soil, vegetation canopy, and snow pack (e.g. Liou and England, 1998b). The evolution of these models has been from empirical models with sufficient free parameters to match observational data, to highly physically based models with ever fewer free parameters that begin to constrain the more parameterized operational models even in the absence of observational data.

SVAT/R models are mature for prairie agricultural hydrology because experimental data from a series of field campaigns in midlatitude prairie were available to test schemes for modeling energy and moisture transport in prairie soils and to calibrate models of prairie terrains. Notable among the field campaigns have been the Konza Prairie observations in 1985 (Schmugge, *et al.*, 1988), the First ISLSCP Field Experiment (FIFE) in 1987 (e.g. Wang *et al.*, 1990), MACHYDRO'90 (Jackson *et al.*, 1994), Washita'92 (Jackson *et al.*, 1995), and the Southern Great Plains Hydrology Experiments – SGP'97 and SGP'99 (Jackson *et al.*, 1999; Jackson *et al.*, 2002; and Guha *et al.*, 2003). There have also been a series of plot-scale experiments to validate modeled linkages between the diurnal, seasonal, and annual characteristics of radiobrightness, and the energy and moisture process in soil vegetation and snow. These experiments have been used in the development of SVAT/R models for prairie agricultural terrains and are beginning to be used in the development of SVAT/R models for arctic tundra. These Radiobrightness Energy Balance Experiments (REBEX) include REBEX-1 in northern prairie during 1992–1993 (Galantowicz and England, 1997), REBEX-3 in arctic tundra in 1994–1995 (Kim and England, 2003), REBEX-4 in northern prairie during the summer of 1995 (Judge *et al.*, 2001), REBEX-5 as part of SGP'97 (Judge *et al.*, 1999), and REBEX-8 in corn during the summer of 2001 (Hornbuckle and England, 2004). There have also been plot-scale empirical examinations of the linkage between radiobrightness and diurnal soil moisture (e.g. Jackson *et al.*, 1997).

(a) The SVAT Model Highly parameterized SVAT models formerly served as the lower boundary for Atmospheric General Circulation Models (AGCMs) (e.g. Trenberth, 1995). Examples of these include the Biosphere Atmosphere Transfer Scheme (BATS) (Dickinson *et al.*, 1986, 1993) and the Simple Biosphere-2 (SiB-2) model (Sellers *et al.*, 1986). Growth of computational power enabled an evolution toward more physically based SVAT models like the Land Surface Model (LSM) (Bonan, 1996) and the Variable Infiltration Capacity (VIC) model (Liang *et al.*, 1994, 1996). Higher fidelity diagnostic SVAT models are used to explore the parameter space of land-surface processes or to provide unique classes of state estimates for other purposes. Reviews and intercomparisons of SVAT models are available in the literature.

The Michigan Land Surface Process (LSP) model is a one-dimensional diagnostic SVAT model that evolved from a simple thermal model for bare soil (England, 1990; England *et al.*, 1992) to one including coupled heat and moisture transport in prairie agricultural terrains. The model provides accurate near-surface moisture gradients throughout the diurnal cycle, through periods of fog, and following precipitation events (Liou and England, 1996, 1998a,b; Liou *et al.*, 1998; Liou *et al.*, 1999; Judge *et al.*, 1999; and Judge *et al.*, 2003). Without the careful coupling of temperature and moisture transport processes, near-surface moisture profiles at the extremes of the diurnal thermal cycle would be unreliable, and because microwave brightness depends upon the near-surface moisture gradient, predicted brightness would be unreliable as well.

Version 3.0 of the LSP model consists of a bilayer vegetation canopy over a 40-node soil. To minimize the number of free parameters, soil constitutive properties are tied to soil texture wherever possible (e.g. de Vries, 1963; Kimball *et al.*, 1976; Lai *et al.*, 1976; Rawls *et al.*, 1991; Rossi and Nimmo, 1994). In theory, each node could delineate a different soil type, but in practice, field data seldom justify more than three soil layers. Node spacing increases exponentially from 2 mm at the surface to span total model thickness (an input parameter), which has been as much as 20 m. The saturation level (water table), also an input parameter, typically lies between 1 and 6 m for prairie sites. Within the saturated zone, moisture flux is assumed to be horizontal and energy flux is assumed to be vertical via heat conduction. Energy and moisture transport in the unsaturated zone are assumed to be vertical and are governed by the following equations (Richards, 1931; Philip and de Vries, 1957; de Vries, 1958);

$$\frac{\partial X_{\mathrm{m}}}{\partial t} = -\nabla \bullet \bar{q}_{\mathrm{m}} \qquad \frac{\partial X_{\mathrm{h}}}{\partial t} = -\nabla \bullet \bar{q}_{\mathrm{h}}$$

$$X_{\mathrm{m}} = \rho_{\mathrm{l}}(\theta_{\mathrm{l}} + \theta_{\mathrm{v}})\; X_{\mathrm{h}} = C_{\mathrm{m}}(T - T_{\mathrm{o}}) + L_{\mathrm{o}}\rho_{\mathrm{l}}\theta_{\mathrm{v}} + \rho_{\mathrm{l}} \int_0^{\theta_{\mathrm{l}}} W \, \mathrm{d}\theta$$

$$\bar{q}_{\mathrm{m}} = -\rho_{\mathrm{l}}(D_T \nabla T + D_\theta \nabla \theta + K\hat{k})$$

$$\bar{q}_{\mathrm{h}} = -\lambda \nabla T + L_o \bar{q}_{\mathrm{v}} + (c_p q_{\mathrm{v}} + c_{\mathrm{l}} q_{\mathrm{l}})(T - T_o) \qquad (1)$$

where X_m and X_h are total moisture and heat contents per unit volume ($kg\,m^{-3}$ and $J\,m^{-3}$)

$\bar{q}_l$, $\bar{q}_v$, and $\bar{q}_m$ are liquid, vapor, and moisture flux densities ($kg\,m^{-2}\,s^{-1}$)

q_h is heat-flux density ($J\,m^{-2}\,s^{-1}$)

ρ_l is the density of liquid water ($kg\,m^{-3}$)

θ_l and θ_v are volumetric liquid water ($m^3\,m^{-3}$) and vapor content (m^3 of precipitable waterper m^3), respectively, and $\theta = \theta_l + \theta_v$

T is absolute temperature (K)

D_T and D_θ are thermal and isothermal moisture (liquid and vapor) diffusivities ($m^2\,K^{-1}\,s^{-1}$)

K is the unsaturated hydraulic conductivity ($m\,s^{-1}$) in the direction of $\bar{q}_m$, $\hat{k}$

C_m and C_d are volumetric heat capacities of moist and dry soils ($J\,m^{-3}\,K^{-1}$)

c_p and c_l are specific heats ($J\,kg^{-1}\,K^{-1}$) of water vapor at constant pressure and of liquid water, respectively

L_o is the latent heat of vaporization ($J\,kg^{-1}$) at the reference temperature, T_o

W is the differential heat of wetting, and

λ is the thermal conductivity of soil ($J\,m^{-1}\,K^{-1}\,s^{-1}$)

Moisture and energy fluxes at the upper boundary are:

$$q_m(0,1) = \rho_l(D_c - E_s - E_{tr} - \text{Runoff})$$
$$q_h(0,1) = R_{ns} - H - L \qquad (2)$$

where q_m (0,1) and q_h (0,1) are moisture and heat-flux densities at the interface between the vegetation and the soil, respectively,

H and L are sensible and latent heat fluxes from the soil, respectively,

D_c is rate of drainage from the canopy ($m\,s^{-1}$), D_c = total precipitation – canopy interception,

E_s is rate of evaporation from the soil ($m\,s^{-1}$),

E_{tr} is the rate of transpiration from the root zone ($m\,s^{-1}$), and

R_{ns} is net radiation (longwave and shortwave) absorbed by the soil ($W\,m^{-2}$).

The lower boundary is assigned to be below the penetration depth of the annual thermal pulse for seasonal studies, or below the penetration depth of a multiyear pulse if the objective is to examine a climate-related sensitivity to a change in forcing. Energy and moisture fluxes at this boundary are set to zero. That is, both soil surface and bottom boundaries are constrained by fluxes – by Neumann boundary conditions.

Temperature and moisture in each layer at time t comprise a state vector that is propagated from time t to time $t + \Delta t$ where Δt is typically 2 min. Elements in the coefficient matrix for the propagation interval are linearized versions of the dynamical relations appropriate for the system's state at time t. The initial state is provided by field measurements or through model spin-up based upon climatic forcing. Propagation can be months for seasonal studies or years for an examination of sensitivity to climate change. Version 3.0 of the prairie LSP model has 1500 lines of Fortran 90 code and propagates one year in less than a minute on a high-end PC running Linux. This performance is achieved by generating look-up tables for the constitutive properties at each expected combination of temperature and moisture content prior to propagating the model rather than recomputing constitutive properties at each propagation interval for each node based upon current state. Performance of the LSP model is illustrated in Figure 4.

(b) The R Model Familiarity with the physics of microwave brightness enables an intuitive expectation for brightness temperatures that warrants a brief tutorial. Primary factors governing the microwave brightness of moist soil are soil temperature and the dielectric properties of water in the form that it is stored in the soil. The dielectric properties of water below ~10 GHz are radically different from those of other common materials in the Earth's environment. The real part of liquid water's complex relative permittivity is ~80 at 1 GHz (see Figure 5) while those of other common materials are less than 10 and generally less than 6. This high relative permittivity results from the coupling between a water molecule's permanent electric moment and the electric field of the passing electromagnetic wave. At 1 GHz, the water molecule physically rotates so that its electric moment is aligned with the wave's electric field. The mechanical energy from this rotation is the source of heat in a microwave oven. As frequency increases, the rotation of the water molecule falls behind the oscillating field of the passing wave. At the upper end of the microwave spectrum, the water molecule does not follow the field and the dielectric properties of water resemble those of most other dielectric media.

Moist soils are a mixture of soil particles, air, free water, water adsorbed to the surface of the soil particles, and ice, if temperatures are below 273 K. The complex relative permittivity of moist soils, $\tilde{\varepsilon}$, is closely approximated by the mixing law,

$$\tilde{\varepsilon}^\alpha = \sum_i \nu_i \tilde{\varepsilon}_i^\alpha \qquad (3)$$

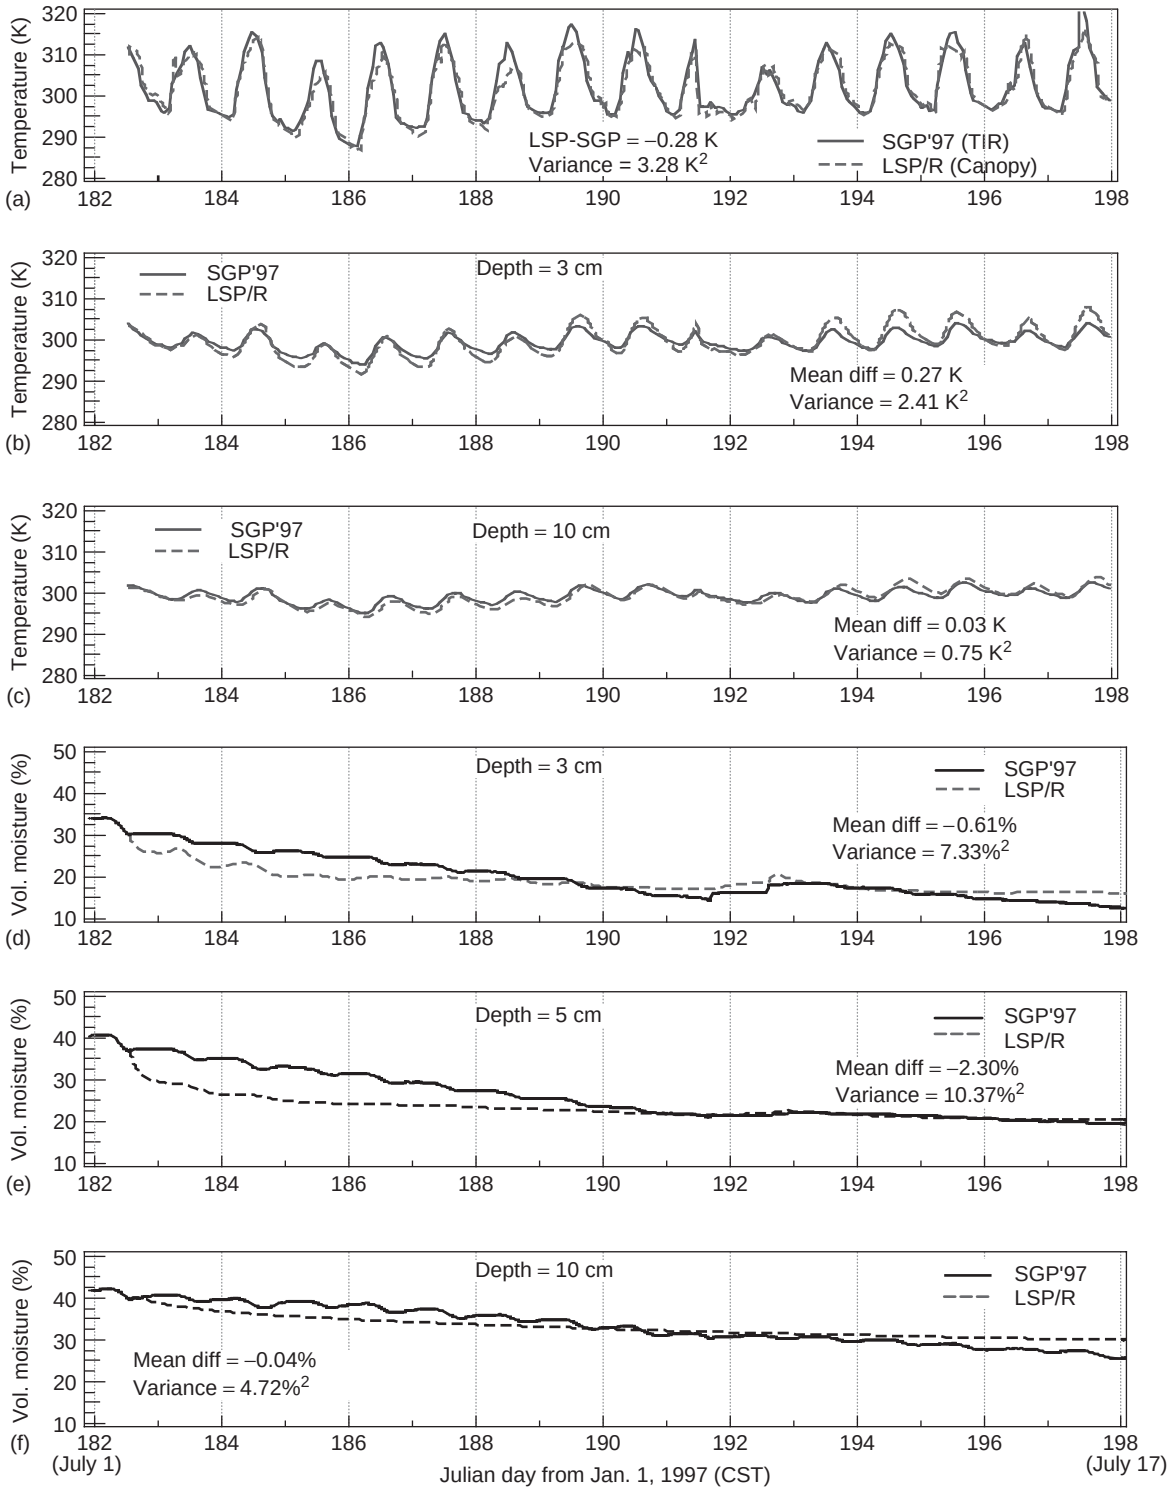

Figure 4 Performance of LSP model during the 1997 Southern Great Plains experiment in Oklahoma (SGP'97). This field contained mixed wheat stubble and short grass. These data were collected in early July. Panel (a) is the measured (solid line) and modeled (dashed line) Thermal Infrared (TIR) temperature or skin temperature of the canopy. Panels (b) and (c) are measured and modeled temperatures at depths of 3 and 10 cm. Panels d–f are measured and modeled volumetric soil moistures at 3, 5, and 10 cm depths, respectively. The errors in soil moisture on days 183–190 are attributable to the soil Moisture Retention Model (MRM). A revised model appears to be more reliable but tests are not completed

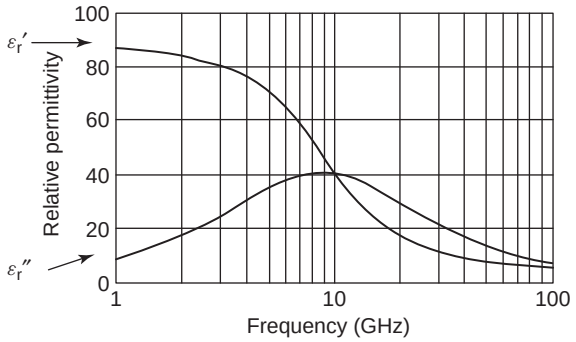

Figure 5 The complex relative permittivity, $\tilde{\varepsilon}_r = \varepsilon_r' - j\varepsilon_r''$, of water at 0 °C (ref). The dielectric properties of water are unique among common materials found in the natural environment. Below the Debye relaxation frequency, ~10 GHz, the real part of the relative permittivity of liquid water can be an order of magnitude greater than those of other materials, and the imaginary part is easily the dominant loss term. Increasing liquid water content in soil or snow means an increasing dielectric contrast between soil or snow and air. This dielectric contrast at the interface reflects upwelling emission within the soil or snow causing darkening of the microwave brightness above the surface. Increasing liquid water content in soil or snow also means increasing opacity so that upwelling emission that escapes the surface originates at shallower depths

where v_i and $\tilde{\varepsilon}_i$ are volume fraction and complex relative permittivity of the i^{th} soil component, respectively, and α is an empirically determined parameter that lies between 0.5 and 1.0. $\alpha = 1.0$ corresponds to a volume-weighted average of complex relative permittivities. The complex index of refraction is $\tilde{n} = \sqrt{\tilde{\varepsilon}}$ so that $\alpha = 0.5$ corresponds to a volume-weighted average of complex indices of refraction. We find that $\alpha = 0.5$ yields an adequate approximation to bulk dielectric properties. Others have found that $\alpha = \sim 0.65$ yields a good fit (Dobson *et al.*, 1985). Theory does not, as yet, guide our choice of α.

The complex index of refraction can be written as $\tilde{n} = n - j\kappa$ where n is the index of refraction and κ is the wave extinction coefficient. Index n governs the wave number, k, of the electromagnetic wave through the relationship $k = k_o$ n in units of rad m^{-1} where k_o is free-space wave number. Note that wave number is spatial frequency (rad m^{-1}) much like $2\pi f$ is angular frequency (rad s^{-1}). Spatial frequency, or wave number, and angular frequency are related through the dispersion relation,

$$\mathrm{k} = \left(\frac{2\pi f}{c}\right) n = \mathrm{k}_o n \qquad \text{rad s}^{-1} \tag{4}$$

where f is frequency, and c is the speed of light in vacuum. The extinction coefficient, κ, governs power loss through the microwave absorption coefficient, $\kappa_a = 2k_o\kappa$ m^{-1}.

A dielectric medium in thermal equilibrium with its extended environment contains electromagnetic radiation obeying Planck's law for spectral radiance (e.g. Bohren and Huffman, 1983). The Rayleigh–Jeans approximation to Planck's law, which is valid at microwave frequencies for all temperatures found in the Earth's natural environment, is

$$B_p^b = \mathrm{k}\left(\frac{fn}{c}\right)^2 \mathrm{T} \qquad \text{W m}^{-2}\ \text{sr}^{-1}\ \text{Hz}^{-1} \tag{5}$$

where B_p^b is Planck spectral radiance of polarization p, k is Boltzmann's constant, and T is temperature in Kelvin of the dielectric and its extended environment. Along any ray element, ds, within the dielectric, Planck brightness, B_p^b, will be incrementally attenuated by $\kappa_a B_p^b$. Thermal equilibrium requires that this loss be balanced by an equal self-emission. This "volume emissive power", $\kappa_a B_p^b$, is an intrinsic property of the dielectric at temperature T.

If the constraint of thermal equilibrium with an extended environment is replaced by the constraint of local thermodynamic equilibrium, then the heuristic differential form of the Radiative Transfer Equation (RTE) in the absence of scattering and refraction is

$$\frac{\mathrm{d}B_p}{\mathrm{d}s} + \kappa_a B_p = \kappa_a B_p^b \qquad \text{W m}^{-3}\ \text{sr}^{-1}\ \text{Hz}^{-1} \tag{6}$$

where B_p is local spectral radiance of polarization, p, $\kappa_a B_p$ is absorption loss in incremental distance ds, and $\kappa_a B_p^b$ is thermal self-emission in incremental distance ds (e.g. Chandrasekhar, 1960). Imposing thermal equilibrium with an extended environment sets $B_p = B_p^b$ and requires the intuitively correct $\mathrm{d}B_p/\mathrm{d}s = 0$. Either equality can be shown to be thermodynamically necessary if the medium is in equilibrium with its extended environment whether or not scattering occurs.

If a nonscattering, nonrefractive medium is nonabsorbing (i.e. $\kappa_a = 0$), equation (6) requires that radiance be invariant along any ray whether or not the medium is in thermal equilibrium with its extended environment. This invariance of B_p is a useful concept where the index of refraction is constant along a ray. For example, the spectral brightness of the Sun is independent of distance from the Sun as observed from anywhere attainable by a ray from the Sun traveling only in the vacuum of space.

The concept of brightness invariance fails when the index of refraction changes as it often does in the earth's environment. Where n changes slowly relative to a wavelength, brightness will change even in the absence of absorption or scattering. Invariance can be reestablished by normalizing spectral brightness by n^2. In practice, spectral brightness is normalized by $\mathrm{k}(fn/c)^2$ to yield brightness temperature,

Tb_p, of polarization p,

$$Tb_p = \frac{B_p}{\mathrm{k}\left(\frac{fn}{c}\right)^2} \qquad \mathrm{K\ sr^{-1}} \tag{7}$$

Steradian is not a true dimension (like radian, it is a ratio), but writing the units of Tb_p as K sr^{-1} reminds us that Tb_p behaves like radiance rather than temperature. Tb_p offers intuitive advantages beyond invariance in the absence of absorption and scattering. The value of B_p^b at 3 GHz for a 300 K black source is 4×10^{-17} W m^{-2} sr^{-1} Hz^{-1}. This awkwardly small number carries little intuitive meaning. In contrast, the brightness temperature, Tb_p, of a 300 K black source is an intuitive 300 K sr^{-1} at all frequencies in any dielectric medium.

Earth's microwave brightness temperature as seen from a satellite, and as shown schematically in Figure 6, is overwhelmingly a product of thermal emission, absorption, and scattering within the earth's environment. The contrast between a warm emitting Earth and the cold extraterrestrial microwave sky gives Earth-viewing microwave radiometry a dynamic range exceeding 150 K. Extraterrestrial microwave sources of significance for our purposes are the isotropic 2.7 K cosmic background at all microwave frequencies, and coronal synchrotron emission from the Sun at microwave noise equivalent temperatures greatly exceeding the Sun's 6000 K blackbody temperature. Solar microwave brightness can saturate or possibly damage a satellite microwave radiometer but is rarely a factor because the Sun occupies only 6×10^{-5} sr of the sky and seldom appears in the beam of an Earth-viewing sensor.

Earth-viewing radiometry is primarily concerned with radiative transfer within horizontally stratified media where the independent variables are height, z (positive upward), and the direction cosine, μ, of the zenith angle. Using $\mathrm{d}s = \mathrm{d}z/\mu$, the RTE for brightness temperature is

$$\mu \frac{\mathrm{d}Tb_p(z,\mu)}{\mathrm{d}z} + \kappa_\mathrm{a}(z) Tb_p(z,\mu) = \kappa_\mathrm{a}(z) T(z) \tag{8}$$

The integral form of equation (8) is

$$\Delta Tb_p(z,\mu) = \int_a^z T(z') \frac{\kappa_\mathrm{a}(z')}{\mu} \mathrm{e}^{-\tau(z',z)/\mu}\, \mathrm{d}z' \tag{9}$$

where $\Delta Tb_p(z,\mu)$ is the contribution at height z in direction μ from emission along the ray between height $z' = a$ to $z' = z$, and $\tau(z',z)$ is the "optical thickness" between z' and z defined

$$\tau(z',z) \equiv \int_{z'}^z \kappa_\mathrm{a}(z'')\, \mathrm{d}z'' \tag{10}$$

Upwelling ($\mu > 0$) and downwelling ($\mu < 0$) brightness temperatures within a layer bounded by $a < z < b$ become, respectively,

$$(\mu > 0) \qquad Tb_p(z,\mu) = Tb_p(a,\mu)\mathrm{e}^{-\tau(a,z)/\mu} + \int_a^z \frac{\kappa_\mathrm{a}(z')}{\mu} T(z') \mathrm{e}^{-\tau(z',z)/\mu}\, \mathrm{d}z' \qquad \mathrm{K\ sr^{-1}} \tag{11a}$$

$$(\mu < 0) \qquad Tb_p(z,\mu) = Tb_p(b,\mu)\mathrm{e}^{-\tau(b,z)/\mu} + \int_b^z \frac{\kappa_\mathrm{a}(z')}{\mu} \mathrm{T}(z') \mathrm{e}^{-\tau(z',z)/\mu}\, \mathrm{d}z' \qquad \mathrm{K\ sr^{-1}} \tag{11b}$$

where $Tb_p(a,\mu)$ in equation (11a) is upwelling brightness temperature entering the layer at $z = a$, and $Tb_p(b,\mu)$ in equation (11b) is downwelling brightness temperature entering the layer at $z = b$. These expressions are equally valid whether the dielectric is an atmosphere, moist soil, a snow pack, or a vegetation canopy to the extent that scattering within these media can be ignored.

If an emitting medium is significantly heterogeneous at the scale of the microwave wavelength, the RTE must be modified to include scattering (e.g. Chandrasekhar, 1960; England, 1974, 1975, 1976; England and Johnson, 1977,

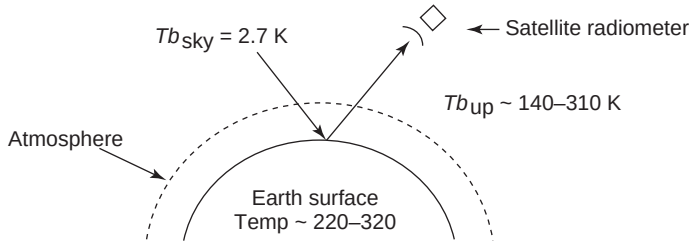

Figure 6 Schematic of microwave brightness as seen by an Earth-viewing satellite. The dynamic range of the Earth's radiometric temperature at 1.4 GHz exceeds 170 K while the dynamic range of the Earth's physical temperature is approximately 100 K. The excess dynamic range of the radiometric temperature is caused by two factors: (i) Dielectric contrasts between the land or water surface and the air, and (ii) the cold sky. If the sky had radiometric temperatures nearer those of the Earth, the upwelling brightness would be less sensitive to dielectric contrasts at the surface. It is often useful to think of a dielectric contrast at the land–atmosphere interface as reflecting cold sky

1978; Tsang and Kong, 2001). For discrete spherical scatterers randomly located at distances large enough that electromagnetic interactions among scatterers can be ignored, the RTE for a horizontally stratified medium becomes

$$\mu \frac{\mathrm{d}Tb_p(z,\mu)}{\kappa_\mathrm{e}\,\mathrm{d}z} + Tb_p(z,\mu) = (1-\omega_\mathrm{o})T(z) + \left(\frac{\omega_\mathrm{o}}{2}\right)\sum_{q=v,h}\int_{-1}^{1} p_{pq}(\mu,\mu')Tb_q(z,\mu')\,\mathrm{d}\mu' \quad (12)$$

where κ_e is total extinction, $\kappa_\mathrm{e} = \kappa_\mathrm{a} + \kappa_\mathrm{s}$, κ_s is scattering loss, ω_o is the single scattering albedo, $\omega_o = \kappa_\mathrm{s}/\kappa_\mathrm{e}$, v and h are vertical and horizontal polarizations, respectively, and $p_{pq}(\mu,\mu')$ is a scattering phase function that accounts for scattering of polarization q from all directions μ' into a brightness temperature of polarization p in direction μ. Numerical solutions of this integral–differential equation typically employ Gaussian quadrature.

Forward solutions of equation 12 are used to understand the effects of scattering, but are too complex to realistically invert. A first-order approximation to equation (12) assumes that the integral term containing the scattering phase function can be ignored. The result is equation (8) with a source that is diminished by the product of $(1-\omega_\mathrm{o})$. This source darkening, or scatter darkening, can be estimated from Raleigh or Mie scattering theory (e.g. Bohren and Huffman, 1983), but is often treated as an empirical parameter to adjust for observed scatter darkening.

The Brightness Temperature of a Vegetation Covered Soil

Temperature and moisture profiles for soil and canopy generated by the SVAT model are used in a Radiobrightness (R) model to compute the expected microwave brightness temperature as sensed immediately above a canopy. The relationship, depicted schematically in Figure 7, is:

$$Tb_p = Tb_p^\mathrm{s} + Tb_p^{\downarrow\mathrm{c}} + Tb_p^{\uparrow\mathrm{c}} + Tb_p^\mathrm{sky} \quad (13)$$

where Tb_p is observed microwave brightness temperature at polarization p (in K sr^{-1}),

Tb_p^s is the brightness temperature of soil attenuated by a canopy,

$Tb_p^{\downarrow\mathrm{c}}$ is downwelling canopy brightness temperature reflected by soil and attenuated by one trip through a canopy,

$Tb_p^{\uparrow\mathrm{c}}$ is an upwelling canopy brightness temperature, and

Tb_p^sky is the sky brightness temperature attenuated by two trips through a canopy and reflected by the soil.

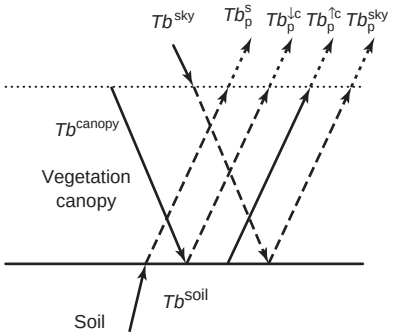

Figure 7 A schematic of contributions to microwave brightness temperature of a vegetation canopy over soil as seen by a satellite sensor. Solid rays indicate sources. Dashed rays indicate absorption. Dotted rays indicate transmission through the atmosphere. Atmospheric absorption and emission is small at low microwave frequencies and is reliably modeled given approximate atmospheric temperature and water vapor profiles. The contributions to brightness temperature above the canopy are, from left to right: unpolarized emission from soil, polarized by transmission through the soil interface, and partially absorbed by the canopy; unpolarized downwelling canopy emission, polarized by reflection from the soil, and partially absorbed by the canopy; unpolarized upwelling canopy emission; and unpolarized downwelling sky brightness temperature, partially absorbed by downward trip through canopy, polarized by reflection at soil interface, and partially absorbed by upward trip through canopy

Downwelling sky brightness temperatures are computed for the atmosphere using equation (11b). A clear atmosphere has brightness temperatures like those shown in Figure 8. Clouds increase these temperatures only at the higher microwave frequencies. Because absorption and emission are inherently linked, this is equivalent to saying that lower frequency microwaves penetrate clouds. Upwelling brightness temperature within soil at $z = 0$ is computed using equation (11a) with $a = -\infty$. The brightness temperature immediately below the soil–canopy interface, $Tb_p(0^-,\mu')$, is dependent upon the temperature profile, $T(z)$, and the dielectric loss profile, $\kappa_\mathrm{a}(z)$, or, equivalently, upon the moisture profile so that recovering soil moisture from an observed brightness temperature requires knowledge or an assumption about these profiles. A common assumption is that temperature and moisture are constant with depth. This assumption can cause errors in 1.4 GHz, h-polarized brightness of 5 to 10 K for moist soils during the heat of an afternoon. A better approach is to use predicted temperature and moisture profiles from an SVAT model.

The upwelling brightness temperature in the moist soil of Figure 7 is partially scattered back into the soil by the wave impedance mismatch at the land–atmosphere interface. The strength of the reflection depends upon the dielectric

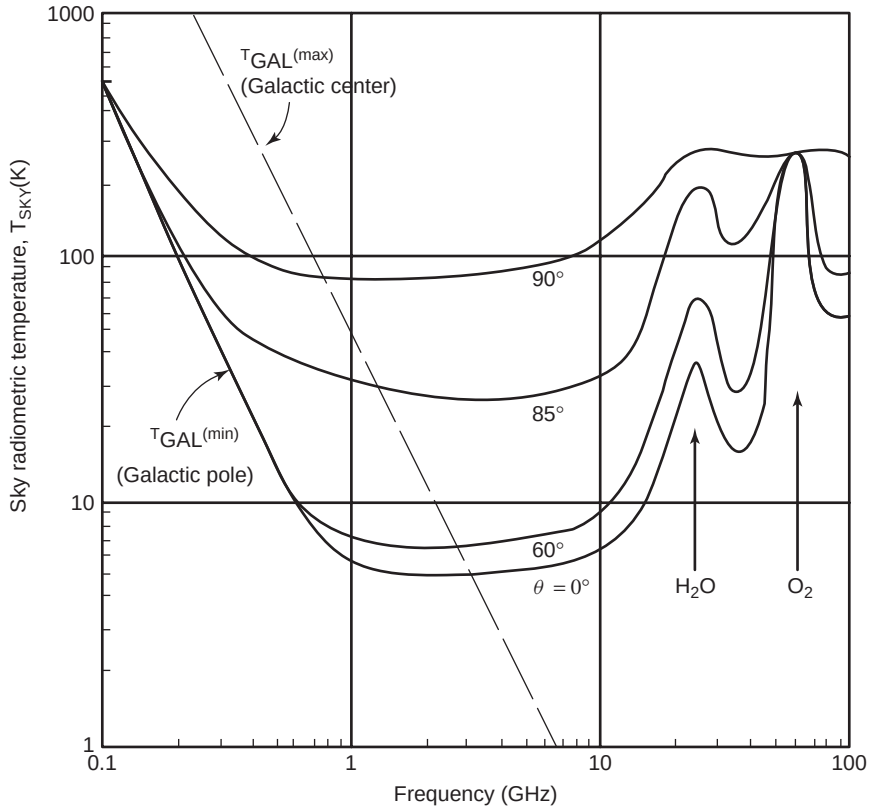

Figure 8 Microwave sky brightness temperature at zenith angles of 0°, 60°, 85°, and 90° for a Standard Atmosphere having a water vapor density of 7.5 g m −3 at sea level. Our galaxy, the Milky Way, is a significant radiometric source at frequencies below 1 GHz. The brightness temperature of a Planck (thermal) source would be a horizontal line on this plot. The −2 slope of the galactic contribution indicates a synchrotron emission process (charges accelerated in magnetic fields). Over a small region around the galactic center, the galactic contribution exceeds 10 K in the 1.4 GHz radiometric window but is negligible by 7 GHz, the next higher common radiometric window. In directions away from the galactic center, the contribution at 1.4 GHz is typically ∼1 K. Emission from the galactic center is a practical consideration only when the sky is being used to calibrate a 1.4 GHz radiometer. Spectral features at 22 GHz and 60 GHz are a water vapor absorption line and the oxygen complex, respectively (Reproduced from Ulaby *et al.*, 1981 by permission of Pearson Education (Addison-Wesley))

contrast between soil and air. If there were no reflection, the emitted brightness temperature would be very close to the physical temperature of the soil at the interface. The large dynamic range in brightness temperature exhibited by soil of varying moisture content is caused by the large variation in reflectivity at the soil–atmosphere interface. This is most easily understood by assuming a quasi-specular soil–vegetation interface. The ratio of reflected to incident wave amplitudes, $\gamma_p(\mu)$, for upwelling radiance in a homogeneous soil is governed by the Fresnel reflection coefficient for polarization p,

$$\gamma_v(\mu) = \left(\frac{\tilde{n}\mu - \mu'}{\tilde{n}\mu + \mu'}\right)$$
$$\gamma_h(\mu) = \left(\frac{\tilde{n}\mu' - \mu}{\tilde{n}\mu' + \mu}\right) \qquad (14)$$

where $\tilde{n}$ is the complex index of refraction of soil at the interface, and μ' and μ are direction cosines of the ray below and above the soil–air interface, respectively. The direction cosines are related by Snell's law,

$$n\sqrt{1-\mu'^2} = \sqrt{1-\mu^2} \qquad (15)$$

The reflectivity for an upwelling brightness temperature at the interface is then

$$R_p(\mu) = \gamma_p(\mu) \cdot \gamma_p^*(\mu) \qquad (16)$$

where $\gamma_p^*(\mu)$ is the complex conjugate of $\gamma_p(\mu)$. If the reflectivity of a quasi–specular interface is $R_p(\mu)$, then its emissivity in direction μ is $e_p(\mu) = (1 - R_p(\mu))$ and the brightness temperature emitted by the soil is

$$Tb_p^s(0^+, \mu) = e_p(\mu) \cdot Tb_p^s(0^-, \mu') \qquad \text{K sr}^{-1} \qquad (17)$$

where $Tb_p^s(0^+, \mu)$ and $Tb_p^s(0^-, \mu')$ refer to the upwelling soil brightness temperature incrementally above and below the interface, respectively. Soil emissivities derived from Fresnel reflection coefficients are good approximations to experimental observations if surfaces are smooth relative to a wavelength and moisture contents vary slowly with depth relative to a wavelength. When surfaces are rough or soils have dried at their immediate surface, Fresnel models yield low estimates of emissivity. Techniques for achieving better estimates require surface roughness statistics if surfaces are not smooth, or temperature and moisture profiles from SVAT models if near-surface temperature or moisture gradients are significant.

Examples of emissivity for a silty loam soil for several percentages of Volumetric Soil Moisture (%VSM) are shown in Figure 9. For a uniform soil half-space temperature of 290 K, the dynamic range of $Tb_h^s(0^+, 1)$ at 1.4 GHz between saturation (~40%VSM) and wilting point (~8%VSM) is ~85 K. For most soils, brightness temperature decreases ~3 K per %VSM increase. For many purposes, knowledge of moisture content to ~4%VSM rms is adequate. Radiometers can be calibrated to better than 2 K and are readily sensitive to 0.5 K. The large dynamic range combined with excellent sensitivity, accuracy, and a minimum of confusing factors in the brightness temperature are reasons that microwave radiometry at frequencies below ~10 GHz is such a powerful tool for sensing soil moisture.

Vegetation canopies are a "confusing factor" of the first order, but ones that are often easily modeled. At lower microwave frequencies, thicknesses of leaves in vegetation canopies are small with respect to a wavelength so that leaves do not scatter but do absorb and emit. This absorption and emission is overwhelmingly by the water within and intercepted upon the leaves. Leaf water can be modeled as uniformly distributed moisture in a homogeneous canopy layer having dielectric properties that are volume-weighted averages of the complex indices of refraction of air, dry leaf material, bound water in leaves, and free water within and upon leaves (England and Galantowicz, 1994). A dual-dispersion model can be used to estimate the dielectric permittivity of water in the leaves (Ulaby and El-Rayes, 1987). The consequent index of refraction of the homogeneous canopy layer, or "cloud" canopy layer, is sufficiently near unity that reflection and refraction at the canopy–air interface can be ignored. Where woody stems, branches, and trunks become a significant fraction of the microwave wavelength, scattering within the canopy will require a second order correction. For a prairie grass canopy, scattering can be ignored at frequencies of 19 GHz and below (England and Galantowicz, 1995). For a corn canopy, scattering

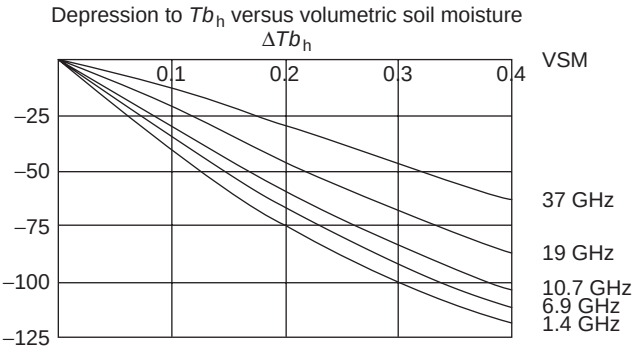

Figure 9 Brightness temperature depression (ΔTb_h) versus Volumetric Soil Moisture (VSM). A silty loam soil having a porosity of 40% is modeled as a uniform half-space having a quasi-specular surface and a temperature just above freezing. The dielectric soil model is from Dobson *et al.* (1985). The depression of the *h*-polarized brightness temperature at a 35° incidence angle is shown as a function of moisture content for 1.4, 6.9, 10.7, 19, and 37 GHz, the five common frequencies of satellite radiometers. The plots are misleading in that they indicate little loss of sensitivity to soil moisture as radiometric frequency increases from 1.4 to 10.7 GHz and only a factor of 2 loss in going to 37 GHz. Three effects not included in this simple model significantly reduce sensitivity to soil moisture with increasing frequency. These are surface roughness, moisture gradients, and vegetation cover, and are discussed in the text. The combination of these effects strongly favor 1.4 GHz for sensing soil moisture

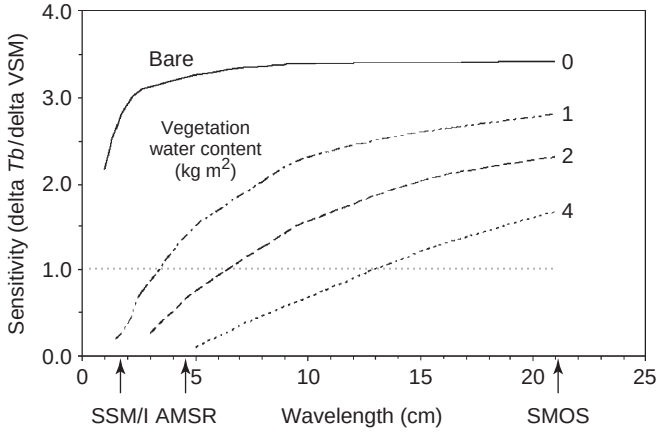

Figure 10 Sensitivity of microwave brightness to moisture in soil under a vegetation canopy. These curves relate the sensitivity of microwave brightness to radiometric wavelength for bare soil (denoted by 0) and for various column densities of liquid water (in kg m^{-2}) in a uniform vegetation canopy. Land-surface modelers typically would like to know volumetric soil moisture (VSM) to something like 4%VSM rms. The usable sensitivity of microwave brightness to soil moisture is ~1 K/%VSM (horizontal dashed line at 1.0 K/%VSM. For example, the figure indicates that microwave brightness at all wavelengths is usably sensitive to moisture in bare soil but, for a canopy moisture column density of 4 kg m^{-2}, about that of mature corn, only the 21-cm wavelength (1.4 GHz) of the SMOS radiometer offers usable sensitivity

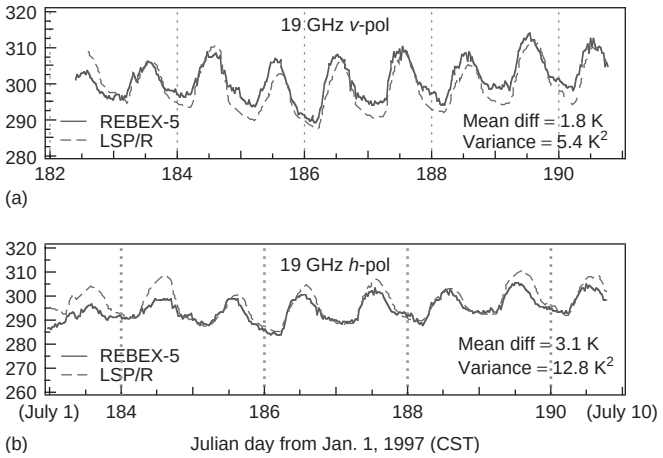

Figure 11 Performance of Radiobrightness model during SGP'97. The field contained mixed wheat stubble and short grass. Panels (a) and (b) compare measured (solid line) and modeled (dashed line) 19 GHz brightness temperatures at the SSM/I's incidence angle of 53°. Panel (a) is vertically polarized brightness temperature and Panel (b) is horizontally polarized brightness temperature

will contribute a few Kelvin error at 1.4 GHz (Hornbuckle *et al.*, 2003).

Propagation within the cloud canopy model is governed by water content expressed as a column density in $kg\,m^{-2}$. Liquid water in and on leaves results in emission and absorption that tends to mask changes in upwelling brightness temperature related to changes in %VSM. The practical limit of useful sensitivity to soil moisture is ~1 K per %VSM. The water column density of short grass might be $1\,kg\,m^{-2}$ and that of mature corn might be $5\,kg\,m^{-2}$. Figure 10 illustrates that a 10 GHz radiometer usefully senses soil moisture through a $\sim 1\,kg\,m^{-2}$ canopy, while for a 1.4 GHz radiometer the limiting canopy column density is nearer $5\,kg\,m^{-2}$. Galactic noise has established the 1.4 GHz protected radio astronomy band as the lowest usable radiometric band. The limits inferred from Figure 10 are consistent both with models and field observations (Hornbuckle and England, 2004). Performance of the R model using these concepts is illustrated in Figure 11.

SATELLITE RADIOMETERS FOR SENSING OF SHALLOW SOIL MOISTURE AND SNOW WATER EQUIVALENT (SWE)

Satellite microwave radiometers that have had, or will have, application to land-surface hydrology appear in Table 2 (e.g. Kramer, 1996). One of the first of these, the Scanning Multichannel Microwave Radiometer (SMMR), was launched on both Seasat and Nimbus-7 spacecrafts in 1978. Seasat failed after only 70 days, but SMMR on Nimbus-7 produced data until it was turned off in July 1988. Figures 5 and 10 suggest that both the 6.6 and 10.7 GHz SMMR channels would have been sensitive to moisture in soil and snow. SMMR's 6.6 GHz data were little used because of their poor quality, but combinations of its 10.7, 18, and 37 GHz data were used in algorithms to classify soils as frozen or thawed, and combinations of 18 and 37 GHz data were used in algorithms to estimate SWE.

In June 1987, the US Defense Meteorological Satellite Program (DMSP) began a series of SSM/I on satellites in LEO. Data from the lowest frequency SSM/I channel, 19 GHz, are sensitive to canopy and soil wetness after rainfall, but their frequency is too high for quantitative estimates of soil moisture where there is any vegetation within the 50-km footprint of the radiometer. Combinations of 19 and 37 GHz SSM/I data are used in algorithms for soil freeze/thaw classification and for SWE.

The Tropical Rainfall Measuring Mission (TRMM) Microwave Imager (TMI) was launched in November 1997. TMI is an evolution of SSM/I but includes 10.7 GHz channels in addition to SSM/I channels. The spatial resolution for the SSM/I channels is twice that of the SSM/I because the instrument is in a lower orbit. Penalties of the lower altitude and inclination are less frequent coverage, observations are not Sun-synchronous, and coverage is limited to $\pm 39°$ of latitude.

Versions of the Advanced Microwave Scanning Radiometer (AMSR) were launched on the National Aeronautics and Space Administration (NASA) Aqua satellite in May 2002 and on the National Space Development Agency (NASDA) ADEOS-2 satellite in December 2002. The ADEOS-2 spacecraft failed in October 2003, but AMSR-E on Aqua continues. The 6.9 GHz channels of AMSR are sensitive to soil moisture through a short grass canopy (Figure 10) if Radio Frequency Interference (RFI), possibly from airports, did not render these channels nearly useless over many land areas. Data from the 10.7 GHz channel appear to be free of RFI over North America but may be experiencing some RFI over Europe.

The National Polar-Orbiting Operational Environmental Satellite System (NPOESS), a cooperative program among the Department of Commerce, (National Oceanic and Atmospheric Administration (NOAA)), the Department of Defense, and NASA, will launch the Conical Scanning Microwave Imager/Sounder (CMIS) in 2008. CMIS will have the AMSR channels plus 60 GHz oxygen- and 183 GHz water vapor channels. It retains the AMSR 2 m aperture and, consequently, its spatial resolution of ~50 km at 6.9 GHz.

The first 1.4 GHz image data from LEO likely will be from ESA's (European Space Agency) Soil Moisture Ocean Salinity (SMOS) mission in 2007 (Kerr *et al.*, 2001). SMOS will be followed by NASA's HYDROS, a 1.4 GHz active/passive mission, in 2010 (see Figure 12) (Entekhabi *et al.*, 2004). The 1.4 GHz brightness temperatures from

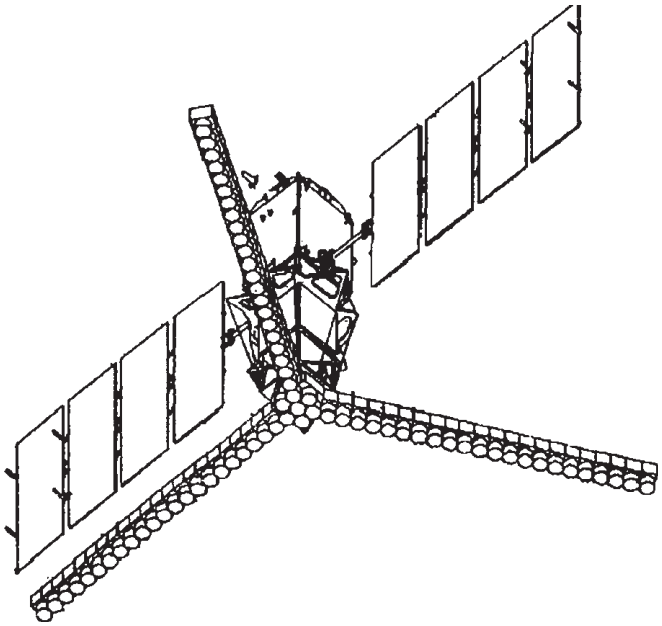

Figure 12 The European Space Agency's (ESA's) Soil Moisture Ocean Salinity (SMOS) satellite. SMOS will be a 1.4 GHz aperture synthesis radiometer in LEO. It is to be launched in 2007 and likely will be the first aperture synthesis radiometer in orbit

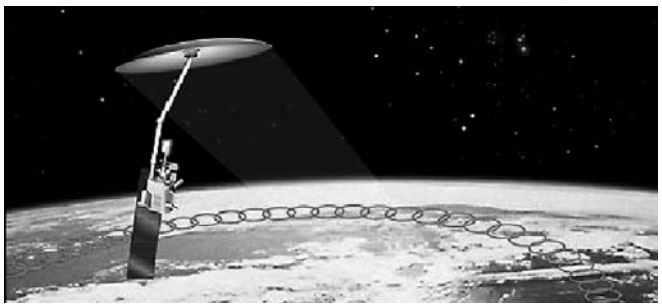

Figure 13 HYDROS is a 1.4 GHz active/passive sensor for mapping soil moisture. HYDROS is a NASA Earth System Science Pathfinder (ESSP) Mission being developed for launch in 2010. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

these satellites will have spatial resolutions of ~40 km and will be sensitive to soil moisture through all but forest canopies. SMOS achieves its spatial resolution with the new aperture synthesis technology – a first for a satellite instrument. NASA's HYDROS (see Figure 13) will be the first active/passive system. The HYDROS strategy is to enhance effective spatial resolution by combining 40 km brightness data with higher spatial resolution radar data to produce a 10-km soil moisture product and a 3-km soil freeze/thaw product.

Fundamentals of a Radiometer

Satellite microwave radiometers are characterized by three primary parameters – spatial resolution or footprint (the 3-dB contour of the antenna beam projected on the ground), uncertainty in noise equivalent temperature or sensitivity (NEΔT), and calibration accuracy (a bias in Kelvins) – and three secondary parameters – antenna radiation efficiency, η_l, antenna beam efficiency, η_a, and receiver noise equivalent temperature, T_{rec}. Even casual users of brightness data should be familiar with the primary parameters. Those who require a quantitative assessment of data quality should understand all six parameters.

An excellent discussion of radiometer fundamentals can be found in Skou (1989). An ideal total power radiometer and its conceptual model are shown schematically in Figures 14(a) and 14(b), respectively. The radiometer is "ideal" because its receiver is linear, gain does not vary with time, and sensitivity is the best achievable for a given

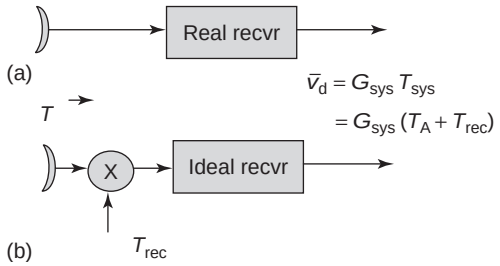

Figure 14 Functional sketch of a radiometer (a) and its model (b). The antenna temperature, T_A, represents the signal and noise delivered to the receiver (Recvr) by the antenna. The ''real'' receiver amplifies T_A and adds its own receiver noise represented by T_{rec}, in the radiometer model. T_{rec} is a fictitious noise added immediately behind the antenna in (b) followed by an ''ideal'' receiver that adds no noise to the output signal. The sum of $T_A + T_{rec} = T_{sys}$ is the system noise. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

system noise and integration period. The radiometer is "total power" because it measures absolute noise equivalent antenna temperatures. In contrast, a Dicke radiometer, typical of the previous generation of radiometers, measures the difference between noise equivalent antenna temperature and noise equivalent reference load temperature. Dicke architecture was used to minimize the effects of nonlinearity and gain instability. Modern radiometers are exceptionally linear and sufficiently stable in gain to be treated as ideal for the few second periods between internal calibrations.

The Antenna

Most radiometer antennas are designed to have narrow, nearly circular beams with side-lobes well below the −13 dB shown from the uniformly illuminated aperture in Figure 15. The directivity of such an antenna, $D_p(\hat{i})$, indicates radiant power of polarization p in direction $\hat{i}$ relative to the radiant power of a hypothetical isotropic radiator emitting equivalent power. Antenna gain is related to directivity by $G_p(\hat{i}) = \eta_l D_p(\hat{i})$ where η_l is radiation efficiency. Radiation efficiencies less than unity are caused by ohmic loss in the antenna. Typical values are ∼0.95 at 1.4 GHz and ∼0.85 at 35 GHz.

A radiometer antenna collects brightness temperatures, $T b_p(\hat{i})$, from all directions to achieve an antenna temperature, T_A,

$$T_A = \int_{4\pi} \frac{D_p(\hat{i})}{4\pi} T b_p(\hat{i})\, d\Omega \qquad K \tag{18}$$

where $d\Omega$ is incremental solid angle in direction $\hat{i}$. If T_o is the physical temperature of an antenna in Kelvin,

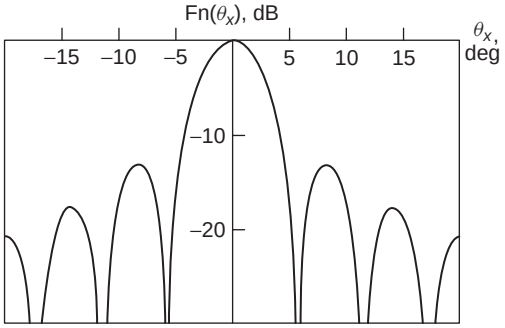

Figure 15 An example of the normalized radiation pattern of a square aperture antenna whose sides are parallel to the x and y axes, and whose normal lies along the z axis. The normalized radiation pattern represents the radiant intensity in a particular direction normalized by maximum radiant intensity. It is measured or modeled at distances from the antenna that are large with respect to any aperture dimension so that the antenna can be considered a point source. The plot is a $y = 0$ cut through the pattern for an aperture whose size to wavelength ratio is 10, and whose radiating field in the aperture plane is uniform in amplitude and phase. The θ_x dimension is angle from the $\hat{z}$ direction measured toward the $\hat{x}$ direction. The maximum lobe, centered on the θ_x, is referred to as the Main lobe. Other lobes are referred to as side-lobes. Because the 1st side-lobe of this antenna is only 13 dB below the Main lobe, it would be considered a poor radiometer antenna. Too much energy would be collected from unwanted directions. Side-lobes of radiometer antennas should be more than 20 dB below the Main lobe. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

then the antenna temperature delivered to a receiver (see Figure 14a) is

$$T'_A = \eta_l T_A + (1 - \eta_l) T_o \qquad \text{or}$$

$$T'_A = \int_{4\pi} \frac{G_p(\hat{i})}{4\pi} T b_p(\hat{i})\, d\Omega + (1 - \eta_l) T_o \qquad K \tag{19}$$

The 3-dB beam width, $\beta_{1/2}$, defines an antenna's angular resolution. The main beam is the solid angle between nulls at $\pm\beta_{null}/2$, and main beam efficiency, η_a, is

$$\eta_a = \frac{\int_{main\ beam} G_p(\hat{i})\, d\Omega}{\int_{4\pi} G_p(\hat{i})\, d\Omega} \tag{20}$$

Communications antennas might have main beam efficiencies less than 0.85, which means that side-lobes account for greater than 15% of the antenna's collecting area. Side-lobes collect energy from undesirable directions and are suppressed in the design of radiometer antennas. Radiometer antennas typically have radiation efficiencies well above 0.90, but achieve this at the cost of some angular resolution.

The projection of the 3-dB beam contour onto the ground defines the footprint of the radiometer. For conically scanning radiometers, like the SSM/I, AMSR, TMI, and CMIS, this footprint is approximately elliptical. The relationship between the radiometer's scanning cone half angle with respect to nadir, θ, and the incidence angle on a spherical Earth, θ', is

$$\sin\theta' = \left(1 + \frac{h}{a_o}\right)\sin\theta \tag{21}$$

where h is satellite altitude above the Earth's surface in km and a_o is the Earth's radius ($a_o = 6400$ km). For example, the SSM/I cone half angle of $\theta = 45°$ and orbit altitude of 833 km results in an incidence angle $\theta' = 53°$ at the Earth's surface. The semimajor axis, X_o, and semiminor axis, Y_o, of the footprint is

$$X_o = \frac{h + a_o(1 - \cos(\theta' - \theta))}{\cos\theta\cos\theta'}\beta_{1/2} \qquad \text{km}$$
$$Y_o = \frac{h + a_o(1 - \cos(\theta' - \theta))}{\cos\theta}\beta_{1/2} \qquad \text{km} \tag{22}$$

where beamwidth, $\beta_{1/2}$, is in radians. The angular resolution for the 19 GHz channel of the SSM/I is 0.0346 radians which corresponds to $X_o = 73$ km and $Y_o = 44$ km. The 19 GHz ground resolution is often quoted as 50 km, which is a slightly optimistic average of the principal axes. The National Snow and Ice Data Center (NSIDC) uses a Backus–Gilbert technique to optimally resample the SSM/I data to a fixed Earth Grid, the Equal Area Scaling Earth–Grid (EASE-Grid), which has a 25-km spacing between grid points. This 25-km data is effectively an oversampling of the original data. The spatial resolution of each resampled point remains $\sim 70 \times 40$ km.

The Receiver

The receiver in Figure 14(a) amplifies the signal from the antenna and adds its own noise. The receiver noise equivalent temperature is modeled in Figure 14(b) as T_{rec} inserted at a point immediately behind the antenna followed by a noise-free receiver. The total noise equivalent temperature, or system noise equivalent temperature, is always defined at the output terminals of the antenna, that is,

$$T_{sys} = T'_A + T_{rec} \qquad \text{K} \tag{23}$$

Voltage samples of a thermal noise signal exhibit a zero-mean Gaussian distribution. The amplitudes of these voltages exhibit a Rayleigh distribution, and the square of the amplitudes, v_d, exhibit an exponential distribution. The square of the amplitude, v_d, is proportional to power or to T_{sys}, so that the mean of v_d is

$$\overline{v_d} = G_{sys}T_{sys} \qquad \text{V} \tag{24}$$

where G_{sys} is the system gain in V K^{-1}. The standard deviation of an exponential distribution is equal to its mean. That is, an estimate of T_{sys} based upon one sample of v_d has uncertainty equal to T_{sys}. Equivalently, the Noise Equivalent uncertainty in Temperature, $NE\Delta T$, for one sample is $NE\Delta T_1 = T_{sys}$ where $NE\Delta T$ is the standard deviation of the expected error in the estimate of T_{sys}. Because thermal noise is a stationary random process, N independent samples of T_{sys} improves the estimate of T_{sys} by $\sqrt{N}$, that is, the $NE\Delta T$ for N samples is

$$NE\Delta T_N = \frac{T_{sys}}{\sqrt{N}} \qquad \text{K} \tag{25}$$

Typical digital radiometers might have system temperatures of $\sim$500 K. Equation (25) requires that $N = 25 \times 10^6$ samples to achieve a desired uncertainty in T_{sys} of 0.1 K. The equivalent for an analog radiometer is $N = \Delta f\tau$ where Δf is the system bandwidth and τ is an integration time. A radiometer whose T_{sys} is 500 K and whose bandwidth is 25 MHz requires an integration time of 1.0 s to achieve an $NE\Delta T$ of 0.1 K.

Equation (25), or its analog equivalent, is an accurate indicator of $NE\Delta T$ if all of the uncertainty results from the statistics of the noise signal. Fluctuations in G_{sys} can add rms contributions that exceed the thermal noise contribution if the physical temperatures of the RF amplifiers are not adequately controlled. This gain instability, caused by fluctuations in temperature among elements within a radiometer, is less of a problem with modern radiometers because their small size and low power consumption allow thermal control to $\sim$20 mK rms. Absolute accuracy always depends upon external calibration.

Calibration

The inherent linearity of microwave radiometers generally permits a two-point calibration as illustrated in Figure 16. Satellite radiometers often use the extraterrestrial sky as the cold load and a heated absorber/emitter as the hot load. Antennas of conically scanning radiometers, like the SSM/I and AMSR, view their calibration loads once per revolution of the antenna. The SSM/I spins at 32 rpm which corresponds to a calibration every 1.9 s.

Calibration is conventionally described by the equations

$$\overline{v_d} = a(T_A + b) \tag{26}$$

where a and b are referred to as gain and offset, respectively. From equations (19), (23), and (24),

$$\overline{v_d} = G_{sys}T_{sys}$$
$$= G_{sys}(T'_A + T_{rec})$$

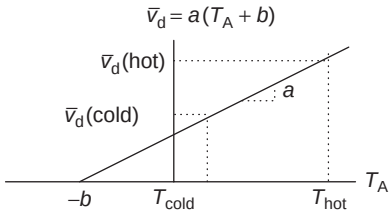

Figure 16 Calibration of a microwave radiometer. The relationship between antenna temperature, T_A, and the average power delivered by a well-designed microwave radiometer (represented by $\bar{v}_d$) is very nearly linear. This linearity allows a two-point calibration, T_{cold} and T_{hot}, to determine gain, 'a', and offset, 'b'. T_{cold} might be the cold sky and T_{hot} might be a black emitter at ambient temperature. Conceptually, 'b' can be thought of as the noise equivalent contribution of the receiver, T_{rec}, and 'a' as the system gain, G_{sys}. In practice, they are not quite equivalent so it is necessary to preserve the distinction between 'a' and G_{sys}, and between 'b' and T_{rec}

$$= G_{sys}(\eta_l T_A + (1-\eta_l)T_o + T_{rec})$$
$$= G_{sys}\eta_l\left(T_A + \left(\frac{1}{\eta_l}\right)((1-\eta_l)T_o + T_{rec})\right) \quad (27)$$

yielding gain and offset,

$$a = G_{sys}\eta_l$$
$$b = \left(\frac{1}{\eta_l}\right)((1-\eta_l)T_o + T_{rec}) \quad (28)$$

The approximation $\eta_l = 1$, a lossless antenna, yields the useful relationships; the slope of the calibration line in Figure 16 is system gain, that is, $a = G_{sys}$, and the $\overline{v_d} = 0$ intercept is the negative of receiver noise equivalent temperature, that is, $b = -T_{rec}$.

IMPROVED SPATIAL RESOLUTION

The section "Stored water as a modeled product" identified stored water as a relevant model-based parameter that could be estimated from a combination of SVAT/R models and assimilated remotely sensed shallow soil moisture. The section "Satellite radiometers for sensing of shallow soil moisture and Snow Water Equivalent (SWE)" identified 1.4 GHz radiometry as the most usefully sensitive single technique for sensing shallow soil moisture. The principal difficulty with their combination is achieving an acceptable spatial resolution. Various criteria are used to define acceptable resolution. The most generous criterion might be the need to resolve a moisture track of a significant precipitation event. Meeting this criterion requires something like a spatial resolution of 10 km. A more aggressive criterion might be to resolve individual agricultural fields so that vegetation canopies within an instrument's footprint would be more nearly homogeneous. Fields in the American Midwest are dominantly a quarter section. This translates to a more demanding spatial resolution of ~1 km. A truly challenging criterion might be to resolve significant spatial heterogeneities in the SWE of an alpine snow pack. Meeting this criterion might require a spatial resolution of 100 m.

Three resolution-enhancing technologies are being pursued. None are likely to yield a 100-m spatial resolution at 1.4 GHz, but the radiometric techniques might achieve 10 km and a combination of radar and radiometry might achieve 1 km. These are disaggregation of brightness temperature observations, aperture synthesis radiometry, and combined active/passive microwave sensing.

Disaggregation of Brightness Temperature Observations

If two distinct terrain types lie within a pixel, the mixed pixel can be tiled with an area-weighted aggregate of SVAT/R models of each terrain. The observed brightness temperature for a pixel is then disaggregated to minimize the sum of squared errors between modeled and observed brightness temperature attributed to each tile. These disaggregated observations are then assimilated into appropriate SVAT/R model. The simplest approach would assume equal confidence in expected brightness temperatures for each tile. A more sophisticated approach would include expected errors in each of the model-based brightness temperatures. Disaggregation of observations has only recently been tried (e.g. Burke *et al.*, 2001; and Burke *et al.*, 2002).

Aperture Synthesis Radiometry

Aperture synthesis radiometry, or Synthetic Thinned Array Radiometry (STAR), is an adaptation of interferometric radio astronomy (e.g. Thompson *et al.*, 1994). Instead of viewing the heavens, STAR radiometers view the Earth either from aircraft or from spacecraft (e.g. LeVine, 1990; LeVine *et al.*, 1994; Camps *et al.*, 1997; Martin-Neira *et al.*, 2002; and Bayle *et al.*, 2002). STAR allows spatial resolutions with sparse arrays that are equivalent to those of filled arrays of a similar circumscribed aperture (see Figure 17), but at a cost of increased signal processing complexity and some loss sensitivity. STAR also offers the flexibility of beam-forming in postprocessing and a reduced aperture flatness requirement. Where the requirement for a real aperture antenna might be a specified shape to 1/20th of a wavelength, the STAR requirement is a more forgiving combination of flatness and knowledge of element location. A hybrid STAR, the 1.4 GHz Electronically Scanned Thinned Array Radiometer (ESTAR) (LeVine *et al.*, 1990), operated successfully on a NASA aircraft between 1990 and

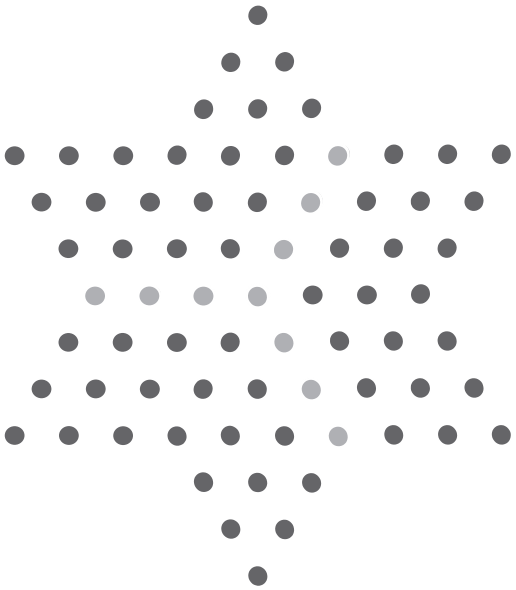

Figure 17 Equivalent filled-aperture antenna. The gray dots represent the actual locations of antenna and receiver elements of an aperture synthesis radiometer, and the combination of gray and black dots represent locations of antenna and receiver elements of an equivalent filled-aperture radiometer. That is, the spatial resolution of this 10-element aperture synthesis radiometer would be equivalent to the spatial resolution of this 73-element real aperture system. The cost is loss of sensitivity in the aperture synthesis system. Whether the cost is acceptable depends upon the application. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

2003. ESTAR used a real aperture along-track and aperture synthesis across-track. STAR-Light (see Figure 18), a 1.4 GHz, 2-dimensional STAR radiometer being developed for arctic land-surface hydrology, will achieve a compactness that is compatible with a light aircraft rather than require the 4-engine turboprop aircraft used by previous generations of instruments. ESA's SMOS instrument (see Figure 12) will be a 1.4 GHz, two-dimensional STAR sensor.

STAR implementations become simpler as radiometers become increasingly digital and compact. A Direct Sampling Digital Radiometer (DSDR) avoids mixers by digitally sampling the 1.4 GHz RF signal (Fischman and England, 1999). A correlation DSDR based upon two 1.4 GHz DSDR radiometers achieved analog performance with 3-bit sampling (Fischman *et al.*, 2002). Early DSDRs required 90 dB of RF amplification prior to sampling with commercially available Analog-to-Digital Converters (ADCs). Newer commercial ADCs now require only 70 dB of amplification and some custom ADCs require as little as 45 dB. DSDRs used off-chip ceramic filters but Micro-Electro-Mechanical Systems (MEMS) mechanical filters

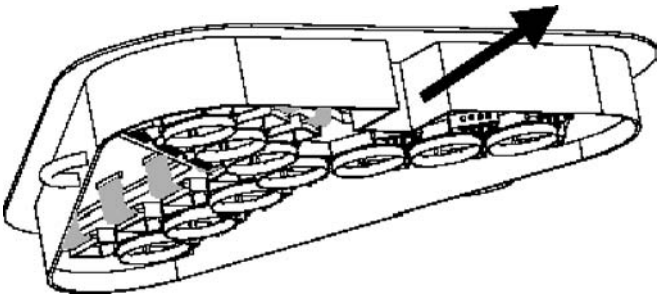

Figure 18 STAR-Light. STAR-Light is a 10 element, 1.4-GHz aperture synthesis radiometer designed to fly on a light aircraft in support of land-surface hydrology in the Arctic. The instrument is approximately 1 m on an edge. The arrow indicates direction of flight. The Office of Polar Programs of the National Science Foundation (NSF) supported development of STAR-Light through Critical Design Review and element prototype fabrication and testing. The prototype elements were used in the Cold Lands Processes Experiment (CLPX) in Colorado during the winter and spring of 2003

have recently operated at 1.4 GHz. We are rapidly approaching the possibility of a complete 1.4 GHz radiometer on a chip with antenna temperature and timing signal in, and digital data out.

Combined Active/Passive Microwave Sensing

Satellite radar has the salient advantage of superior spatial resolution. One hundred meter spatial resolution from LEO with a sensitivity that is appropriate for soil moisture retrieval is within the capability of current technology. In principle, radar and radiometry at the same frequency have similar sensitivities to soil moisture (Du *et al.*, 2000). In practice, scattering from woody elements of a canopy, rough soil surfaces, ice lenses in snow packs, and combinations of these can easily overwhelm the subtle differences caused by variations in soil moisture. The difficulty of soil moisture or SWE retrieval from radar backscatter alone can be appreciated by analogy. Radar sensing through a vegetation canopy and a rough soil surface or through a tree canopy and embedded scatterers in a snow pack is similar to optically viewing objects through frosted glass when the objects are illuminated by a source on the viewer's side of the glass. Light backscattered by the glass tends to overwhelm light reflected by objects behind the glass. Radiometry is like viewing objects through frosted glass when the illumination is on the objects' side of the glass. Where vegetation is relatively sparse, polarimetric radars and multifrequency radars have been used to unravel the contributions of soil moisture or SWE from those of soil surface roughness. As scattering becomes more complex, radar is increasingly limited to the qualitative detection of temporal or spatial changes in soil moisture or SWE. In

these cases, radiometry may play the essential role of calibration of the overall radar scene average. The literature on these investigations is extensive and beyond the scope of this review.

Satellite radar for soil moisture is more difficult to interpret, is of higher cost relative to satellite radiometry, and typically has unacceptably long intervals between repeat coverage. Even with these disadvantages, radar is still the only technology that will achieve the high spatial resolution that some land-surface hydrology demands. The emerging compromise is a combination of radar and radiometry. NASA's HYDROS (see Figure 13) will be the first example of a passive/active microwave system (Entekhabi *et al.*, 2004). The science behind these complementary data is not yet mature, but will be the focus of many investigations over the next decade.

48: Ground-based and Airborne Lidar

R MICHAEL HARDESTY AND LISA S DARBY

NOAA Environmental Technology Laboratory, Boulder, CO, US

Lidar remote sensing techniques can be applied to measure a wide variety of atmospheric parameters important in the hydrological sciences, including aerosol distribution, cloud properties, ozone and water vapor concentration, and wind fields. Lidar measurements make use of scattering and extinction of laser radiation in the atmosphere. Instruments are deployed on surface and aircraft platforms to investigate phenomena such as moisture spatial distribution and temporal evolution, ozone sources and transport, boundary-layer height, aerosol distribution, cloud microphysics, and wind structure. New satellite-based instruments enable lidar techniques to be applied on a global scale.

INTRODUCTION

Light Detection And Ranging (Lidar) refers to an active remote sensing technique with significant application in the hydrological sciences for remote probing of atmospheric quantities such as water vapor, cloud and aerosol particles, and winds. Lidar remote sensing involves the transmission and scattering of light to remotely probe the atmosphere. Fundamentally, lidar methodology is directly analogous to radar, differing primarily by the wavelength of the transmitted and received electromagnetic energy (*see* **Chapter 63, Estimation of Precipitation Using Ground-based, Active Microwave Sensors, Volume 2**). Radar systems used for atmospheric observations operate in the radio wave and microwave portions of the electromagnetic spectrum, with wavelengths ranging from about 1 mm to 10 m, while atmospheric lidar systems utilize ultraviolet, visible, and infrared light at wavelengths from approximately 250 nm to 10 μm. The different operating wavelengths result in very different atmospheric scattering and transmission properties. Energy at radar wavelengths is scattered efficiently by rain, clouds, and meter-size atmospheric density inhomogeneities, but is only weakly scattered by atmospheric molecules and aerosol particles. Energy at optical wavelengths, on the other hand, is efficiently scattered by atmospheric aerosol particles and molecules but strongly attenuated by most clouds and heavy precipitation. Consequently, the two instruments are typically deployed in different and sometimes complementary applications. Radars are used to investigate phenomena such as precipitating storms and cloud microphysics, and to measure winds based on the motion of hydrometeors or refractive index inhomogeneities. Lidars are applied to characterize atmospheric density, trace species, and aerosol structure, and to measure wind speeds in optically clear air by observing the movement of molecules and aerosol particles.

In a lidar, a laser transmitter directs a pulse of monochromatic light into the atmosphere. As the light propagates, some of it is scattered by the molecular and aerosol constituents of the atmosphere. Scattering from aerosols (Mie scattering) is elastic (at the same wavelength as the incident beam), while scattering from molecules has both elastic and Raman components. The Raman-scattered light is much weaker than the elastic-scattered portion and is shifted in wavelength by an amount uniquely characteristic of the scattering molecule. If the scatterer is moving toward or away from the lidar due to wind or thermal motion, the wavelength of the scattered radiation is also shifted because of the Doppler Effect. Some of the propagating light may be attenuated by certain species or particles present within the beam that selectively absorb radiation at the transmitted wavelength. Scattering and absorption processes in the atmosphere reduce the intensity of both the forward propagating beam and the backscattered radiation (light scattered directly back toward the source). The lidar receiver collects, detects, and analyzes the backscattered light (the portion of the light scattered directly back to the receiver) as a function of time. By measuring the time elapsed since the laser pulse

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

was transmitted, the range to the portion of atmosphere from which information is received at a given time is determined. The detected backscattered signal contains information on the distribution, concentration, and optical properties of atmospheric constituents, and may also be analyzed to estimate wind velocities and atmospheric turbulence.

SCATTERING AND TRANSMISSION OF LASER RADIATION IN THE ATMOSPHERE

The scattering and transmission properties of light in the atmosphere are fundamental to lidar measurements. The scattering properties of an atmospheric particle depend on its refractive index, shape, size and orientation. In the special case when the particle is much smaller than the wavelength of the incident radiation, as is the case for laser radiation scattered by atmospheric molecules, the scattering process is characterized as *Rayleigh* scattering. In the Rayleigh scattering regime, the energy backscattered by a particle increases proportionally as the inverse of the fourth power of the wavelength. Consequently, lidar systems based on molecular scatter usually operate at short wavelengths, that is, in the visible or ultraviolet spectral regions, to maximize the backscattered signal.

Aerosol particles, the other component of the atmosphere that scatters laser light, result in *Mie* scattering, which applies when the diameter of the scatterers is on the order of or larger than the incident wavelength. Atmospheric aerosol particles that scatter laser light include organic and inorganic particles, such as sulfates and nitrates, dust, soot, smoke, and pollen, as well as liquid water and ice. Although for Mie scattering the relationship between the power backscattered by an ensemble of aerosol particles and the incident wavelength is not simply characterized, typically, the backscattered energy increases roughly proportional to the first or second power of the inverse of the incident wavelength, depending on the refractive index and shape of the scattering particles. In a polluted environment, such as in the vicinity of urban areas, an abundance of large particles often results in a roughly linear relationship between the inverse of the incident wavelength and the backscattered energy, while in more pristine environments such as the free troposphere, the inverse wavelength/backscatter relationship can approach or exceed a square-law relationship. Mie scattering is asymmetric, with more light scattered in the forward direction, and less scattered back toward the lidar.

Figure 1 shows a typical spectrum of elastic backscattered light collected at the lidar receiver for a volume of atmosphere irradiated by a monochromatic laser pulse. Molecular scattering produces the broadband distribution in Figure 1, where the broadening results from the Doppler shifts of the radiation backscattered from molecules moving randomly at their thermal velocities. The width of the molecular velocity distribution in the atmosphere ranges

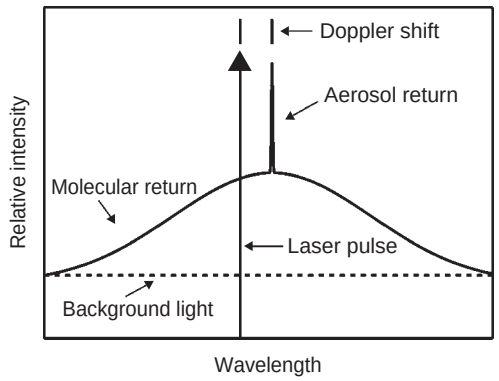

Figure 1 Spectrum of atmospheric elastic backscatter for illumination by a single frequency laser source, showing narrowband aerosol return, wideband molecular return, and Doppler shift of the spectrum resulting from particle motion

from about 320 to 350 $m\,s^{-1}$, scaling as the square root of the temperature. In the center of the spectrum is a much narrower peak resulting from scattering of the light by aerosol particles. Because the thermal velocity of the much larger aerosol particles is very low, the width of the distribution of the aerosol return is determined by the range of velocities of particles moved about by turbulence within the scattering volume. This width is typically on the order of a few $m\,s^{-1}$. Also shown in Figure 1 is an additional broadband distribution due to scattered solar radiation collected at the receiver. In Figure 1 the laser source is shown as monochromatic; if the laser source is not monochromatic, the backscattered signal spectrum is additionally broadened, with the resulting spectrum being the convolution of the spectrum shown in Figure 1 with the spectrum of the laser pulse. As seen in the figure, the entire spectrum of the backscattered radiation is Doppler-shifted in frequency relative to the frequency of the laser pulse because of the mean wind. Because wind velocities are in the order of tens of $m\,s^{-1}$ or less, the mean Doppler shift is less than the width of the molecule-scattered spectrum, but can be much greater than the aerosol-scattered spectrum width.

Both Rayleigh and Mie scattering processes are elastic, where the wavelength of the scattered signal is not altered by the scattering process. Scattering from atmospheric atoms and molecules also includes Raman scatter, which results from a process in which energy is exchanged between the scattered photon and the scattering species. A fundamental characteristic of Raman scatter is the shift of the wavelength of the scattered light from that of the incident light by an amount that is uniquely characteristic of the scattering molecule. As a result, the Raman-scattered spectrum can be analyzed to identify the molecule (e.g., nitrogen or water vapor), determine its number density, and estimate its energy state by comparing the populations in different energy levels. The Raman scattering component

of backscattered light is typically two or three orders of magnitude weaker than the Rayleigh-scattered radiation, however, use of high-quality optical filters to separate the Raman-scattered light enables identification and monitoring of specific atmospheric constituents such as nitrogen and water vapor.

Some of the laser light propagating toward and back from the scattering volume may also be absorbed by specific atmospheric molecules and particles along the propagation path. Different gases and particles typically have distinctive absorption characteristics. The absorption cross sections of aerosol particles usually vary slowly with wavelength, while some molecular absorption spectra may be highly structured, particularly in the infrared portion of the electromagnetic spectrum. The technique known as *differential absorption lidar* (DIAL) takes advantage of this fine structure to measure gaseous species concentrations. In DIAL applications, two closely spaced wavelengths are transmitted, with the wavelengths chosen such that the radiation at one wavelength is more strongly absorbed by the species of interest than at the second wavelength. By comparing the difference in attenuation across a common portion of the transmit/receive path, the concentration of the species of interest may be calculated.

LIDAR SYSTEM CHARACTERISTICS

The basic components that make up a lidar system include the laser transmitter, transmission optics to direct the laser beam into the atmosphere, a telescope to collect the light, and a detector package to convert photons to an electrical signal for analysis and storage. The specific characteristic of each component depends on the application for which the instrument is developed. A primary system characteristic is the laser transmitter wavelength. Rayleigh backscatter and Raman lidar systems designed to estimate atmospheric constituent concentrations and density operate in the visible or ultraviolet region of the spectrum where scattering from molecules is strongest. Lidars for characterizing aerosol properties are more likely to employ lasers transmitting at longer wavelengths, ranging from the visible to the near-infrared or even thermal-infrared regions (i.e., from 0.5 μm to 11 μm wavelengths), where the backscatter from aerosol particles relative to molecular scatter is higher. DIAL system transmitters include two wavelengths, and can incorporate separate lasers or a single tunable laser. Because absorption features of atmospheric gases occur over many regions of the spectrum, DIAL systems operate anywhere from the ultraviolet (e.g., to measure ozone) to the infrared (for water vapor measurements).

The versatility of lidars for observing atmospheric characteristics has resulted in a wide variety of deployment configurations and platforms. Although most lidar systems are still used in research configurations involving operators and intermittent operation, an increasing number of instruments has been demonstrated for stand-alone, unattended operation. Over the past 5 years, autonomous lidar systems that measure aerosol backscatter and depolarization, cloud and aerosol extinction, water vapor and ozone concentrations, and wind shear have been deployed in both short-term and extended observational programs. Lidar systems have also been deployed on aircraft and ships to profile atmospheric properties during a wide variety of field measurement campaigns.

The remainder of this entry focuses on the use of lidars for atmospheric probing. However, lidar methodology is also applicable for a variety of other geophysical activities. Most notably, lidar altimeters employing short pulses have been deployed on aircraft and satellites to map surface topography and coastal bathymetry. Airborne lidars have also been used to investigate sea surface–wave structure, and to locate and characterize fish schools and floating ocean debris.

LIDARS FOR MEASUREMENT OF CLOUD AND AEROSOL PROPERTIES

Aerosol particles suspended in the atmosphere play an important role in a variety of weather and climate processes. For example, increases in anthropogenic aerosols over the past several decades are thought to have mitigated some of the global warming effects of increased greenhouse gases by reflecting solar radiation back to space. Because certain small aerosol particles serve as cloud condensation nuclei, their presence can change the microphysical and radiative properties of clouds, which on large scales can alter the global radiation balance. Also, layers of absorbing aerosols characterized by significant fractions of elemental carbon can alter the thermodynamic structure of the atmosphere, stabilizing or de-stabilizing the atmosphere depending on the height of the absorbing aerosol layer.

Aerosols are air pollutants. Because of the health hazards associated with inhalation of small particles, in 1997, the US Environmental Protection Agency established air quality limits specifying maximum permissible mass concentrations of particles below 2.5 μm in size. Aerosol particles when present in sufficient concentrations also limit visibility, especially in humid regions where the particles can contribute to local smog by increasing their size through deliquescence. The issue of visibility reduction in pristine areas such as national parks has drawn considerable public and research attention in recent years.

Lidar is an excellent tool for investigating the structure and transport of atmospheric aerosol particles in weather and climate research. The signal received from the atmosphere by an aerosol backscatter lidar is expressed in the

single-scattering lidar equation (Collis and Russell, 1976):

$$P_r(R) = P_0 \left(\frac{c\tau}{2}\right) \beta(R) A_r R^{-2} \exp\left[-2 \int_0^R \sigma(r)\, \mathrm{d}r\right] \quad (1)$$

where P_r is the instantaneous received power from range R, P_0 is the transmitted power at time t_0 (the time when the laser pulse is transmitted), c is the velocity of light, τ is the pulse duration, β is the volume backscattering coefficient of the atmosphere, R is the range, A_r is the effective area of the receiver telescope, and σ is the extinction coefficient for the atmosphere through which the beam propagates. Equation (1) is valid for a rectangular pulse and assumes that the volume backscattering coefficient β does not vary over the scale of the pulse. Note that equation (1) refers to the power received by the lidar, not the power detected and analyzed.

Equation (1) is indeterminate because both the backscatter and extinction coefficients are unknown. However, because backscatter lidars frequently operate at wavelengths in the visible or infrared spectral regions where atmospheric absorption is minimal, the absorption term in equation (1) can often be neglected to provide an uncalibrated estimate of the relative backscatter as a function of range. Such measurements provide insights into structure and processes in the atmosphere as shown in the example of Figure 2. This image depicts the aerosol structure observed by a downward-looking, aircraft-mounted, ultraviolet lidar operating at 360 nm wavelength (Alvarez *et al.*, 1998) as it crosses the shoreline of Galveston Bay near Houston, Texas. The aerosol profiles clearly show the large difference between the marine and terrestrial mixed layer depths. Mixed layer depth, indicated by the region with significant aerosol scattering capped by a strong backscatter gradient, is much deeper over the warmer land surface. Because mixed layer depth determines the volume in which air pollutants can be trapped, lidar measurements are helpful in understanding changes in surface pollution concentrations due to dilution processes. Lidar aerosol measurements can also be useful in characterizing entrainment, diffusion, and transport processes that affect local air quality (e.g., Senff *et al.*, 1998).

The lidar observations shown in Figure 2 were obtained with a research lidar operating in the ultraviolet region of the spectrum. Most aerosol backscatter lidars, however, incorporate Nd:YAG lasers transmitting at 1.06 μm wavelength. Nd:YAG lasers are widely used as lidar sources because the technology is mature, the lasers are commercially available from many sources, the atmosphere has good transmission characteristics at 1.06 μm, and the output can be doubled using a nonlinear crystal to produce laser radiation at 532 nm in the visible region of the spectrum.

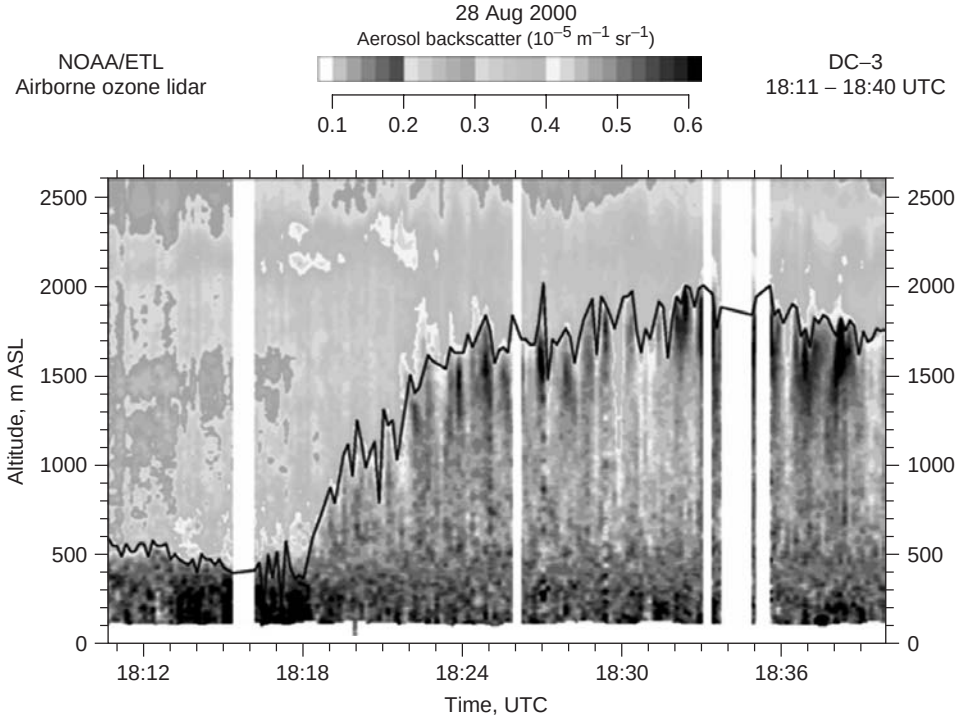

Figure 2 Nadir-pointing airborne backscatter measurements showing strong scattering in the mixed layer, thermal plumes and difference in mixing layer depth over water (left) and land (right) obtained near Houston, Texas (Courtesy C. Senff, University of Colorado). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Some backscatter lidars transmit and receive both 1.06 μm and 532 nm radiation to provide information on wavelength differences in backscattered radiation characteristics.

Although, for simplicity, most backscatter lidars operate in a fixed-pointing mode for observation of the vertical structure of aerosol particles, a scanning capability enables characterization of a 3-dimensional aerosol field. Figure 3 shows a horizontal scan of the aerosol structure just above Lake Michigan as observed by the shore-deployed University of Wisconsin 1.06 μm volume imaging aerosol lidar (Piironen and Eloranta, 1995). The individual fine-scale aerosol structures are well observed by the lidar, which can resolve atmospheric features of about 30 m. The lidar used to obtain the image in Figure 3 is somewhat unique in that the beam can be scanned rapidly in azimuth and elevation, providing very visual images of the three-dimensional evolution of aerosol structure in the internal boundary layer over the lake. Because the 1.06 μm transmitted beam is not eye-safe, even at extended ranges, a human spotter is necessary when the Wisconsin system is operated in a scanning mode. Eye-hazard considerations have led to the development of eye-safe instruments, such as a scanning 1.54 μm aerosol lidar demonstrated at the National Center for Atmospheric Research for tracking clouds of aerosols for Homeland Security and air quality applications (Mayor and Spuler, 2004).

Qualitative backscatter measurements contribute greatly to the understanding of atmospheric structure; however, the importance of understanding the impact aerosol particles have on the earth's radiation requires quantitative estimates of aerosol backscatter and extinction from lidar returns. Because both the backscatter and extinction terms are unknown in equation (1), calibrated estimates of extinction and backscatter profiles are not easily obtained. In many cases, a stable solution for inversion of equation (1) can be obtained by incorporating assumptions on the relationship between $\beta(r)$ and $\sigma(r)$ as well as a boundary value of extinction or backscatter (Klett, 1985). Many inversion techniques used to estimate backscatter and extinction incorporate an estimate of the ratio of extinction to backscatter coefficients $\sigma(r)/\beta(r)$, which is usually referred to as the *lidar ratio*, which has units of sr. The lidar ratio can vary by a factor of three or more; studies aimed at quantifying the lidar ratio for different aerosol regimes have reported values ranging roughly between about 20 sr to more than 70 sr, depending on the type, shape, and chemical composition of the aerosol particles.

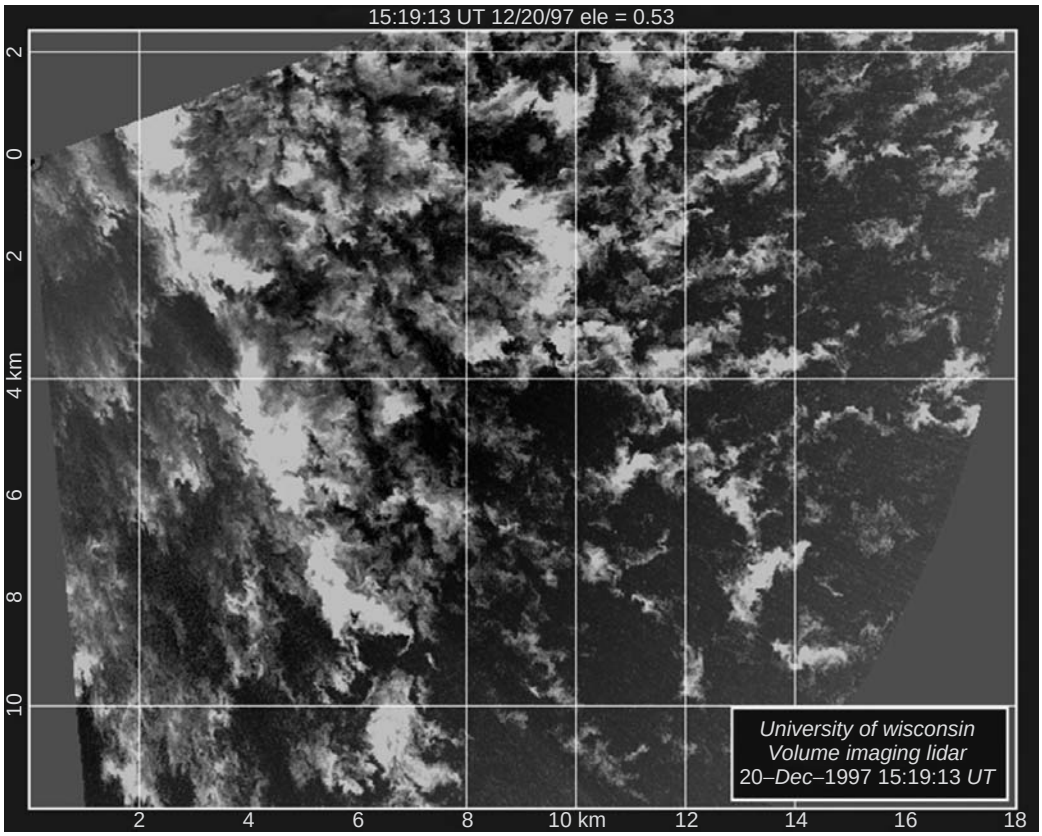

Figure 3 Volume imaging lidar horizontal scans showing regions of high aerosol above Lake Michigan (Courtesy E. Eloranta, University of Wisconsin). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

By employing lidar designs and techniques capable of separating aerosol and molecular-backscattered returns in equation (1), more robust estimates of extinction and backscatter can be calculated. Because molecular scattering and extinction can be accurately specified given information on atmospheric density (i.e., temperature and pressure) available from meteorological analyses, isolating the molecular lidar return enables a direct solution for the range-dependent total extinction of the molecular-backscatter signal. Once the extinction is known, the range-dependent aerosol backscatter coefficient can be computed.

A High Spectral Resolution Lidar (HSRL) design takes advantage of the difference in spectral width between the aerosol and molecular-scattered signals, evident in Figure 1, to separate the two returns. In an HSRL receiver, the collected backscattered signal, which contains both aerosol and molecular-scattered light, is split into two paths. For one path, a narrowband filter removes the aerosol-scattered light prior to detection, while the entire aerosol-plus-molecular scattered light is detected on the other path. By comparing the two signals, the separate aerosol and molecular components of the return are determined, which enables direct solution for the extinction and backscatter coefficients and calculation of the lidar ratio. To achieve the separation of aerosol and molecular-scattered signals, both the transmitter and receiver of a HSRL system must be more complex than those employed in simple backscatter lidars. The transmitted pulse must be spectrally narrow in order to assure that aerosol light does not leak through the receiver aerosol filter, and the receiver must include two receiver paths, each containing very stable filters.

Figure 4 shows estimates of calibrated backscatter and depolarization from a HSRL developed at the University of Wisconsin (Piironen and Eloranta, 1994) for stand-alone

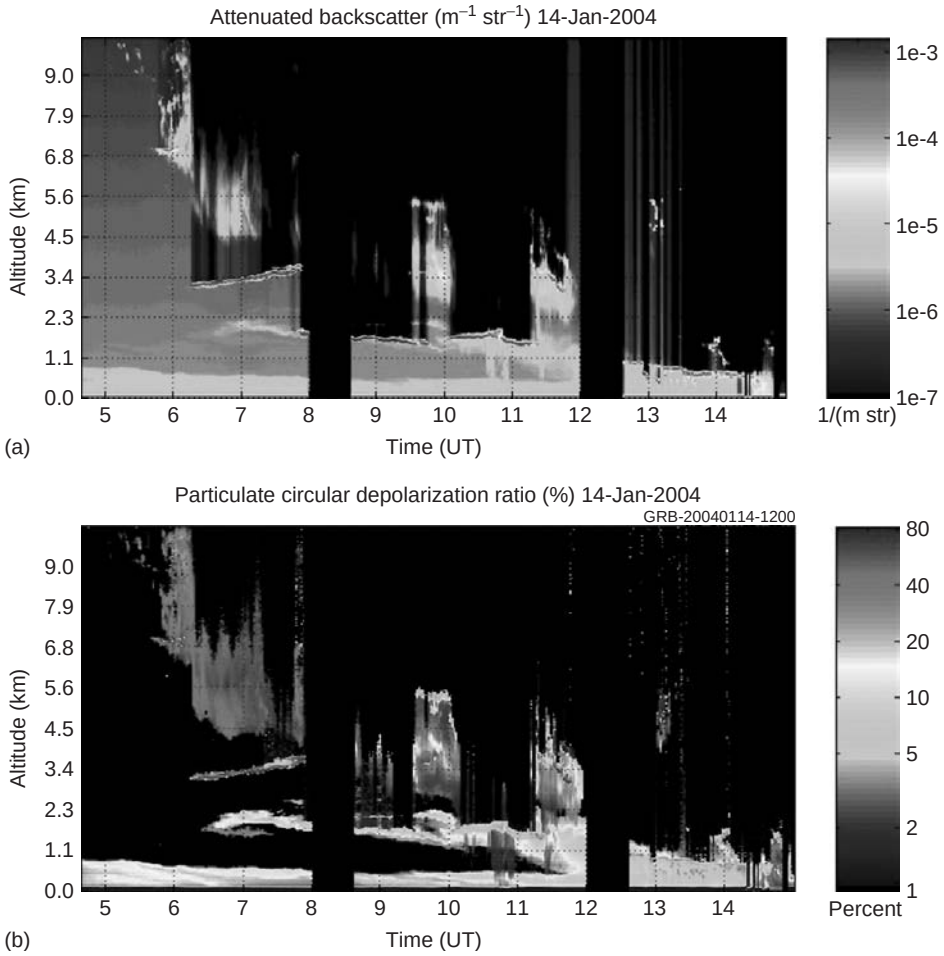

Figure 4 Surface-based high spectral resolution lidar time-height measurements showing calibrated backscatter (a) and depolarization ratio (b) from multiple layers of cloud and aerosol particles over Madison, Wisconsin. Black regions above clouds in (a) are regions of no signal due to extinction of the lidar beam by the clouds (Courtesy E. Eloranta, University of Wisconsin) (*see* **Chapter 65, Estimation of Water Vapor and Clouds Using Microwave Sensors, Volume 2**). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

probing of cloud water and ice and aerosol properties. The Wisconsin lidar incorporates so-called micropulse lidar technology, whose primary characteristics are a low energy, high-pulse repetition rate laser transmitter and photon-counting receiver (Spinhirne *et al.*, 1995). The lidar includes a frequency-doubled Nd:YAG laser transmitting 0.15-mJ, 532-nm pulses at a rate of 4 kHz as the lidar source. A 40-cm diameter telescope collects the backscattered light and directs it into the receiver, where an iodine absorption filter is used to remove the aerosol-backscattered light from the molecular channel. The Wisconsin HSRL produces continuous calibrated profiles of backscatter, extinction (not shown), and depolarization ratio. From the backscatter and extinction information, the optical depth profile is computed, as is seen in Figure 5. Because ice particles introduce more depolarization than water droplets, the depolarization channel provides important information on ice/water phase in clouds (Sassen, 1991). Additional cloud information can be obtained by jointly deploying an HSRL system alongside a mm-wavelength cloud radar, which penetrates extensively into optically thick clouds, and an infrared radiometer. The combination of radar, lidar and radiometer enables differentiation of ice, water, and precipitation, as well as providing information on the size and number concentration of the cloud particles (e.g., Intrieri *et al.*, 2002).

Raman lidar provides another method for separating molecular- from aerosol-backscattered returns to obtain calibrated measurements of cloud and aerosol properties. For characterizing aerosol properties, the receiver includes a channel to measure the combined aerosol and molecular elastic backscatter returns and other channels to measure the Raman-scattered return from nitrogen and water vapor. The Raman channels serve the same function as the molecular channel in an HSRL receiver. Because the Raman-scattered radiation is weak, Raman lidars are characterized by high-power transmitters and large-optic receivers. An example of a Raman lidar is the instrument operating at the Department of Energy's Atmospheric Radiation Measurement Southern Great Plains (SGP) site in northern Oklahoma (Goldsmith *et al.*, 1998). The lidar incorporates a frequency-tripled Nd:YAG lidar transmitter operating at 30 Hz with 350–400 mJ pulses. A 61-cm diameter telescope collects the scattered light. The SGP instrument includes receiver channels at 355 nm (elastic backscattered radiation), 387 nm (nitrogen Raman scatter), and 408 nm (water vapor Raman scatter). The SGP Raman lidar is notable because it has been operating continuously for several years, producing daily records of aerosol backscatter and extinction as well as water vapor concentrations. The instrument is capable of measurements throughout the troposphere at night. During daytime, the strong solar background introduces noise on the Raman channels and limits measurements to a maximum height of roughly 4–6 km above the surface.

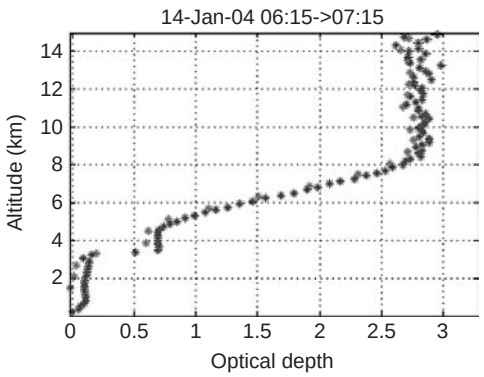

Figure 5 Optical depth profile measured between 6:15 and 7:15 UTC for data shown in Figure 4. Optical depths are computed for 150 m and 600 m vertical averages (Courtesy E. Eloranta, University of Wisconsin). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Measurement of aerosol extinction, backscatter, and depolarization at multiple lidar wavelengths enables estimation of some microphysical properties of the aerosol. Scientists at the Institute for Tropospheric Research in Leipzig, Germany, have deployed a lidar system that transmits at 355, 400, 532, 710, 800, and 1064 nm (Müller *et al.*, 1998). The receiver measures elastic backscatter at each of the six wavelengths, as well as nitrogen Raman backscatter at 387 and 607 nm and water vapor Raman backscatter at 660 nm. Depolarization at 710 nm is also measured. By applying an inversion algorithm specifically designed for the available optical data sets, estimates of effective radius, volume, surface area, number concentration, and refractive index are computed. Results of these lidar inversions were shown to compare well with similar measurements derived from sun photometer observations and direct *in situ* measurements. Although the Leipzig instrument suite is quite complex and the comparison data sets are limited to a few cases, these results provide an indication of the amount of information potentially available from aerosol lidar measurements.

Surface-based, continuously operating aerosol profiling lidars incorporating low pulse energy, high repetition rate, micropulse technology have become widespread. The NASA-sponsored Micropulse Lidar Network (MPLNET) was founded in 2000 to link together similar micropulse lidars for acquisition of long-term observations of aerosol and cloud vertical profiles at several sites around the world (Welton *et al.*, 2001). The MPLNET lidars are colocated with sun photometers to assess aerosol optical properties at different locations and validate satellite retrievals of aerosol optical properties. Another aerosol lidar network, the European Aerosol Research Lidar Network (EARLINET) incorporates 19 different research lidar systems from 11 countries (Matthais *et al.*, 2004). EARLINET aims to provide a quantitative, statistically relevant data set of the vertical

aerosol distribution over Europe, and has also been used to investigate phenomena such as Saharan dust outbreaks, forest fires, and air pollution episodes. EARLINET sites include both aerosol backscatter and Raman lidars to provide calibrated measurements of backscatter and extinction. EARLINET is unique in that quality assurance was carried out among the participating lidar systems based on comparison with a mobile "standard" system and sun photometers. The interest in global aerosol distributions and climatologies has led to the formation or planning of other lidar networks for investigating aerosol distributions in Asia (Murayama *et al.*, 2001), South America, Russia, and the eastern United States.

LIDARS FOR MEASUREMENTS OF ATMOSPHERIC GASES

Lidar systems are also frequently employed to profile gas species concentrations in the atmosphere. In the DIAL technique, laser pulses are transmitted at two wavelengths into the atmosphere along the same atmospheric path. One wavelength (the *online* wavelength) is precisely selected and stabilized to coincide with a spectral absorption feature of the gas of interest. The second wavelength, usually referred to as the *offline* wavelength, is chosen to match the wing of the absorption line or a window region of the spectrum where absorption is minimal. The pulses at the two wavelengths can either be emitted simultaneously using separate laser transmitters, or sequentially. As in an aerosol lidar system, the pulses propagate and are scattered by atmospheric aerosol particles and molecules. Some of the energy in the online wavelength pulse is absorbed by the target gas, with the amount of absorption proportional to the number density of absorbing molecules encountered on the outgoing and returning propagation path. Typically, the online and offline wavelengths are transmitted nearly simultaneously and chosen to be sufficiently close together that differential scattering and extinction by gases other than the gas of interest are negligible. Under these conditions, the range-resolved concentration $\rho(R)$ can be estimated from (Schotland, 1974):

$$\rho(R, R+\Delta R) = \frac{1}{2(K_L - K_W)\Delta R} \times \left[\ln \frac{P_L(R)}{P_L(R+\Delta R)} - \ln \frac{P_W(R)}{P_W(R+\Delta R)}\right] \quad (2)$$

where $\rho(R)$ is the average density of the gas over the range segment from range R to range $R + \Delta R$, P_L and P_W are the optical power received at the online and offline wavelengths respectively, K_L is the gas absorption cross section at the online wavelength and K_W is the gas absorption cross section at the offline wavelength. Equation (2) is derived by applying equation (1) for each of the two wavelengths and forming the difference of the logarithm of $P(R)$ evaluated at R and $R + \Delta R$ for both the online and offline wavelengths.

The DIAL technique has been used to measure a number of atmospheric gases, including water vapor, ozone, ethylene, ammonia, and nitrogen dioxide. The method is most commonly applied to observe water vapor and ozone because of their importance in weather, climate, and air quality processes. DIAL water vapor measurements are usually carried out in the near-infrared at wavelengths below 1 μm, where a large number of absorption features are present. By operating on the strongest absorption lines, measurements of water vapor can be obtained even in the upper troposphere and stratosphere, where water vapor concentrations can be as low as a few ppm by volume. Figure 6 shows an example of water vapor measurements obtained from the NASA Lidar Atmospheric Sensing Experiment (LASE) in an airborne DIAL water vapor system (Ismail *et al.*, 2000) on a flight from Barbados to Wallops Island, Virginia. It can be seen that this system is capable of measuring variations in water vapor that range over about three orders of magnitude between the surface and the tropopause. Figure 6 also shows that features in the moisture field associated with a tropopause fold and frontal lifting are well observed by the lidar. Measurements such

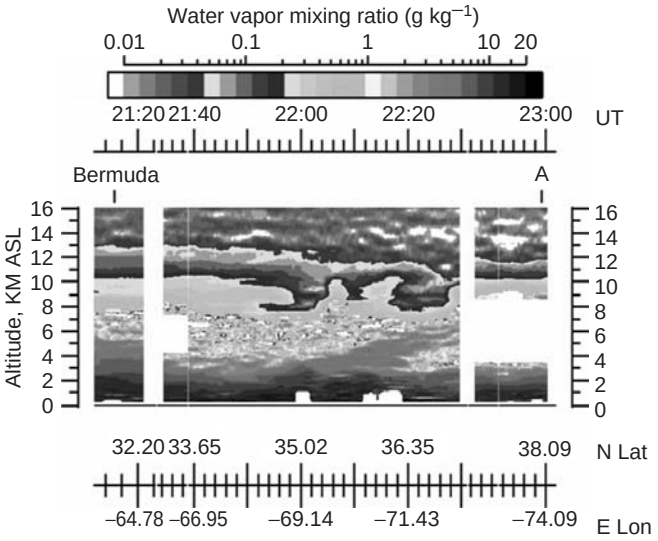

Figure 6 Water vapor measurements obtained by the LASE (Lidar Atmospheric Sensing Experiment) system operating from the NASA ER-2 aircraft on a flight from Bermuda to Wallops Island, Virginia (marked as point A), in July 1996. A tropopause fold containing low stratospheric water vapor can be seen in the top-center of the figure, and the lifting of moisture along a front leading from the boundary layer to cloud formation above 8 km near Wallops Island can also be seen (Reprinted from Browell *et al.*, 2003. ©2003, with permission from Elsevier). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

as those shown in Figure 6 require very precise laser frequency stabilization. The all-solid transmitter in the LASE system is a Ti:sapphire laser pumped by a doubled Nd:YAG laser. The frequency of the Ti:sapphire laser is controlled by injection seeding, using a diode laser that is frequency locked to a water vapor line in the 815-nm region. The online and offline wavelengths are produced by varying the diode laser frequency and are separated by less than 70 pm in wavelength. Another airborne DIAL system, developed and operated at the German Aerospace Center (DLR), operates in the stronger 940 nm region and has been used to measure water vapor in dry regions of the upper troposphere and lower stratosphere (Ehret *et al.*, 1999). DIAL systems such as the NASA and DLR instruments have been applied to observe a variety of important phenomena, including tropospheric/stratospheric exchange, initiation of convection, moisture structure around the dry line, and inflow of moisture into hurricanes.

DIAL methods are also used to measure ozone in the troposphere and stratosphere. The discovery of the ozone hole and subsequent agreements aimed at eliminating chemicals that destroy stratospheric ozone have elevated the importance of ozone measurements. Although global mapping of stratospheric ozone is done from satellites, surface-based lidar instruments at several locations worldwide are being used to study the structure and variability of stratospheric ozone as part of the international Network for the Detection of Stratospheric Change (e.g. Godin-Beekmann *et al.*, 2003). More recently, the importance of lower tropospheric ozone has also been recognized because of its role both as a greenhouse gas and an air pollutant. Tropospheric and stratospheric ozone lidars operate at wavelengths within the Hartley and Huggins ultraviolet absorption bands from about 260 to 355 nm. At these wavelengths Rayleigh scattering dominates, such that much of the atmospheric scattering is from molecules. An example of a tropospheric ozone measurement is presented in Figure 7, which shows ozone measurements made by a downward-looking airborne ozone lidar on a flight directly over the city of Nashville during a high pollution period (Banta *et al.*, 1998). A region of enhanced ozone forms a dome over the city. During the night, ozone above the surface remained as an elevated residual layer and was transported to different locations within the region by elevated wind flows, where it was available for mixing down to the surface on the following day. The lidar that produced the measurements shown in Figure 7 incorporated a KrF excimer laser transmitting at wavelengths of 272, 292, 313, 319,

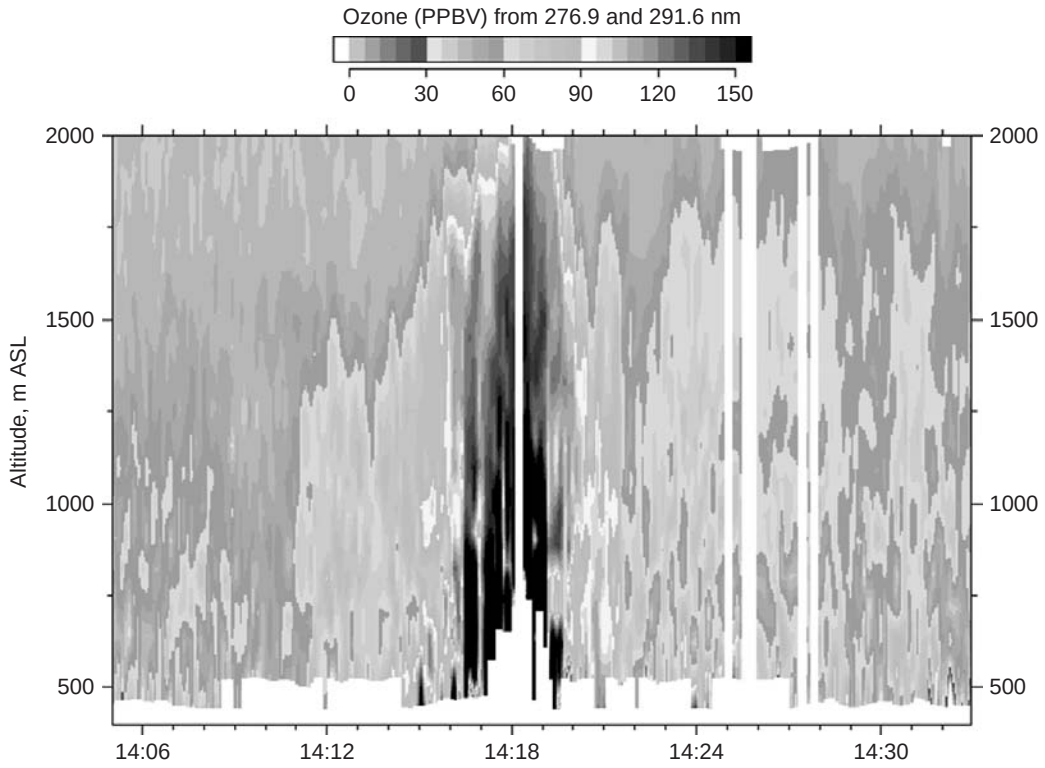

Figure 7 Ozone dome observed by airborne ozone lidar during a flight over Nashville, Tennessee during an air quality stagnation event. The area of high ozone roughly corresponds to the Nashville urban area (Reproduced from Banta *et al.,* 1998 by permission of American Geophysical Union). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

and 360 nm simultaneously; the light was collected by a 50-cm diameter receiver. The multiple wavelengths each correspond to different ozone absorption cross sections and enable optimal system operation for a range of ozone concentrations.

As noted previously, Raman lidars can also measure atmospheric constituents by detecting the Raman backscattered light from specific molecules. Raman lidar is applied most commonly to measure the water vapor mixing ratio (Whiteman *et al.*, 1992). In a Raman system, mixing ratio is computed by comparing the signal in the water vapor receiver channel with that from a nitrogen channel after correcting for transmission effects. Raman lidars are capable of providing measurements with sufficiently high range and temporal resolution to observe a variety of processes that affect moisture distribution in the atmosphere. Raman lidars operating at night, when solar background light is not present, can profile water vapor well into the upper troposphere. An example of a water vapor measurement is seen in Figure 8, which shows a 24-h water vapor profile generated by the Raman lidar at the SGP site in Oklahoma. Evolution of the water vapor structure is clearly seen. During the early and latter parts of the period, corresponding to daytime measurement, the water vapor concentrations are well mixed. However, during the 12-h period from about 0900 UTC to 2100 UTC, the region of high water vapor appears in a thin layer at about 1 km height and is decoupled from the surface. Measurements such as these are being used to examine and improve cloud and radiative transfer models and to investigate interesting weather phenomena as they occur over the SGP site. Figure 8 also illustrates the effect of sunlight on Raman lidar measurements. Although the daylight measurements (after 12:00 noon UTC) are noticeably noisier, especially in the region above about 4 km, the data in Figure 8 indicate the capability of the instrument to provide high scientific-quality data on a continuous basis.

The potential benefits of continuously profiling water vapor and ozone above the surface have stimulated efforts to produce inexpensive, continuously operating instruments. Although the SGP Raman lidar operates continuously, the size and expense of the system limit the feasibility of deploying multiple systems for extended periods in, for example, mesoscale arrays. Current efforts to produce an economical stand-alone instrument have focused on a micropulse-type lidar system employing off-the-shelf components. Figure 9 shows an example of measurements obtained at night with a stand-alone micropulse DIAL lidar that employs a diode laser transmitter and flared amplifier operating at 823 nm in the infrared (Machol *et al.*, 2004). The lidar observations show good agreement with the radiosonde profile. However, the diode laser plus flared amplifier combination used to produce the measurements of Figure 9 produced insufficient energy to overcome solar background for daytime operation. Although other

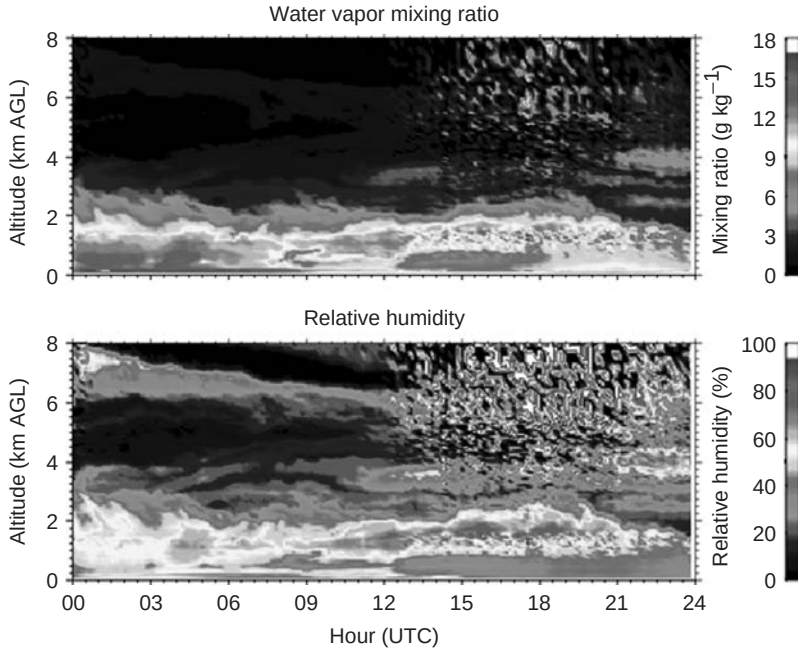

Figure 8 Time-height plot of water vapor obtained with a Raman water vapor lidar at the Atmospheric Radiation Measurement Program Southern Great Plains site in Oklahoma, showing change in water vapor structure and signal intensity during a 24-h period. Increased noise at upper levels during daytime is seen beginning at sunrise (12:00 PM UTC). (Courtesy D. Turner, Battelle). lasers with higher pulse energies and suitable wavelength for stand-alone DIAL are readily available, the challenge remains to identify a laser that is sufficiently economical to enable production and deployment of multiple stand-alone water vapor lidar systems analogous to the MPLNET aerosol network.

LIDARS FOR MEASUREMENT OF WINDS

Lidars applied to measure atmospheric winds make use of the Doppler effect, in which radiation scattered or emitted from a moving particle or molecule is shifted in frequency as a result of the movement of the scatterer. Atmospheric Doppler lidars irradiate a volume of atmosphere with a pulse of very narrow-band laser radiation, then detect the change in frequency of the radiation backscattered from atmospheric aerosol particles or molecules present in the volume. Doppler lidars are well suited for obtaining detailed wind and turbulence observations for a wide variety of applications. A lidar beam can be easily scanned or pointed to characterize wind fields within very confined three-dimensional spaces such as shallow atmospheric boundary layers, narrow canyons, and turbulent structures. Also, the relative compactness of some Doppler lidars makes deployment on aircraft or other moving platforms extremely viable. Doppler lidars deployed on satellites have been proposed, with one instrument under development, to obtain global measurements of atmospheric wind fields. By scanning a lidar beam from an orbiting satellite and analyzing the returns backscattered from clouds, aerosols, and molecules, a satellite-based instrument could provide important wind information from regions that are currently not well observed for assimilation into numerical forecast models.

Frequency analysis in a Doppler lidar receiver is carried out using one of two techniques: *coherent* detection (also known as *heterodyne* detection) or *direct* detection (alternately labeled *incoherent* detection). In a heterodyne receiver, a digitized time series created by mixing laser radiation with the backscattered radiation at the face of a detector is numerically analyzed. Direct detection Doppler lidars employ an interferometer to provide information on the Doppler shift. The interferometer can be implemented in either of two ways: it can serve as a spectrum analyzer to produce a light pattern which contains the information on the frequency content (the so-called *fringe-imaging technique*), or it can used as a frequency discriminator whose output is proportional to the frequency of the input radiation (often called the *edge technique*).

Coherent lidar makes use of a local oscillator (LO) laser with constant amplitude and whose frequency is precisely controlled to be a known frequency offset, typically on the order of tens of MHz, from that of the laser transmitter. The LO beam is made collinear (i.e., mixed) with the backscattered radiation, and directed into an optical detector, which generates, after high-pass filtering, a time-varying electrical signal with amplitude proportional to the amplitude of the backscattered electromagnetic field and frequency equal to the difference between the backscattered field frequency and the LO laser field frequency. This signal is digitized, and spectral analysis applied to estimate its frequency characteristics and compute the Doppler shift. Because the mixing process effectively limits the bandwidth of the receiver, solar background light is not a major source of noise in coherent lidar systems, and performance is not degraded during daytime hours.

Coherent lidars have been used to measure winds for a variety of applications and from an assortment of platforms such as ships and aircraft. Since these lidars operate in the infrared, where aerosol scattering dominates molecular scattering, they require aerosol particles to be present at some level to obtain usable returns. Although clouds also provide excellent lidar targets, most of the more useful applications of coherent lidars involve probing the atmospheric boundary layer or lower troposphere where aerosol content is highest. The capability to scan the narrow lidar beam directly adjacent to terrain, in particular, enables unique, high-resolution probing of wind structure and evolution in complex terrains such as mountains and valleys.

Winds in complex terrain can be complicated to measure and predict because the terrain can force the winds to behave differently at different heights. Also, the evolution of winds over time at different levels can be quite

variable, on account of shallow layers of thermally forced flows. Effects of complex terrain on local winds are often enhanced at night. Doppler lidars measure winds with much more detail in time and space than any standard or even enhanced network of anemometers. In addition to characterizing the winds near the surface, Doppler lidars can observe the wind structure above the surface, typically 1 to 4 km above ground level, depending on the scattering properties of the atmosphere. Two important benefits of applying Doppler lidar for measurements in complex terrain have been (i) increasing the understanding of wind flow by filling in the gaps of standard measurements, both horizontally and vertically, and (ii) providing detailed two- and three-dimensional datasets for use in model evaluations.

An example of the use of Doppler lidar for complex terrain studies can be seen in results from the Vertical Transport and Mixing Experiment (VTMX) in Salt Lake City, Utah. The lidar in this study employed low-elevation-angle conical scans to measure the winds across the Salt Lake City basin. From these scans, the horizontal variability of the winds resulting from the complex terrain was observed, including convergence of winds, canyon outflows, low-level jet (LLJ), and horizontal eddies, as shown in Figure 10. It was apparent from the lidar measurements that the LLJ associated with a notch in the high terrain to the south of the basin was a significant wind feature (Banta *et al.*, 2004). Since the LLJ is elevated, the extensive full-time network of surface measurements that exists in the basin did not detect this feature; the details of its existence were not known previous to the analysis of the VTMX Doppler lidar measurements.

In addition to increasing understanding of the winds in the Salt Lake City basin, lidar measurements were also used to assess the performance of a mesoscale numerical model, the Regional Atmospheric Modeling System (Fast and Darby, 2004; Banta *et al.*, 2004). Issues investigated included the model's ability to predict the horizontal variability of the winds, which includes the LLJ and canyon outflows, the timing of the reversal between up-basin and down-basin flow, and the penetration of the canyon outflows into the basin. A sample comparison between the model output and lidar data is shown in Figure 11.

Doppler lidars can also provide important information on mixing of atmospheric constituents such as pollutants or moisture. Figure 12 shows a Doppler-lidar vertical-plane scan of a gust front during the Southern Oxidants Study (SOS) in Nashville. By analyzing measurements from the Doppler lidar and a colocated ozone profiling lidar, the role of the gust front passage in temporarily redistributing the vertical concentrations of ozone, leading to an increase of ozone at the surface, was apparent (Darby *et al.*, 2002).

Direct detection Doppler lidars are most effective in measuring winds when aerosol particles are not present on account of their capability to estimate the Doppler

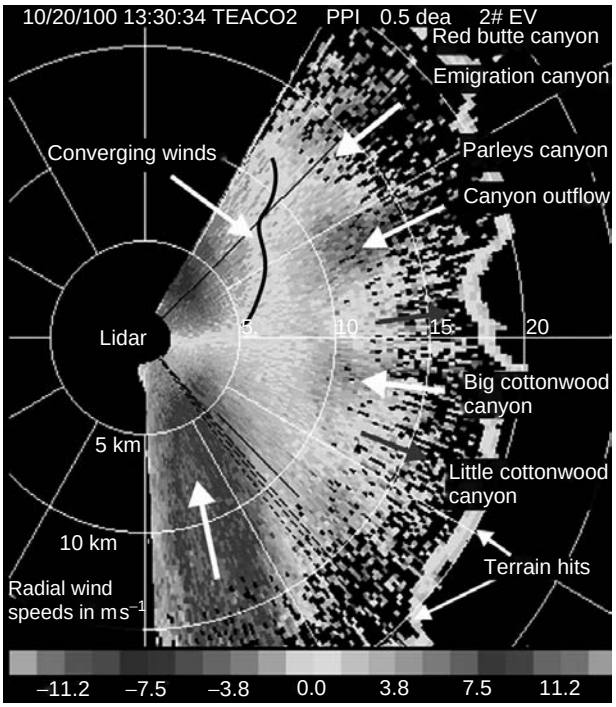

Figure 10 Nearly horizontal azimuth scan (0.5° elevation) from Doppler lidar deployed at Salt Lake City, Utah. Range rings are at intervals of 5 km and velocities on color bar in $m\,s^{-1}$ (positive values toward the lidar). The major canyons are annotated on the figure. Figure shows down-basin jet coexisting with outflows from the major canyons (white arrows), forming a convergence line (Banta *et al.,* 2004. ©2004 AMS). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

shift of radiation scattered by atmospheric molecules. Measurement of Doppler shifts from molecular-scattered radiation is challenging, however, because of the large Doppler-broadened bandwidth of the return (equivalent to approximately $320-350\,m\,s^{-1}$), which is two orders of magnitude greater than the desired measured precision of a few $m\,s^{-1}$ or better. Consequently, large numbers of photons must be detected to reduce the uncertainty in the measurement to an acceptable level. To obtain these high photon counts from molecular-backscattered returns at ranges beyond a few kilometers, some combination of multiple pulse averaging, powerful lasers, and large receiver optics is required.

Molecular-scatter wind measurements have been demonstrated in the visible spectral region at 532 nm wavelength as well as at 355 nm in the near ultraviolet, using both fringe-imaging (Skinner and Hays, 1994) and edge (Gentry *et al.*, 2000) receivers. The ultraviolet region has the dual advantages of enhanced molecular scatter and less restrictive laser eye-safety restrictions. Figure 13 shows a time series of the vertical profile of horizontal wind speeds measured in the troposphere using a molecular-scatter,

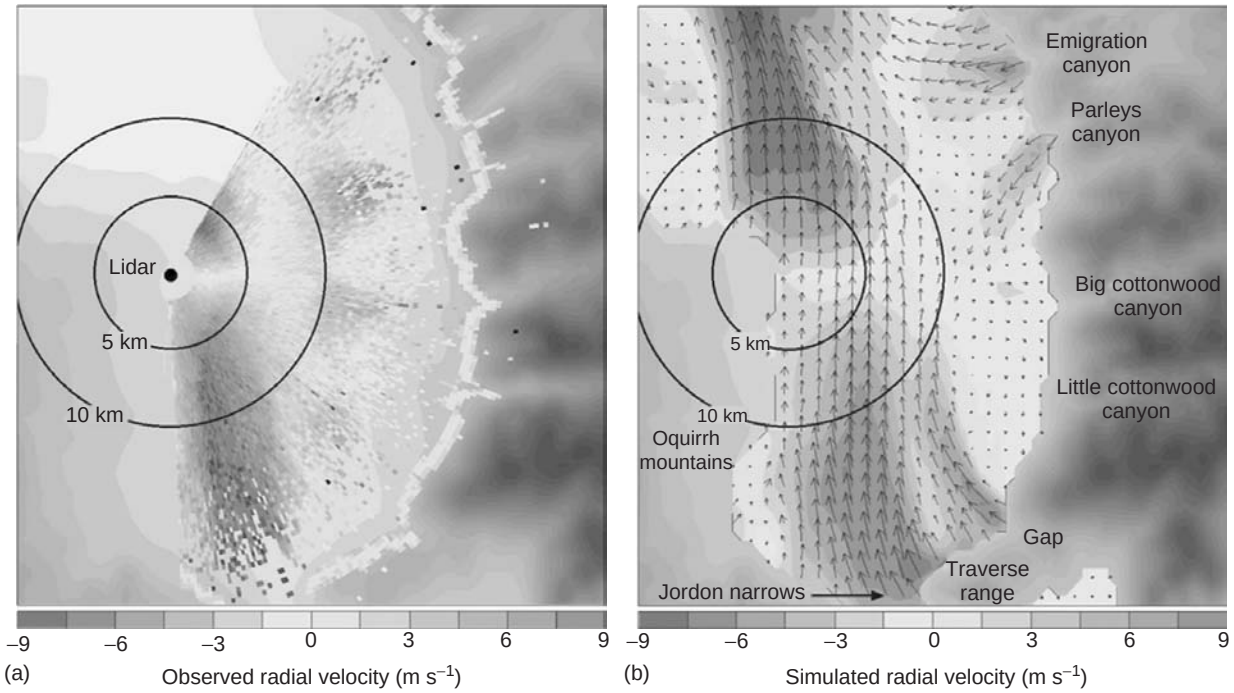

Figure 11 Doppler-lidar data from an azimuth scan at 1/2° elevation as in Figure 10, with radial velocities in m s^{-1} (a). Simulated Doppler-lidar azimuth scan at 1/2° fixed elevation calculated from RAMS model output as described in the text (b). Arrows indicate full horizontal wind vector on the simulated sloping scan surface. Radial velocities indicates the model-derived radial wind component that would be observed by a lidar (Banta *et al.*, 2004. ©2004 AMS). ground-based, 355-nm wavelength Doppler fringe-imaging lidar at Mauna Loa, Hawaii (Dehring *et al.*, 2003), showing measurements throughout the troposphere. To obtain these measurements, backscattered photons were collected by a 0.5-m receiver aperture, averaged for 1 min, and processed. Figure 14 shows, in more detail, a wind speed profile measured during the period.

FUTURE DIRECTIONS FOR LIDAR REMOTE SENSING

Over the next several years, lidar remote sensing of the environment is expected to expand along several fronts.

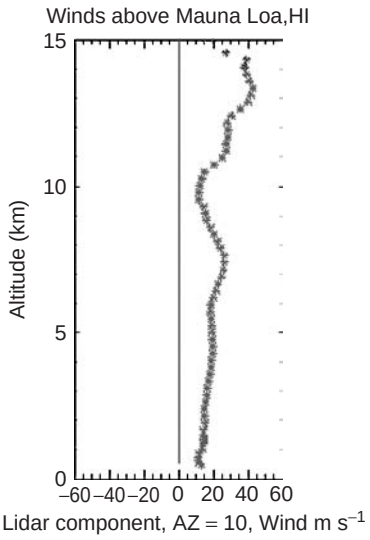

Figure 14 Higher resolution depiction of a wind speed profile measured during observational period shown in Figure 13 (Courtesy M. Dehring, Michigan Aerospace Corporation). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Most notable will be deployments of lidar systems on orbital platforms for global observations of important atmospheric and land surface parameters. The successful launch of the Ice, Cloud, and land Elevation Satellite (ICESat), with its Geophysical Laser Altimeter System (GLAS) illustrated the promise and impact of space-deployed lidar systems. ICESat has provided important measurements of surface ice sheet changes as well as global observations of clouds and aerosol particles. A further step forward will be the deployment of the NASA Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observations (CALIPSO) spacecraft, scheduled for the middle of 2005. CALIPSO, which will fly in formation with the CloudSat spacecraft, will include a three-channel aerosol lidar and passive radiometers to provide key observations of global aerosol and cloud properties, climatologies, and processes. Knowledge gained from CALIPSO will lead to improved characterization of cloud and aerosol radiative and transport processes. Scheduled to follow CALIPSO, in 2007, is the European Space Agency's Atmospheric Dynamics Mission (ADM, Stoffelen *et al.*, 2005), aimed at measuring global wind fields for assimilation into numerical weather forecast models. Data sets from ICESat, CALIPSO, and ADM should provide a strong demonstration of the application of lidar techniques to significantly advance knowledge of important earth system processes.

Improvements in optics technology will also enable new advances in surface-based lidars. Significant research is being focused on improving optical detectors in the eye-safe infrared region beyond 1.5 μm, which will likely pave the way for a new generation of lidars to measure atmospheric aerosol properties, species, and winds. Work also is continuing on development of better and more efficient methods to generate laser radiation in the ultraviolet and infrared spectral regions, and to enable easy tuning of laser wavelengths to probe specific spectral regions. Other technology research is being directed toward making optical components more compact, robust, and economical, which would likely stimulate development of smaller, cheaper, and more portable systems suitable for operation from highway vehicles or unattended aerial vehicles. Ultimately, cheaper instruments that can be produced in quantity should become possible, permitting more extensive deployments of instrument arrays. Such arrays could provide information on, for example, regional distribution of ozone and aerosol particles for air quality forecasting, or, by codeploying water vapor and wind profiling remote sensors, could characterize regional water vapor distribution and moisture transport.

49: Estimation of Surface Insolation

RACHEL T PINKER

Department of Atmospheric and Oceanic Science, University of Maryland, College Park, MD, US

The incoming solar radiation from the sun (insolation) that reaches the Earth's surface (about 50% of that emitted from the sun) determines the exchange of energy between the land and the atmosphere and consequently, controls climate and climate change. Environmental satellites are considered useful tools for providing information on surface radiative fluxes at various temporal and spatial scales, improving estimation of terrestrial water and energy storage. For several years now, observations from satellites have been used to obtain information on the various components of atmospheric and surface radiative fluxes, initially, retrospectively, and more recently, operationally. In this paper, discussed are the needs for information on radiative fluxes in hydrological applications, methodologies for obtaining such information by methods of remote sensing, accuracy of such estimates, and current status of data availability. Examples of applications in hydrological studies and climate research are provided, and links to international activities and future prospects are indicated.

INTRODUCTION

Need for Information

Information on the spatial and temporal distribution of surface radiative fluxes is required for

1. modeling the hydrologic cycle (Rind *et al.*, 1992; Ohmura and Wild, 2002; Sorooshian *et al.*, 2002; Mitchell *et al.*, 2004);
2. representing interactions and feedbacks between the atmosphere and the terrestrial biosphere (Dickinson, 1986; Henderson-Sellers, 1993; Prince and Goward, 1995; Hicke *et al.*, 2002);
3. estimating global terrestrial and oceanic net primary productivity (Platt, 1986; Goward, 1989; Running *et al.*, 1999; Zhao *et al.*, 2005);
4. validating climate models (Garrat *et al.*, 1993; Wild *et al.*, 1995; Wielicki *et al.*, 2002);
5. improving the understanding of transport of heat, moisture, and momentum across the surface–atmosphere interface (Betts *et al.*, 1997; Berbery *et al.*, 1999; Baumgartner and Anderson, 1999; Sui *et al.*, 2002);
6. improving land–atmosphere interaction parameterizations (Chen *et al.*, 1996); and
7. providing information on the dominant forcing functions of the surface energy budgets (Wielicki *et al.*, 1995; Wood *et al.*, 1997; Mitchell *et al.*, 2004; Rodell *et al.*, 2004).

Studies of long-range weather forecasting are performed with the aid of numerical weather prediction and general circulation models (GCMs). Satellite observations are considered the only source of information that can be used for model evaluation on a global scale. Progress in the use of satellites for probing the atmosphere has enabled research to refocus on developing advanced satellite methods in climate research. The Joint Scientific Committee (JSC) of the WCRP endorsed the Global Energy and Water Cycle Experiment (GEWEX) as one of several core activities that should ultimately lead to the prediction of global and regional climate change (Chahine, 1992; Sorooshian, 2003). GEWEX includes radiation, hydrometeorology, and modeling and prediction activities. The objective of the radiation component is to determine atmospheric and surface radiative fluxes at a level of accuracy that will allow the prediction of transient climate variations and long-term climate trends. The WCRP GEWEX Surface Radiation Budget (SRB) project is specially tasked to produce, validate, and assess long-term surface and atmospheric radiative budgets on a global scale (Stackhouse *et al.*, 2000, 2002, 2004).

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Specific national research interests are linked to the GEWEX program via continental-scale GEWEX experiments such as the GEWEX Continental-scale International Project GCIP/GAPP over the Unites States, (the GEWEX Americas Prediction Project (GAPP) is a continuation of GCIP), the Large-scale Biosphere-Atmosphere Experiment in Amazonia (LBA), the Baltic Sea Experiment (BALTEX), the GEWEX Asian Monsoon Experiment (GAME) and the African Monsoon Multidisciplinary Analyses (AMMA) project. Methods for deriving surface radiative fluxes have been developed for most of these basin-scale studies (Pereira *et al.*, 1996; Ceballos and Moura, 1997; Hollmann *et al.*, 1999; Raschke *et al.*, 1998; Takamura *et al.*, 2001; Nakajima, 2001; Pinker *et al.*, 2003; Sekiguchi *et al.*, 2003).

Each of these continental-scale regions is characterized by unique climatic conditions, and addresses a wide range of scientific issues. For example, the specific objectives of the GEWEX Continental-scale International Project (GCIP) and the GAPP (a continuation of GCIP) (WCRP-67, 1992; NRC, 1998) are the determination of the time/space variability of the hydrologic cycle and energy budget over the Mississippi River Basin; development and validation of macroscale hydrologic models; and, utilization of existing and future satellite observations for achieving these objectives (Leese, 1994; 1997). A summary of what has been achieved can be found in Mitchell *et al.* (2004) and Roads *et al.* (2003).

Another example is the LBA, whose major objective is to improve understanding of the hydrological cycle of the Amazon region. This region serves as a major modulator of hemispheric climate in part because of the release of latent heat associated with heavy precipitation, which is a major energy source for the atmosphere. Other objectives include monitoring of land use changes and improving estimates of Net Primary Productivity, and soil biogeochemistry of carbon, nutrients, and trace gases (Nobre *et al.*, 2001; Keller *et al.*, 2001; Avissar *et al.*, 2002). The LBA is an excellent example of a multidisciplinary, international research effort, aimed at understanding the climatological, ecological, biogeochemical, and hydrological functioning of Amazonia, its interaction with the Earth system, and its response to land use change.

BALTEX is a long-term multinational project for studying coupled hydrological processes between complicated terrain, sea, ice, and the atmospheric circulation to determine the energy and water budgets of the Baltic Sea and related river basins (Raschke *et al.*, 2002). Major emphasis in BALTEX is given to a thorough understanding of hydrological processes that are to be parameterized in global and limited area models. The goal of the McKenzie GEWEX Study (MAGS) is to improve understanding of the water and energy cycle of the Mackenzie River Basin and provide an improved understanding of cold regions, high latitude hydrological and meteorological processes, snow and ice processes, permafrost, arctic clouds and radiation interactions (Stewart *et al.*, 1998). The GAME aims to improve our understanding of the role of the Asian monsoon in the global climate system and develop methods for long-range forecasting.

Information on surface radiative fluxes is needed to address all of the above issues.

Feasibility

Retrospective Studies

Long-term satellite observations over large spatial scales are now available for implementing inference schemes for radiative fluxes. Under the joint NOAA/NASA PATHFINDER activity (Ohring and Dodge, 1992), uniform, long-term data sets from observations made from numerous satellites, have been prepared into homogeneous time series. Some of these data are processed into reduced resolution, multisatellite, global coverage information, and are known as *International Satellite Cloud Climatology Project* (ISCCP) D1 data (Schiffer and Rossow, 1985). Because of their representation of the diurnal cycle and long-term availability, these data are of particular interest to scientists working on land–atmosphere and ocean–atmosphere interactions, and hydrologic modeling. Parameters derived from these data are based on satellite observations and on ancillary data, as appended to the GEWEX (WCRP-67, 1992) ISCCP D1 product at a nominal resolution of 2.5° (Rossow and Schiffer, 1991, 1999). The satellites that are being used usually have between two to five channels in spectral intervals that are relevant both for inferring the shortwave flux (visible) and for detecting clouds. An example of the channels on selected Geostationary Operational Environmental Satellites (GOES) and the Advanced Very High Resolution Radiometer (AVHRR) on the polar orbiting satellites are given in Table 1. The ISCCP D1 product is an improved version of the ISCCP C1 product (Schiffer and Rossow, 1985). Improvements are related to new cloud screening methodology used for producing the D1 version resulting in better cloud detection over snow cover, in particular, in the Polar Regions.

Table 1a Characteristics of the GOES-8 satellite (After Menzel and Purdom, 1994.)

Channel	Wavelength (μm)	Field of view (km)	Subpoint resol. (km)
1	0.52–0.72	1.0 × 1.0	0.57 × 1.0
2	3.78–4.03	4.0 × 4.0	2.30 × 4.0
3	6.47–7.02	8.0 × 8.0	2.30 × 8.0
4	10.20–11.20	4.0 × 4.0	2.30 × 4.0
5	11.50–12.50	4.0 × 4.0	2.30 × 4.0

Table 1b Characteristics of the AVHRR channels

Channel	Satellites: NOAA-6, 8, 10 (μm)	Satellites: NOAA-7, 9, 11, 12, 14 (μm)	IFOV (millirad)
1	0.580–0.68	0.580–0.68	1.39
2	0.73–1.10	0.73–1.10	1.41
3	3.55–3.93	3.55–3.93	1.51
4	10.50–11.50	10.30–11.30	1.41
5	10.50–11.50	11.50–12.50	1.30

In the last two decades, it has been demonstrated that radiative fluxes could be derived from satellite observations with reasonable accuracy (Raschke and Preuss, 1979; Tarpley, 1979; Pinker *et al.*, 1995, 2003; Frouin and Pinker, 1995; Rossow and Zhang, 1995; Whitlock *et al.*, 1995; Ohmura *et al.*, 1998; Gupta *et al.*, 1997; Zhang and Rossow, 2004). Methods to derive SW fluxes from satellite observations have been implemented by several groups on different spatial and temporal scales. METEOSAT, GOES, GMS and polar orbiting satellites have been all used (Stuhlmann *et al.*, 1990; Pinker and Laszlo, 1992a; Gupta *et al.*, 1999, 2001; Chou, 1994; Brisson *et al.*, 1994; Li *et al.*, 1993; Rossow and Zhang, 1995; Ceballos and Moura, 1997; Ceballos *et al.*, 2004). Valuable experience has been gained from the merging of various global data sets (observations from the TIROS Operational Vertical Sounder (TOVS); snow cover) into the ISCCP data base. Two SW algorithms developed at the University of Maryland (Pinker and Laszlo, 1992a; denoted SRB SW hereafter) and at the NASA Langley Research Center (Gupta *et al.*, 2001) respectively, are currently used at NASA Langley Research Center in support of the WCRP/GEWEX SRB activities. A configuration of satellites, both geostationary and polar orbiting, as illustrated in Figure 1, is needed to cover the entire globe with observations that depict the diurnal cycle. Geostationary satellites cover only part of the globe up to about 50° north and south. The polar orbiting satellites provide coverage at higher latitudes. Figure 2 shows the mean surface radiative fluxes ($W\,m^{-2}$) averaged for the years 1983–2001 for January (a) and July (b) as obtained from the ISCCP D1 data (Rossow and Schiffer, 1991) as

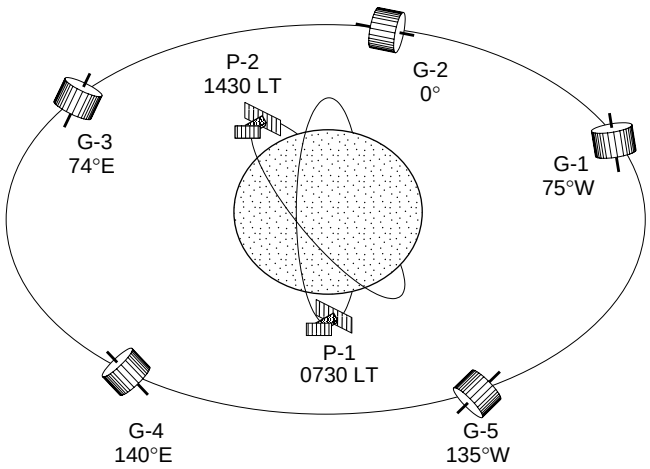

Figure 1 Satellite configuration required for obtaining diurnally resolved surface radiative fluxes includes both geostationary (g) and polar orbiting satellite (morning and afternoon overpass); geostationary satellites cover the globe only up to about 50° north and south

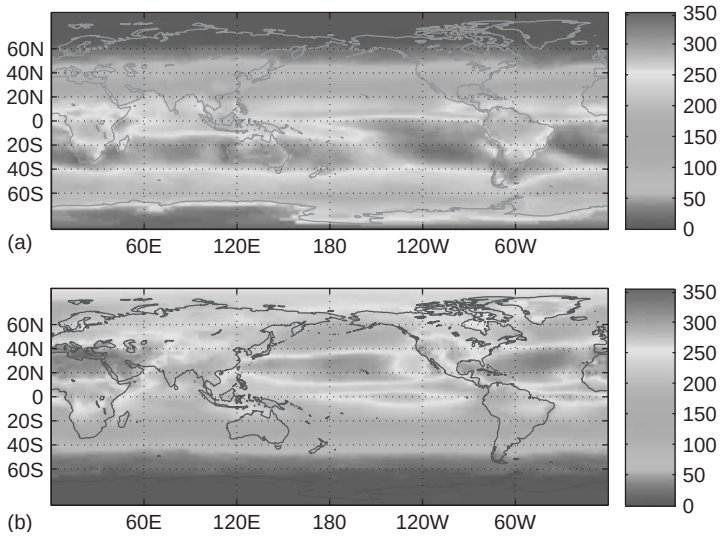

Figure 2 The mean surface radiative fluxes ($W\,m^{-2}$) averaged for the years 1983–2001 for January (a) and July (b) as obtained from the ISCCP D1 data (Rossow and Schiffer, 1991) as inferred from optimally merged geostationary and polar orbiting satellites observations at 2.5° spatial resolution (Zhang *et al.*, 2005). inferred from optimally merged geostationary and polar orbiting satellites observations at 2.5° spatial resolution (Zhang *et al.*, 2005).

Real-time Estimates

Operational implementation of retrieval methodologies has been successful and examples will be presented. In support of the World Climate Research Program (WCRP), GEWEX GCIP, and the GAPP, real-time estimates of shortwave radiative fluxes, both at the surface and at the top of the atmosphere, are being produced operationally by the National Oceanic and Atmospheric Administration (NOAA)/National Environmental Satellite Data and Information Service (NESDIS), using observations from the GOES. This is a collaborative effort between NOAA/NESDIS, NOAA/National Centers for Environmental Prediction (NCEP), and the University of Maryland. Inferred shortwave radiative fluxes include total and diffuse quantities (as appropriate), as well as spectral components (e.g. photosynthetically active radiation (PAR)). The interface between the satellite data and inference models has been developed at NOAA/NESDIS (Tarpley *et al.*, 1996). NOAA/NCEP provides information on the state of the atmosphere and surface conditions, as available from analyzed output fields from the Eta model (Rogers *et al.*, 1996). The University of Maryland is involved in model development and modifications (Pinker and Laszlo, 1992a,b; Pinker *et al.*, 2003), sensitivity studies, validation against ground observations, data archiving, and data distribution. The SRB SW model is implemented at NOAA/NESDIS in real time on an hourly basis, for 0.5-degree targets for an area bounded by 66°–126° W longitude and 24°–54° N latitude belts. For each target, at appropriate forecast times, selected data from the NCEP regional forecast model are delivered to the satellite data stream as inputs to the SRB SW model. This approach ensures timely and high quality information input to the satellite inference scheme. In turn, derived radiative fluxes help to diagnose the NCEP forecast model as to its ability to predict correctly radiative fluxes. The website `http://www.atmos.umd.edu/~srb/gcip/webgcip.htm` provides the following hourly, daily, and monthly parameters: shortwave surface downward flux; shortwave surface upward flux; visible surface downward flux (PAR); visible surface upward flux; shortwave top of the atmosphere net flux (down-up). These parameters represent the most needed information on radiative fluxes, and are only a subset of parameters produced by the inference scheme. A comprehensive summary of evaluation of this satellite product against ground truth is presented in Pinker *et al.* (2003). Results from the evaluation of a more recent product in which cloud detection over snow was improved is illustrated in Figure 3. Given is the frequency distribution of differences between daily values as estimated from satellites

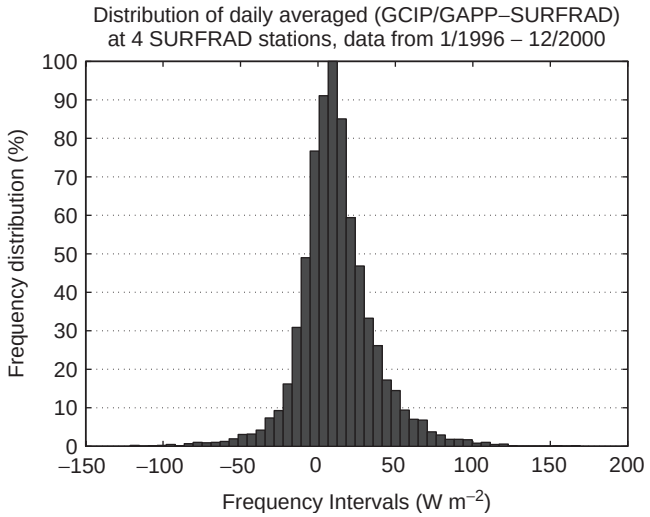

Figure 3 Statistics of errors of the satellite estimates when evaluated against ground observations at four SURFRAD station for the period (1996–2000), daily timescale. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

for the period of 1996–2000 and ground observations at four Surface Radiation Monitoring Network (SURFRAD) stations. As evident, most of the differences are in the range of -50 to $+50\,\mathrm{W\,m^{-2}}$. Attempts to derive surface radiative fluxes over the Amazon region in real time are in progress at the Centro de Previsao de Tempo e Estudos Climaticos (CPTEC)/INPE (Ceballos *et al.*, 2004) and at several European operational centers.

REVIEW OF SELECTED INFERENCE SCHEMES

Methods spanning a wide range of complexities have been developed to derive surface radiative fluxes from satellite observations. Several have been reviewed in Schmetz (1989, 1991, 1993) who critically evaluated sensitivities to input parameters, as well as the physical principles of these methodologies. In reviews that followed, the different parts of the spectrum were discussed independently. The current status of SW retrievals is summarized in Pinker *et al.* (1995) and Whitlock *et al.* (1995). Methods for deriving PAR are described in Frouin and Pinker (1995). A summary of current and future satellite observations of relevance for SRB research is presented in Wielicki *et al.* (1995). In this review, emphasis will be on methods that have consistently provided data sets relevant in climate research.

Physical Principles

In his discussion of the physical principles that allow derivation of SRB from satellite observations, Schmetz (1989) has stressed the importance of the close linear

coupling between SW (0.2–4.0 μm) reflected radiance at the top of the atmosphere (albedo) and the surface irradiance. Cloud extinction (transmittance) and albedo are linearly related since atmospheric constituents do not emit radiation at solar wavelength. There is dependence on solar zenith angle, gaseous and aerosol absorption and scattering, surface reflectivity, and clouds.

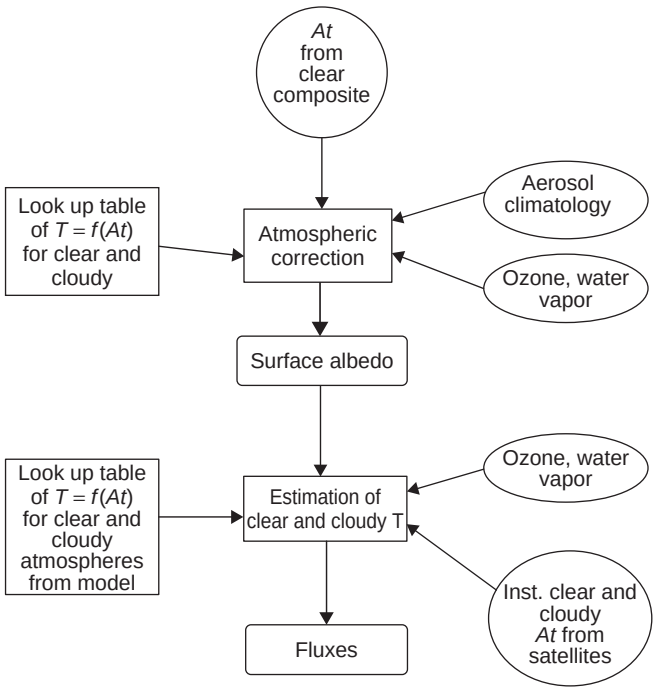

Figure 5 Summary of the processing sequence to infer surface radiative fluxes

Examples of Current Methodologies

In this section, a possible prototype of satellite retrieval methodology of shortwave radiative fluxes at the surface and at the top of the atmosphere (TOA) is illustrated. Existing retrieval methodologies can be viewed as variants of the principles presented here. Several existing methodologies are applicable for the derivation of surface fluxes only. Components of shortwave radiative fluxes are illustrated in Figure 4. Derivation of surface fluxes is possible because for a given atmosphere and surface, TOA albedo and flux transmittance are uniquely related to each other. The discussion in this paragraph will define this relationship. A diagram of the flux retrieval process is presented in Figure 5. TOA downward flux (F_{td}) is calculated from extraterrestrial solar spectrum, accounting for variation in sun–earth distance and position of the sun in the sky relative to local vertical (solar zenith angle). Downward flux at the surface (F_{sd}) is obtained by determining what fraction of F_{td} reaches the surface as radiation is transferred through the atmosphere. This fraction, which is referred to as flux transmittance (T), depends on the composition of the atmosphere (e.g. amount of water vapor and ozone, optical thickness of cloud and aerosol), on length of path the radiation travels through the atmosphere (determined by the solar zenith angle), and to a lesser degree, on the albedo of the surface. Once T is known, surface downward flux is obtained as $F_{sd} = T F_{td}$. The algorithm estimates T from satellite-derived TOA albedo. Once F_{sd} is known, upward flux at the surface (F_{su}) is calculated as $F_{su} = A_s F_{sd}$, where A_s is surface albedo. Similarly, flux reflected to space by the earth–atmosphere system (TOA upward flux, F_{tu}) is obtained from the product of F_{td} and the TOA albedo (A_t), namely, $F_{tu} = A_t F_{td}$. T is determined from a comparison of modeled values of shortwave (0.2–4.0 μm) TOA albedos to shortwave TOA albedo obtained from satellite measurement, and transmittance corresponding to modeled TOA albedo that matches satellite-derived value is selected. For practical reasons, pairs of albedos and transmittances are calculated for atmospheres with a nonreflecting lower boundary. Surface reflection is added in a separate step. Modeled TOA albedos and corresponding transmittances can be calculated spectrally for discrete values of solar zenith angle, amount of water vapor and ozone, aerosol and cloud optical thickness, using a radiative transfer method of preference. Radiative properties of aerosols and clouds can be obtained from independent sources. Absorption by ozone and water vapor needs to be parameterized, for example, as proposed by Ramaswamy and Freidenreich (1992) or others. The albedo-transmittance pairs are made available in a lookup table for the algorithm separately for clear and cloudy atmospheres, and the flux transmittances for clear and cloudy skies are determined by matching the satellite-observed clear and cloudy shortwave TOA albedos, respectively. For a given

solar zenith angle, surface albedo and amount of ozone and water vapor, the matching process involves the adjustment of the aerosol optical depth for clear sky and that of the cloud optical depth for cloudy sky. For example, for GCIP/GAPP, the satellite-observed TOA shortwave albedo is obtained from the visible (0.55–0.75 μm) radiance measured by the imager instrument onboard the GOES satellites through spectral and angular transformations (Zhou *et al.*, 1996). The clear-sky radiance as observed by the satellite is affected both by the surface albedo and the intervening atmosphere. It is quite difficult to separate the affects of each independently. Therefore, at times, information on surface albedo is taken from independent sources or estimated from the "clearest" shortwave TOA radiative flux (or albedo) observed over a number of days (clear-sky composite albedo), and then nominally corrected for Rayleigh scattering, aerosol extinction, and absorption by ozone and water vapor. Next, albedo-transmittance pairs are selected from the lookup table according to the solar zenith angle, water vapor and ozone amount, and are combined with the surface albedo to yield shortwave TOA albedos. One set of pairs is for varying values of aerosol optical depth (clear atmosphere), and the other is for varying values of cloud optical depth (cloudy atmosphere). Finally, the shortwave albedos derived from the instantaneous satellite-observed clear-sky and cloudy-sky radiances are matched with the clear and cloudy sets of albedo-transmittance pairs and clear-sky and cloudy-sky transmittances, and from these, clear-sky and cloudy-sky fluxes are obtained. The clear-sky and cloudy-sky fluxes are then weighted according to the cloud cover (defined as the ratio of number of cloudy pixels to the total number of pixels) to determine the all-sky fluxes. The implementation of the model requires preprocessing of the satellite data and separation of clear and cloudy radiances. The ISCCP D1 and DX data sets provide such information. When original satellite observations are used, there is a need to first separate between clear and cloudy pixels. For the GCIP/GAPP product, this is performed at NOAA/NESDIS (Tarpley *et al.*, 1996). The Clouds and Earth's Radiant Energy System (CERES) instrument on board several Earth Observing System (EOS) satellites from NASA's Earth Science Enterprise (ESE) program provides an opportunity for deriving accurate estimate of SW fluxes (Wielicki *et al.*, 1995). CERES provides a direct measurement of TOA broadband reflectance and augments this measurement with higher resolution retrievals of atmospheric, cloud, and aerosol properties to estimate radiative fluxes. The Surface and Atmospheric Radiation Budget (SARB) component of CERES computes the surface and atmospheric fluxes by iterating retrieved atmospheric properties with the measured TOA fluxes. Intercomparison of older techniques using ISCCP approach described above and the CERES-SARB will occur within the next several years. Progress on derivation of surface albedo and aerosols over land is being made with EOS observations from MODIS and the Multiangle Imaging SpectroRadiometer (MISR) instruments (e.g. Liang *et al.*, 2002; Schaaf *et al.*, 2002).

The various elements of the retrieval algorithms should be tested in a number of different ways. The radiative transfer component needs to be evaluated. A framework for doing so was provided by the Intercomparison of Radiation Codes in Climate Models (ICRCCM) (Fouquart *et al.*, 1991). Surface down-flux estimates can be compared with ground measurements. Several organized activities in the framework of the Satellite Algorithm Intercomparison as sponsored by WCRP and NASA (Whitlock *et al.*, 1995) were conducted with older surface SW measurements, reporting average agreement with ground observations to within $10\,W\,m^{-2}$ on a monthly timescale over a large number of surface sites. Intercomparison with surface sites is ongoing within the GEWEX SRB (Stackhouse *et al.*, 2004) and CERES-SARB programs (Charlock *et al.*, 2000a,b) reporting agreement with ground observations within $10\,W\,m^{-2}$ on a monthly timescale. Numerous independent evaluations were also conducted by algorithm developers or by users (Pinker *et al.*, 2003; Luo *et al.*, 2003). In the GEWEX SRB SW algorithm, the fluxes are calculated in the spectral intervals of 0.2–0.4, 0.4–0.5, 0.5–0.6, 0.6–0.7 and 0.7–4.0 μm. Thus, it is possible to obtain fluxes at spectral intervals known to be of significance (e.g. PAR) (Figure 6). This is important, because current GCMs are run in a mode that separates shortwave fluxes at 0.7 μm (Roesch *et al.*, 2002), to allow incorporation of newly derived satellite-based parameters, such as fractional vegetation cover, derived from the Normal Difference Vegetation Index (NDVI), and for

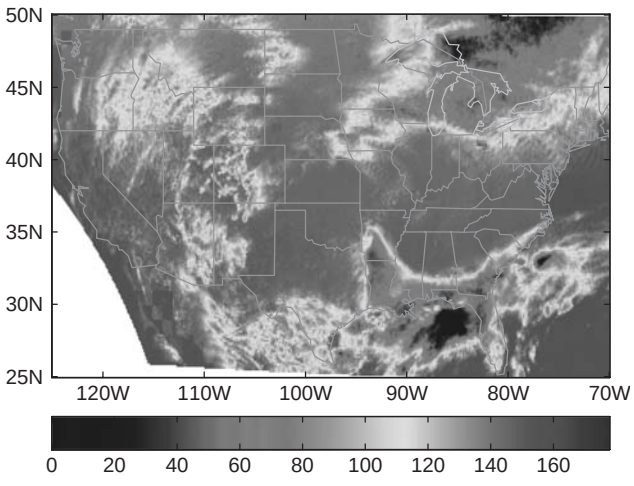

Figure 6 Daily mean surface downward PAR ($W\,m^{-2}$) at 0.5-degree resolution for August 15, 1998. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

improving parameterizations of surface/atmosphere interactions (Gallo and Huang, 1998; Goward and Huemmrich, 1992; Townshend and Justice, 1995; Gutman *et al.*, 1995). Moreover, shortwave fluxes are separated into direct and diffuse components, which is of interest for improved modeling of radiative interaction with vegetation and oceans. Other parameters that are derived include clear-sky and all-sky albedos at the top of the atmosphere and at the surface, and aerosol and cloud optical depths. The shortwave and spectral fluxes are computed separately for clear and all-sky conditions, thus making it possible to derive information on the radiative effects of clouds, known as *cloud-radiative forcing* (Ramanathan *et al.*, 1989).

CURRENT STATUS OF DATA AVAILABILITY

In this section reviewed are products that are readily available, that have been produced for periods of time of interest in climate research, and that have been evaluated against ground observations.

Early GEWEX SRB products are based on ISCCP C1 observations, as provided in:

- First WCRP Surface Radiation Budget Global Data Sets, Shortwave Radiation Parameters March 1985–December 1988, NASA Earth Observing System Distributed Active Archive Center, NASA Langley Research Center, Hampton, VA (Whitlock *et al.*, 1995), at monthly and daily timescales.
- Global l Data Sets Land-Atmosphere Models, ISLSCP Initiative I: 1987–1988, Volume 1–5, NASA Goddard DAAC Science Data Series, include surface shortwave and PAR data, at three hourly intervals at one degree spatial resolution (Seller *et al.*, 1996).
- Global Ecosystem Database, Disk B, National Environmental Satellite, Data, and Information Center National Geophysical Data Center, Boulder, Colorado, November 1997, which provides information at three hourly intervals, monthly averaged on PAR, for the period July 1983 to July 1988 (Kineman, 1997).
- Global l Data Sets Land-Atmosphere Models, ISLSCP Initiative II: consists of a 10-year global data set spanning the years 1987 to 1995 at spatial resolutions of one-quarter to one degree, and available at: **`http://islscp2.sesda.com/ISLSCP2 1/html pages/islscp2 home.html`**

Improved surface SW products using improved ISCCP and other satellite measurement platforms:

- Release 2 of the GEWEX SRB dataset featuring version 2.1 of the SRB SW algorithm using ISCCP DX data mapped to one-degree grids is now available (Stackhouse *et al.*, 2004). The dataset uses water vapor amounts from the NASA Goddard Earth Observing System data assimilation version 1 (GEOS-1). Release 2 spans from July 1983 through October 1995. The dataset also includes fluxes from the thermal infrared (i.e. long wave). An expanded ground measurement database is used, including Baseline Surface Radiation Network (BSRN) measurements, for the assessment of the SW flux products, distributed in space and time, at over 1000 locations.
- ISSCP Flux Data (FD) (Zhang *et al.*, 2004) and University of Maryland GEWEX SRB SW data (Pinker *et al.*, 2005) based on ISSCP D1, for July 1983 through December 2001, at nominal resolution of 280-km. Both are accessible via the internet at respective institutions.
- CERES experiment instruments were launched aboard the Tropical Rainfall Measuring Mission (TRMM) in November 1997 and on the EOS Terra satellite in December 1999 and two additional instruments on the EOS Aqua spacecraft in 2002. Products include both solar-reflected and Earth-emitted radiation from the top of the atmosphere to the Earth's surface. Analyses of the CERES data build upon the foundation laid by previous missions such as the Earth Radiation Budget Experiment (ERBE). The CERES data collected so far demonstrate that the CERES instruments are substantially improved over the ERBE instruments. The CERES data product descriptions are given in the Data Products Catalog that can be accessed on the web at: **`http://asd-www.larc.nasa.gov/DPC/DPC.html.`**
- Real-time GCIP/GAPP data since January 1996 are distributed at: **`http://www.meto.umd.edu/~srb.`** All the input and output parameters, produced in support of GCIP/GAPP (currently, a total of 71), are stored at the University of Maryland. Four types of information are archived: satellite-based information, used to drive the model; auxiliary data used to drive the model; Eta model output products relevant for hydrologic modeling; independently derived satellite products.

EVALUATION OF SATELLITE ESTIMATES USING SURFACE MEASUREMENTS

Evaluation of the SW fluxes is critically dependent upon accurate surface measurements. Historic surface SW measurements were collected under the auspices of the WCRP at the World Radiation Data Center in St. Petersburg, Russia. This database includes sites from all continents and contains measurements in the form of daily and monthly averages. From these sites, the Swiss Federal Institute of Technology derived the Global Energy Balance Archive (GEBA) (Ohmura *et al.*, 1998). These data and data from other historical networks such as the NOAA Climate Monitoring and Diagnostics Laboratory (CMDL) are compiled at the NASA Langley Data Center in the validation

of the GEWEX SRB algorithms. Globally distributed surface measurements over the last 10 years are improving with the advent of the GEWEX BSRN (Ohmura *et al.*, 1998; Whitlock *et al.*, 1995). BSRN is dedicated to providing long-term high quality measurements at locations around the globe critical for satellite validation. New regional-scale networks of surface measurements are also used for validation. Examples of these are observations from the SURFRAD (Hicks *et al.*, 1996; Augustine *et al.*, 2000) and the Atmospheric Radiation Measurement (ARM) observations of shortwave fluxes are obtained from the UnitedStates Southern Great Plain (SGP) central facility operated according to the specifications of the BSRN (Michalsky *et al.*, 1999). Data from special campaigns are also frequently used such as the CERES Program/ ARM Validation Experiment (CAVE) (Rutan *et al.*, 2001), which represents an ongoing campaign that provides calculated radiative fluxes, input data, and validating measurements over the ARM Cloud and Radiation Test bed (CART) site in Oklahoma. In the validation effort, of interest are also the accuracy limits of ground observations as discussed in Shi and Long (2002) and summarized in Table 2 for instantaneous values. More work is needed to better quantify the operational measurement uncertainties (P. Stackhouse and E. Dutton, personal communication, 2003).

Indirect evaluation of the satellite products on global scale against various GCM outputs as well as against ground observations that were extrapolated to global scale is presented in Figure 7. The GCM models were compared to each other under the Atmospheric Model Intercomparison

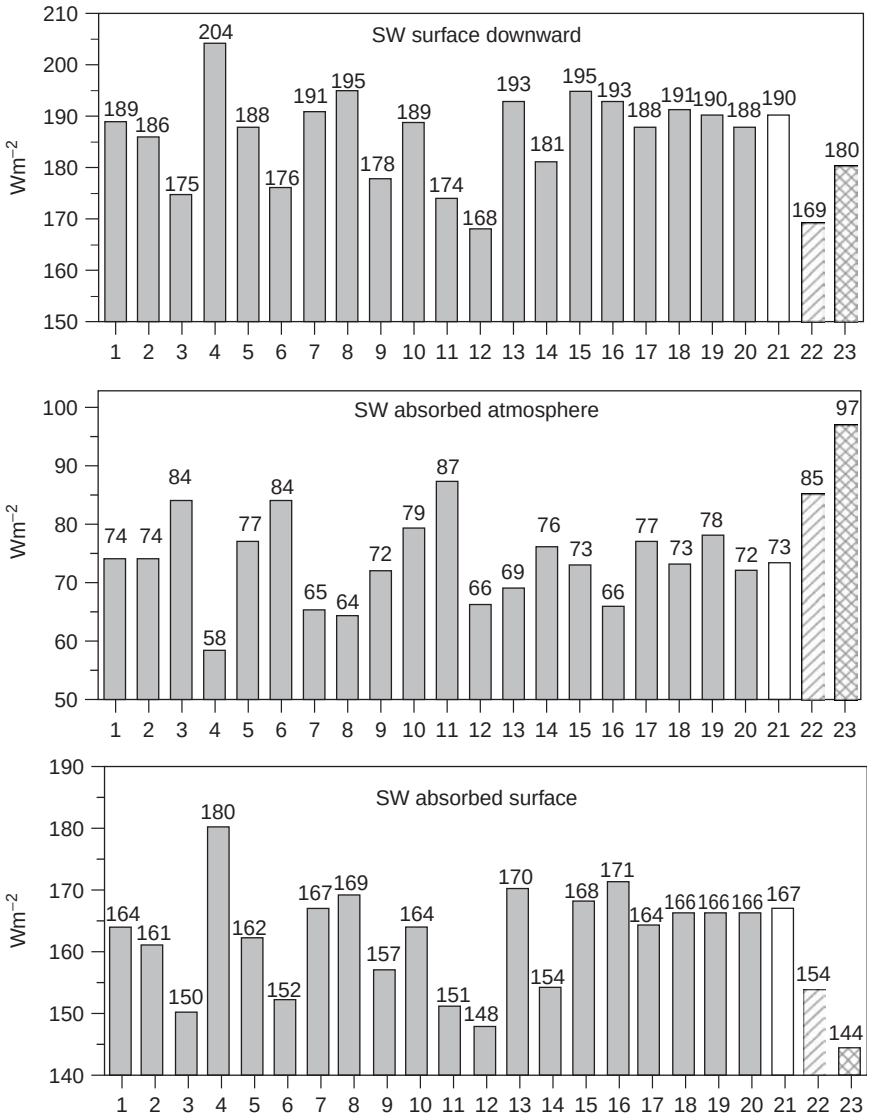

Figure 7 Comparison of global averages of satellite-based estimates of radiative fluxes at the Top of the Atmosphere, the surface and within the atmosphere with those obtained from selected global climate models (After M. Wild, 2005)

Table 2 Operational limits on measured shortwave radiation ($W\,m^{-2}$) (After Shi and Long, 2002)

	Best	Typical	Worst
Diffuse	$4.0 + 1.4$	$9.0 + 3.1$	$12.0 + 3.8$

SW surf albedo	60S-60N	9.69%

Project (AMIP) (Gates *et al.*, 1999), which was an international effort to determine the systematic climate errors of atmospheric models under realistic conditions using the observed monthly averaged distributions of sea-surface temperature and sea ice as boundary conditions. Twenty models that initially participated in the intercomparison are numbered in Figure 7 from 1 to 20 (CCCM; CCSR; CNRM; COLA; DNM; ECMWF; GISS; GLA; JMA; MGO; MPI; MRI; NCAR; NCEP; PNNL; SUNYA; UGAMP; UIUC; UKMO; YONU); details are provided in Appendix A. Column number 21 represents average results from about 20 years of satellite-derived surface fluxes from ISCCP D1 (Pinker *et al.*, 2005); columns 21 and 22 represent results as obtained by Wild *et al.* (1998) and Gilgen and Ohmura (1999), respectively. In Table 3 presented are selected global and large-scale averages of various radiative parameters as derived from the 20 year satellite record.

APPLICATIONS

LDAS and GLDAS

The importance of land-surface processes for climate and weather modeling has been recognized, and current general circulation and climate models are coupled with Land–surface Models (LSM). Improving weather and seasonal climate prediction requires information on initial states of the atmosphere, oceans, and land. Sparse observations need to be assimilated from various observing platforms into atmospheric initial states via 4-dimensional data assimilation (4DDA) to blend observations with the background fields of an LSM. Global atmospheric 4DDA have been used in operational NWP (Kalnay *et al.*, 1996), yet, errors remain in soil moisture/temperature and surface energy/water fluxes, because of biases in the surface forcing. Under the North American Land Data Assimilation System (NLDAS) project (Mitchell *et al.*, 2004) quality controlled, spatially and temporally consistent, real-time and retrospective forcing data sets were constructed. These data sets were obtained from the best available observations and model output to support LSM activities with the Noah Mosaic (Koster and Suarez, 1992), Variable Infiltration Capacity model (VIC) (Liang *et al.*, 1996) and Sacramento (Burnash *et al.*, 1973) models. They feature hourly temporal resolution and 1/8th degree spatial resolution, and have been evaluated in Luo *et al.* (2003) and Pinker *et al.* (2003). A comparison of radiative forcing from LDAS and Eta Data Assimilation System (EDAS) against ground observations is shown in Figure 8. The studies by Cosgrove *et al.* (2003) and Luo *et al.* (2003) describe the data sources, generation and validation of NLDAS forcing, produced in real-time and retrospectively on the NLDAS grid. This activity is a first real-time operational prototype of a continental-scale uncoupled land 4DDA assimilation executed daily at NCEP. Used are real-time streams of hourly to daily data based on observations of precipitation and insolation fields (from satellites and/or ground observations) that drive four LSMs running in parallel to produce hourly output on a 1/8 degree. It is hoped that such an approach will reduce the errors in the storage of soil moisture and energy that are often present in NWP models and which degrade the accuracy of forecasts.

In parallel to the NLDAS activity, a Global Land Data Assimilation System (GLDAS) is being developed jointly by scientists at NASA's Goddard Space Flight Center (GSFC) and NOAA's National Centers for Environmental Prediction (NCEP) in order to produce such fields (Rodell *et al.*, 2004). Its purpose is similar to that of NLDAS but runs globally at high (0.25°) resolution, and produces results in near-real time (typically within 48 h of the present). In GLDAS, observation-based precipitation and downward radiation and output fields from the best available global coupled atmospheric data assimilation systems are employed as forcing data. The global land-surface fields provided by GLDAS will be used to initialize weather and climate prediction models and will promote various hydrometeorological studies and applications. Currently, GLDAS drives three land-surface models: Mosaic, Noah, and the Community Land Model (CLM). Additional models are slated for future incorporation, including the VIC (Liang *et al.*, 1996) and the Catchment Land–surface Model (Koster *et al.*, 2000).

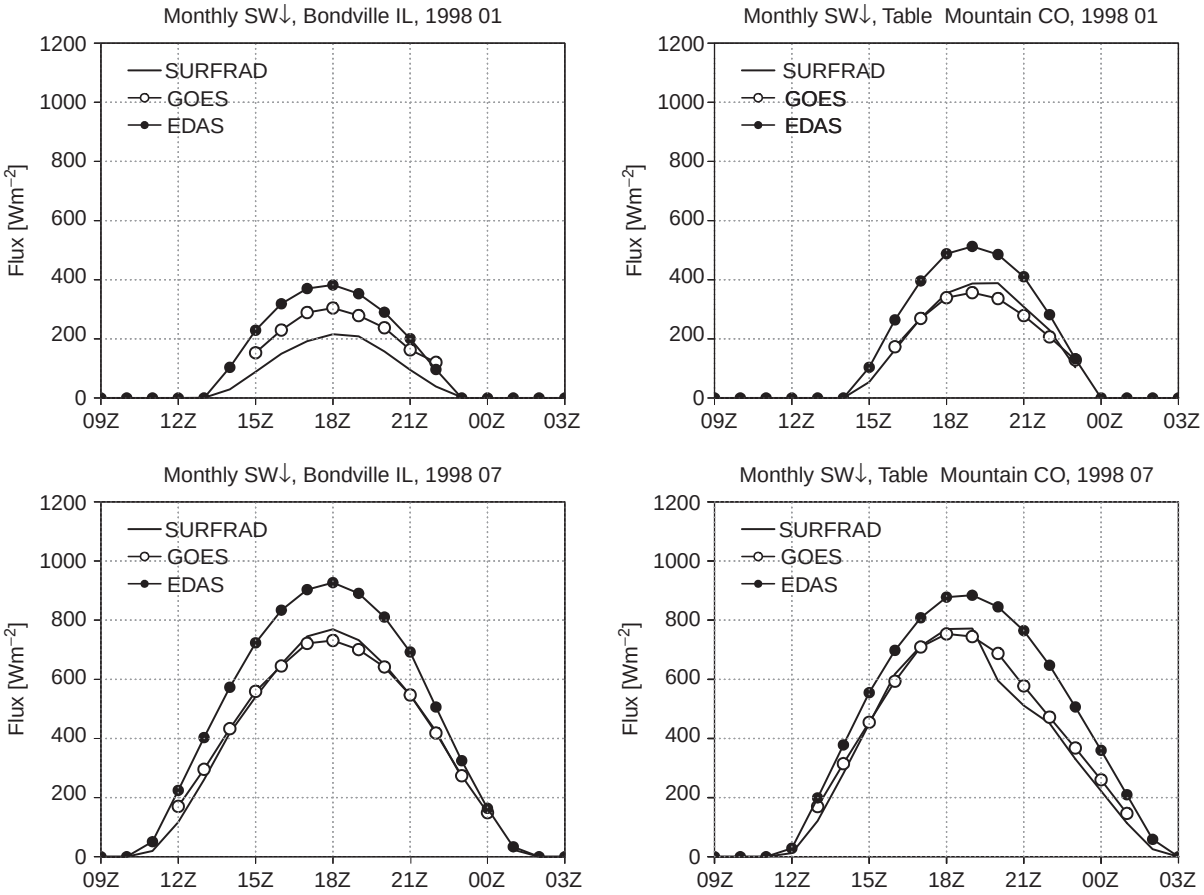

Figure 8 Validation of NLDAS GOES-based (open circles) and EDAS-based (closed circles) shortwave radiation ($W\,m^{-2}$) against SURFRAD ground-based measurements (solid line) at Bondville, IL and Table Mountain, CO for January and July of 1998. Snow cover leads to a wintertime high bias in GOES radiation values at Bondville, IL (upper left) (C.-J. Meng, private communication)

International Satellite Land Surface Climatology Project (ISLSCP) Carbon Cycle Initiative

An important element in predicting climate change is to understand how carbon, energy, and water are exchanged between the atmosphere and the terrestrial biosphere. Climate models require worldwide information about terrestrial changes that are responsible for interactions between the atmosphere and the land surfaces. All activities within the International Satellite Land Surface Climatology Project (ISLSCP) aim at assessing these changes in terms of the physical and biological quantities, which can be related to the exchange of energy and water between the surface and atmosphere. ISLSCP, established in 1983 under the United Nation's Environmental Programme, promotes use of satellite data for the global land-surface data sets needed for climate studies. ISLSCP has played a key role in addressing land-surface processes, developing climate models, experiment design and implementation, and data set development, and as such, has been accepted as a component of the GEWEX program. Its specific objectives are:

1. demonstrate the types of surface and near-surface satellite measurements that are relevant to climate and global change studies;
2. develop and improve algorithms for the interpretation of satellite measurements of land-surface features;
3. develop methods to validate area-averaged quantities derived from satellite measurements for climate simulation models;
4. prepare the groundwork for future operational production of land-surface data sets, which can be directly applied to climate problems.

Initiative I

ISLSCP Initiative I, a pilot project, produced the first global land-cover, hydrometeorology, radiation, and soils data sets regridded to a common 1×1-degree format for 1987–1988. It supported a wide range of uses: weather forecast improvements, hydrological applications, macroscale basin modeling, biogeochemical and carbon tracer models, global carbon flux model comparisons, general circulation models, model validation and comparison,

algorithm development and education. The ISLSCP I data collection is also accessible electronically via the NASA GSFC DAAC.

Initiative II

ISLSCP Initiative II (Hall *et al.*, 2005) consists of a 10-year core global data collection spanning the years 1987 to 1995 at spatial resolutions of one-quarter to one degree. It also includes selected data sets spanning the period, 1982–1999. Included are carbon data sets designed to support global carbon cycling studies. Several WCRP and International Geospehere-Biosphere Program (IGBP) initiatives are leveraged in ISLSCP II, including the GEWEX Global Soil Wetness Project–2 (GSWP-2), the Global Carbon Observing System (GCOS), the NASA's Interdisciplinary Science Projects (IDS), the NASA Seasonal to Interannual Prediction Project (NSIPP), the GEWEX Global Land Atmosphere System Study (GLASS) and others. Many of the data sets are now available electronically at: **`http://islscp2.sesda.com/ISLSCP2_1/html_pages/islscp2_home.html`**

European LDAS Activity (ELDAS)

In the European version of Land Data Assimilation Systems (ELDAS) a fast offline integration scheme is applied to modify NWP model cloud fields based on Meteosat visible and infrared observations. From the updated cloud fields, downward shortwave and longwave radiation at the surface are computed using the NWP radiative transfer model (Meetschen *et al.*, 2004).

Global Soil Wetness Project

Global landmass three-hourly solar forcing for the Global Soil Wetness Project (GSWP-1 and GSWP-2) is being generated at the Center for Ocean-Land-Atmosphere (COLA) Studies. The generation of the surface insolation for the two-year 1987–1988 GSWP-1 is described in Sellers *et al.* (1996). Production and analysis of GSWP-2 (1983–1995) is discussed in Zhao and Dirmeyer (2004).

Oceanic Applications

There is a need for information on accurate global air–sea fluxes for improving and evaluating numerical weather prediction models. As yet, such information is not available (Taylor, 2001). Radiative fluxes absorbed at the ocean surface affect the ocean temperatures and the entire surface energy budget. In the past, latent and sensible heat fluxes have been estimated using bulk formulas (Liu *et al.*, 1979; Geernaert *et al.*, 1987), while more recently, multisensor techniques using microwave radiometers and scatterometers have yielded promising results (Bentamy *et al.*, 2001). As reported in WCRP-112 (WMO/TD-No., 1036) (2000), there are numerous scientific disciplines that require air-sea flux data of heat, water, and momentum. Radiative fluxes are a required input to the estimates of these fluxes. It is also stated that the parameterizations for obtaining the net surface shortwave and long wave fluxes from ship observations are relatively crude and rely on the estimation of cloud amount. For instance, in the studies of Bunker (1976) and Esbensen and Kushnir (1981), shortwave flux parameterization is based on the work of Berlyand (1961) and Budyko (1963). In the study of Hsiung (1986) and Isemer and Hasse (1987), use is made of the parameterization of Reed (1977). In the study of Oberhuber (1988), the parameterization of Zillmann (1972) is used. In the study of Da Silva *et al.* (1994) and Josey *et al.* (1999), a Reed (1977) type approach is used while the study of Lindau (2000) uses the Malevskii *et al.* (1992) approach. In addition to such estimates, number of researchers have also attempted and continue to calculate net fluxes at the ocean surface using radiometers mounted on buoys (e.g. the Tropical Ocean Global Atmosphere Coupled Ocean Atmosphere Response Experiment (TOGA COARE)) (Weller *et al.*, 1996) and are also part of the ongoing Climate Variability and Predictability (CLIVAR) Pan American Climate Studies (PACS), which is a component of the US Global Ocean–Atmosphere–Land System (GOALS) program (**`http://www.ogp.noaa.gov/mpe/cppa/pacs/index.html`**). The overall goals of CLIVAR PACS are to extend the scope and improve the skill of operational seasonal-to-interannual climate prediction over the Americas and the boundary forcing of seasonal-to-interannual climate variations over the Americas. Particular emphasis is placed on warm season rainfall, which is not yet predictable. It is believed that satellite estimates of insolation over the oceans will play an important role in improving the heat flux estimates and will be instrumental in reaching some of the above stated goals. Observations of radiative fluxes over the Atlantic are planned under the Pilot Research Moored Array in the Tropical Atlantic (PIRATA) program. While the evaluation of satellite-based estimates over the oceans has been limited, it is believed that the results over land are good indicators of what can be expected over the oceans, assuming that auxiliary information over the oceans is also available.

FUTURE PROSPECTS

The Coordinated Enhanced Observing Period (CEOP) program is designed to integrate research activities as outlined by the GEWEX Hydrometeorology Panel (GHP). It aims to determine more accurately the water cycle with respect to climate variability and change, as well as providing data to assess the impact of this variability on water resources. Specifically, it plans to carry out intensive regional water and energy cycle experiments with a focus on the five Continental–scale Experiments (CSEs), namely,

BALTEX, GAME, GCIP, LBA, and MAGS. Added to this list was also the Coupling of the Tropical Atmosphere and the Hydrological Cycle (CATCH) region to aid in the study of the Western African Monsoon now known as the *African Monsoon Multidisciplinary Analysis* (AMMA). It is a multidisciplinary project that aims to answer scientific questions related to the understanding of the West African monsoon variability and issues related to prediction and applications. It will require cooperation with several other programs such as the CLIVAR, the emerging Climate and Cryosphere (CliC) project, and the Integrated Global Observing Strategy Partnership (IGOS-P). The Committee on Earth Observation Satellite (CEOS) will contribute to the CEOP satellite data integration and the field campaigns. Satellites are to play a key role in acquiring information under CEOP, in particular, on surface radiative fluxes. New satellite systems will play a key role. These include TERRA, AQUA, ENVISAT, and ADEOS-II, TRMM, Landsat-7, NOAA-K series and other operational satellites. At the same time, numerical weather prediction centers (NCEP, ECMWF, JMA, NASA) have made impressive gains in reanalysis and data assimilation techniques that will benefit CEOP.

SUMMARY

Historical and real-time information on surface and top of the atmosphere radiative fluxes, both on global and regional scales, are now available for the evaluation and improvement of climate models. Such information has already been extensively used, and results have been reported in the open literature. The accuracy of the result is sufficient to detect variability at hourly timescales, as well as to detect major climatic signals, such as the El Nino. Research in this field is now well posed for utilizing new satellite systems that are becoming available, and for integration of ancillary information necessary for the improvement of inference schemes. Many challenges still remain. Clouds are the major modulators of the SRBs. As yet, information on their physical properties and vertical structure is not readily available to evaluate the next stage of possible improvements. Unique situations such as deforestation and biomass burning, volcanic eruptions or pollutant transport, require special attention. For instance, cloud detection techniques that allow to detect the presence of smoke, have to be introduced. There is also a need for improved spectral resolution of the derived fluxes (e.g. PAR and NIR), that are relevant for hydrological and biogeophysical modeling.

Acknowledgments

The work that led to some of the products on surface insolation described in this paper was supported by grants NAGW59634, NAG59916 and NNG04GD65G from NASA and grant NA06GP0404 from OGP NOAA. The help of B. Zhang in the preparation of some of the figures presented here is appreciated. Inputs from K. Mitchell, B. Cosgrove, M. Rodell (NLDAS and GLDAS

50: Estimation of the Surface Energy Balance

ZHONGBO SU

International Institute for Geo-Information Science and Earth Observation (ITC), Enschede, The Netherlands

Radiation and latent and sensible heating are among the most important processes in land–atmosphere exchanges. Hence, quantitative understanding and accurate estimation of these fluxes at large scales are imperative for research and applications in areas ranging from numerical weather forecast, climate research, water cycle study, to water resources management, sustainable agricultural production, and ecological conservation. Quantitative remote sensing is probably the only efficient and economically viable technology to provide regional to global radiometric observations of several physical quantities that are relevant to the estimation of these fluxes. This article examines the physical principles underlying the radiation and turbulent heating, along with exploring the possibilities and difficulties for estimation of these fluxes using remote sensing measurements. Past efforts, recent progresses are reviewed, and future research needs are identified. In particular, the Surface Energy Balance System(SEBS), recently developed in Wageningen, is introduced and its strengths and weakness are analyzed in view of future space-borne sensor systems. Several applications derived on the basis of SEBS, including estimation of turbulent heat fluxes, evaporative fraction and actual evaporation, estimation of relative soil moisture, and drought monitoring are discussed.

INTRODUCTION

The international environmental sciences communities have seen a very rapid evolution over the last years. A new global, interdisciplinary science of the Earth System has emerged at the interface of science and policy development. The need to bridge, in a more focused way, the gap between earth sciences and sustainable management of the terrestrial environment is already emerging as an overall priority both in the International Geosphere Biosphere Programme (IGBP) and the World Climate Research Programme (WCRP) (e.g. Kabat, 1999). In this regard, understanding the interactions between terrestrial ecosystems and the atmosphere is essential to address issues such as climate change and environmental degradation. Extensive scientific investigations over the past decades have demonstrated beyond doubt that the biosphere is tightly coupled to its physical environment over a wide range of space and timescales and the atmospheric circulation is strongly influenced by land surface properties and their variability in space and time. Since radiation and turbulent heating are among the most important processes in land–atmosphere exchanges, accurate estimation of these fluxes at large scales is imperative for research and applications in areas ranging from numerical weather forecast, climate research, water cycle study, to water resources management, sustainable agricultural production, and ecological conservation. Such importance may be viewed in the following context. In dealing with climate–land interactions – especially in studies concerning terrestrial water, energy, and carbon cycles, models are often used to assist urgent policy decisions on environmental issues – but we must ask the following questions before the results derived from such models being used for further decision-making processes:

Is the interaction with a dynamic terrestrial biosphere in global models properly understood so that our forecasts of the long-term evolution of climate are reliable?
Are processes at scales from global to local properly linked so that our assessment of the impacts of climate variability on land and water resources is reliable and scenarios on the evolution of the terrestrial biosphere are realistic?

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Are the political decisions based on the current model simulations/predictions/scenarios well founded?

To be able to answer these questions, there is a critical need to understand the feedbacks between the land surface and the atmosphere at various scales (Wood, 1998). As shown by recent works, the land component of the climate system must be viewed as an active participant in the coupled system, rather than a passive recipient of atmospheric forcing (Entekhabi *et al.*, 1999; Koster *et al.*, 2000). In this view, accurate representation of land surface dynamics is more important than it had been thought previously. It has also been suggested that, in the 2001 Intergovernmental Panel on Climate Change (IPCC) report, the role of land surface in modifying the climate has not been adequately considered and the effects of land-cover change on climate may be comparable to, and, perhaps larger than, the effects on climate due to changes in atmospheric composition. The current level of scientific understanding in land–atmosphere interactions has been characterized as "very low" (Pielke, 2001a, b). A recent study by Kalnay and Cai (2003) clearly shows that the impact of land use on climate change has been underestimated. Further, the current parameterizations of land processes in all earth system models are based on simple conceptions that are representative, at best, of homogeneous flat land surfaces, and few observation data sets over complex terrain exist to allow integrated long-term off-line testing that is essential to evaluate land surface parameterizations in climate models. Abilities to estimate radiation and turbulent heat fluxes using radiometric measurements from satellite sensors will help to resolve the above-mentioned uncertainties and difficulties.

Several land–atmosphere exchange processes can be distinguished in terms of exchanges of radiation, heat, water, and carbon, and other gasses. More specifically, we may consider: solar radiation, thermal radiation, sensible heat flux, latent heat flux including phase change, soil heat flux and advection, precipitation, water and vapor transport in soil, as well as biochemical processes in soil and canopy. The driving forces of these processes are solar radiation and wind. Since most of these processes vary continuously in space and time from local to global scale, and from seconds to decades and centuries, their adequate quantification also requires measurements with corresponding spatial-temporal coverage. It is in this aspect that remote sensing can play an essential role. In the following, we will briefly review some progress made in the estimation of turbulent heat fluxes.

A BRIEF HISTORY IN REMOTE SENSING OF TURBULENT HEAT FLUXES

The estimation of atmospheric turbulent fluxes (or evaporation when the latent heat flux is expressed in water depth; in this article, evaporation refers to the rate of the conversion of liquid water to water vapor from water, soil surfaces, and through vegetation) at the land surface has long been recognized as the most important process in the determination of the exchanges of energy and mass among hydrosphere, atmosphere, and biosphere (e.g. Bowen, 1926; Penman, 1948; Monteith, 1965; Priestley and Taylor, 1972; Brutsaert, 1982; Morton, 1983; Menenti, 1984; Famiglietti and Wood, 1994; Sellers *et al.*, 1996; Su and Menenti, 1999). Conventional techniques that employ point measurements to estimate the components of energy balance are only representative of local scales and cannot be extended to large areas because of the heterogeneity of the land surface and the dynamic nature of heat transfer processes. Remote sensing is probably the only technique that can provide representative measurements of several relevant physical parameters at scales from a point to the whole globe. Techniques using remote sensing information to estimate atmospheric turbulent fluxes are therefore essential when dealing with processes that cannot be represented only by point measurements.

In developing remote sensing algorithms for the estimation of atmospheric turbulent fluxes, two basic physical principles, the conservation of energy and turbulent transport, must be considered. The former is the basis of the energy balance approach, and the major challenge is the ability to determine the various physical quantities involved with the required accuracy. The rationale behind the energy balance approach is that evaporation is a change of state of water by demanding a supply of energy for vaporization. The whole problem then reduces to determine all other sources and sinks for energy such as to leave evaporation as the only unknown. The latter recognizes the importance of wind in transporting vapor away from the evaporating surface and, when successful, providing a direct estimate to evaporation. This is often called the *aerodynamic approach* and employs, typically, gradients of wind velocity, temperature, and water vapor density in the near-surface atmosphere where the measurements of these gradients are available. Since the energy budget (i.e., available energy to the surface less the soil heat flux) in the energy balance approach needs to be distributed between sensible heat and latent heat fluxes, which involves, again, the principle of turbulent transport, a complete treatment of both the conservation of energy and turbulent transport processes becomes necessary for developing relevant remote sensing algorithms for these fluxes.

In general, we can distinguish two types of methodologies in remote sensing of turbulent heat fluxes and evaporation: analytical versus (semi-) empirical. The former takes into consideration detailed physical processes at the scale of interest but usually involves complex relationships and requires various input variables, including those that can be observed directly by radiometric measurements

and meteorological variables at a proper reference height. The latter tries to employ empirical relationships and data available chiefly from remote sensing observations. Representative works of the first type include, among others, Jackson *et al.* (1981, 1988) that derived the Crop Water Stress Index (CWSI) by applying the Penman–Monteith equation (Monteith, 1981) to radiometric measurements; Kalma and Jupp (1990), who utilized the dual-source model proposed by Shuttleworth and Wallace (1985), which, by itself, was an extension of the Penman–Monteith approach to take into account the soil and the canopy explicitly; Moran *et al.* (1994) further extended the CWSI approach to partial canopies (the so-called trapezoid-method). More recent work in the same line are those of Chehbouni *et al.* (2001) and Boegh *et al.* (2002), who thoroughly examined the CWSI concept for its strengths and weakness using detailed field measurements collected in Denmark. Other relevant works but of different concepts are those of Chanzy *et al.* (1995) for soil evaporation and Norman *et al.* (1995) using a new type of dual-source model aiming at utilizing directional radiometric measurements. More recently, Kustas and Norman (1999) applied actual soil and vegetation component temperatures to the dual-source model of Norman *et al.* (1995) but did not obtain better results than using only composite temperature without changing the applied Priestley and Taylor (1972) coefficient to a much high value. Mecikalski *et al.* (1999) have applied the Norman *et al.* (1995) approach to continental scale with encouraging results. Efforts related to combined modeling and data assimilation using radiometric measurements have been reported by Castelli *et al.* (1999), Olioso *et al.* (2002), Boni *et al.* (2001a, b), and Caparrini *et al.* (2003, 2004).

Where the (semi) empirical approaches are concerned, the earlier works of Jackson *et al.* (1977) and Seguin and Ittier (1983) are representative and many more recent works still follow the same type of approaches but incorporate more remote sensing variables (e.g. in Nishida *et al.*, 2003a, b, besides using remotely sensed surface radiometric temperature as in Jackson *et al.* (1977), vegetation index is also used).

In addition, Menenti (1993), Carlson *et al.* (1995), Kustas and Norman (1996), and Zhang (1996) have provided excellent reviews to the then up-to-date approaches in remote sensing of turbulent heat fluxes and evaporation.

Similarly, the progress made in Wageningen, the Netherlands, can also be mapped in the analytical *versus* (semi-) empirical fashion. The foundation of the analytical approaches were laid by Menenti (1984) by proposing a two-layer combination equation for a drying soil that was later shown by Menenti (1993) to be able to reduce to the Penman–Monteith combination equation and was also shown by Stanghellini (1987) to be equally valid for a green-house canopy. In a further attempt, Menenti and Choudhury (1993) extended the CWSI concept to the so-called Surface Energy Balance Index (SEBI) approach. While the CWSI was based on surface meteorological scaling, the SEBI concept used Planetary Boundary Layer (PBL) Scaling. However, the parameterization used in SEBI was limited to the then state-of-the-art concepts, namely, the ratio between aerodynamic roughness and thermal dynamic roughness was taken as 10 and the stratification correction was simply taken as 2.9. Application of the SEBI concept to the Aral Sea by Menenti *et al.* (2001) revealed that the parameterization was probably not universal and caused some unexplained scatters in the results. More recently, Su (2002) has proposed the Surface Energy Balance System (SEBS) by extending the SEBI concept with a dynamic model for thermal roughness (Su *et al.*, 2001), the Bulk Atmospheric Similarity (BAS) theory of Brutsaert (1999) for PBL scaling, and the Monin–Obukhov Atmospheric Surface Layer (ASL) similarity for surface layer scaling such that SEBS can be used for both local scaling and regional scaling under all atmospheric stability regimes, thus providing a link for radiometric measurements and atmospheric models at various scales. Using SEBS, Jia *et al.* (2003) have successfully coupled model forecast fields of a large scale Numerical Weather Prediction (NWP) model to radiometric measurements from the Along Track Scanning Radiometer (ATSR) onboard the European Remote Sensing Satellite (ERS-2). Rauwerda *et al.* (2002) have extended SEBS to a parallel-source model and have showed significant improvement in estimated turbulent heat fluxes. On the application side, SEBS has been used to generate daily, monthly, and annual evaporation in a semiarid environment (Li, 2001; Su *et al.*, 2003a) and for drought monitoring (Su *et al.*, 2003b). Another development is that of Jia *et al.* (2001), who have proposed a dual-source model for using component (soil and vegetation) temperatures such as those derivable form ATSR data. The scheme is similar to the Shuttleworth and Wallace (1985) dual-source model but employs the boundary-resistance formulation of Stanghellini (1987) and shows much flexibility in dealing with heterogeneous surfaces.

On the empirical side, the work of Nieuwenhuis *et al.* (1985) was among the earliest attempts but was valid only for single crops. Later, Bastiaanssen (1995) proposed the Surface Energy Balance Algorithm for Land (SEBAL) that required simultaneous presence of absolute dry and wet pixels and has been used for many irrigation studies. More recently, Su *et al.* (1999) have made correction in SEBAL to remedy a theoretical problem and added a scheme to apply NWP fields with an up-scaling and down-scaling approach. In another effort, Roerink *et al.* (2000) proposed a Simplified Surface Energy Balance Index (S-SEBI) by fitting dry and wet cases present in the spatial radiometric data and showed reasonable success for application to semiarid areas.

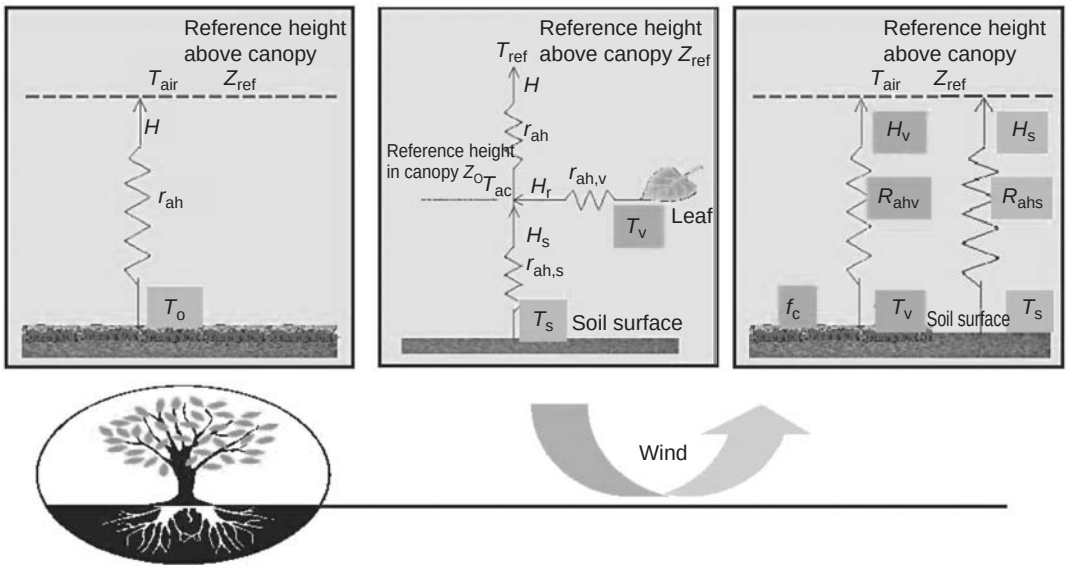

Figure 1 Flux parameterization schemes. Remote sensing of heat fluxes and evaporation – single-source, dual-source, and parallel-source has been shown in the figure. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

In order to give a clear picture of the differences in various schemes encountered in turbulent heat fluxes parameterization, Figure 1 summarizes the single-source, dual-source, and parallel-source schemes. In the following, we will review the difficulties and the relationships between radiometric measurements and atmospheric boundary meteorological variables in estimation of turbulent heat fluxes by means of SEBS (Su, 2002).

THE SURFACE ENERGY BALANCE SYSTEM (SEBS) FOR ESTIMATION OF TURBULENT HEAT FLUXES AND EVAPORATION

SEBS was developed for the estimation of atmospheric turbulent fluxes using satellite earth observation data more coherently. SEBS, as proposed by Su (2002), consists of: a set of tools for the determination of the land surface physical parameters, such as albedo, emissivity, temperature, vegetation coverage, and so on, from spectral reflectance and radiance; an extended model for the determination of the roughness length for heat transfer of Su *et al.* (2001); and a new formulation for the determination of the evaporative fraction on the basis of energy balance at limiting cases. In the application, SEBS requires as inputs three sets of information. The first set consists of land surface albedo, emissivity, temperature, fractional vegetation coverage and leaf area index, and the height of the vegetation (or roughness height). When vegetation information is not explicitly available, the Normalized Difference Vegetation Index (NDVI) is used as a surrogate. These inputs can be derived from remote sensing data in conjunction with other information about the concerned surface. The second set includes air pressure, temperature, humidity, and wind speed at a reference height. The reference height is the measurement height for point application and the height of the PBL for regional application (in this latter case, PBL-averaged meteorological variables are to be used. See later for detailed discussions). This data set can also be variables estimated by a large-scale meteorological model. The third data set includes downward solar radiation and downward longwave radiation that can either be direct measurements, model output, or parameterization.

In SEBS, the friction velocity, the sensible heat flux, and the Obukhov stability length are obtained by solving the system of nonlinear equations. For field measurements performed at a height of a few meters above ground, since the surface fluxes are related to surface variables and variables in the atmospheric surface layer, all calculations use the Monin–Obukhov Similarity (MOS) functions given by Brutsaert (1999). By replacing the MOS stability functions with the Bulk Atmospheric Boundary Layer

Similarity (BAS) functions proposed by Brutsaert (1999), the system equations can be used to relate surface fluxes to surface variables and the mixed layer atmospheric variables provided either by radiosonde data or obtained from atmospheric model fields. The relevant atmospheric boundary layer (ABL) that needs to be considered in different scaling is shown in Figure 2 (*see also* **Chapter 29, Atmospheric Boundary-Layer Climates and Interactions with the Land Surface, Volume 1**). The determination of the evaporative fraction (the ratio of latent heat flux to the available energy) on the basis of energy balance at limiting cases is carried out, and, finally, the turbulent heat fluxes are determined by utilizing the surface energy balance. Further, by utilizing the conservative characteristics of the evaporative fraction, the daily evaporation can be determined, given the total daily available energy. The different steps involved in SEBS are discussed below.

Determination of Evaporative Fraction Based On Energy Balance at Limiting Cases

The surface energy balance is written in SEBS as

$$R_n = G_0 + H + \lambda E \qquad (1)$$

where R_n is the net radiation, G_0 is the soil heat flux, H is the turbulent sensible heat flux, and λE is the turbulent latent heat flux (λ is the latent heat of vaporization and E is the actual evapotranspiration).

The equation to calculate the net radiation is given by

$$R_n = (1 - \alpha) \cdot R_{swd} + \varepsilon \cdot R_{lwd} - \varepsilon \cdot \sigma \cdot T_0^4 \qquad (2)$$

where α is the albedo, R_{swd} is the downward solar radiation, R_{lwd} is the downward longwave radiation, ε is the emissivity of the surface, σ is the Stefan-Bolzmann constant, and T_0 is the surface radiative temperature measured by a remote sensor (*see also* **Chapter 52, Estimation of Surface Temperature and Surface Emissivity, Volume 2**). α, ε, and T_0 can be derived from remote sensing data from the visible to the thermal infrared spectral range. The simplest of form to calculate the downward solar radiation is $R_{swd} = I_{sc} \cdot e_0 \cdot \cos\theta_z \cdot \exp(-m \cdot \tau)$, where $I_{sc} = 1367\ W \cdot m^{-2}$ is the solar constant, e_0 the eccentricity factor, θ_z the solar zenith angle, m the air mass, and τ the optical thickness. Details on the determination of all the parameters can be found in Iqbal (1983) (*see also* **Chapter 39, Surface**

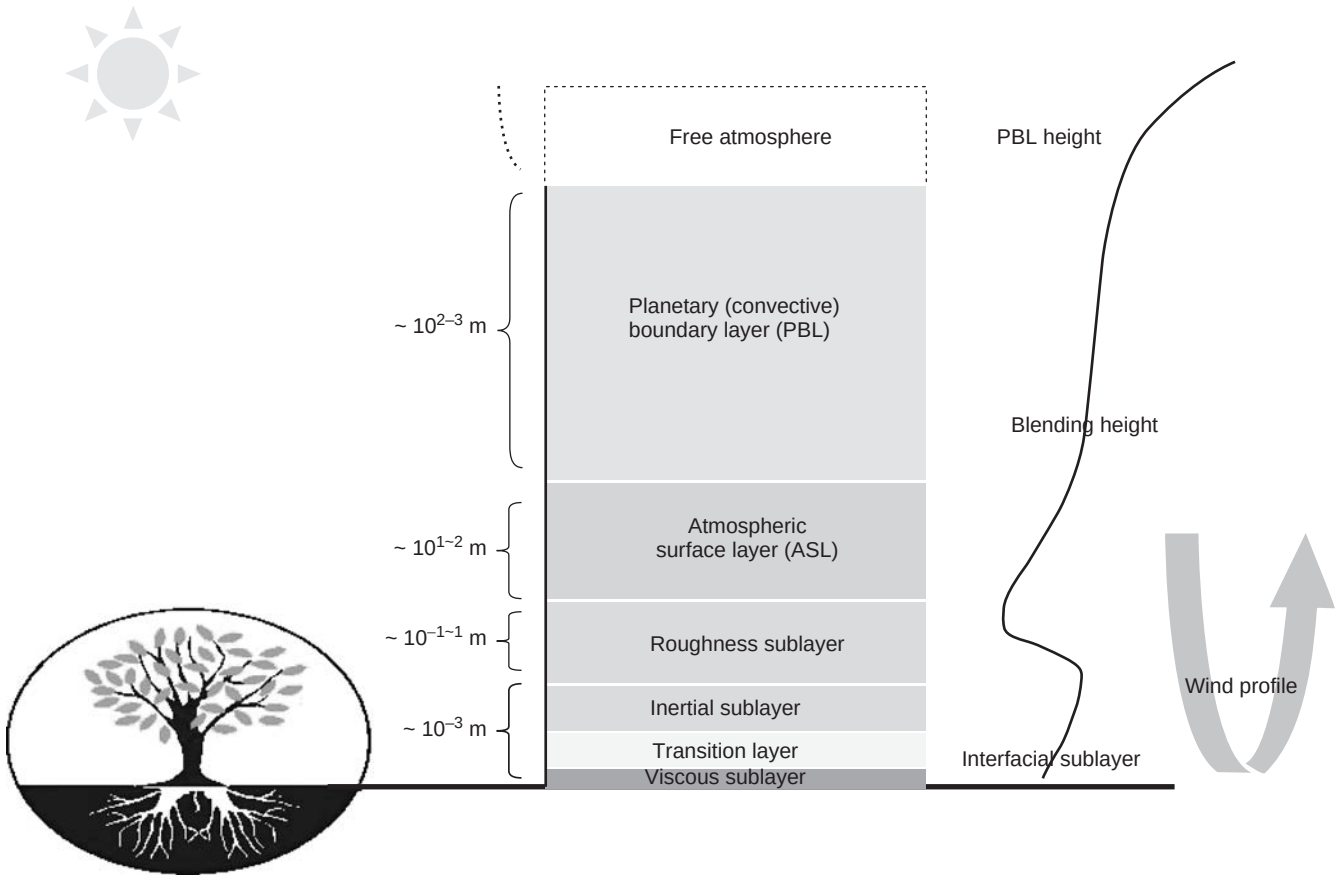

Figure 2 Typical structure of the atmospheric boundary layer. SEBS includes both surface scaling and PBL scaling. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Radiation Balance, Volume 1). The downward longwave radiation R_{lwd} can be calculated as $R_{lwd} = \varepsilon_a \sigma T_a^4$ when there is no measurement, where ε_a is the emissivity of the atmosphere that can be estimated using the Swinbank formula as given by Campbell and Norman (1998) in the form $\varepsilon_a = 9.2 \cdot 10^{-6} \cdot (T_a + 273.15)^2$, with T_a the air temperature at the reference height. Su *et al.* (2001) and Su (2002) have shown that equation (2) provides accurate estimation of the net radiation.

The equation to calculate the soil heat flux is parameterized as

$$G_0 = R_n \cdot [\Gamma_c + (1 - f_c) \cdot (\Gamma_s - \Gamma_c)] \tag{3}$$

in which it is assumed that the ratio of soil heat flux to net radiation is $\Gamma_c = 0.05$ for full vegetation canopy (Monteith, 1973) and $\Gamma_s = 0.315$ for bare soil (Kustas and Daughtry, 1989). An interpolation is then performed between these limiting cases using the fractional canopy coverage, f_c, which can be determined from remote sensing data.

In order to determine the evaporative fraction, energy balance considerations at limiting cases are used. Under the dry limit, the latent heat (or the evaporation) becomes zero due to the limitation of soil moisture, and the sensible heat flux is at its maximum value. From equation (1), it follows,

$$\begin{aligned} \lambda E_{\text{dry}} &= R_n - G_0 - H_{\text{dry}} \equiv 0, \\ \text{or} \quad H_{\text{dry}} &= R_n - G_0 \end{aligned} \tag{4}$$

Under the wet limit, where the evaporation takes place at potential rate, λE_{wet}, (i.e., the evaporation is only limited by the available energy under the given surface and atmospheric conditions), the sensible heat flux takes its minimum value, H_{wet}, that is,

$$\begin{aligned} \lambda E_{\text{wet}} &= R_n - G_0 - H_{\text{wet}}, \\ \text{or} \quad H_{\text{wet}} &= R_n - G_0 - \lambda E_{\text{wet}} \end{aligned} \tag{5}$$

The relative evaporation then can be evaluated as

$$\Lambda_r = \frac{\lambda E}{\lambda E_{\text{wet}}} = 1 - \frac{\lambda E_{\text{wet}} - \lambda E}{\lambda E_{\text{wet}}} \tag{6}$$

By substituting equations (1), (5), and (4) in equation (6) and after some algebra, one obtains

$$\Lambda_r = 1 - \frac{H - H_{\text{wet}}}{H_{\text{dry}} - H_{\text{wet}}} \tag{7}$$

The evaporative fraction is finally given by:

$$\Lambda = \frac{\lambda E}{H + \lambda E} = \frac{\lambda E}{R_n - G} = \frac{\Lambda_r \cdot \lambda E_{\text{wet}}}{R_n - G} \tag{8}$$

Equations (1–8) constitute the basis formulation of SEBS. Further, in SEBS, the actual sensible heat flux H is obtained by solving a set of non-linear equations and is constrained in the range set by the sensible heat flux at the wet limit H_{wet}, and the sensible heat flux at the dry limit H_{dry}.

Determination of Sensible Heat Fluxes H, H_{dry}, H_{wet}

In order to derive the actual sensible heat flux H, the similarity theory is used. In SEBS, distinction is made between the ABL or PBL and the Atmospheric Surface Layer (ASL) similarity. ABL refers to the part of atmosphere that is directly influenced by the presence of the Earth's surface and responds to the surface forcings with a timescale of an hour or less, while ASL refers to usually the bottom 10% of ABL but above the roughness sublayer, that is, the ASL is where turbulent fluxes and stress vary by less than 10% of their magnitude (Stull, 1988; *see also* **Chapter 29, Atmospheric Boundary-Layer Climates and Interactions with the Land Surface, Volume 1**). The roughness sublayer (or the interfacial layer) is the near-surface thin layer of a few centimeters where the molecular transport dominates over turbulent transport (see Figure 2). The thickness of the roughness sublayer is thought to be around 35 times the surface roughness height, or three times the vegetation height (Katul and Parlange, 1992). In ASL, the similarity relationships for the profiles of the mean wind speed, u, and the mean temperature, $\theta_0 - \theta_a$, can be written in integral form as

$$u = \frac{u_*}{k} \left[\ln\left(\frac{z - d_0}{z_{0m}}\right) - \Psi_m\left(\frac{z - d_0}{L}\right) + \Psi_m\left(\frac{z_{0m}}{L}\right) \right] \tag{9}$$

$$\theta_0 - \theta_a = \frac{H}{k u_* \rho C_p} \left[\ln\left(\frac{z - d_0}{z_{0h}}\right) - \Psi_h\left(\frac{z - d_0}{L}\right) + \Psi_h\left(\frac{z_{0h}}{L}\right) \right] \tag{10}$$

where z is the height above the surface, $u_* = (\tau_0/\rho)^{1/2}$ is the friction velocity, τ_0 is the surface shear stress, ρ is the density of air, $k = 0.4$ is the von Karman constant, d_0 is the zero-plane displacement height, z_{0m} is the roughness height for momentum transfer, θ_0 is the potential temperature at the surface, θ_a is the potential air temperature at height z, z_{0h} is the scalar roughness height for heat transfer, ψ_m and ψ_h are the stability correction functions for momentum and sensible heat transfer respectively, L is the Obukhov length defined as

$$L = -\frac{\rho C_p u_*^3 \theta_v}{k g H} \tag{11}$$

where g is the acceleration due to gravity, θ_v is the potential virtual temperature near the surface.

For field measurements performed at a height of a few meters above ground, clearly, since the surface fluxes are related to surface variables and variables in the atmospheric surface layer, all calculations use the MOS stability functions (e.g. Brutsaert, 1999). By replacing the MOS stability functions with the BAS functions proposed by Brutsaert (1999), the system of equations (9–11) can be used to relate surface fluxes to surface variables and the mixed layer atmospheric variables. The criterion proposed by Brutsaert (1999) is used to determine if the MOS or the BAS scaling is appropriate for a given situation. The above functions are valid for unstable conditions only. For stable conditions, the expressions proposed by Beljaars and Holtslag (1991) and evaluated by Van den Hurk and Holtslag (1995) are used for atmospheric surface layer scaling, and the functions proposed by Brutsaert (1982, p. 84) for ABL scaling.

The friction velocity, the sensible heat flux, and the Obukhov stability length are obtained by solving the system of nonlinear equations (9–11) using the method of Broyden (Press *et al.*, 1997). It is important to note that the derivation of the sensible heat flux using equations (9–11) requires only the wind speed and temperature at the reference height as well as the surface temperature, and is independent of other surface energy balance terms.

As stated previously, this derived actual sensible heat flux H is further subjected to constraints in the range set by the sensible heat flux at the wet limit H_{wet}, and the sensible heat flux at the dry limit H_{dry} in SEBS.

The sensible heat flux at the dry limit H_{dry} is given by equation (4) and the sensible heat flux at the wet limit H_{wet} can be derived by combining equation (5) and a combination equation similar to the Penman–Monteith combination equation (Monteith, 1965). Menenti (1984) showed, when the resistance terms are grouped into the bulk internal (or surface) and external (or aerodynamic) resistances, the combination equation can be written in the following form,

$$\lambda E = \frac{\Delta \cdot r_e \cdot (R_n - G_0) + \rho C_p \cdot (e_{\mathrm{sat}} - e)}{r_e \cdot (\gamma + \Delta) + \gamma \cdot r_i} \tag{12}$$

where e and e_{sat} are actual and saturation vapor pressure, respectively; γ is the psychrometric constant, and Δ is the rate of change of saturation vapor pressure with temperature (i.e. $\partial e_{\mathrm{sat}}(T)/\partial T$); r_i is the bulk surface internal resistance, and r_e is the external or aerodynamic resistance. In the above equation, it is assumed that the roughness lengths for heat and vapor transfer are the same (Brutsaert, 1982). It is worthwhile to point out that the Penman–Monteith equation is strictly only valid for vegetation canopy, whereas the definition by means of equation (12) is also valid for soil surface with properly defined bulk internal resistance. The difficulty in using equation (12) to estimate latent heat flux lies in the difficulty to determine the bulk internal resistance r_i, which is strongly regulated by soil water availability. Because the latter is generally not known *a priori*, an alternative is thus proposed in SEBS to avoid the direct use of r_i in estimating λE.

At the wet limit, the internal resistance $r_i \equiv 0$ by definition. Using this property in equation (12) and changing the subscripts correspondingly to reflect the wet-limit condition, the sensible heat flux at the wet limit is obtained as

$$H_{\mathrm{wet}} = \left((R_n - G_0) - \frac{\rho C_p}{r_{ew}} \cdot \frac{e_s - e}{\gamma}\right) \Big/ \left(1 + \frac{\Delta}{\gamma}\right) \tag{13}$$

The external resistance depends also on the Obukhov length, L, which in turn is a function of the friction velocity and sensible heat flux (equation 11). With the friction velocity and the Obukhov length determined by the numerical procedure described previously, the external resistance can be determined from equation (10) as

$$r_e = \frac{1}{k u_*}\left[\ln\left(\frac{z - d_0}{z_{0h}}\right) - \Psi_h\left(\frac{z - d_0}{L}\right) + \Psi_h\left(\frac{z_{0h}}{L}\right)\right] \tag{14}$$

Similarly, the external resistance at the wet limit can be derived as

$$r_{ew} = \frac{1}{k u_*}\left[\ln\left(\frac{z - d_0}{z_{0h}}\right) - \Psi_h\left(\frac{z - d_0}{L_w}\right) + \Psi_h\left(\frac{z_{0h}}{L_w}\right)\right] \tag{15}$$

and the wet-limit stability length can be determined as

$$L_w = -\frac{\rho u_*^3}{k g \cdot 0.61 \cdot (R_n - G_0)/\lambda} \tag{16}$$

Determination of the Roughness Length for Heat Transfer

In the above derivations, the aerodynamic and thermal dynamic roughness parameters need to be known first. When near-surface wind speed and vegetation parameters (height and leaf area index) are available, the within-canopy turbulence model proposed by Massman (1997) can be used to estimate aerodynamic parameters, d_0, the displacement height, and z_{0m}, the roughness height for momentum. This model has been shown by Su *et al.* (2001) to produce reliable estimates of the aerodynamic parameters. If only the height of the vegetation is available, the relationships proposed by Brutsaert (1982) can be used. If a detailed land-use classification is available, the tabulated values of Wieringa (1993) can be used. However, since the aerodynamic parameters depend also on wind speed and wind direction besides the surface characteristics, the latter two approaches should only be used when the first method

cannot be used due to lack of data. When all of the above information is not available or not convenient to use, the aerodynamic parameters can be related to vegetation indices derived from satellite data. However, in this case, care must be taken, because the vegetation indices saturate at higher vegetation densities and the relationships are vegetation-type dependent.

The scalar roughness height for heat transfer, z_{0h}, changes with surface characteristics, atmospheric flow, and thermal dynamic state of the surface (Blümel, 1999; Massman, 1999a). Based on the work of Massman (1999a), a simple roughness model for heat transfer was proposed by Su *et al.* (2001). However, in their model, a functional form to describe the vertical structure of the vegetation canopy is needed in order to calculate the within-canopy wind speed profile extinction coefficient, n_{ec}. For local studies, this information is easily obtained, but for large-scale applications, it is generally impossible to obtain detailed information on the vertical structure of the canopy. In SEBS, n_{ec}, is formulated as a function of the cumulative leaf drag area at the canopy top,

$$n_{ec} = \frac{C_d \cdot LAI}{2u_*^2/u(h)^2} \tag{17}$$

where C_d is the drag coefficient of the foliage elements assumed to take the value of 0.2, LAI is the one-sided leaf area index defined for the total ground area, and $u(h)$ is the horizontal wind speed at the canopy top. The scalar roughness height for heat transfer, z_{0h}, can be derived from

$$z_{0h} = \frac{z_{0m}}{\exp(kB^{-1})} \tag{18}$$

where B^{-1} is the inverse Stanton number, a dimensionless heat transfer coefficient. To estimate the kB^{-1} value, an extended model of Su *et al.* (2001) is proposed as follows,

$$kB^{-1} = \frac{kC_d}{4C_t \frac{u_*}{u(h)}(1 - e^{-n_{ec}/2})} f_c^2 + 2f_c f_s \frac{k \cdot u_*/u(h) \cdot z_{0m}/h}{C_t^*} + kB_s^{-1} f_s^2 \tag{19}$$

where f_c is the fractional canopy coverage and f_s is its compliment. C_t is the heat transfer coefficient of the leaf. For most canopies and environmental conditions, C_t is bounded as $0.005N \le sC_t \le 0.075N$ (N is number of sides of a leaf to participate in heat exchange). The heat transfer coefficient of the soil is given by $C_t^* = \mathrm{Pr}^{-2/3}\,\mathrm{Re}_*^{-1/2}$, where Pr is the Prandtl number, the roughness Reynolds number $\mathrm{Re}_* = h_s u_*/\nu$, with h_s the roughness height of the soil. The kinematic viscosity of the air is given by $\nu = 1.327 \cdot 10^{-5}(p_0/p)(T_a/T_{a0})^{1.81}$(Massman, 1999b), with p and T_a the ambient pressure and temperature, and $p_0 = 101.3\,k\mathrm{Pa}$ and $T_{a0} = 273.15\,\mathrm{K}$. Physically and geometrically, the first term of equation (19) follows the full canopy-only model of Choudhury and Monteith (1988), the third term is that of Brutsaert (1982) for a bare soil surface, while the second term describes the interaction between vegetation and bare soil surface. A quadratic weighting based on the fractional canopy coverage is used to accommodate any situation between the full vegetation and bare soil conditions. For bare soil surface, kB_s^{-1} is calculated according to Brutsaert (1982)

$$kB_s^{-1} = 2.46(\mathrm{Re}_*)^{1/4} - \ln[7.4] \tag{20}$$

The MOS Stability Correction Functions

The MOS stability correction functions for momentum and sensible heat transfer ψ_m and ψ_h, respectively, are defined in the following integrated form

$$\Psi_i(y) = \int_0^y [1 - \phi_i(x)]\frac{\mathrm{d}x}{x} \tag{21}$$

where $y = -(z-d)/L \cdot i$ equals m, or h for momentum and sensible heat transfer, respectively.

The ϕ_i functions are proposed by Brutsaert (1999) as

$$\phi_m(y) = \frac{\left(a + b \cdot y^{m+\frac{1}{3}}\right)}{a + y^m} \tag{22}$$

$$\phi_h(y) = \frac{(c + d \cdot y^n)}{c + y^n} \tag{23}$$

On the basis of data reported by Högström (1988) and Kader and Yaglom (1990), Brutsaert (1999) assigned the constants in equations (22–23) as $a = 0.33$, $b = 0.41$, $m = 1.0$, $c = 0.33$, $d = 0.057$, and $n = 0.78$.

Upon integration of equations (22) and (23) using equation (21), the required MOS stability functions for free convective conditions are obtained.

$$\Psi_m(y) = \ln(a + y) - 3 \cdot b \cdot y^{1/3} + \frac{b \cdot a^{1/3}}{2} \ln\left[\frac{(1+x)^2}{(1 - x + x^2)}\right] + 3^{1/2} \cdot b \cdot a^{1/3} \tan^{-1}\left[\frac{(2 \cdot x - 1)}{3^{1/2}}\right] + \Psi_0, \quad \text{for} \quad y \le b^{-3} \tag{24a}$$

$$\Psi_m(y) = \Psi_m(b^{-3}), \quad \text{for} \quad y > b^{-3} \tag{24b}$$

$$\Psi_h(y) = \left[\frac{(1-d)}{n}\right] \ln\left[\frac{(c + y^n)}{c}\right] \tag{25}$$

where $x = (y/a)^{1/3} \cdot \Psi_0 = (-\ln a + 3^{1/2} \cdot b \cdot a^{1/3} \cdot \pi/6)$ is an integration constant.

Equations (24–25) are extensions to the Businger–Dyer function for unstable conditions. For stable conditions, the expressions proposed by Beljaars and Holtslag (1991) and evaluated by Van den Hurk and Holtslag (1995) can be used. These are given below:

$$\Psi_m(y_s) = -\left[a_s \cdot y_s + b_s\left(y_s - \frac{c_s}{d_s}\right) \cdot \exp(-d_s \cdot y_s) + \frac{b_s \cdot c_s}{d_s}\right] \quad (26)$$

$$\Psi_h(y_s) = -\left[\left(1 + \frac{2a_s}{3}y_s\right)^{1.5} + b_s \cdot \left(y_s - \frac{c_s}{d_s}\right) \cdot \exp(-d_s \cdot y_s) + \left(\frac{b_s \cdot c_s}{d_s} - 1\right)\right] \quad (27)$$

where $y_s = (z-d)/L$, $a_s = 1$, $b_s = 0.667$, $c_s = 5$ and $d_s = 1$.

The Bulk Atmospheric Boundary Layer (ABL) Similarity (BAS) Stability Correction Functions

Under free convective conditions, the outer region of the ABL is well mixed such that the mean profiles of wind and potential temperature are nearly constant with height. This is equivalent to state that the unstable ABL consists of two regions, an inner region where MOS is valid, and a slab outer region where the profiles are constant.

According to Brutsaert (1999), experimental evidence suggests that the height of the ASL, h_{st}, should be scaled with the thickness of the ABL over moderately rough surfaces, but with the surface roughness over very rough terrain. More quantitatively, h_{st}, can be determined in the following ways

$$h_{st} = \alpha_b \cdot h_i \quad (28)$$

where h_i is the height of the ABL and α_b is around 0.10–0.15, or

$$h_{st} = \beta_b \cdot z_0 \quad (29)$$

where β_b is around 100–150
whichever is larger. Setting typical values of $\beta_b/\alpha_b = 10^3$, and $h_i = 10^3\,m$, gives $z_0 = (\alpha_b/\beta_b) \cdot h_i = 1\,m$, which separates very rough from moderate rough terrain.

For moderately rough terrain satisfying $z_0 < (\alpha_b/\beta_b) \cdot h_i$, joining the inner with the outer region such that $u(z-d_0) = u_m$, $\theta_a(z-d_0) = \theta_m$, at $z - d_0 = h_{st}$, (where the subscript m indicates average of the variable in question over the lower half of the mixed layer, which is an advise for practical applications because the entrainment of warmer air into the ABL affects both the potential temperature and the wind profiles in the upper half of the ABL), allows to derive the bulk stability functions

$$B_w = -\ln(\alpha_b) + \Psi_m\left(\frac{\alpha_b \cdot h_i}{L}\right) - \Psi_m\left(\frac{z_0}{L}\right) \quad (30)$$

$$C_w = -\ln(\alpha_b) + \Psi_h\left(\frac{\alpha_b \cdot h_i}{L}\right) - \Psi_h\left(\frac{z_{0h}}{L}\right) \quad (31)$$

Equations (30–31) show that the bulk stability functions depend on both the surface roughness and the height of the ABL for moderately rough terrain.

Similarly, for very rough terrain, that is, $z_0 \geq (\alpha_b/\beta_b) \cdot h_i$, we obtain

$$B_w = -\ln\left(\frac{h_i}{(\beta_b \cdot z_0)}\right) + \Psi_m\left(\frac{\beta_b \cdot z_0}{L}\right) - \Psi_m\left(\frac{z_0}{L}\right) \quad (32)$$

$$C_w = -\ln\left(\frac{h_i}{(\beta_b \cdot z_0)}\right) + \Psi_h\left(\frac{\beta_b \cdot z_0}{L}\right) - \Psi_h\left(\frac{z_{0h}}{L}\right) \quad (33)$$

which state that the bulk stability functions depend on only the surface roughness for very rough terrain.

Finally, for stable conditions, that is, when $h_i/L > 0$, we use (Brutsaert, 1982, equation 4.93, p. 84)

$$B_w = -2.2 \cdot \ln\left(1 + \frac{h_i}{L}\right) \quad (34)$$

$$C_w = -7.6 \cdot \ln\left(1 + \frac{h_i}{L}\right) \quad (35)$$

Both stability correction functions may need to be verified using data from more recent large-scale field experiment and updated accordingly when necessary.

Determination of Turbulent Heat Fluxes and Actual Evaporation

By inverting equation (8), the actual sensible and latent heat fluxes can be obtained as,

$$H = (1-\Lambda) \cdot (R_n - G)$$
$$\lambda E = \Lambda \cdot (R_n - G) \quad (36)$$

When the evaporative fraction is known, the daily evaporation can be determined as

$$E_{\text{daily}} = 8.64 \times 10^7 \times \bigwedge_0^{24} \times \frac{\overline{R_n} - \overline{G_0}}{\lambda \rho_W} \quad (37)$$

where E_{daily} is the actual evaporation on daily basis $(mm \cdot d^{-1}) \cdot \bigwedge_0^{24}$ is the daily average evaporative fraction, which can be approximated by the SEBS estimate since

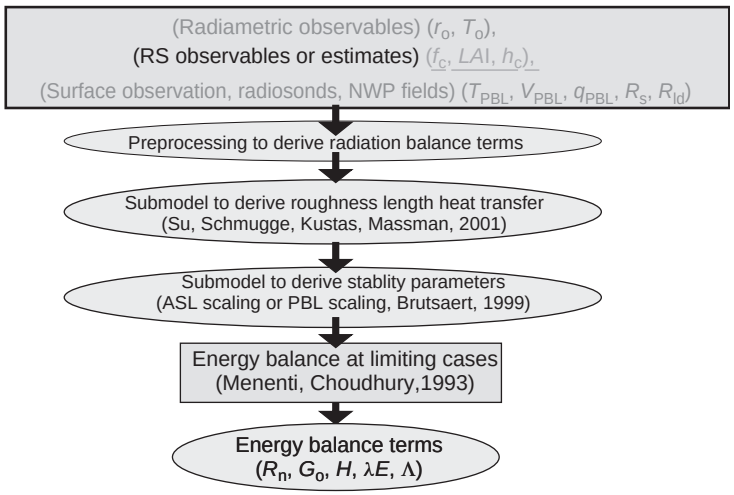

Figure 3 Schematic representation of SEBS. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

the evaporative fraction is conservative (Shuttleworth *et al.*, 1989; Sugita and Brutsaert, 1991; Crago, 1996). $\overline{R_n}$ and $\overline{G_0}$ are the daily net radiation flux and soil heat flux, λ is the latent heat of vaporization ($J\,Kg^{-1}$), ρ_w is the density of water ($Kg\,m^{-1}$).

Since the daily soil heat flux is close to zero because the downward flux in daytime and the upward flux at night balance each other approximately, the daily evaporation only depends on the net radiation flux given by

$$\overline{R_n} = (1-\alpha)K_{24}^{\downarrow} + \varepsilon L_{24} \tag{38}$$

where $K_{24}^{\downarrow}$ is the daily incoming global radiation (*see* **Chapter 49, Estimation of Surface Insolation, Volume 2**) and L_{24} is daily net longwave radiation. The daily average albedo, α, and emissivity, ε, can be approximated easily with the same values as used previously in the energy balance equation.

By summing up the corresponding daily evaporation for a certain period, the actual evaporation for that period (i.e., a week, a month, or a year) can be determined. However, errors will occur due to cloud effects. Such effects can be further removed by using the time series processing or by data assimilation procedures. A schematic presentation of SEBS is given in Figure 3 for clarity of the steps involved.

SOME ISSUES IN THE APPLICATION OF SEBS

Difficulty in Determination of Aerodynamic Roughness Height

Aerodynamic roughness height (the displacement height is often related to it) influences greatly the turbulent characteristics near the surface where the heat fluxes originate. Currently, there are several methods that can be used for its determination as shown in Figure 4, including retrievals from wind profiles, which is probably the most accurate method but is limited to the local topographic and canopy structure and varies with wind speed (different fetch) and direction (for heterogeneous terrain). Other methods are based on either vegetation height or land-use

Table 1 Land-use classes in the PELCOM land-use database and associated z_{0m} values

	Land-use class	$z_{0m}(m)$

· Retrievals from wind profiles (Point values)

· z_{0m} = 0.136 *h (Vegetation height)

· Land use + look up table (z_{0m} per class) (e.g. in atmospheric models)

· z_{0m}~ Vegetation index relationships (e.g. z_{0m} = exp(A+B*NDVI))

· Land use + modelling (Hasager, Jensen, 1999)

· LIDAR measurements (e.g. Menenti, Ritchie, 1994)

· Vegetation canopy LIDAR ???

Figure 4 Summary of some methods used to determine the aerodynamic roughness height. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

classes, and assigning each class a nominal value, or using a relationship with vegetation index. One particular promising method is that of Hasager and Jensen (1999) that is able to consider the dynamic flow characteristics and actual land-use characteristics. Menenti and Ritchie (1994) showed that airborne LIDAR measurements of vegetation heights provided reliable determination of the aerodynamic roughness, so that a space-borne LIDAR system when available might be quite promising. An example for the aerodynamic roughness height for each classes of the PELCOM land-use map (Pan-European Land-Use and Land-Cover Monitoring, Mücher *et al.*, 2001) is given in Table 1. Table 2 shows the dependency of the aerodynamic roughness height on wind direction (different land surfaces) and season (summer or winter), and shows the uncertainties that might be encountered when using any of the methods indicated in Figure 4.

At any rate, despite great efforts in the past, the determination of aerodynamic roughness remains a challenging issue for large-scale applications both for remote sensing of surface turbulent heat fluxes and mesoscale and global-scale atmospheric modeling. Figure 5 shows a map of z_{0m} values for the Netherlands with values corresponding to Table 1.

Coupling with Large-Scale Numerical Weather Prediction Models

Owing to its flexibility in scaling between surface and atmospheric variables, SEBS can be easily coupled to the meteorological fields generated by a large-scale atmospheric model. A first attempt has been made by Jia *et al.* (2003) to couple model fields from a NWP model to radiometric measurements from the ATSR onboard the European Remote

Table 2 Effective roughness length (m), representative of a few kilometers of upstream terrain from the Cabauw tower in the Netherlands for 18 wind direction classes (degrees relative to North, after Beljaars and Bosveld, 1997)

Wind direction	0–20	20–40	40–60	60–80	80–100	100–120	120–140	140–160	160–180

Sensing Satellite (ERS-2). In order to validate the effectiveness of the approach, three Large Aperture Scintillometers (LAS) providing line-averaged measurements of sensible heat flux over path lengths from 1 km to 5.2 km are used. The instruments were located far apart at three locations in Spain over different combinations of land cover and hydrological conditions and were operated continuously from April through September 1999. The LAS were installed at sites near Lleida, Badajoz, and Tomelloso (Figure 6). Each scintillometer site is additionally equipped with a shortwave radiometer to measure global radiation. Additional data that are necessary for the processing of LAS data were obtained from weather stations in the near surroundings.

The scintillometer near Lleida is installed in a region with small-scale irrigation at an altitude of 130 m. Main crops are fruit trees (peaches) and alfalfa. The distance between transmitter and receiver is approximately 4690 m. Both receiver and transmitter are installed on a hill, on a tripod at a height of, respectively, 45 m and 39 m above the surface. Meteorological data are obtained from the meteorological station near Juneda (41°33'N 0°49.5'E).

The Badajoz LAS is located in a region with large-scale irrigation (sprinkler irrigation) at an altitude of 168 m. Crops being grown are wheat, corn, alfalfa, lettuce, olives, beans, and tomatoes. The distance between transmitter and receiver is 5250 m ± 200 m. The receiver is installed on top of a hill on a house, 68 m above the surrounding terrain. The transmitter is installed on a water tower, 56 m above the surrounding terrain. Meteorological data are obtained from a station with short grass ground cover some 7 km from the LAS receiver.

The landscape of the Tomelloso site comprises a nearly level, alluvial floodplain to the north and a tilted old alluvial plain to the south. The vegetation consists of nonirrigated vineyards and a few olive orchards. The vines are broadly spaced and trellises are not used. The distance between transmitter and receiver is 1070 m ± 40 m. Both receiver and transmitter are installed on a steel mast at a height of, respectively, 4.15 m and 4.56 m above the surface at an altitude of 670 m. Meteorological data are obtained from a meteorological station near Tomelloso (39°10'29.22 "N, 3°0'2.16"W). Ground cover of the station is bare soil and grass. Longwave and shortwave radiation data, both incoming and outgoing, are available from this meteorological station.

Sensible heat flux H is calculated using SEBS at the ATSR passing time for corresponding days at each experimental site. The meteorological fields of wind, potential temperature, and humidity of air were generated by an advanced NWP model, the Regional Atmospheric Climate Model (RACMO) (Christensen *et al.*, 1996), integrated over the PBL. This implies that a single value of the reference wind, potential temperature, and humidity of air is used for each model grid, that is, 25 km × 25 km, while

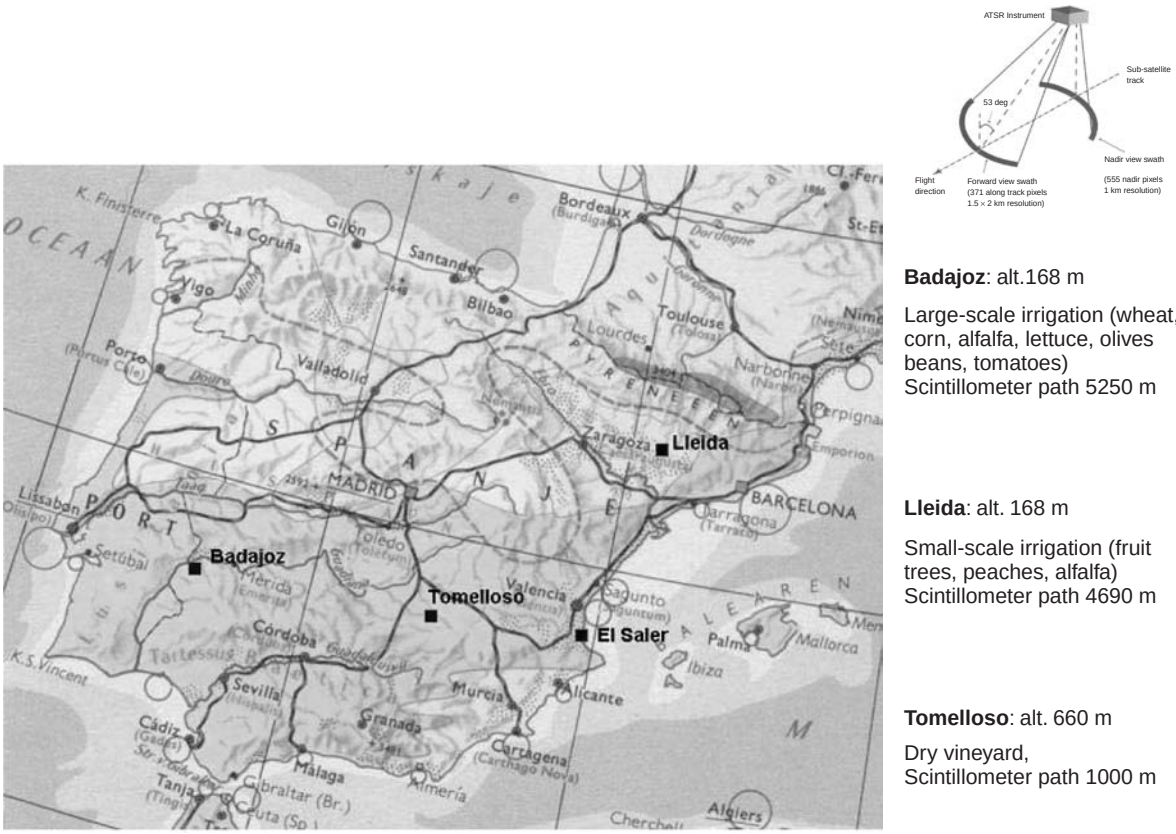

Figure 6 Location of the three study sites in Spain (ATSR data plus meteorological data from nearest stations) and their characteristics. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

the observations of vegetation properties have a resolution of 1 km × 1 km and account for sub-grid variability of land cover and hydrological conditions. The path lengths of the LAS measurements correspond to about five, six, and two ATSR pixels for the Lleida, Badajoz, and Tomelloso sites, respectively. The results from SEBS are quite comparable with the measurements as shown in Figure 7. In judging the validation results, it is important to keep the following issues in mind. First, the footprints in LAS measurements and in SEBS estimates are different. While the LAS-measured sensible heat flux is a line average along the path that only captures the contributions of turbulence from upwind direction over the averaging period, the SEBS estimates of sensible heat flux by using ATSR-measured surface variables and the NWP model-derived PBL variables are the average over a larger area, at least at ATSR pixel scale. Second, different temporal scales certainly contribute to the differences for the observed and estimated fluxes. Measurements from LAS are the mean values over 10 minutes, which represent the mixed turbulent characteristics and heat-exchange processes over the observation time, while a satellite only provides the instantaneous observations of surface variables at the satellite passing time. Moreover, if the surface shows large degree

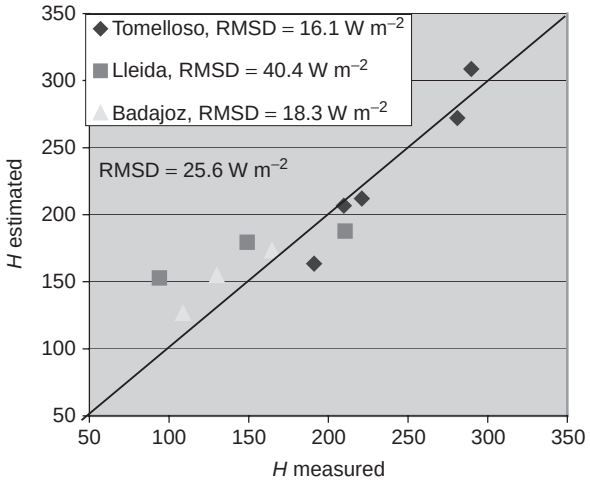

Figure 7 Comparison of sensible heat flux values between SEBS and LAS measurements at the three experimental sites. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

of heterogeneity, the determination of adequate pixels used to compare with the LAS-measured flux should be dealt with carefully.

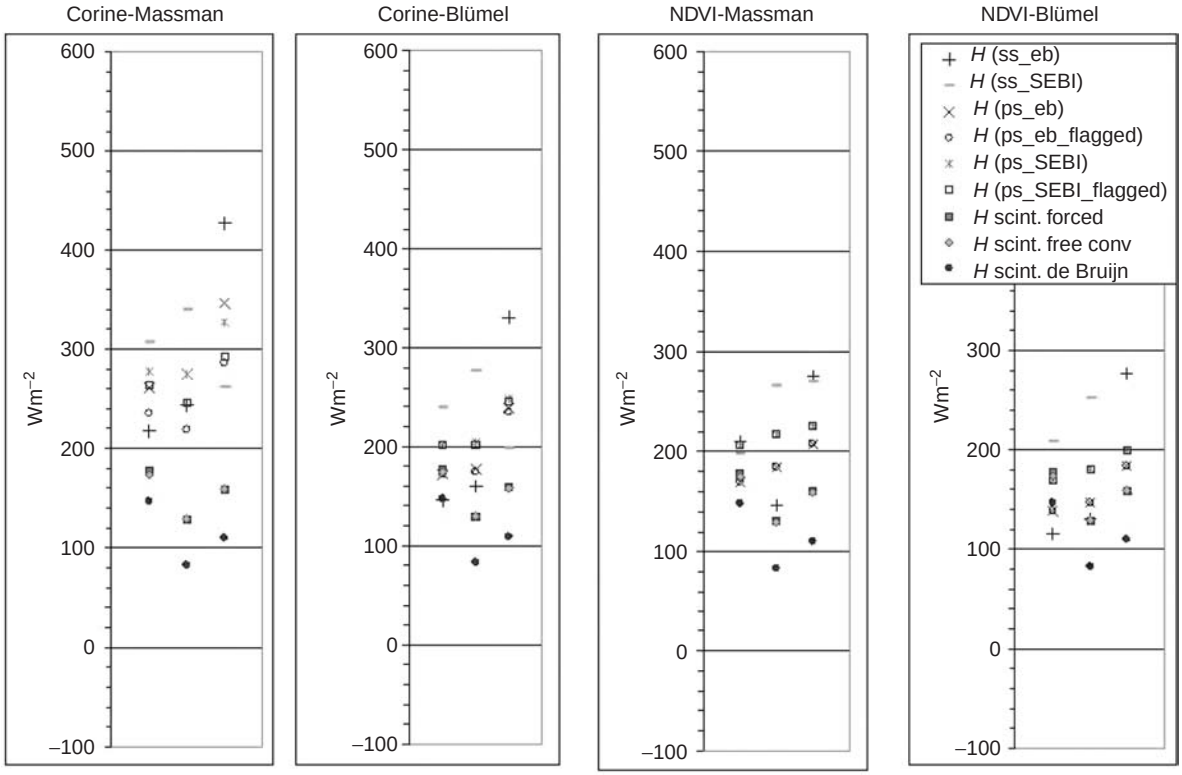

Figure 8 Results derived from both single-source and parallel-source SEBS for Badajoz site (Corine refers to aerodynamic roughness derived from Corine land use map; Massman refers to the thermal dynamic roughness model of Su *et al.*, 2001; Blümel refers to the thermal dynamic roughness model of Blümel (1999); NDVI refers to aerodynamic roughness derived with NDVI – Normalized Difference Vegetation Index; ss – single source; ps – parallel source; eb – sensible heat flux derived from the nonlinear equations; sebi – sensible heat flux derived on the basis of the SEBI concept; flagged – energy limits are applied, that is, SEBS; scint, Forced. scint, Free convection. scint, de Bruin refer to three different ways of estimation of sensible heat fluxes from scintillometer measurements). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Further details about the measurements can be found in Moene and De Bruin (2001); Moene (2001). For details on the scintillometer method, the reader is referred to De Bruin (2002), and more details of the comparison can be found in Jia *et al.* (2003).

Single-source SEBS versus Parallel-source SEBS

Essentially, the parameterization in single-source SEBS and parallel-source SEBS (see Figure 1 for details) are the same except in the case of the parallel-source SEBS, we first set the fractional cover of vegetation as unity and calculate the energy balance and turbulent heat-flux terms, then we do the same for soil by setting the fractional cover of soil as one, and finally we sum up the fluxes terms weighted by their actual fractional coverage.

Despite the simplicity of such a scheme, the results from the parallel-source SEBS are remarkably improved over the single-source SEBS as shown by Rauwerda *et al.* (2002) for three sites in Spain discussed above when the estimated turbulent heat fluxes are compared to scintillometer measurements (see Figures 8, 9 and 10) . The uncertainties caused by the different methods in determination of the roughness height for momentum are also amply demonstrated. It is also helpful to notice the differences in the LAS measurements derived from different processing methods. Further details on the comparison between single-source and parallel-source SEBS and ground measurements are given in Rauwerda *et al.* (2002).

Some SEBS Applications to Water Sources Management

Besides the results presented above, SEBS has been used for several studies for water resources management conducted recently. Examples are estimation of actual evaporation in a semiarid inland basin in Northwest China (Li, 2001; Su *et al.*, 2003a) and drought disaster monitoring (Su *et al.*, 2003b).

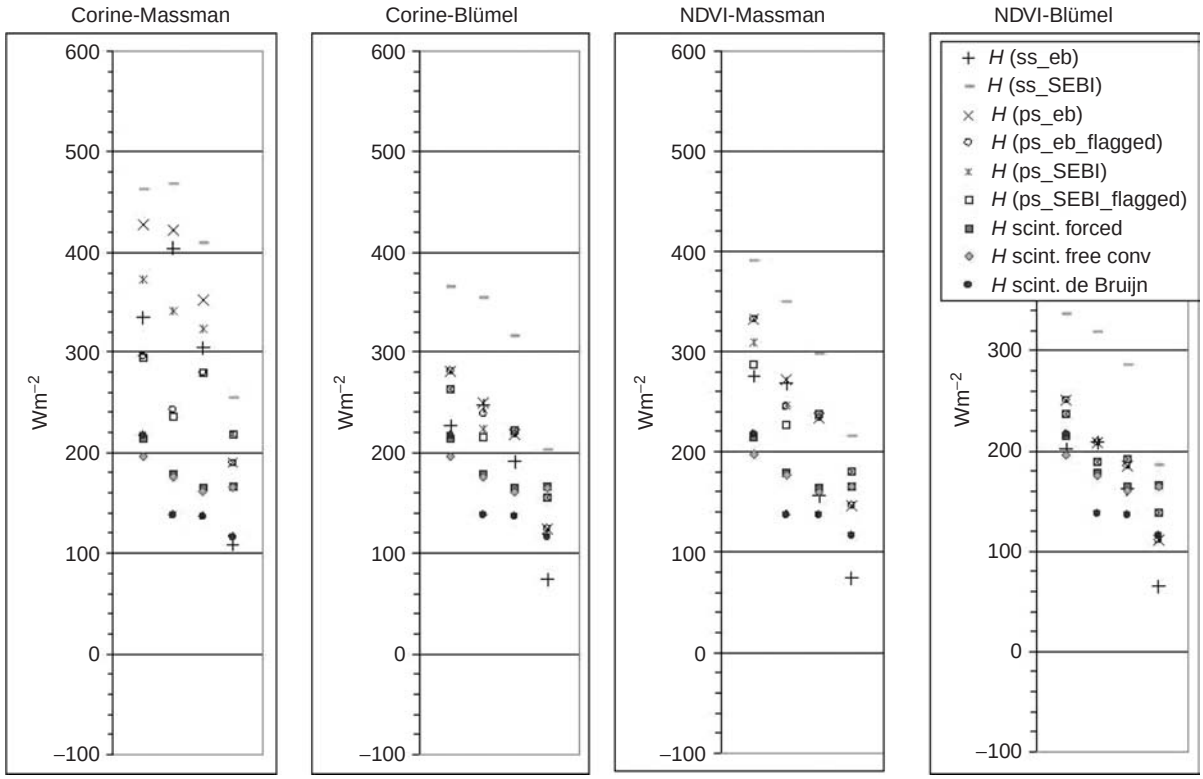

Figure 9 Results derived from both single-source and parallel-source SEBS for Lleida site (explanation of symbols is the same as for in Figure 8). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

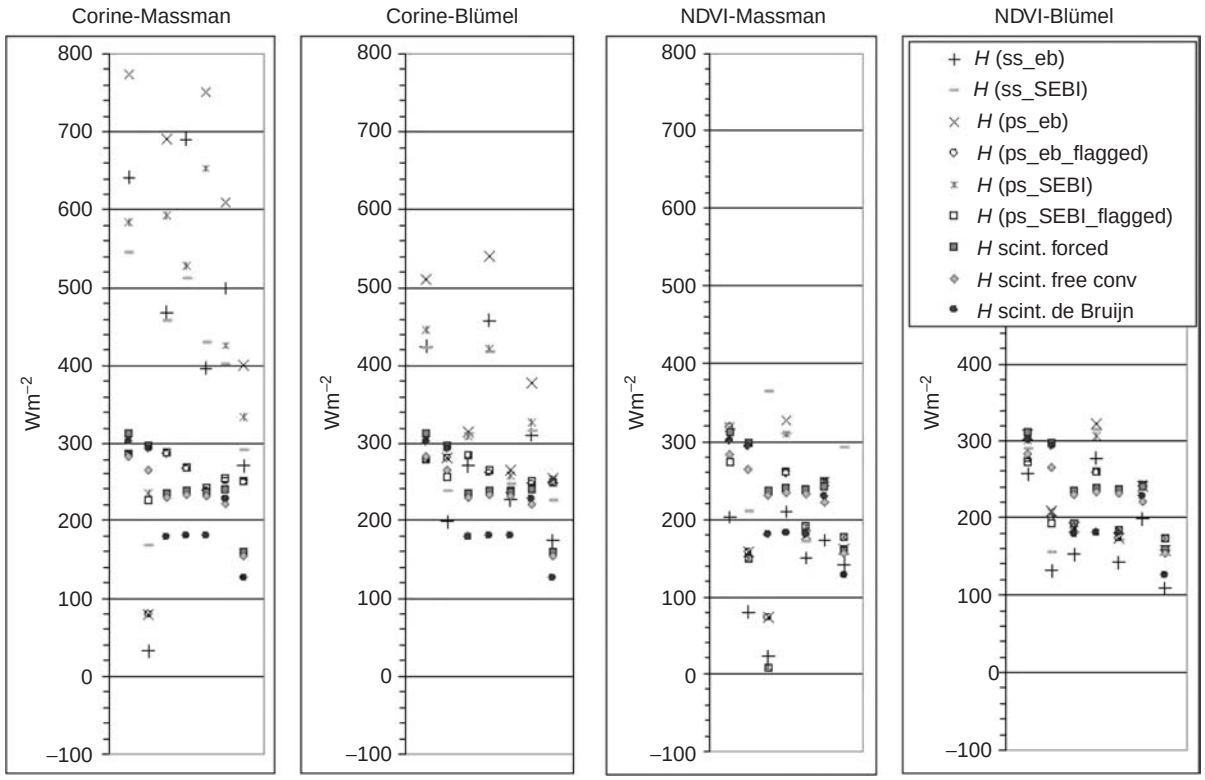

Figure 10 Results derived from both single-source and parallel-source SEBS for Tomelloso site (explanation of symbols is the same as for in Figure 8). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Estimation of Actual Evaporation in the Urumqi River Basin

SEBS is applied to Advanced Very High Resolution Radiometer (AVHRR) data for the estimation of actual evaporation in the Urumqi River Basin located in Xinjiang Uygar Autonomous Region in Northwest China. The Urumqi River Basin has all the features of a continental arid climate. Its diversity in topography offers a variety of land cover and vegetation. As such, the methodology and procedures developed for the Urumqi River Basin can be easily applied to other river basins in Northwest China and elsewhere in the world. Two water balance field experimental stations: Changji Station and Wulapo Station, equipped with routine meteorological instruments, evaporation pans of different sizes (E20, E60, and E5000), and lysimeters with different soils and vegetation types, provided sufficient information for calculation and verification. The size of the AVHRR data being processed for evaporation estimation was set between 86°38'E–88°59'E and 43°07'N-45°02'N, with a total area of about 27 800 km^2. Hundred-and-five scenes in 1995 covering the basin were downloaded from Satellite Active Archive, among which 12 scenes were carefully chosen for evaporation calculation. Meteorological information is derived from the Changji meteorological station including wind speed (m/s), relative humidity, potential air temperature (K), and surface air pressure (Pa), and is scaled to PBL variables using the logarithmic profiles.

Verifications of the derived evaporation are performed by comparing with evaporation from different types of land surface collected in intensive field surveys for water resources assessment of the Urumqi River Basin (Li, 2001). Comparison between the annual evaporation derived from SEBS against the field measurements shows that the estimated values agree very well with the ground data except for the midmountainous area. The reason for the large relative error for the mountainous area could be due to the input of average elevation during the calculation as well as the uncertainty associated with the field information. More details on this case study can be found in Li (2001).

Application of SEBS in Drought Monitoring

On the basis of SEBS, Su *et al.* (2003b) have proposed a method for assessing relative soil moisture with remote sensing data and have theoretically shown that the relative soil moisture in the rooting zone can be derived from relative evaporation. The relationship derived between the relative soil moisture and relative evaporation is confirmed with experimental data collected with lysimeter measurements in an eight-year-old orchard of peach trees (Girona *et al.*, 2002), and with measurements collected in an intensive field experiment in the Global Energy and Water Experiment (GEWEX) Asia Monsoon Experiment in Tibet (GAME/Tibet) in 1998 (Koike, 2000; Ma *et al.*, 2002). Further, it was shown that the proposed theory can be used to define a Drought Severity Index (DSI) for drought monitoring, with the relative evaporation determined with remote sensing data. A demonstration for the latter was performed for North China in 2000 using remote sensing data AVHRR and routine meteorological data obtained from the operational measurement network of the National Meteorological Center of China. In the growing season with low rainfall, the value of DSI was high, and in the reverse case, the DSI value was low, which demonstrates that the DSI is in accordance with the data of rainfall in time and can be used to quantify drought situation both in temporal and spatial scales. Spatially, the derived DSI could identify that the central, the Northern, and then the Southern part of Shanxi province suffer under severe drought conditions in decreasing drought intensity in 2000. Temporarily, low soil water deficit was identified in July and August in most parts of Shanxi province. Higher soil water deficit occurred in April, May, and September 2000 with decreasing degree of intensity. Comparisons between the estimated relative evaporation and the actual measurements of soil moisture confirmed the general validity and robustness of the proposed method, but more extensive validation with field measurements at regional scale is considered necessary to quantify the accuracy of the proposed DSI method.

In all applications, benefits when using radiometric measurements are clearly demonstrated.

Using SEBS in a Data Assimilation System Environment

A valuable first attempt in this direction has been made recently by Wood *et al.* (2003) who applied SEBS to the Southern Great Plains (SGP) region of the United States where the Atmospheric Radiation Measurement (ARM) program is carried out by the US Department of Energy. Energy Balance Bowen Ratio (EBBR) and Soil Water And Temperature System (SWATS) are also available at many ARM/Cloud And Radiation Testbed (CART) stations, and provide measurements of surface latent, sensible, and ground heat fluxes, as well as soil moisture and soil temperature. The surface meteorology used in SEBS is retrieved from the Eta Data Assimilation System (EDAS), while the solar radiation was processed by National Oceanic and Atmospheric Administration (NOAA/NESDIS) as part of the North American Land Data Assimilation System (NLDAS) (Mitchell *et al.*, 1999). The temperature product from the Moderate-Resolution Imaging Spectroradiometer (MODIS) on the Earth Observation Satellite (EOS) Terra was used to estimate the land surface temperature across the domain.

Measurements from the EBBR sites were compared with model-derived latent heat fluxes. For the 40 clear-sky days, an areal average instantaneous flux was calculated across the nine EBBR sites from the collocated SEBS pixels, with observations approximately 20% less than predictions.

Table 3 Statistics of estimated versus observed heat fluxes of the Cotton dataset of Kustas (1990) with different algorithms (Root mean-squared difference between estimated and measured fluxes (Wm^{-2}))

Method & reference	R_n	G_0	H	λE	No. of observations
Observed mean value ($W\,m^{-2}$)	561.74	140.37	116.63	304.74	19
RMSD for SEBS (Su, 2002, Table 1)	22.82	5.42	21.22	29.22	19
RMSD for Two-source model (Kustas and Norman, 1999, Table 3)	19	18	23	42	19
RMSD for Two-source model (Kustas and Norman, 1999, Table 4)	21	13	25	37	19
RMSD for Two-source model (Kustas and Norman, 1999, Table 5)	20	10	36	47	19

Such differences may be attributed to the uncertainties in SEBS, especially in the roughness parameterization as discussed previously, but may similarly be attributed to uncertainties in surface flux measurements, because comparisons among different measurement setups may easily produce discrepancies of up to 25% (e.g. Twine *et al.*, 2000). While there exists a systematic overprediction in the SEBS/MODIS estimates when compared to the EBBR data, the results are encouraging and indicate that the SEBS approach has promise in estimating surface heat flux from space for data assimilation purposes.

Results for SEBS and Other Techniques When Applied to Experimental Data Sets

In order to assess the accuracy of SEBS in comparison with some other techniques, results obtained with the same experimental data sets will be briefly discussed. Three field datasets obtained from flux stations that have been used extensively to benchmark surface energy balance algorithms (e.g. Norman *et al.*, 1995; Zhan *et al.*, 1996; Kustas and Norman, 1999; Su *et al.*, 2001; Su, 2002) will be used as examples. These three datasets are the Cotton dataset of Kustas (1990), the Shrub, and the Grass dataset of Kustas *et al.* (1994).

For the application of SEBS, the aerodynamic parameters are the model estimates as discussed in Su (2003). All other input variables are measured except the downward longwave radiation that is estimated with the Stefan-Bolzmann radiation equation with the measured air temperature at the reference height. The parameterization used in SEBS is meant to be site-independent and, therefore, there is no site-specific adjustment or optimization involved. The details of the application of the other techniques are given in Kustas and Norman (1999) and Zhan *et al.* (1996) with some different site-specific parameterizations involved. The latter has evaluated four different techniques using the same data sets.

Table 3 shows the statistics of estimated versus observed heat fluxes of the Cotton dataset of Kustas (1990) with SEBS and the two-source model of Norman *et al.* (1995) using three different parameterizations (Kustas and Norman, 1999). Given the observed mean values of the net radiation, soil heat flux, sensible heat flux, and latent heat flux, the uncertainties of the estimated values (here expressed as the ratio of the root mean squared difference (RMSD) between the estimated and the observed values) are all within 20% of the mean observed values, except the sensible heat flux for the last row, which reaches 30% of uncertainty. The higher uncertainty in the latter case was due to the use of explicit soil and vegetation component temperatures and might be considered as an indication that the used two-source model needs some modification in order to be able to take advantage of the availability of the component temperatures. It should be noticed that an uncertainty of 20% or less in the estimated turbulent heat fluxes represents the best case that can be achieved given the uncertainties in all the involved parameters and variables in the algorithms as well as the uncertainties in the measured turbulent heat fluxes. More details on the uncertainty analysis can be found in Su (2002).

Tables 4 and 5 display the statistics of estimated versus observed heat fluxes of the Shrub and the Grass dataset of Kustas *et al.* (1994) for SEBS and four different algorithms, including the two-source model of Norman *et al.* (1995). The accuracy of SEBS are comparable to the best case analyzed by Zhan *et al.* (1996), who only reported the statistics for the sensible heat fluxes estimated with the four different algorithms. It is worthwhile to point out that while in SEBS all the available data in the two datasets are used (320 and 281 observations, respectively), the application of the four other algorithms were restricted to well-developed unstable atmospheric surface layer by excluding the more problematic transitions periods and night-time observations (114 and 103 observations, respectively).

Table 4 Statistics of estimated versus observed heat fluxes of the Shrub dataset of Kustas *et al.* (1994) with different algorithms (Root mean-squared difference between estimated and measured fluxes ($W\ m^{-2}$))

Method (Reference)	R_n	G_0	H	λE	No. of observations
SEBS (Su, 2002, Table 2)	35.11	46.29	28.61	82.79	320
Single-source model of Kustas *et al.* (1989) (Zhan *et al.*, 1996, Table 6)	–	–	33	–	114
Single-source model of Troufleau *et al.* (1997) (Zhan *et al.*, 1996, Table 6)	–	–	48	–	114
Dual-source model of Lhomme *et al.* (1994) (Zhan *et al.*, 1996, Table 6)	–	–	52	–	114
Dual-source model of Norman *et al.* (1995) (Zhan *et al.*, 1996, Table 6)	–	–	33	–	114

Table 5 Statistics of estimated versus observed heat fluxes of the Grass dataset of Kustas *et al.* (1994) with different algorithms (Root mean-squared difference between estimated and measured fluxes ($W\ m^{-2}$))

Method (Reference)	R_n	G_0	H	λE	No. of observations
SEBS (Su, 2002, Table 3)	41.26	42.95	36.19	61.34	281
Single-source model of Kustas *et al.* (1989) (Zhan *et al.*, 1996, Table 7)	–	–	41	–	103
Single-source model of Troufleau *et al.* (1997) (Zhan *et al.*, 1996, Table 7)	–	–	33	–	103
Dual-source model of Lhomme *et al.* (1994) (Zhan *et al.*, 1996, Table 7)	–	–	124	–	103
Dual-source model of Norman *et al.* (1995) (Zhan *et al.*, 1996, Table 7)	–	–	34	–	103

From the above evaluations, it might be concluded that SEBS can be applied to different sites and different atmospheric stability situations while maintaining the same parameterizations. This might prove important and critical when application to large scale is desired where no sufficiently detailed information on the site characteristics or the local atmospheric stability regime is available.

DISCUSSION AND CONCLUSIONS

In this article, a brief introduction in estimation of radiation and turbulent heat fluxes using radiometric observations is given. In general, after the derivation of sensible heat flux, it is possible to estimate the latent heat flux as a residual by means of the energy balance equation, as was done in many other studies (e.g. Kalma and Jupp, 1990). However, the associated uncertainty in the derived latent heat flux and consequently in the evaporative fraction is large. This is because the sensible heat flux is, under given surface conditions, determined solely by the surface temperature and the meteorological conditions at the reference height and is not constrained by the available energy. If the surface temperature or the meteorological variables have large uncertainty, a straight propagation of such uncertainty into the resultant latent heat flux and evaporative fraction cannot be avoided. In the SEBS formulation, this uncertainty is limited by consideration of the energy balance at the limiting cases, because the actual sensible heat flux is constrained in the range set by the sensible heat flux at the wet limit derived from a combination equation, and the sensible heat flux at the dry limit set by the available energy. In this aspect, SEBS is similar to previous algorithms that estimate relative evaporation by means of an index (e.g. the CWSI) using a combination equation (Jackson *et al.*, 1981, 1988; Menenti and Choudhury, 1993; Moran *et al.*, 1994). However, none of these previous algorithms incorporated explicitly the formulation of the roughness height for heat transfer, instead they used fixed values. Since the roughness height for heat transfer can vary with geometrical

and environmental variables in several orders of magnitude for different surface types, this ignorance has been shown by several studies to cause great uncertainties in estimation of heat fluxes or evaporation using radiometric temperature measurements (e.g. Verhoef *et al.*, 1997; Su *et al.*, 2001). Although it is possible to calibrate these algorithms such that their estimates reproduce observations at local scale, it would be very difficult to extend them to regional/continental studies by means of satellite observations. These shortcomings are avoided in SEBS. In addition, the application of SEBS does not require any *a priori* knowledge of the actual turbulent heat fluxes, indicating that SEBS is a credible and independent approach. Due to this property, SEBS results may be used for validation and initialization of hydrological, atmospheric, and ecological models that usually require proper partition of the sensible and latent heat flux at different scales. SEBS results can also be used *via* data assimilation in the above models to increase the reliability of the model simulations and predictions. Another valuable approach would be to implement the representation of surface flux exchanges as described in SEBS into a data assimilation system for assimilating remote-sensing data using modern data assimilation techniques. Some initial encouraging attempts have been made recently by Jia *et al.* (2003) and Wood *et al.* (2003) in this direction.

The examples on the use of parallel-source SEBS clearly indicate the benefit to be gained when more detailed measurements of the state of the land surface can be made. Currently, it has been possible to separate several important variables into their components, for example, the temperature of soil and that of vegetation using currently available sensors (e.g. ATSR and AATSR – the Advanced ATSR on the ENVISAT satellite). By means of multidirectional and multispectral to hyperspectral measurements, it would also be possible to derive more detailed component variables, for example, the temperature of soil and that of vegetation separately for sunlit and sun-shade portions using future available sensors. Use of these variables in algorithms will enable much detailed description of the physical processes involved in land–atmosphere interactions.

In summary, it may be stated that advances on improving parameterization and predictability of hydrological and earth system models, in particular, physically based distributed models, will heavily rely on the understanding of physical processes at different scales as well as the ability to obtain distributed physical information, satellite earth observation will prove of paramount importance in the future. Understanding and quantification of radiation and latent and sensible heating through quantitative remote sensing may hold the key to understand the interaction of terrestrial ecosystems and the hydrological cycles from local to global scales, and as such shall meet the challenges in research and applications in areas ranging from numerical weather forecast, climate research, water cycle study, to water resources management, sustainable agricultural production, and ecological conservation.

Acknowledgments

Researches leading to the work presented here were jointly funded by the Dutch Remote Sensing Board (BCRS), the Dutch Ministry of Agriculture, Nature Management, and Fisheries (LNV), and the Royal Netherlands Academy of Science (KNAW). The author has benefited greatly from discussion and debates with many colleagues. In particular, assistance and constructive comments from Li Jia, Jun Wen, Han Rauwerda, Gerbert Roerink, Katja Sintonen and Claire Jacobs (Alterra), Massimo Menenti and Zhao-Liang Li (TRIO/ULP), Bart van den Hurk (KNMI), Jieming Wang and Yaoming Ma (CAREERI/CAS), Henk de Bruin and Arnold Moene (WU), Renhua Zhang and Xiaoming Sun (IGSNRR/CAS), Xiaomei Li and Li Wan (China University of Geosciences), Tom Schmugge and Bill Kustas (USDA/ARS), Bill Massman (USDA/FS), Wilfried Brutsaert (Connell University), Jetse Kalma (The University of Newcastle) and Eric Wood (Princeton University) are gratefully appreciated.

51: Spatially Resolved Measurements of Evapotranspiration by Lidar

WILLIAM E EICHINGER

IIHR Hydroscience and Engineering, University of Iowa, Iowa City, IA, US

Spatially resolved estimates of evapotranspiration may be made over an area of about a square kilometer, with relatively fine (25 m) spatial resolution, derived from three-dimensional measurements of water vapor concentration made by a scanning Raman lidar. The method is based upon the Monin–Obukhov similarity theory applied to spatially and temporally averaged data. The method has been applied at several locations to produce maps of the spatial distribution of evapotranspiration rates at regular intervals throughout the day. The estimates of evapotranspiration rates made compare favorably with estimates made using eddy correlation methods. The method is limited in that it assumes that the surface roughness, friction velocity, and Obukhov length are assumed constant over the examined areas. Values for the friction velocity and Obukhov length are required from conventional point instruments. The three-dimensional water vapor concentration and the evaporation maps can be used in a wide variety of ways to study the spatial variations in evapotranspiration caused by changes in soil type and moisture content, canopy type, and topography.

INTRODUCTION

Evapotranspiration is one of the critical variables in both the water and energy balance models of hydrologic systems. These systems as well as the local weather are driven by the way in which energy is partitioned at the earth's surface. This partitioning is determined by the conditions at the soil–plant–atmosphere interface and are often highly spatially variable. Traditional techniques of measuring evapotranspiration rely on point sensors to collect information, which is then assumed to be representative of a much larger area. However, data from individual point sensors near the surface are of limited value. This is due to their relatively small footprint, the necessarily limited number of sensors, and our current inability to extend the values measured at a point (or series of points) to understanding the details of processes that are occurring on larger scales. Part of the problem is that the bulk of the earth's surface is not horizontally homogeneous with respect to topography, soil moisture availability, soil type, or canopy characteristics. More highly resolved information is necessary to separate the contributions of each of these variables. Eddy correlation techniques using fast-response sensors have been successfully used from aircraft to cover large areas, but the usefulness of the data has been called into question for use in mixed canopies where spatially resolved fluxes are desired (for example, Mahrt, 1998). It is possible to obtain spatially resolved evapotranspiration estimates from surface temperature measurements made by aircraft (Neale *et al.*, 2001) or satellite (Moran *et al.*, 1989; Anderson *et al.*, 1997, 2004). These measurements also require supporting meteorological information and require assumptions of local homogeneity and surface roughness characteristics.

The three-dimensional scanning Raman lidar (laser radar) built by Los Alamos National Laboratory (LANL) can provide detailed maps of the water vapor concentration in three dimensions with high spatial (approximately 1.5 m) and temporal resolution (approximately 15 min to scan a field). A method has been developed to estimate spatially resolved evaporative fluxes over the scanned area using this information. A description of the method used to measure the water vapor concentrations is followed by the details of the method used to determine the evapotranspiration rates from the water vapor concentration.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

MEASUREMENT OF WATER VAPOR

There are two methods by which lidars can measure spatially resolved water vapor concentrations. The first uses Raman scattering from nitrogen and water vapor molecules in the atmosphere (Kovalev and Eichinger, 2004). The second is the differential absorption lidar (DIAL) method that uses the difference in absorption between two laser wavelengths, one of which is tuned to an absorption line of the molecule of interest (Measures, 1984).

Raman Lidar Method

Raman lidars are a type of laser radar that use a technique originally pioneered by Cooney *et al.* (1969), Cooney (1970), and Melfi *et al.* (1969). A Raman lidar operates by emitting a pulsed laser beam, usually in the ultraviolet or near ultraviolet, into the atmosphere. Atmospheric gases, such as nitrogen, oxygen, and water vapor absorb this light via the Raman scattering process, causing light of longer wavelengths to be emitted. The amount of the wavelength shift is unique to each molecule. For example, the light scattered by nitrogen is shifted by $2331\,\mathrm{cm}^{-1}$ from the laser wavelength. This enables the measurement of different atmospheric gases by this technique. Figure 1 is a plot of the spectrum of light returning from an emitted 248-nm pulse, showing the peaks from the major atmospheric constituents. Because of the small value of the backscatter cross sections for Raman scattering, the number of photons returning to the lidar is small. Since the probability of Raman scattering is proportional to λ^{-4}, the use of short wavelengths increases the magnitude of the signal. Modern Raman lidars are typically found at ultraviolet wavelengths, particularly at 248 nm (KrF excimer), 266 nm (quadrupled Nd : YAG), 308 nm (XeCl excimer), 351 nm (XeF excimer), and 355 nm (tripled Nd : YAG).

The LANL Raman lidar (shown schematically in Figure 2, photograph in Figure 3) is a typical Raman lidar. In this lidar, the laser is mounted below the telescope. A series of mirrors and lenses is used to expand the beam to make it eye-safe and collinear with the telescope. A forty-five-degree mirror is used to change the optical direction to vertical, allowing the system to make vertical soundings. The scanning mirror enables the system to perform three-dimensional scanning near the earth's surface. At the back of the telescope, the light at the two Raman-shifted wavelengths (from nitrogen and water vapor) is separated and directed to different photomultipliers using a series of dichroic beam splitters. Narrow band interference filters are used to further block unwanted wavelengths of light going to each photomultiplier.

Because of the small cross section for Raman scattering, the number of photons returning to the lidar is small so that photon counting is required to achieve meaningful

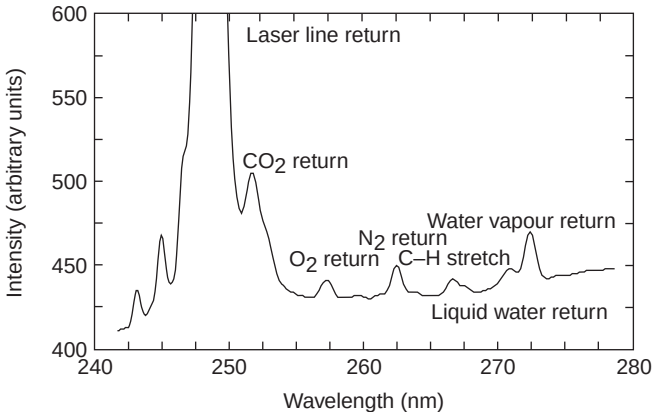

Figure 1 A plot of the spectrum of light returning from a 248 nm Raman lidar showing the peaks from the various atmospheric constituents

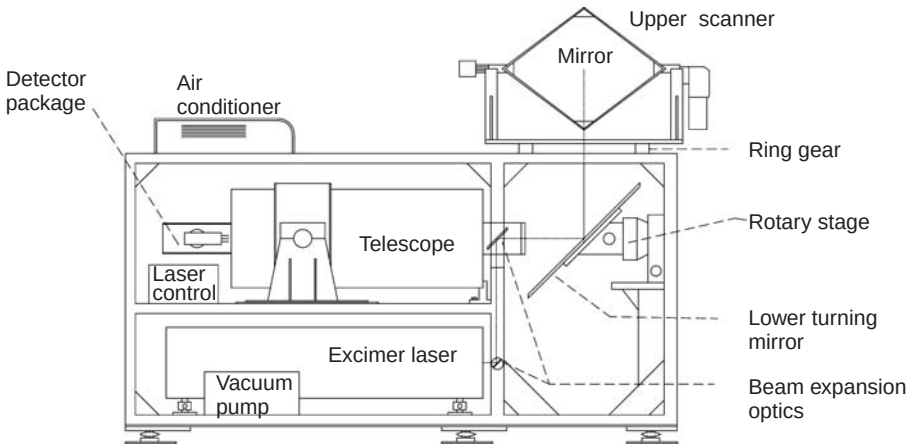

Figure 2 Diagram showing the layout of the Los Alamos Raman lidar. With the exception of the scanning mirror, the arrangement is typical of Raman lidars

Figure 3 Photograph of the LANL Scanning Raman Lidar

signals at long ranges (greater than 1 km). The discrimination of these photons from background light is another issue that must be addressed. To work during the day, many systems operate in the region of the spectrum below about 300 nm where ozone and oxygen strongly absorb sunlight and are thus "blind" to solar photons. Daytime, solar-blind operation for Raman lidars was developed by Renault *et al.* (1980), Cooney *et al.* (1985), and Renault and Capitini (1988). Solar-blind operation requires the use of a laser near 250–260 nm so that the Raman-shifted lines will be below 300 nm. The use of a laser with a wavelength longer than 266 nm will have contamination from sunlight at the Raman-shifted wavelengths. The use of laser wavelengths shorter than 248 nm will be so strongly absorbed by ozone and oxygen absorption at both the emission and Raman-shifted wavelengths that long-range use is not possible. Since wavelengths longer than 300 nm are not strongly absorbed by atmospheric ozone, and molecular scattering is reduced at longer wavelengths, much greater ranges are possible with the use of longer wavelength lasers. However, if the system is expected to operate during the day, the use of an extremely narrow field of view in the receiving telescope is required along with spectrally narrow filters. While several nonsolar blind systems have been built (Cooney, 1983; Ansmann *et al.*, 1992; Goldsmith *et al.*, 1998), there are a multitude of technical issues that make them quite difficult, particularly for use in the boundary layer. Because of the limited amount of returning light, Raman lidar systems tend to use large, powerful lasers and large telescopes so that systems are unusually large and require significant amounts of power. Figure 3 is a photograph of the LANL Scanning Raman lidar mounted on its trailer. The size and power requirements of such systems restrict where they can be used and make them difficult for use in the field.

At least in part because of the limitations of photon counting, most Raman lidars operate in a vertically staring mode. Currently, the two exceptions are the NASA Goddard Space Flight Center (GSFC) Raman lidar (Ferrare *et al.*, 1998), which can scan in a vertical plane, and the LANL Scanning Raman Lidar (Eichinger *et al.*, 1999), which can scan in three dimensions. The GSFC Raman lidar operates primarily in a staring mode along different elevation angles. Operating at various angles to the ground enables the system to achieve higher vertical resolution at low altitude. The typical maximum horizontal range for the LANL lidar, when not using a photon counting mode, is approximately 700 m when scanning, with a corresponding spatial resolution of 1.5 m over that distance. The upper scanning mirror allows three-dimensional scanning of 360 degrees in azimuth and ±22 degrees in elevation.

The backscattered signals from the nitrogen and water vapor Raman scattering are given by the following equations:

$$P_{N_2}(r) = \frac{C_{N_2} E n_{N_2}(r) \sigma_{N_2} \times \exp\left[-\int_0^r [\kappa_t(r', \lambda) + \kappa_t(r', \lambda_{N_2,R})]\, dr'\right]}{r^2}, \tag{1}$$

and

$$P_{H_2O}(r) = \frac{C_{H_2O} E n_{H_2O}(r) \sigma_{H_2O} \times \exp\left[-\int_0^r [\kappa_t(r', \lambda) + \kappa_t(r', \lambda_{H_2O,R})]\, dr'\right]}{r^2} \tag{2}$$

where λ is the laser wavelength, $\lambda_{N_2,R}$ and $\lambda_{H_2O,R}$ are the Raman N_2 and H_20 scattered wavelengths, respectively. Note that the Raman scattered wavelengths in the above equations have different values, $\lambda_{N_2,R}$ for nitrogen and $\lambda_{H_2O,R}$ for water vapor. The functions $P_{N_2}(r)$ and $P_{H_2O}(r)$ are the received signals in the nitrogen and water vapor channels, E is the laser energy per pulse; σ_{N_2} and σ_{H_2O} are the Raman backscatter cross sections for the laser wavelength; r is the distance from the lidar; $n_{N_2}(r)$ and $n_{H_2O}(r)$ are the number density of nitrogen and water molecules at range, r; $\kappa_t(r, \lambda)$, $\kappa_t(r, \lambda_{N_2,R})$, and $\kappa_t(r, \lambda_{H_2O,R})$ are the total extinction coefficients at the laser wavelength, λ, and at the Raman-shifted wavelengths of nitrogen and water vapor molecules; and C_{N_2} and C_{H_2O} are the system coefficients that take into account the effective area of the telescope, the transmission efficiency of the optical train, and the detector quantum efficiency at the Raman-shifted wavelengths.

The principal advantage of the Raman lidar technique lies in having an additional signal from a ubiquitous atmospheric gas (specifically nitrogen or oxygen) in addition to the water vapor signal and the conventional elastic signal. This signal can be used to normalize the signal from water vapor. The backscatter coefficient from a particular

molecule is proportional to the gas density with altitude. The nitrogen density is known or can be calculated from temperature and pressure measurements, which in turn can be obtained from meteorological balloons or climatological data. The extinction coefficients at the emitted and Raman scattered wavelengths in the exponent term of equations (1) and (2), $\kappa_t(h, \lambda)$, $\kappa_t(h, \lambda_{N_2,R})$, and $\kappa_t(h, \lambda_{H_2O,R})$, are nearly the same if the Raman shift is small.

The mixing ratio of any gas is the mass of gas divided by the mass of the dry air in a given volume. A combination of equations (1) and (2) allows determination of the water vapor mixing ratio as a function of distance from the lidar. The mixing ratio can be obtained from the ratio of the signal magnitude in the water vapor channel, $P_{H_2O}(r)$, to the magnitude of the signal in the nitrogen channel, $P_{N_2}(r)$, using the formula (Melfi, 1972),

$$q_w(r) = \frac{P_{H_2O}(r)}{P_{N_2}(r)} \left[\frac{C_{N_2}\sigma_{N_2}n_{N_2}}{C_{H_2O}\sigma_{H_2O}n_{H_2O}fr_{N_2}} \right] \exp\left[\int_0^r [\kappa_t(r', \lambda_{N_2,R}) - \kappa_t(r', \lambda_{H_2O,R})]\, dr' \right] \quad (3)$$

where fr_{N_2} is the fractional N_2 content of the atmosphere (0.78084). Thus, the water vapor mixing ratio at any distance, r, is given by the ratio of the magnitude of the signal in the water vapor channel to the magnitude of the signal in the nitrogen channel, a multiplicative constant (the part in large square brackets), and an exponential correction due to the difference in extinction between the nitrogen-shifted and water vapor–shifted wavelengths. The multiplicative constant can be determined by comparison of the lidar signal with radiosondes (although there are issues with respect to the accuracy of the humidity sensors at low concentrations (Connell and Miller, 1995; Ferrare *et al.*, 1995; Sherlock *et al.*, 1999) or by aiming the lidar horizontally and comparing with calibrated water vapor point sensors at various distances from the lidar.

When the lidar aims along a given line of sight, data are obtained every 1.5 m along that line. By aiming the lidar in a series of different directions, a two or three-dimensional map of the water vapor concentrations can be assembled. Figure 4 is a conceptual drawing showing how the various lidar lines of sight are used to scan the area and produce an image such as the one shown in Figure 5. Figure 5 is a typical scan from the LANL Raman lidar showing the water vapor concentration in a vertical plane above a cornfield in Iowa during the Soil Moisture-Atmospheric Coupling Experiment (SMACEX) (details of SMACEX can be found in Kustas *et al.* (2004)). The dark grey color at the bottom is a result of the attenuation of the laser beam by the ground or canopy (in this case, corn). The change in the lidar signal as it reaches the canopy top enables one to determine the shape and orientation of the surface.

Uncertainty

The uncertainty in the values for the mixing ratio is a strong function of distance from the lidar. Details of the derivation of the uncertainty for Raman lidar water vapor estimates can be found in Eichinger *et al.* (2000). For a mid-range distance (~350 m), the estimated uncertainty is approximately 3.6%. This is consistent with the comparisons of lidar and calibrated references over land surfaces along horizontal paths. The standard deviation between the lidar and capacitance hygrometer data taken at concurrent times and locations was found through regression to be $\pm 0.34\,g\,kg^{-1}$. A large part this uncertainty is due to significant differences between the lidar

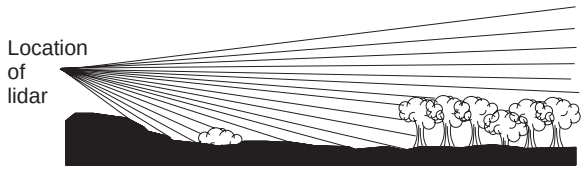

Figure 4 A conceptual drawing showing how different lines of sight from the lidar are combined to map the water vapor concentration in a vertical slice of the atmosphere. The water vapor concentration is determined every 1.5-m along each of the lines shown. The lines of sight in actual practice are 0.07 to 0.25 degrees apart

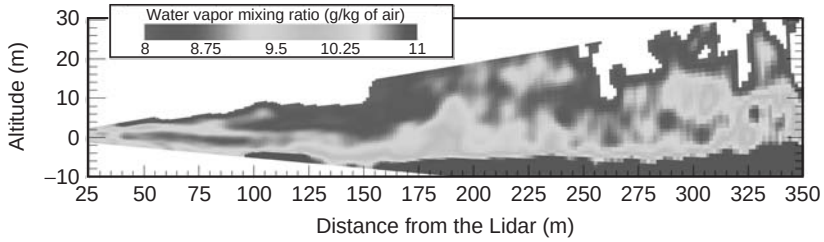

Figure 5 A vertical scan from the Raman lidar showing the water vapor concentrations in a plane perpendicular to the ground over a cornfield in Iowa during SMACEX. Lighter colors represent highest water concentrations and dark grey represent the lowest concentrations. The approximately horizontal dark grey zone at the bottom of the figure is the top of the corn canopy. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

and hygrometers that occur in regions where the water vapor concentration changes dramatically. In these regions, the slower time resolution of the capacitance hygrometer "averages" the changes in atmospheric structure as compared to the higher resolution lidar data (Cooper *et al.*, 1996).

Differential Absorption Lidar Method

The choice of a Raman lidar to scan and determine spatial water vapor concentrations is unusual. This type of lidar is most often used for high altitude water vapor measurements using photon counting techniques with relatively poor range resolution. The main competitor to the use of Raman systems is the DIAL method. In this method, two different, but closely spaced, wavelengths of laser light are used. One wavelength is absorbed by the molecule of interest, the other is not. Because the two wavelengths are nearly the same, their atmospheric transmission properties are similar, except for the amount of absorption by the molecule of interest. Thus, any differences in the intensity of the returning light can be used to determine the range resolved concentrations. The water vapor concentration is proportional to the logarithm of the ratio of the lidar returns at the two wavelengths, the distance over which the attenuation occurs (which is the range resolution) and the absorption coefficient of the particular molecular absorption line used. Many of these types of lidars have been or are in use (for example, Higdon *et al.*, 1994; Ehret *et al.*, 1993; Hinkley, 1976). DIAL systems have a number of inherent advantages over Raman lidars. They are generally smaller, lighter, and use considerably less energy than Raman systems. They are especially well suited for use in aircraft because they rely on atmospheric backscatter, which increases with range in a downward looking system, and thus partially compensates for the r^{-2} decrease in signal with range. Because of the strong atmospheric attenuation of UV and near UV light, DIAL systems in the near-infrared are better suited for deep atmospheric sounding. Both systems must average the return from large numbers of laser pulses to obtain data with sufficient statistical significance. However, high energy (250–400 mJ per pulse) excimer lasers with pulse rates of 200 Hz are common. In contrast, the materials commonly used in water vapor DIAL systems (flashlamp or Nd : YAG pumped dyes, alexandrite, and Ti : Sapphire lasers) have inherent limitations on the pulse rates that limit high power systems to 10 to 50 Hz. Thus, Raman systems have the potential for better temporal resolution. While the range resolution of DIAL systems is dependent upon the strength of the absorption feature used, existing systems have range resolutions on the order of 15 to 500 m, which makes them unsuitable for the evapotranspiration technique described here which requires high spatial resolution measurements near the surface. An excellent discussion of the relative technical merits of each type of system can be found in Grant (1991).

DIAL systems have been used to estimate the evaporative flux. A combination of lidar measurements at some point in the middle of the atmospheric boundary layer and measurements of the vertical wind velocity have been used to make an eddy correlation estimate of the evaporative flux. Kiemle *et al.* (1997) used an airborne DIAL system to estimate the entrainment flux at the top of the boundary layer. Senff *et al.* (1994) used a DIAL lidar along with a radar RASS system to obtain the vertical wind velocity. Geiz *et al.* (1999) used a DIAL lidar along with a Doppler lidar to measure the vertical wind velocity. As the height of the measurement increases, the rate at which measurements must be made decreases. The rate at which measurements need to be made must be fast enough to capture all of the frequencies that contribute to the flux (Brutsaert, 1982). In the middle of the boundary layer (300 to 1000 m above the surface), the required data collection rates begin to match those that a DIAL lidar and a RASS system can achieve. It could be argued that, in this situation, DIAL lidars will certainly capture the motion of the large structures that transport the bulk of the water vapor. One of the issues associated with the use of multiple remote sensors, with different divergences, in this way is ensuring that both instruments are measuring the same volume of air.

LIDAR-DERIVED FLUX METHOD

Monin–Obukhov Similarity

The water vapor concentration in the vertical direction can be described using the Monin–Obukhov Similarity Method (MOM) (Brutsaert, 1982). With this theory, the relationship between the water vapor concentration at the surface and that at some height, z, within the inner region of the boundary layer is

$$q_s - q(z) = \frac{E}{L_e k u_* \rho}\left[\ln\left(\frac{z-d_0}{z_{ov}}\right) - \psi_v\left(\frac{z}{L}\right)\right] \qquad (4)$$

where the Obukhov length, L, is defined as:

$$L = -\frac{\rho {u_*}^3}{kg\left[\dfrac{H}{Tc_p} + 0.61E\right]} \qquad (5)$$

where z_{0v} is the roughness length for water vapor; q_s is the surface-specific humidity; T, is the atmospheric temperature; $q(z)$ is the specific humidity at height z; H is the sensible heat flux; E is the latent energy flux (the evapotranspiration rate in Joules); ρ is the density of the air; L_e is the latent heat of evaporation for water; u_* is the friction velocity (Brutsaert, 1982); k is the von

Karman constant (taken as 0.40); d_0 is the displacement height; and g is the acceleration due to gravity. Ψ_v is the Monin–Obukhov stability correction function for water vapor and is calculated for unstable conditions as

$$\psi_v\left(\frac{z}{L}\right) = 2\ln\left[\frac{(1+x^2)}{2}\right]$$

where

$$x = \left(1 - 16\frac{z}{L}\right)^{1/4}$$

and where x_{ov} represents the function x calculated for the value of z_{ov}. The roughness length is a free parameter to be calculated based upon the conditions onsite. The Obukhov length, L, is negative when the atmosphere is unstably stratified. This kind of condition occurs when the soil/canopy is warmer than the air above, causing convective mixing to occur. The value of L is positive when the atmosphere is stably stratified. In this case, the potential temperature increases with altitude, suppressing vertical transport. L is infinite in a neutral atmosphere, when the potential temperature is constant with altitude. This condition normally occurs only in the transition from day to night or night to day but may occur when the winds are exceptionally still.

Heat and momentum fluxes are often determined from measurements of temperature, humidity, and wind speed at two or more heights. These relations are valid in the inner region of the boundary layer where the atmosphere reacts directly with the surface. This region is limited to an area between the roughness sublayer (the region directly above the surface roughness elements) and extending to a height of 5 to 30 m above the canopy top. The concentrations of passive scalars are semilogarithmic with height in this region. The vertical extent of this layer is highly dependent upon the local conditions and wind velocity. The top of this region can be readily *identified by* a departure from the logarithmic profile near the surface. Figure 6 is an example of a water vapor profile with a logarithmic fit showing such a departure at approximately 6 m above the canopy top. The suggestion has been made that the atmosphere is also logarithmic to higher levels and may integrate fluxes over large areas (for example, Brutsaert, 1998).

The method currently used (Eichinger *et al.*, 1993a, 2000) begins by rearranging equation (4) into a linear form

$$q(z) = -Mz' + c \tag{6}$$

where M is the slope of the fitted function ($M = E/(L_e k u_* \rho)$), z' is a reduced height parameter ($z' = \ln(z - d_0) - \Psi_v((z - d_0)/L)$), and c is a regression constant ($c = M\ln(z_o) + q_s$). Measurements of the slope are made on the basis of a least-squares fit to several hundred measurements of water vapor concentration. Having determined M from the slope of the fitted line, the flux is then

$$E = L_e M k u_* \rho \tag{7}$$

where u_* and L are obtained from local measurements using three-dimensional sonic anemometers.

The method is similar to other gradient methods for determining fluxes that are well established (Stull, 1988; Brutsaert, 1982). The lidar method is unique in that it uses

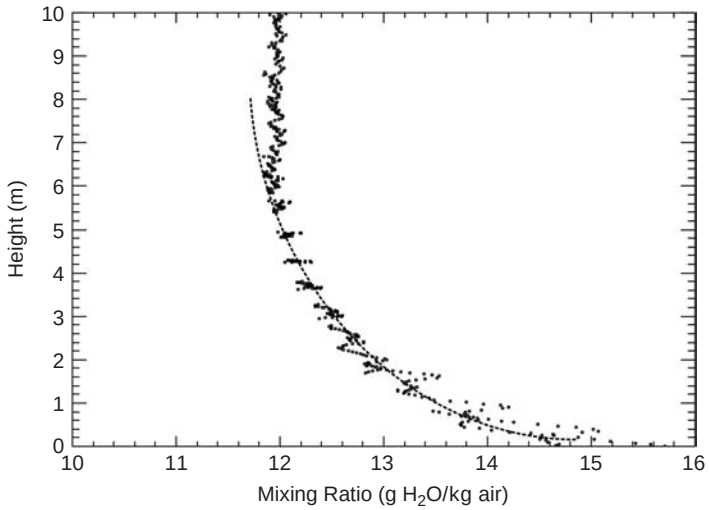

Figure 6 An example of a lidar fitted vertical profile and the data from which it was calculated. The data are from a 25-m section from a vertical scan over salt cedar near the Rio Grande River. The variability in the data about the fitted line is due to the presence of discrete structures. If a large enough area is averaged, the mean value at each elevation converges to a logarithmic profile

a large number of measurements to determine the vertical water vapor gradient. The extension of the method to rough terrain presents issues relating to assumptions of horizontal homogeneity as well as the determination of the canopy top location (with respect to the lidar) and the direction of the normal to the surface.

The flux estimation method used assumes that in some region, which is generally taken to be 25 m in size, but may be any user selected value, the slope of the water vapor concentration in the z direction can be determined from a curve fit using all of the measurements of the water vapor concentration above that region. This assumes horizontal homogeneity inside the region and with the region immediately upwind that the aggregate of the values constitutes a measurement of the average condition over the region, and that the slope in water vapor concentration is the result of conditions inside that region. The effect of these assumptions will be discussed later.

A key capability of the lidar that is useful in estimating fluxes over complex terrain is the ability to determine the location of the canopy top. The lidar is sited so that it overlooks the experimental site and is thus able to determine the location of the canopy top for all of the canopy types. For the case of mixed terrain and canopy, the lidar is used to find the location of the canopy top in the range interval under investigation. Figure 7 is a conceptual drawing of how this is accomplished. The top of the canopy is found either from the abrupt change in the apparent water concentration or from the abrupt change in the elastic lidar signal which is also recorded along each line of sight. The location of the top of the canopy as a function of distance is determined using multiple lines of sight. A linear least-squares fit is made to determine the elevation and slope of the top of the canopy within the range interval under consideration.

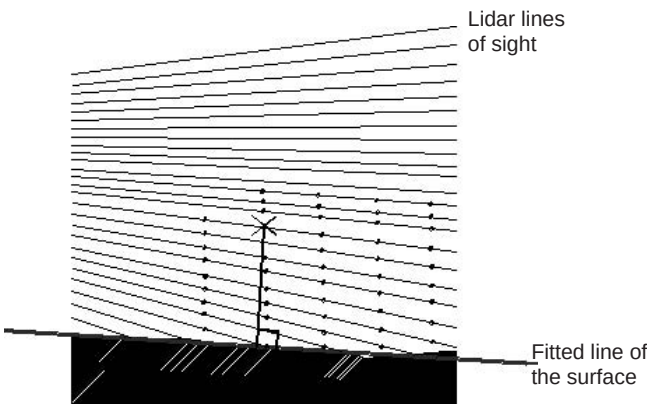

Figure 7 A conceptual drawing of a 25-m region and all of the lidar lines of sight within it. The location of a line approximating the surface is determined and the distance from each measured value to this line along a perpendicular to the line is calculated. All of the measured values of water vapor concentration are used to create vertical profiles similar to that in Figure 6. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

For an individual water vapor measurement, the distance from the measured point to the surface along a line perpendicular to the measured slope and elevation is used as the corrected height above the surface (see Figure 7). This means that the z direction is taken to be the direction perpendicular to the canopy top and not the vertical (gravitational) direction. The reasoning is that, near the surface, the flow of air will be parallel to the local surface and that dispersion of the water vapor released from the surface in the direction perpendicular to the mean flow is most important to the estimation of evapotranspiration (Kaimal and Finnigan, 1994).

For an individual scan, all of the measurements within a region are used to estimate the slope of the single line described by equation (4). While there is spread in the measurements at each height above the ground, the slope can be determined to an accuracy of a few percent. The spread in the measurements is due to the existence of coherent structures containing high and low water vapor concentrations. These structures can be seen in the two-dimensional plot shown in Figure 5. Currently, a measured value of the Obukhov length from point instruments is used to adjust for atmospheric stability. However, in practice, the use of this correction results in a small (usually on the order of 5% or less) change in the estimated flux. A severe limitation of this method is the lack of a u_* measurement for each 25-m region. In the ideal case, we divide the region into surface types and use a measured u_* typical of that region.

When using this method to determine fluxes, the optimum maximum height for which water vapor measurements are included must be determined. This corresponds to the height of the change in slope shown in Figure 6. While the largest possible distance over which the measurements are made leads to the greatest accuracy, measurements too close to the canopy top or so high that they are outside the inner region lead to erroneous estimates of the water concentration gradient. This height varies throughout the day so the method for determination must be dynamic and adjust to the existing conditions. In this analysis, the same height has been used over all of the canopy types, but the possibility exists that different heights would be appropriate over different canopies.

Uncertainty

The fractional uncertainty of the lidar flux measurements can be estimated using

$$\frac{\sigma E}{E} = \left[\left(\frac{\sigma u_*}{u_*} \right)^2 + \left(\frac{\sigma M}{M} \right)^2 + \left(\frac{\sigma \rho}{\rho} \right)^2 + \left(\frac{\sigma q}{q} \right)^2 \right]^{1/2}$$

where σu_*, σM, $\sigma \rho$, and σq are the uncertainties in the u_*, slope, air density, and water vapor concentration measurements respectively (Bevington and Robinson, 1992). The last term on the right is a contribution from a systematic uncertainty (or bias errors) in the lidar measurement of water vapor. While an individual measurement may be uncertain to the 3 to 4% level (a measure of the precision error), the determination of the mean concentration from a number of measurements (a measure of the bias error) is more accurate. This contribution is determined by the calibration error of the instrument and is a function not only of the lidar but also of the instrument(s) used to calibrate the lidar. For this reason, calibration is done with instruments traceable to the U.S. National Institute of Standards and Technology (NIST). As the range increases, the precision of the lidar degrades because of the decreasing signal-to-noise ratio caused by the r^{-2} decrease in the signal (the amount of noise is approximately constant with range), but the mean value of the measurements is maintained. Thus the variation in the data about the fitted line is generally observed to increase with distance, but since the mean value of the measurements is maintained, this should have a minimal effect upon the slope measurements and thus the estimated flux. The bias error in the mean value is taken to be less than 2%.

The value of the slope can be estimated with high certainty due to the large number of measurements used in fitting equation (6). The nominal uncertainty in the least-squares determined value of the slope is 1 to 2%. The air density is obtained from local measurements of temperature and air pressure. The uncertainty in the value of the air density is much less than 2%. The value of the friction velocity, u_*, is normally the primary source of uncertainty. While there are no reported estimates of the accuracy of $u*$ estimates from eddy correlation methods, it is reasonable to assume that the accuracy will be similar to those for eddy correlation flux measurements, which normally range from 5% to 25% (Wilson *et al.*, 2002). The value of the uncertainty of u_* is a function of the uncertainty in the measurements of u_* at a given point but it also contains a contribution from the assumption that a measurement at one point may be applied to a similar surface some distance away (the magnitude of which is highly site-specific). The uncertainty in a measurement of u_* is difficult to assess. While uncertainty estimates based upon the accuracy of the anemometer wind measurements result in estimates on the order of 5%, two anemometers a meter apart in nonideal conditions may have u_* values that differ by as much as 35% (although typical values are generally much less). For a typical measurement of the evaporative flux, the total uncertainty is determined almost totally by the uncertainty in u_* and leads us to estimate an overall uncertainty on the order of 15%. For areas far from u_* measurements, the uncertainty is potentially as much as twice as large.

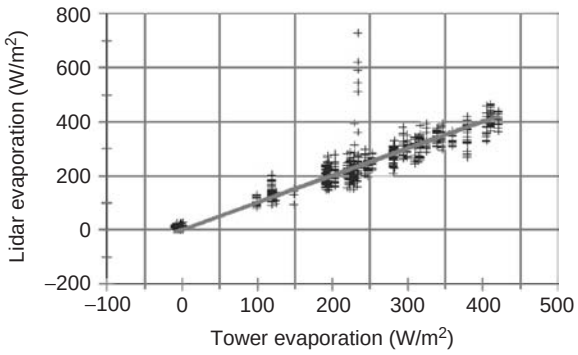

Figure 8 A comparison of eddy correlation evapotranspiration rates over a salt cedar canopy with lidar estimated evapotranspiration rates made in the same 25-m lidar pixel. The agreement is generally good and along the 1 : 1 line. The six point excursion was from an afternoon with exceptionally high winds in which the eddy correlation instruments may have been above the inner region

Figure 8 is a comparison of the latent heat flux estimates from eddy correlation measurements with lidar measurements made in the same 25-m region. These measurements represent half-hour averages. The differences between the two instruments are smaller when more data are available from the lidar for either temporal or spatial averaging. The lidar coordinate system is spherical, so that near the lidar more data are available with which to determine the vertical profile. The smaller the area to be covered, the faster the lidar can revisit the same locations, providing more data for analysis.

The evapotranspiration estimate obtained from each of the 25-m squares can be assembled into a map of the evapotranspiration rates over the scanned area. Figure 9 is a comparison of an evapotranspiration map over salt cedar and a high-resolution thermal infrared image of the same area at the same time. The prevailing wind is from the SW. There is a correlation between the dark grey areas in the thermal infrared image (which are areas of high sensible heat flux, low evapotranspiration) and regions of relatively low evapotranspiration rate (dark greys and blacks). The correlation is not perfect and there is generally a 50 to 75-m offset between the two images in the direction of the wind. As with conventional point instruments, the water vapor concentration in the air above a given point is a function of the emission rate in the upwind direction. As the height above the canopy increases, the farther upwind is the primary source area that determines the concentration. The offset distance seen in this comparison is consistent with footprint calculations for this site and conditions (Cooper *et al.*, 2003).

Limitations of the Method

Despite the successes that have been achieved, there remain significant questions about the method. The method used

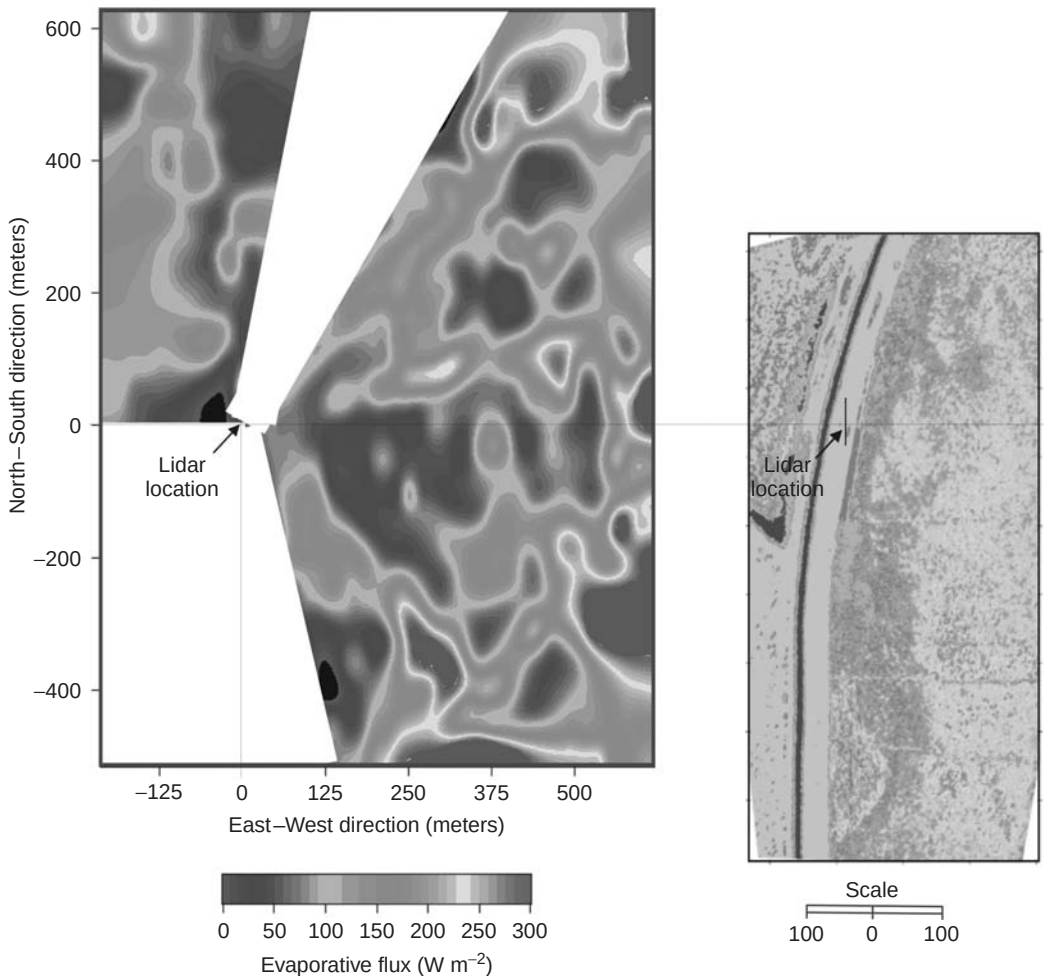

Figure 9 A comparison of an aerial thermal infrared photograph of the field site and a lidar-generated evapotranspiration map. Dark grey areas of the photograph indicate areas that are hot (which should have low evapotranspiration rates) while the lighter areas that are cool, which should have high evapotranspiration rates. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

here to develop maps of the evaporative flux in complex terrain assumes that, in some small region, the slope of the water vapor concentration in the direction perpendicular to the surface is governed by Monin–Obukhov similarity theory. This in turn assumes horizontal homogeneity inside the region and in the region immediately upwind that the aggregate of the values constitutes a measurement of the average condition over the region, and that the slope in water vapor concentration is the result of conditions in that region. Clearly, in transition areas where the canopy type or groundwater availability changes dramatically, these conditions will not apply.

Conditions may occur near areas with sharp transitions in which moist areas upwind alter the water vapor concentration near the canopy top so that it is not logarithmic with height. When this occurs, the methodology described here cannot be used. When the concentrations are not logarithmic with height, the flux estimation method does not always produce evapotranspiration estimates that are unreasonable and thus this condition can be found only by visual examination of the vertical scans. In complex terrain, changes in the canopy lead to changes in the evapotranspiration rate, which lead to changes in the water vapor concentration along the surface. The conservation of water vapor equation can be used to estimate the magnitude of the effect:

$$\frac{\partial q}{\partial t} + \overline{u}\frac{\partial q}{\partial x} + \overline{v}\frac{\partial q}{\partial y} + \overline{w}\frac{\partial q}{\partial z} = -\left[\frac{\partial}{\partial x}(\overline{u'q'}) + \frac{\partial}{\partial y}(\overline{v'q'}) + \frac{\partial}{\partial z}(\overline{w'q'})\right] + \kappa_v \nabla^2 q \quad (8)$$

where u, v, and w are the three components of wind velocity; κ_v is the diffusion coefficient for water molecules in air; and the overline indicates a time average and primed quantities represent fluctuations. Under most circumstances,

the diffusion term (the last term on the right), and terms involving $\overline{v}$, $\overline{v'q'}$, and $\overline{w}$ are small enough to be ignored. Because of advection, changes in evapotranspiration rates may result in flux divergence, particularly in the vertical direction, $\partial\overline{w'q'}/\partial z$. The size of this term can be estimated from the $\overline{u}\partial\overline{q}/\partial x$ and $\partial\overline{q}/\partial t$ terms in the conservation of water vapor equation. It is not uncommon to find horizontal gradients in water vapor concentration on the order of 0.2 g water per kg air in a 25-m by 25-m analysis region downwind of the riparian area. This can lead to a divergence of about 50 W m^{-2} per meter of height above ground. At this time, the effect of advection on the Monin–Obukhov flux method is unknown, but is a subject of current research. We have found that the corrections due to nonstationarity are, in general, small. The changes in water vapor concentration over a 10-min period are on the order of 0.3 to 0.4 g water per kg air or less. This results in a correction of less than 5 W m^{-2}.

Related to the question of advection is the question of the location of the source (also *known as the* footprint) for a measurement at a given height. This is a subject of considerable current interest (for example, LeClerc and Thurtell, 1990; Horst and Weil, 1994; Finn *et al.*, 1996; Horst, 1999). More than two-thirds of the measurements used in any given profile are below 8 m. On more than half of the profiles, the maximum height used is 8 m or less. The greatest curvature in the profile is found at heights less than 4 m, and it is those measurements that play the greatest role in determining the slope of the line. Using the methodology outlined by Horst and Weil (1994), one can estimate the upwind distance contributing to the flux at a given height. For a height of 8 m, the upwind distance, past which less than 20% of the flux is generated, is a factor of approximately 5 to 10 times the measurement height, or about 40 to 80 m. This would tend to indicate that the bulk of the flux in a given 25-m section is generated inside that section and the section immediately upwind. Thus it would be prudent to recognize that the flux locations as given by the methodology are not exact, but rather are somewhat diffuse in the upwind direction. In practice, this has not been an issue in that the estimated fluxes do not show many instances of large, abrupt changes.

Lastly, there remains the question of how well the measurements averaged over distances as short as 25 m and less than a minute in time can represent the average conditions. An individual scan will often show structure near the canopy top. In most cases, this will produce deviations both above and below the average value of the water vapor concentration, but which average to profiles that are logarithmic. Occasionally, there are plumes that contain water vapor concentrations that are significantly higher than normal. In such cases, the profiles are significantly altered and may no longer be logarithmic. At present, when such events are found, the evapotranspiration estimate from that 25-m section is discarded. No analysis method has been found that can incorporate such structures to produce an evapotranspiration estimate. A more detailed analysis of the structure of the water vapor concentrations and fluxes is presented in Cooper *et al.* (2000).

While limitations of the method exist, the amount and type of data provided by the lidar allows one to visually determine what is happening at a particular location that causes the estimates to be anomalous. The existence of visual two-dimensional information that allows one to correct for unusual circumstances is a very powerful asset and offers the potential for improved algorithms which may overcome the deficiencies in the current formulation. At present, these conditions require the intervention of a human analyst to determine the proper method of analysis to be made. However, because of the sheer volume of data that must be processed to use this methodology, it must be highly automated if it is to be truly efficacious.

DISCUSSION

The availability of three-dimensional water vapor concentrations, and two-dimensional evapotranspiration maps and their variation in time provides opportunities to study spatial processes that are difficult or impossible to accomplish with point instruments. For example, evaporation maps are currently being used to examine the relative contributions of near-surface soil moisture and canopy as well as the statistics of the spatial distribution. Similarly, three-dimensional water vapor concentrations have been used to measure the Monin–Obukhov stability correction functions and to estimate the Obukhov length, L.

Evapotranspiration Maps

The evapotranspiration maps can be used to study the spatial variability of evaporation in a number of different ways (Kustas *et al.*, 2004; Eichinger *et al.*, 2004). Figure 10 has examples of evapotranspiration maps made from 08 : 15 to 12 : 15 central daylight time, June 27, 2002 over corn and soybean fields in Iowa during the SMACEX experiment. Each map represents a half-hour average ($\pm$15 min from the given time). The average height of the corn was 1.37 m. The set of maps also includes a high-resolution (1.5 m pixel) multispectral digital image, presented as a false-color composite, of three spectral bands simulating the Landsat Thematic Mapper bands TM2 (green), TM3 (red) and TM4 (near-infrared), at the same scale, showing the canopy condition (Neale and Crowther, 1994; Cai and Neale, 1999). It can be seen that the cornfield canopy (north half of the image) had considerably more biomass than the soybean crop (south half of the image), which shows distinct patterns of low canopy cover and bare soil. While there are recurring correlations between the dark grey areas

in the aerial photograph (which are areas of high canopy cover) and regions of relatively high evapotranspiration rate and, conversely, the correlation is not perfect, nor consistent. This is not totally surprising in that the lidar senses the water vapor content in the atmosphere and is thus sensitive to fluctuations in the wind direction and the intermittent nature of turbulence. Early in the morning on the 27th, there was sufficient near-surface soil moisture so that evapotranspiration was at or near the potential rate and nearly constant over the two fields. By 10 a.m., the soil surface moisture was significantly depleted, but in small areas, it was possible to have evapotranspiration rates higher than the average. By noon, the near-surface water is exhausted and evapotranspiration in the soybean area is appreciably lower than that in the corn. Because the LAI of the soybeans is much less than 1, it is reasonable to assume that the spatial evapotranspiration rates are dominated by soil surface moisture considerations.

Spatial Structure of Evapotranspiration

Evaporative Structure Functions

It has been previously observed that the variance of soil moisture as a function of area follows a power law (Rodriguez-Iturbe *et al.*, 1995; Hu *et al.*, 1997). These investigators found that the spatial correlation remains unchanged with the scale of observation and follows a power law typical of scaling processes. The evapotranspiration maps in Figure 10 can be used to determine if this scaling extends to evapotranspiration and other atmospheric processes that depend on available soil moisture. While it stands to reason that evapotranspiration rates are governed by the availability of soil moisture, there are at least two reasons to expect some modulation. First, there is a great deal of evidence that, at least in the surface layer, the atmosphere acts as an integrator (Brutsaert, 1998). This concept underlies footprint studies in which the water vapor concentration at a given point is a weighted sum of contributions from an upwind region (Lenschow and Stankov, 1986; LeClerc and Thurtell, 1990; Horst and Weil, 1994; Finn *et al.*, 1996; Baldocchi, 1997; Mahrt, 1998; Horst, 1999). The size of the region is a function of the height of the point in question and the properties of the turbulent flow. The second reason is that the plant canopy modifies the evapotranspiration rate by intercepting solar energy, preventing the sun from warming the soil, and by transpiring itself. Separating the effects of canopy and canopy transpiration from the soil contribution has been the subject of a great deal of effort.

Structure functions have been used to examine the spatial variability of discretely measured data sets, most often on one-dimensional data sets. The structure function is calculated as

$$S(lag) = \overline{[E(\vec{r}) - E(\vec{r} - \vec{lag})]^2} \qquad (9)$$

where $\vec{r}$ is the location of a particular evapotranspiration measurement, $\vec{lag}$ is the distance between the two measurements, and the overline denotes averaging of all of the possibilities at each value of $\vec{lag}$. The structure function then provides information on the mean square differences between evapotranspiration measurements separated by various distances. The structure functions for the data sets shown in Figure 10 are typical of the types of data that are seen.

Figure 11 shows the structure functions for the evapotranspiration maps shown in Figure 10 for June 27. The red boxes represent the structure functions for the soybean field and the diamonds represent the corn field. Note that the corn and soybean functions have similar shapes and are offset from each other. The systematic offset is likely caused by the difference in the average evapotranspiration in the two regions. Note that the shapes of the structure functions are not a straight line, which would be anticipated on the basis of the previous work on soil moisture scaling albeit at larger scales. Except for the last 6 to 10 data points on the right side of each plot, each of the values was calculated from several thousand comparisons. The data is smooth and changes systematically. Previous work has indicated a power law profile (Rodriguez-Iturbe *et al.*, 1995; Hu *et al.*, 1997), although over considerably larger areas (~200 m to 20 km) and with considerably sparser range increments. While one could draw a straight line through each of the curves in Figure 11, the data appears to be more complex than what can be explained by a simple power law. Using data from the 1997 Southern Great Plains Experiment, Nykanen and Foufoula–Georgiou (2001) came to a similar conclusion that soil moisture patterns do not exhibit the same scaling patterns at all scales nor under all conditions.

The shapes of the structure functions shown in Figure 11 are more complex than a simple power law. At 8 am, when there is surface moisture available and the canopy cover is considerably sparser, the soybean field structure function is systematically larger than the corn field. The structure functions at 10 a.m. are larger and nearly the same for both crops. By 12 a.m., when the ground has dried, the soybean structure function is systematically lower than that of the corn. At distances longer than 650 m, nearly all decrease in magnitude. While the trends are systematic, these values are determined by fewer and fewer comparisons as the distances get longer, so that an anomalous measurement can have a significant effect. It may be that there is considerably more variability in evapotranspiration rates (and thus more shape and texture to the structure functions) during the periods when dry-down occurs than when the area is either at field capacity or at the wilting point. The slopes of the structure functions at 8 and 10 a.m. are nearly the same at short and medium distances, while the slopes of the two functions at 12 a.m. are smaller and similar to those found

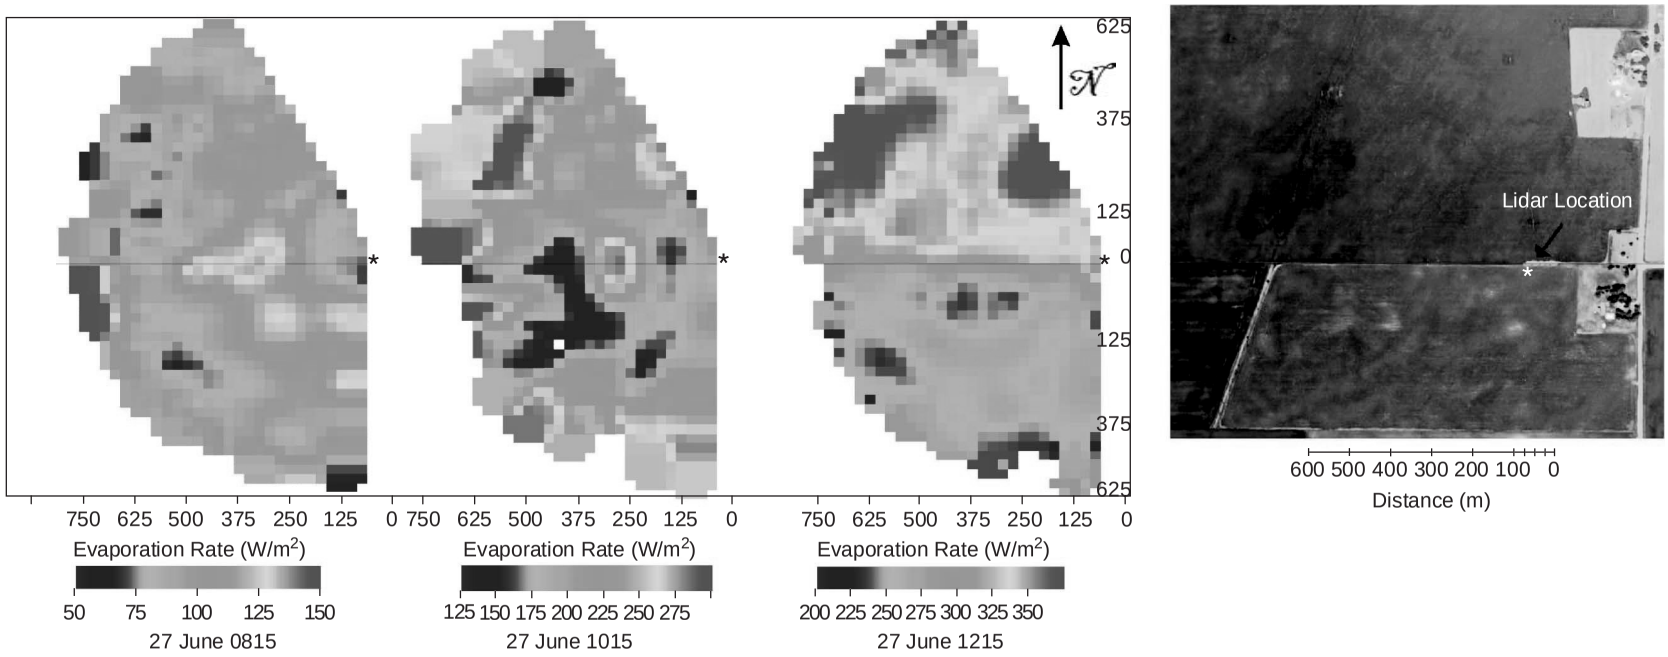

Figure 10 Three evapotranspiration maps of the area around the lidar at various times on June 27th. Light greys indicates areas of higher evapotranspiration and dark greys are lowest. In order to show the variability of the fields, the grey scales are different for each time. Soybeans were planted to the south of the lidar and corn to the north. The dividing line is the fence that can be seen in the photograph just below the lidar location. Also shown is an aerial three-band false-color composite of canopy reflectance at the same scale, for comparison. Dark greys are indicative of greater amounts of biomass. when there is little or no surface moisture. Clearly, the availability of near-surface soil moisture affects the details of the structure function.

Evaporative Covariance Functions

The covariance function also provides spatial information. The covariance function, calculated as

$$\mathrm{Cov}(lag) = \frac{\overline{((E(\vec{r}) - E_{\mathrm{ave}}) * (E'(\vec{r} + l\vec{a}g) - E'_{\mathrm{ave}}))^2}}{\sigma_E \sigma_{E'}} \tag{10}$$

where σ_E and $\sigma_{E'}$ are the standard deviations of the two sets of evapotranspiration measurements. The covariance function provides information on whether the deviations from the mean are correlated or anti-correlated at various distances. The distance at which the measurements are uncorrelated (the zero crossing point) provides a measure of the "typical" size of the regions over which evapotranspiration is similar.

Figure 12 shows the covariance functions for the three data sets from June 27. The shapes of the functions are similar, but with significantly different zero crossing points (125 to 275 m). The structure functions for the soybean fields on June 27 are nearly identical and possess a shape similar to those found when there is little or no water available at the soil surface. The cornfield, however, shows a systematic decrease in the location of the zero crossing, 200 m at 8 a.m., 175 m at 10 a.m., and 125 m at noon. While the size of the patches in the evapotranspiration maps seems to increase with time in Figure 10, the size of the differences is getting larger, causing the zero crossing point to decrease. The shapes of the correlation functions after the first zero crossing vary significantly. Since the soybean correlation function does not change with surface moisture availability but that for corn does suggests that the corn is significantly affecting the overall evapotranspiration rate in this dry-down period. In the soybeans with significantly lower canopy coverage, Figure 12 suggests that the availability of near-surface soil moisture does not affect the typical structure size.

Determination of the Obukhov Length

The requirement to measure the friction velocity, u^*, and Obukhov length, L, is a major limitation of the lidar method of evapotranspiration estimation. Efforts are being made to estimate the Obukhov length from measurements of the integral length scale derived from lidar measurements of water vapor. The integral length scale is the integral of a given variables' autocorrelation function in space which can be determined using two-dimensional lidar data. The integral length scale can also be estimated from meteorological variables using the empirical relationship (Cooper *et al.*, 2004):

$$\Lambda = \overline{u}\left[\frac{k(z-d)}{1.25u_*\left(1-\beta_1\frac{z}{L}\right)^a}\right] \tag{11}$$

where β_1 and a are empirically determined constants and k is the von Karman constant. Equation (11) can be simplified by noting that

$$\overline{u}(z) = \frac{u^*}{k}\left[\ln\left(\frac{z-d_0}{z_0}\right) - \psi_m\left(\frac{z-d_0}{L}\right)\right] \tag{12}$$

Substituting and solving for the Obukhov length gives

$$L = \frac{(z-d_0)\beta_1}{1-\left(\dfrac{\Lambda_{q\ \mathrm{lidar}}}{C_1(z-d_0)\left[\ln\left(\dfrac{z-d_0}{z_0}\right)-\Psi_m\left(\dfrac{(z-d_0)}{L}\right)\right]}\right)^a} \tag{13}$$

where C_1 has been substituted for the empirically determined constant 1.25 in equation (11). Values for the constants were determined using a least-squares fit to be $C_1 = 1.15$, $a = 0.25$, and $\beta_1 = 16$. The stability correction function for momentum, Ψ_m, for unstable atmospheres is given by

$$\psi_m\left(\frac{z}{L}\right) = 2\ln\left(\frac{1+x}{2}\right) + \ln\left(\frac{1+x^2}{2}\right) - 2\arctan(x) + \frac{\pi}{2}$$

$$x = \left(1 - 16\frac{z}{L}\right)^{1/4} \tag{14}$$

Equation (16) requires only knowledge of the integral length scale and the height of the measurements to determine L, albeit by an iterative process. Equation (15) can be compared to an empirically derived equation developed by Wilson *et al.* (1981)

$$\Lambda = 0.5\left(1 - 6\frac{(z-d)}{L}\right)^{1/4} \tag{15}$$

A comparison of lidar-derived values of L with those from conventional point instruments is shown in Figure 13. The data used for the estimates comes from water vapor measurements in the Bosque del Apache in New Mexico (Cooper *et al.*, 2004). Note that the bulk of the estimates fall within the ±15% limits. The method also compares favorably with the relationship developed by Wilson *et al.* (1981).

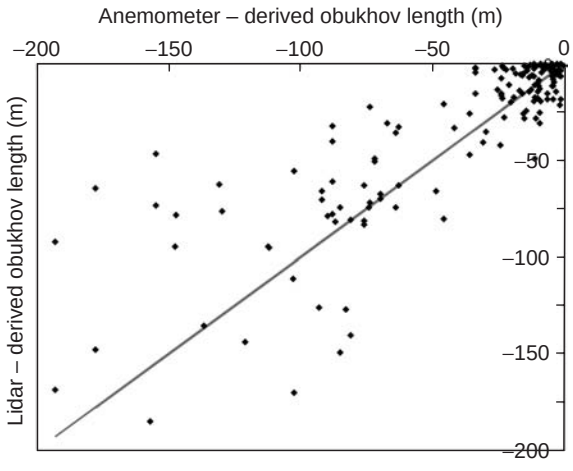

Figure 13 A comparison of lidar-derived Obukhov lengths and eddy covariance derived Obukhov lengths from two field campaigns in New Mexico. A one to one line is shown. The r^2 for the comparison is 0.71

Stability Correction Functions

Measurements of the stability correction functions are historically difficult to make because they require noninterfering measurements of the humidity profile at a range of heights inside the surface layer. A lidar RHI scan makes a large number of measurements at many heights over distances of several hundred meters. The concentrations at all heights in a given range interval are used in the analysis. An advantage of using the lidar is that a relatively large number of data points are obtained, so that one can calculate the degree to which the data fit the model, and thus estimate the uncertainty associated with a least-squares fit to the model. The desire to make accurate measurements of these functions was motivated by the suggestion by Kader and Yaglom (1990) that there are actually three distinct sublayers in convective conditions. An experiment was carried out at the Campbell Tract of the University of California, Davis in August, 1991 over an irrigated bare field (details can be found in Eichinger *et al.*, 1993b). An array of micro-meteorological instruments were used in the study to provide the surface heat and momentum flux values.

The water vapor concentration data from RHI scans (similar to those in Figure 5) were fitted using a least-squares technique to a second-order polynomial in $\ln(z-d_0)$ in a manner similar to Hogstrom (1988):

$$q = q_0 + A[\ln(z-d_0)] + B[\ln(z-d_0)]^2 \tag{16}$$

Derivatives of equation (16) were used to obtain values of dq/dz. Simultaneous values of u_*, L, and E were obtained from the meteorological instruments. These were used to calculate the values of ϕ_v (ζ) (where $\zeta = (z-d_0)/L$) with

$$\phi_v(\zeta) = -\frac{[ku_*(z-d_0)\rho]}{E}\frac{\mathrm{d}q}{\mathrm{d}z} \tag{17}$$

Lidar measurements of the water vapor stability function were made and the results averaged over a wide range of values of ζ. Values were averaged over intervals of 0.01 and the standard deviation of all the values in the interval were calculated. Because of the very large number of measurements (greater than 41 000), an uncertainty can be calculated in each interval of ζ as shown in Figure 14. The ranges of each of the sublayers postulated by Kader and Yaglom (1990) are marked in Figure 14 with a transition section separating each interval.

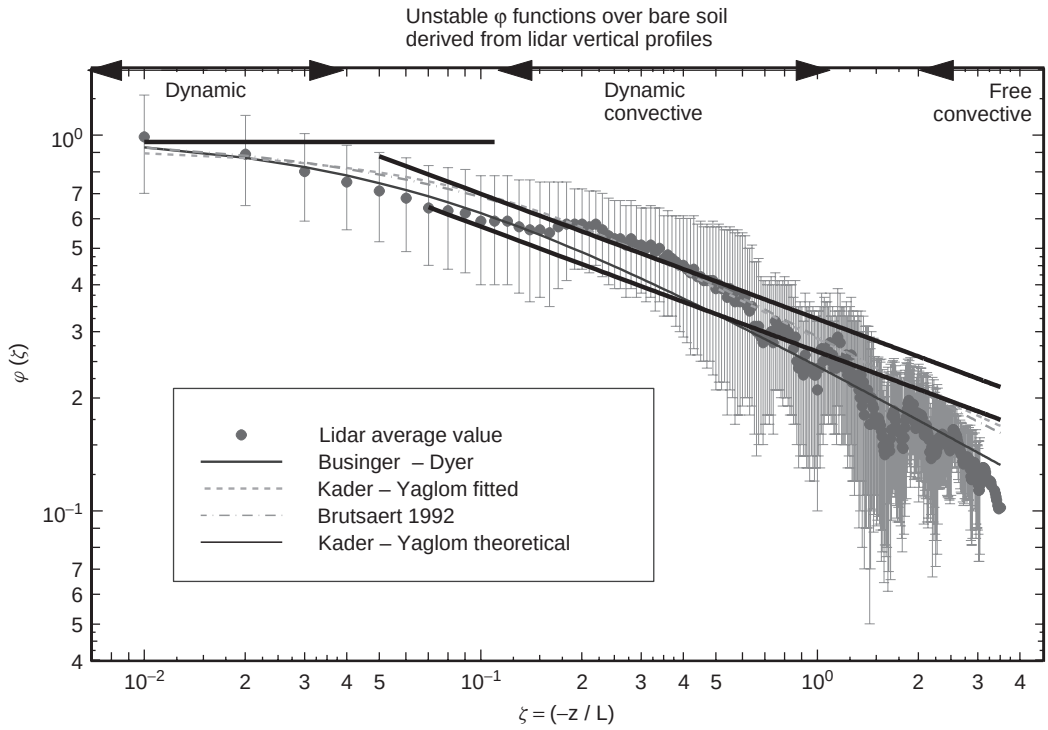

Figure 14 Comparison of lidar-derived stability correction functions to the traditional Businger–Dyer parameterization and the Kader and Yaglom parameterization. The error bars represent the standard deviations of the measurements. The small error bars on the largest values of ζ are indicative of a limited number of measurements and not necessarily decreased uncertainty. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

The ϕ_v values are plotted in Figure 14 along with the Businger–Dyer function (Businger *et al.*, 1971; Dyer, 1974), the Kader–Yaglom sublayer models and the smooth Brutsaert function based on the Kader–Yaglom sublayer models. In the dynamic layer, the ϕ_v data clearly show a falloff in comparison to the constant value predicted by the Kader and Yaglom theory though they match the Businger–Dyer parameterization well. In the dynamic-convective sublayer there is a clear and distinct jump in the data which matches the ϕ_h function of Kader–Yaglom remarkably well on average. The Businger–Dyer curve underestimates the mean ϕ_v observations, though it falls within the standard deviation limits. In the free convective sublayer, the data are limited in quantity and range of values; nevertheless, they appear to follow the Businger–Dyer function better than the Kader–Yaglom function, which is remarkable since the Businger–Dyer functions were not based on much data in the free-convective limit. In the region beyond $\zeta = 2$, more measurements are required to better determine all of the scalar and momentum similarity functions.

As noted by Dyer and Bradley (1982), measurements in the free-convective portion of the atmosphere are subject to considerable variability, owing to lack of stationarity and homogeneity despite detrending of data and spatial or temporal averaging of the data. In fact, as pointed out by Dyer and Bradley, the atmosphere has its own statistics and does not necessarily follow average laws at all locations at all times. This is evident in the size of the standard deviations on the data in Figure 14 despite the relative accuracy of a large number of measurements. While the data indicate an improved understanding of the physical processes in the dynamic-convective and free-convective sublayers, given the small differences in the various similarity functions in comparison to the inherent uncertainties, changing from the Businger–Dyer parameterization is, in practice, probably unwarranted.

An additional result from the measurement of the ϕ_v values is the determination of, k, the von Karman constant. This value is normally taken as 0.40 and was used in Figure 14. Using the raw data and fitting the 12 values of ϕ_v below $\zeta = 0.11$ to a second-order polynomial in $\ln(\zeta)$, the y intercept can be determined. The intercept value is the inverse of k, which was found to be 0.37 ± 0.02. Given the scatter in the data, using a number for k other than 0.4 is unwarranted.

SUMMARY

Maps of the spatial distribution of evapotranspiration can be produced using spatial water vapor concentration data

from a scanning Raman lidar. The estimates of evapotranspiration rates from the lidar compare favorably with other estimates made using more conventional methods. The method described allows estimates of the evapotranspiration rate to be made with relatively small (25 m) spatial resolution over an area approaching a square kilometer. Because of the amount of data (25 to 40 Mbytes) and time required to perform the analysis, methods and criteria are currently under development to automate the entire analysis process over all of the azimuthal angles for a given averaging time period. Criteria are being developed to flag and ignore data that do not converge to a logarithmic profile and to not include data above the internal boundary region in the analysis. Automation of the analysis will allow near real time determination of the evapotranspiration estimates.

While there are significant limitations to the method, it remains a relatively direct method of estimating the fluxes in situations where conventional methods fail or when the topography makes it difficult to site instruments or field enough of them to achieve an areal average. A major limitation is related to changes in the topography, and how much of the atmosphere above a given site can be considered to be influenced by the surface and thus used to estimate the flux in that region. An advantage of this method is that the spatial water vapor measurements themselves can be used to determine the regions in which these problems may occur. The large number of water vapor measurements used to determine the slope also makes it possible to determine where the slopes change and thus limit the maximum height of the water vapor measurements used to determine the slope.

Efforts are currently underway to improve the range of the lidar system by increasing the photon efficiency of the system. This will make it possible to scan faster so that more scans can be repeated over a larger area. Efforts are also being made to add the ability to measure spatially resolved temperature using a Raman technique (Nedeljkovic *et al.*, 1993). The addition of temperature will allow determination of the partitioning of solar energy between sensible and latent heat fluxes using similar methods. The ability to estimate these fluxes in a spatial manner will enable progress in a number of fields that examine the role that the canopy plays in partitioning solar energy.

The method used here can provide reliable estimates of the evapotranspiration rate over a relatively large area with relatively fine spatial resolution. The method is a more direct method of estimating the fluxes than most remote sensing techniques that estimate the evapotranspiration rate as a residual. It is, however, limited in that it assumes a single measurement of the friction velocity is representative of the value over a large region. It also provides regular estimates throughout the day as opposed to intermittent satellite or aircraft measurements. This information can be used in a wide variety of ways to study the spatial variations in evapotranspiration caused by changes in soil type and moisture content, canopy type, and topography. Because of the extensive nature of the estimates in space and time, evaluation of the relative contributions of each of these can be determined. The type of measurements provided also provide the opportunity to span the scales between the footprint of point measurements and the kilometer scale measurements made by satellites.

Acknowledgments

The development of the Raman lidar technology and the associated analysis methods have involved a large number of people. In particular, the following people have made significant contributions: Dan Cooper, John Archuleta, Jennifer Nichols, John Prueger, Larry Hipps, Heidi Holder, Bill Kustas, Chris Neale, Rene Van't Land, and Larry Tellier. Without the assistance of Los Alamos National Laboratory, IIHR of the University of Iowa, and the National Soil Tilth Laboratory, this work could never have been done.

52: Estimation of Surface Temperature and Surface Emissivity

THOMAS J SCHMUGGE

Formerly of: USDA/ARS Hydrology & Remote Sensing Lab, Beltsville, MD, US & Currently at: College of Agriculture, New Mexico State University, Las Cruces, NM, US

Measurements of thermal radiation at infrared wavelengths (7 to 14 μm*) yield much information about the land surface. The primary use of these observations is for surface temperature determination as the emissivity is usually close to one. For this purpose, it is fortuitous that the peak in the thermal emission occurs in an atmospheric transmission window. In addition, there are variations in the emissivity of minerals and soils in the 7–14* μm *region, which can be interpreted for identification purposes. These also produce significant emissivity variations for arid or desert areas, where there are considerable exposed soils and rocks. The emissivity for vegetative canopies has been found to be close to one, with little spectral variation. Applications of the derived surface temperature to study the surface energy balance and to estimate the energy fluxes from the land surface are discussed.*

INTRODUCTION

Measurement of the thermally emitted radiation at various wavelengths from the earth's surface can yield much useful information about parameters such as surface soil moisture and temperature. These two parameters are very important for the study of the land–atmosphere interaction. The partitioning of the net radiation into latent and sensible heating components is determined by the moisture available in the soil for the evapotranspiration process. The magnitude of the surface temperature is the result of this partitioning. If sufficient moisture is available, the surface temperature will be close to that of the air. If not, the surface temperature will rise above that of the air and contribute more strongly to the sensible heat flux.

Climatological observations of surface temperature are also an important indicator of climate change. Jin and Dickinson (2002) have analyzed data from the AVHRR (Advanced Very High Resolution Radiometer) on the National Oceanographic and Atmospheric Administration (NOAA) series of polar-orbiting weather satellites for the period 1982 to 1998 and observed a 0.4 °C increase per decade. This increase is consistent with that found for the global land air temperature and is even somewhat higher. The Moderate Resolution Imaging Spectroradiometer MODIS sensor on National Aeronautic and Space Administration (NASA's) Earth Observation System (EOS) will provide a good tool for extending this time series (Wan *et al.*, 2002).

To estimate surface temperatures, radiation at wavelengths around 10 μm is used because the peak intensity of the thermal emission occurs in this region for terrestrial temperatures (≈300 K), and in addition the atmosphere is relatively transparent and the observed variations in the intensity of radiation are mainly related to surface temperature. However, it must be kept in mind that variations in emissivity of 1% yield brightness temperature variations of 0.3–0.6 K depending on sky radiance. To estimate surface soil moisture, radiation at much longer wavelengths (10's of cm) is used. Changes in the intensity of the emitted radiation at these wavelengths are primarily due to the variation of the emissivity with the moisture content of the soil. This effect results from the large dielectric contrast between water and dry soils. This topic is discussed in a later article (*see* **Chapter 54, Estimation of Surface Soil Moisture Using Microwave Sensors, Volume 2**).

The monitoring of the land-surface fluxes at regional spatial scales is recognized as important for applications such

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

as the modeling of atmospheric behavior, the monitoring of water resources, and the estimation of plant or crop water use (Jackson, *et al.*, 1977). Surface temperature is a key boundary condition for many land-surface atmosphere models, and is a variable that can be measured by satellite remote sensing on a global basis. Indeed, considerable progress has been made in accounting for atmospheric effects and the variation in surface emissivity so that the uncertainty in radiometric surface temperature measurements from satellites is within 1–2 degrees (Norman *et al.*, 1995). This accuracy has been verified with recent results from satellite-borne sensors (Hook *et al.*, 2003; Wan *et al.*, 2002, 2004).

An example of a thermal infrared image from a satellite sensor, the Advanced Spaceborne Thermal Emission and Reflection radiometer (ASTER) (Yamaguchi *et al.*, 1998) onboard NASA's Terra satellite is presented in Figure 1. This figure presents land-surface temperatures derived using ASTER satellite imagery covering an area around the USDA-ARS Grazinglands Research Facility in El Reno, Oklahoma on September 4, 2002. The spatial distribution of land-surface temperature, T_{SURF}, reflects some significant differences in land-cover conditions this time of the year (September), with large areas of bare soil and wheat stubble from harvested winter wheat fields, the light colored areas with temperatures up to 57 °C, and small areas of irrigated crop lands and water bodies, the dark areas with temperature down to 36 °C. Amongst these extremes, are grasslands used for cattle grazing. This type of spatially distributed information is very useful for evaluating spatial patterns of *ET* over large areas, as will be demonstrated later in this article.

When one looks at this image, it is obvious that the large variations in surface brightness temperatures, T_{B}, arise from differences in the surface energy balance for the different surfaces. Recall that T_{B} is a measure of the radiation emitted from the surface, and is directly related to the temperature of the surface and its emissivity. In Figure 1, the hotter fields (white, with $T_{\mathrm{B}} > 50\,^{\circ}\mathrm{C}$) are either bare soil or fields with sparse, newly emerging vegetation. The cooler fields (black, with $T_{\mathrm{B}} \approx 36$–$40\,^{\circ}\mathrm{C}$) are completely vegetated grasslands or forested riparian zones along the streams. These temperature contrasts among fields with different vegetation conditions imply a different partition of the incoming solar energy into latent and sensible heat components. In general, cooler temperatures indicate that there is sufficient moisture available so that most of the incoming energy goes into latent heat or evaporation, while hotter temperatures indicate that most of the incoming energy goes into the sensible or convective heating of the atmosphere. The problem is to quantify these fluxes in terms of the remotely sensed T_{B}. There is a long history on the use of T_{B} to monitor these surface fluxes (e.g. Jackson *et al.*, 1977; Price, 1980; Soer, 1980; Seguin and Itier, 1983) and in this article, we will describe the contributions remotely sensed thermal infrared data can make towards quantifying these fluxes.

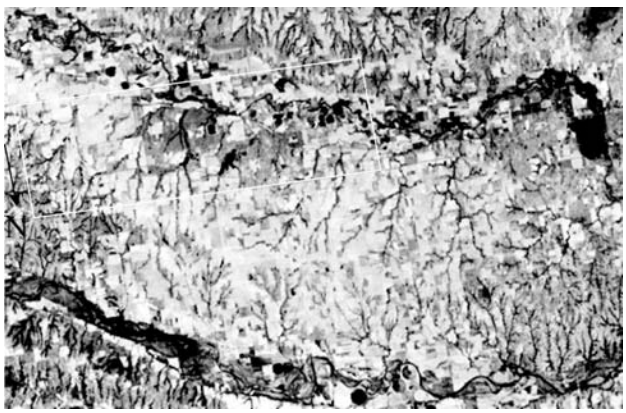

Figure 1 ASTER Thermal Infrared (TIR) imagery for a region in central Oklahoma, just west of Oklahoma City. The data was taken on September 4, 2000 at 17:34 GMT and are for band 13 of ASTER, $\lambda = 10.7\,\mu\mathrm{m}$. The temperatures range from 36 C (black) −57 °C (white). The spatial resolution is 90 m

THERMAL INFRARED RADIATION

The intensity of the thermal radiation from an object is described by the Planck blackbody relationship given as a function of frequency in equation (1a) and as a function of wavelength in equation (1b):

$$L_{BB}(\nu, T) = \frac{2h\nu^3/c^2}{\exp(h\nu/kT) - 1} \tag{1a}$$

$$L_{BB}(\lambda, T) = \frac{2hc^2/\lambda^5}{\exp(hc/\lambda kT) - 1} \tag{1b}$$

where h is Planck's constant ($6.626\mathrm{A}10^{-34}$ joule sec), c is the speed of light and k is Boltzmann's constant ($1.381\mathrm{A}10^{-23}$ joule K^{-1}). The units are $\mathrm{W\,m^{-2}\,sr^{-1}}$ per Hz for equation (1a) or $\mathrm{W\,m^{-2}\,sr^{-1}}$ per meter for equation (1b). Equation (1a) is plotted in Figure 2 for several temperatures. In this figure, the reflected solar radiation is also plotted for albedos of 0.1 and 1 to show that at the wavelengths where the terrestrial thermal radiation peaks, that is, at $\lambda \approx 10\,\mu\mathrm{m}$, the reflected solar radiation is several orders of magnitude weaker. The wavelength for the maximum in the thermal emission curve is given by the Wien displacement law where $\lambda_{\max} T \approx 2.898\mathrm{A}10^{-3}\,\mathrm{mK}$. Thus for a temperature of 300 K, $\lambda_{\max} \approx 9.7\,\mu\mathrm{m}$. The measurements around this wavelength should therefore yield information on surface temperature without any contamination by reflected solar radiation. The cosmic background radiation at $T = 3\,\mathrm{K}$ is also shown for reference.

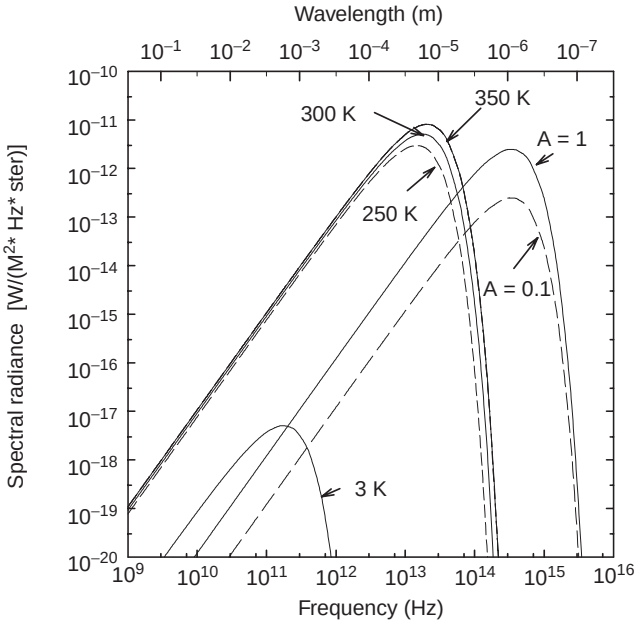

Figure 2 The spectral radiance of a blackbody according to equation (1a) for a typical range of terrestrial temperatures and the cosmic background (3 K). The reflected solar irradiance with indicated values of the albedo (α) is also plotted for comparison

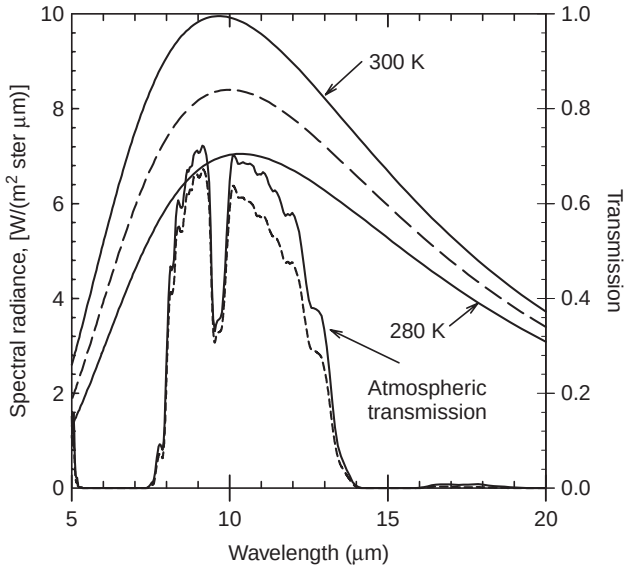

Figure 3 The spectral radiance of a blackbody according to equation (2) for typical terrestrial temperatures and the atmospheric transmission for the United States standard midlatitude summer atmosphere with two moisture levels: the upper curve is for a columnar water content of 2.9 g cm^{-2} and the lower is for 3.5 g cm^{-2}

In the infrared, we usually speak in terms of wavelength, while in the microwave, frequency and wavelength are used interchangeably. This perhaps results from the techniques used to quantify the waves; in the infrared wavelengths can be measured, but not frequency, while in the microwave both frequency and wavelength can be measured. It should be noted that in the infrared, frequency is usually expressed in terms of wave number, that is, $\nu = 1/\lambda$, in cm^{-1}. In this case equation, (1a) is usually represented as

$$L_{BB}(\nu, T) = \frac{\in C_1 \nu^3}{\exp(C_2 \nu / T) - 1} \tag{2}$$

where C_1 is 1.19104×10^{-8} W/(m^2 sr cm^{-4}), C_2 is 1.4388 cmK, and ν is expressed in wave number (cm^{-1}) $\in$ and is the emissivity. For a perfect emitter or blackbody $\in = 1$, and for real surfaces $\in < 1$.

Atmospheric Effects

In Figure 3, we have plotted equation (2) for the wavelength range 5–20 μm at temperatures of 280, 290, and 300 K, that is, near the low range of terrestrial temperatures. At these temperatures, the peak emission occurs in the 8–10 μm range of wavelength. In this figure, we have also plotted the clear sky atmospheric transmission calculated with the Modtran4 path radiance model (Berk *et al.*, 1998; Berk *et al.*, 1999) for the midlatitude summer atmosphere, assuming the radiometer is at satellite altitude. While the atmosphere is relatively transparent in the 8–12 μm range compared to adjacent wavelengths, there is still significant attenuation. As seen in Figure 3, there is only 60–70% transmission with a major dip at about 9.5 μm due to ozone absorption. With the exception of this dip, water vapor is the dominant absorber in the 8–12 μm window. This is mainly due to what is called the *water vapor continuum*, since only in the 8–9 μm range are there any relatively strong absorption lines. Thus, the magnitude of the atmospheric effect will depend on the water vapor content of the intervening atmosphere. The atmospheric transmission for a 20% increase in water vapor is also plotted to indicate this sensitivity to water vapor. This unknown or uncertain atmospheric contribution is one of the problems for the remote sensing of surface temperature at infrared wavelengths. This, of course, is in addition to clouds that will totally obscure the surface at visible and infrared wavelengths.

The radiation values given in Figure 3 are those which would be observed right at the surface; the relation between the radiation, L_i, seen by a radiometer on a satellite or aircraft and the surface temperature is:

$$L_i = [\varepsilon_i \cdot L_{BB_i}(T) + (1 - \varepsilon_i) \cdot L_{\mathrm{atm}_i}(dn)] \cdot \tau_i + L_{\mathrm{atm}_i}(up) \tag{3}$$

where the subscript i indicates the integral of these quantities over the bandwidth for channel i of the radiometer, L_{BBi} is the Planck function given by equation (1), the

L_{atm}'s are the upward and downward components of the atmospheric radiation, and τ is the atmospheric transmission. The values of L_{atm} and τ can be calculated using a model for atmospheric path radiance such as Modtran4, however, it would be preferable to eliminate the atmospheric effects using the multispectral information.

Several approaches have been developed for eliminating atmospheric effects in the estimation of sea surface temperature from space using multichannel thermal data. The technique used with the AVHRR data from the NOAA series of polar-orbiting satellites involves the differential water vapor absorption in the 10–13 μm window with the 11.5–13 μm portion being more strongly absorbed, the so-called *split-window technique* (McClain *et al.*, 1983; Grassl, 1989). However, this assumes that the surface emissivity is constant over this spectral band, which is not the case for land surfaces (Becker, 1987; Grassl, 1989). In order to better understand thermal infrared radiation, we need to study the behavior of the emissivity of terrestrial materials or surfaces.

Owing to the lack of adequate atmospheric profile observations, the development of alternative approaches such as so-called "split-window" methods would be more operationally applicable (e.g. Price, 1984). These split-window methods employ two channels at slightly different wavelengths, λ^1 and λ^2 in equation (4) and (5) to essentially eliminate (using a few approximations) the need for estimating the atmospheric transmission and radiances. This approach has been used quite successfully over oceans where the emissivity is close to one and its spectral variation is small. Over land, this is not the case and the split-window methods are sensitive to uncertainty in the emissivities in the two channels; for example, at a brightness temperature 300 K, a difference, $\{\in\}^1 - \{\in\}^2 \sim 0.01$ can yield an error in land-surface temperature of ~2 K (Price, 1984), which can be corrected for, if the emissivities are known. There has been much recent work on the use of these split-window techniques using the two thermal channels of the (AVHRR) instrument on the NOAA series of meteorological satellites (Wan and Dozier, 1989; Becker and Li, 1990, Kerr *et al.*, 1992, Prata, 1994; Coll and Caselles, 1997). This approach is being used with the multispectral thermal infrared data from the MODIS, onboard the NASA Terra satellite. They use a database of land-surface emissivities based on land cover to correct for emissivity effects (Wan and Dozier, 1996; Wan *et al.*, 2002, 2004) and have been rather successful.

Infrared Emissivity

There has been much use of the spectral variation of infrared emissivities for geological purposes; here we are more interested in the emissivities of soils and vegetation. This discussion is based on papers by Salisbury and D'Aria (1992a,b) which present emissivity spectra in the 8–12 μm range for soils and vegetation. These results were based on laboratory and field measurements made with an interferometer. The reader is referred to a special issue of Remote Sensing of Environment of emissivity (Salisbury, 1992).

To extract the emissivity from the radiance measurements, the assumption is made that the emissivity is unity somewhere in the wave band observed. A blackbody curve is fitted to that portion of the spectra to obtain the temperature. The emissivity is then determined by dividing the observed radiance by the blackbody radiance at that temperature (Kahle and Alley, 1992). However, to do this with field measurements it is necessary to take into account the reflected sky radiation as indicated in Figure 4, where the true and apparent emissivity are plotted as functions of wavelength for a case with significant downwelling radiance. Figure 4a shows the downwelling atmospheric radiance calculated with Modtran4 for a tropical atmosphere with 4.2 g cm^{-2} of water vapor. The upper three curves show surface radiances; the top is for a blackbody at 300 K, the lowest of the three is for the emission from a quartz rich sandy soil, and the middle curve is the upwelling radiance at the surface, that is, the term in brackets in equation (3) which includes the reflected downwelling radiance. When the latter two curves are divided by the blackbody curve, the true and apparent emissivities are obtained as shown in lower portion of the figure. This example shows the importance of measuring the downwelling sky radiance in emittance measurements. Note that for the quartz sand shown here, the emissivity is about 0.8 at $\lambda = 9.2$ μm.

An example of the emissivity variation of soils is given in Figure 5 where spectral variation for three soils from the United States are presented. The soils data are from the Jornada Experimental Range in New Mexico and their spectra were measured at the Jet Propulsion Laboratory. The soils shows the pronounced effect of quartz (SiO_2) (light sand), and gypsum on the emissivity spectra for the two soils with emissivity being less than 0.9 for $\lambda <$ 9.5 μm for quartz or gypsum. Note that in the 10–12 μm range, the emissivity is high ~0.95 and relatively constant. The response functions for the 5 channels of the ASTER radiometer are also shown.

The White Sands National Monument in New Mexico provides an opportunity to obtain data over a surface of relatively homogeneous composition. The White Sands gypsum dunes cover an area of about 20 by 30 km in south central New Mexico. We have a number of good ASTER observations covering the gypsum dunes. The radiances for a 2 by 2 pixel area (180 by 180 m) were analyzed for several dates. The emissivity results are presented in Figure 6 as the filled symbols for eight observations between May 2000 and December 2002. The emissivities were extracted from the atmospherically corrected radiances for the 5 ASTER bands using the

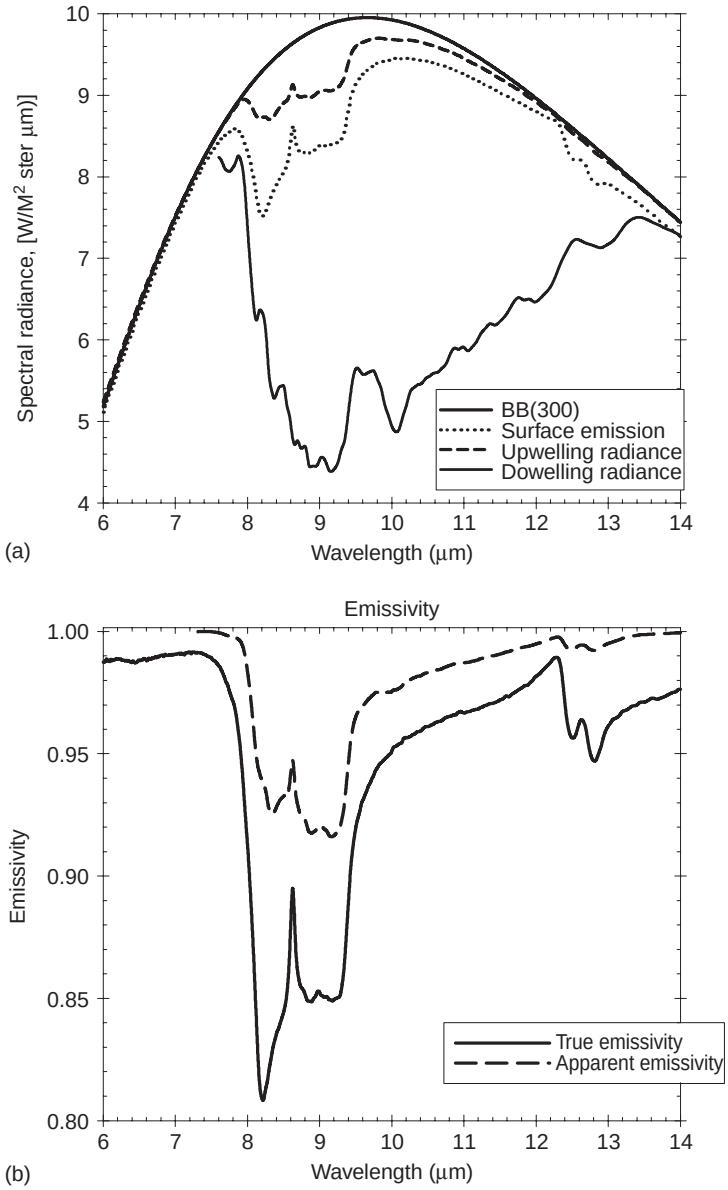

Figure 4 The effect of downwelling atmospheric radiance on apparent emissivity. (a) Radiances; the surface radiance components to equation (3), the bottom curve is the downwelling radiance, the top curve is the blackbody radiance from equation (2), the curve below that is upwelling radiance at the surface, that is, the term in brackets in equation (3) and final curve is the emission from the surface. (b) Emissivity; the true and apparent emissivity

Temperature Emissivity Separation (TES) developed for use with ASTER data (Gillespie *et al.*, 1998). TES relies on an empirical relation between the range of emissivities and the minimum value for the 5 ASTER bands. It works best for areas with significant spectral contrast in the emissivity, for example, arid regions with minimal vegetation cover. The lab results are the open squares and were obtained for each ASTER channel by integrating the product of the ASTER response and gypsum emissivity curve shown in Figure 5. The ASTER results show excellent agreement with the laboratory results and with each other for the center 3 bands. The agreement is particularly clear for the low-emissivity 8.6 μm channel. Bands 10 (8.29 μm) and 14 (11.29 μm) show the biggest differences. Band 10 is the one with the strongest atmospheric effects and the differences may indicate inadequate atmospheric correction. The cause for the band 14 differences is uncertain at the present time.

The open diamond symbols are the results from a CIMEL CE312 (Legrand *et al.*, 2000; Brogniez *et al.*, 2003) radiometer, which has approximately the same 5 spectral bands as ASTER. The shortest wavelength band of the

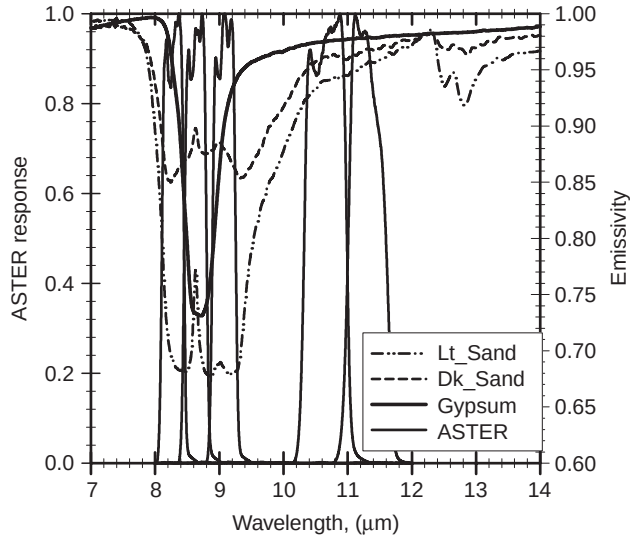

Figure 5 Laboratory measurements of the emissivity for three soils from the United States with the filter functions for the six TIMS channels. The soils are: (i) Brown sand with 0.5% organic carbon, 2% clay, and 96% quartz; (ii) White gypsum dune sand with 0% organic carbon, 0% clay, and 99% gypsum with a trace of quartz; and (iii) Black loam with 6.6% organic carbon, 30% clay, and 56% quartz

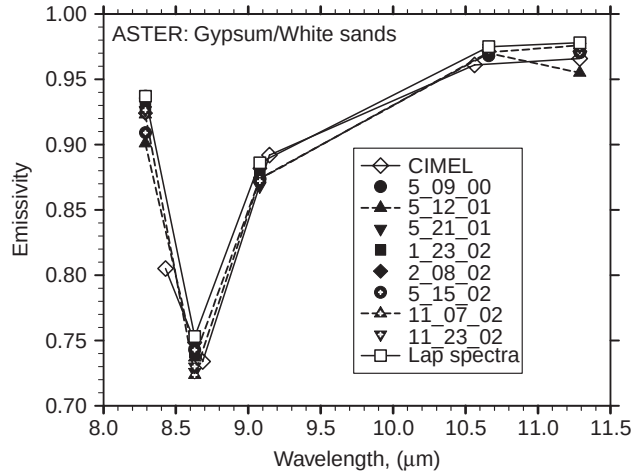

Figure 6 ASTER emissivity results for a gypsum site at the White Sands National Monument in New Mexico. The open symbols are for laboratory (squares) and ground measurements with the CIMEL radiometer (diamonds). The filled symbols are the ASTER results for eight days. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

CIMEL is broader than that of the ASTER band, and as a result shows a much lower emissivity than those observed by ASTER band 10. For the other channels, the agreement is very good. CIMEL results for the bare soil at the other sites were also in good agreement with lab measurements. This agreement is an indication validity of TES for surfaces with large emissivity contrasts. The agreement of the ASTER results with both the CIMEL and lab measurements for the gypsum sands is a demonstration that these data can be used to estimate the surface emissivity over large areas. Additional results from the other sites also show good agreement. These results indicate that the TES algorithm appears to work as well with the data from space as it did with the aircraft data presented earlier (Schmugge *et al.*, 2002). This is encouraging for the application of the technique for mapping emissivity over large areas. Examples of this are presented in the papers by Ogawa *et al.* (2002, 2003) where the window emissivity is mapped for a large (400×1500 km) desert area in North Africa and to all of North Africa using a combination of ASTER and MODIS data (Ogawa and Schmugge, 2004).

In addition to minerals and soils Salisbury and D'Aria (1992a), present spectra for a number of terrestrial materials. Of most interest to us, are the results for vegetative components such as green and senescent foliage. For the green foliage, the reflectances are generally less than 5%, emissivity >0.95, while for senescent vegetation the reflectance is generally higher. As expected, the soil litter has low reflectance. When these components are combined to form a vegetative canopy, the results become more complicated because of scattering within the canopy. The net result is simpler because multiple scattering by the leaf surfaces with their low reflectance yields a canopy emissivity very close to one with little spectral variation. This was observed for the prairie grass in FIFE by Palluconi *et al.* (1990) who found an emissivity of 0.99 ± 0.01, with no spectral variation. In Hydrologic and Atmospheric Pilot Experiment-Modelisation du Bilan Hydrique (HAPEX-MOBILHY), Schmugge *et al.* (1991) found little or no spectral variation over a coniferous forest or an oat field and over the Tiger-Bush site in HAPEX-Sahel (Schmugge *et al.*, 1998), using Thermal Infrared Multispectral Scanner (TIMS) data from an aircraft platform. These results for vegetation are in substantial agreement with modeling studies of Norman *et al.* (1990) who derived a value of 0.99 for the emissivity of the grass canopy in FIFE.

SURFACE FLUXES

Energy and Moisture Balance

Evapotranspiration

To understand better how thermal infrared observations can contribute to the determination of the surface fluxes, let us consider the basic energy and moisture balance equations. In the absence of advection or precipitation, the energy balance at the land surface is given by:

$$R_n - G - H - LE = 0 \tag{4}$$

where R_n is the net radiation, G the soil heat flux, H the sensible heat flux, and LE the latent heat or moisture flux into the atmosphere. Here we are treating the heat fluxes (G, H, and LE) away from the surface as being positive. The net radiation is the sum of the incoming and outgoing short and long-wave radiation fluxes:

$$R_n = (1 - \alpha) \cdot R_s + (1 - \varepsilon) \cdot R_{L\downarrow} - \varepsilon \sigma T^4 \tag{5}$$

where α is the surface albedo, R_S is the incoming solar radiation, $R_{L\downarrow}$ is the incoming long-wave radiation, ε is the surface emissivity, and T is the surface temperature in Kelvins.

A later article (*see* **Chapter 50, Estimation of the Surface Energy Balance, Volume 2**) discusses the estimation of the surface evapotranspiration (LE) flux using remotely sensed data and provides an excellent background and introduction to the topic. The Surface Energy Balance System (SEBS) is presented there with examples. This model is based on the Surface Energy Balance Algorithms for Land (SEBaL) model of Bastiaanssen *et al.* (1998a,b). Here we will present an alternate approach for the estimation of LE with remotely sensed data.

This alternate approach considers the soil and vegetation contribution to the total or composite heat fluxes and the soil and vegetation temperatures to the radiometric temperature measurements in a so-called "Two-source" Modeling (TSM) scheme (Norman *et al.*, 1995b). One of the more common ways in estimating ET is to rearrange equation (4) solving for the latent heat flux, LE, as a residual in the energy balance equation for the land surface, namely,

$$LE = R_N - G - H \tag{6}$$

Remote sensing methods for estimating these radiation components of R_N are described in Kustas and Norman (1996). Typically with reliable estimates of solar radiation, differences between remote sensing estimates and observed $R_N - G$ are within 10%.

The largest uncertainty in estimating LE comes from computing H. In resistance form, the relationship between H and the surface-air temperature difference is expressed as

$$H = \rho \cdot C_p \frac{T_0 - T_A}{R_A} \tag{7}$$

where T_0 is the aerodynamic surface temperature (T_0 is the temperature satisfying the traditional expressions for the resistances; see Norman and Becker, 1995), T_A is the near-surface air temperature, D is air density, C_P is the specific heat of air, and R_A is the aerodynamic resistance. Since T_0 cannot be measured, the surface radiometric temperature is often substituted in equation (10) and is frequently rewritten as (e.g. Stewart *et al.*, 1994),

$$H = \rho C_P \frac{T_R(\theta) - T_A}{R_A + R_{EX}} \tag{8}$$

where R_{EX} is the so-called "excess resistance", which attempts to account for the nonequivalence of T_0 and $T_R(\theta)$. The radiometric temperature observations, $T_R(\theta)$, at some viewing angle θ, are converted from satellite brightness temperatures and are an estimate of the land-surface temperature, T_{SURF}. Thus, equations (6)–(8) offer the possibility of mapping surface heat fluxes on a regional scale if R_A and R_{EX} can be estimated appropriately. R_{EX} has been related to the ratio of roughness lengths for momentum, z_{OM}, and heat, z_{OH}, and the friction velocity u_* having the form (e.g. Stewart *et al.*, 1994),

$$R_{EX} = k^{-1} \ln\left(\frac{Z_{OM}}{X_{OH}}\right) u_*^{-1} \tag{9}$$

where $k \approx 0.4$ is von Karman's constant. This is the classical definition which addresses the fact that momentum and heat transport from the roughness elements differ (Brutsaert, 1982), but is just one of several that have been formulated (e.g. McNaughton and Van den Hurk, 1995). There have been numerous efforts in recent years to apply equations (8) and (9) and determine the behavior of R_{EX} or z_{OH} for different surfaces, but no universal relation exists (Kustas and Norman, 1996). Large spatial and temporal variations in the magnitude of z_{OH} have been found. Nevertheless, solving the LE with the approach summarized in equations (6)–(9) is still widely applied.

The TSM scheme (Norman *et al.*, 1995b) allows for equation (7) to be recast into the following expression

$$H = \rho C_P \frac{T_R(\theta) - T_A}{R_R} \tag{10}$$

where R_R is the radiometric-convective resistance given by (Norman *et al.*, 1995b),

$$R_R = \frac{T_R(\theta) - T_A}{\dfrac{T_C - T_A}{R_A} + \dfrac{T_S - T_A}{R_A + R_S}}. \tag{11}$$

T_C is the canopy temperature, T_S is the soil temperature, and R_S is the soil resistance to heat transfer. An estimate of leaf area index or fractional vegetation cover, f_C, is used to estimate T_C and T_S from $T_R(\theta)$,

$$T_R(\theta) \approx (f_C(\theta) T_C^4 + (1 - f_C(\theta)) T_S^4)^{1/4} \tag{12}$$

where $f_C(\theta)$ is the fractional vegetative cover at radiometer viewing angle θ, and R_S is computed from a relatively simple formulation predicting wind speed near the soil

surface (Norman *et al.*, 1995b). With some additional formulations for estimating canopy transpiration, and the dual requirement of energy and radiative balance of the soil and vegetation components, closure in the set of equations is achieved. Through model validation studies, revisions to the original two-source formulations have been made (Kustas and Norman, 1999 and 2000; Kustas *et al.*, 2001, Kustas *et al.*, 2004) which improved the reliability of flux estimation under a wider range of environmental conditions. The modifications include: (i) replacing the commonly used Beer's Law expression for estimating the divergence of the net radiation through the canopy layer with a more physically based algorithm; (ii) adding a simple method to address the effects of clumped vegetation on radiation divergence and wind speed inside the canopy layer, and radiative temperature partitioning between soil and vegetation components; (iii) a scheme for adjusting the magnitude of the Priestley and Taylor (1972) coefficient, α_{pt}, used in estimating canopy transpiration for advective and stressed canopy conditions; and (iv) developing a new soil aerodynamic resistance formulation whose magnitude is a function of both convective (temperature) and mechanical (wind) turbulent transport.

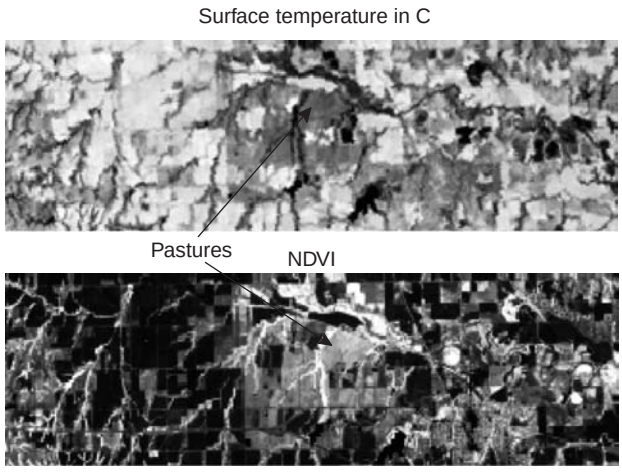

Figure 7 Surface temperatures and *NDVI* values for the portion of Figure 1 outlined by the white box. The area is approximately 30 by 8 km. The temperatures range from 36–57 °C and the *NDVI* values range from −0.1–0.5

Examples of Flux Estimation

An example of an application of the TSM approach for estimating daily *ET* is illustrated in Figures 7 and 8 for the September 04, 2000 ASTER data. Images of $T_R(\theta)$ and Normalized Difference Vegetation Index (*NDVI*) computed from the ASTER red and near-infrared reflectance data and the multispectral thermal infrared data are given in Figure 7 (French *et al.*, 2002; French *et al.*, 2003). The *NDVI* image shows bare soil with values ∼0.0 (light gray) and senescent grazing lands with values ∼0.2 (dark gray). Surface temperature imagery distinguishes bare soils at 55–60 °C (light gray) and from grazing lands at ∼45 °C (medium gray). These remote sensing inputs, in combination with TSM, resulted in 90 m scale estimates of *H* and *LE*. Comparison with ground-based energy balance observations using the Bowen ratio technique show underestimated *H* and *Rn*, but close agreement for *LE*. Assuming constant daytime evaporative fraction, instantaneous values can be integrated to yield daily evaporative flux estimates given in Figure 8. The latter range from about 5 mm day^{-1} for the grazing lands and 8 mm day^{-1} for the water bodies. Many of the low *ET* rates are from fields that are either bare soil or contain wheat stubble from the summer–winter wheat harvests, which generally have the highest $T_R(\theta)$ and $0 \leq$

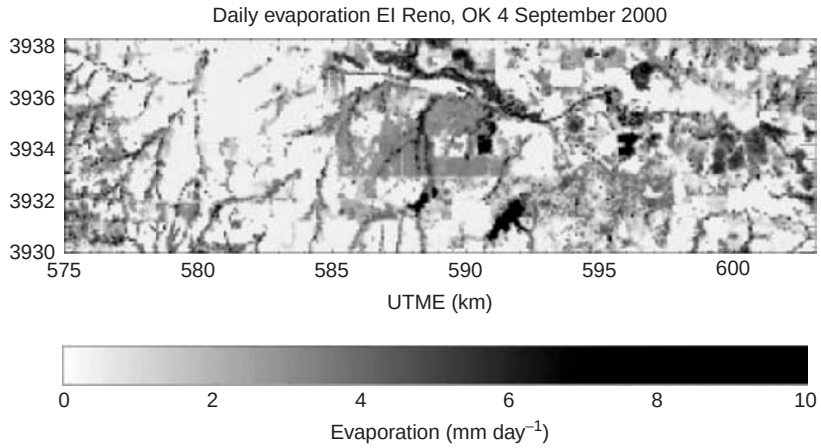

Figure 8 Estimated daily evapotranspiration over the El Reno, Oklahoma study area using ASTER observation at about 11 : 30 am. A drought occurred during the summer of 2000, and by September many of the fields were either plowed or contained senescent vegetation. In this image, 0–1 corresponds to dry soils, 4 to grass lands, and 6–8 to lakes, ponds, and riparian zones

$NDVI \leq 0.1$. Higher ET rates come from grassland sites ($NDVI \geq 0.2$) with the highest rates over irrigated crop fields and riparian areas along streams where $NDVI \geq 0.4$ and water bodies where $NDVI \leq 0$ (Figure 8).

DISCUSSION

In this article, we have reviewed the physics of the thermal radiation emitted from the land surface including the effects of the atmosphere and the surface emissivity. An approach for using the remotely sensed surface temperature to estimate the surface energy fluxes is presented and an example of its application is presented.

The transition of the landscape between predominantly frozen and nonfrozen conditions in seasonally frozen environments impacts climate, hydrological, ecological, and biogeochemical processes profoundly. Satellite microwave remote sensing is uniquely capable of detecting and monitoring a range of related biophysical processes associated with the measurement of landscape freeze/thaw status. This chapter provides an overview of the development, physical basis, current techniques, and selected hydrological applications of satellite-borne microwave remote sensing of landscape freeze/thaw states for the terrestrial cryosphere. Major landscape hydrological processes embracing the remotely sensed freeze/thaw signal include timing and spatial dynamics of seasonal snowmelt and associated soil thaw, runoff generation, and flooding, ice breakup in large rivers and lakes, and timing and length of vegetation growing seasons and associated productivity and trace gas exchange. This chapter also summarizes the physical principles of microwave sensitivity to landscape freeze/thaw state, recent progress in applying these principles towards satellite remote sensing of freeze/thaw processes over broad regions, and potential for future global monitoring of this significant phenomenon of the global cryosphere.

INTRODUCTION

The terrestrial cryosphere comprises cold areas of Earth's land surface where water is either permanently or seasonally frozen. This includes most regions north of 40 degrees North latitude and most mountainous regions where elevation is greater than 1000 m (Figure 1). The state transition of the land surface between frozen and thawed conditions affects a number of terrestrial processes that cycle between wintertime dormant and summertime active states. These processes occur each year over more than 50 million km^2 of the global cryosphere, affecting surface hydrological activity, meteorological conditions, and ecological trace gas dynamics profoundly (Figure 2). Abrupt near 0 °C, this state transition represents the closest analog to a hydrological and biospheric on/off switch existing in nature. Spatial patterns and timing of landscape freeze/thaw state transitions within the terrestrial cryosphere show substantial variability with measurable impacts to climate, hydrological, ecological, and biogeochemical processes.

In seasonally frozen environments, as early spring air temperatures rise above freezing, the snow pack and surface soil layer reach 0 °C and begin to thaw, resulting in a state change of the included water from solid to liquid. Snowmelt is initiated and runoff and stream discharge are accelerated with this onset of the spring thaw transition period. Ecosystem responses to these changes are equally rapid, with soil respiration and plant photosynthetic activity accelerating with warmer temperatures and the new abundance of liquid water (e.g. Goulden *et al.*, 1998; Black *et al.*, 2000; Jarvis and Linder, 2000). A critical component of the hydrological cycle, seasonal snow cover stores large amounts of freshwater, is a major source of freshwater over wide areas of the midlatitudes, and is the principal source of regional runoff in mountainous areas.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

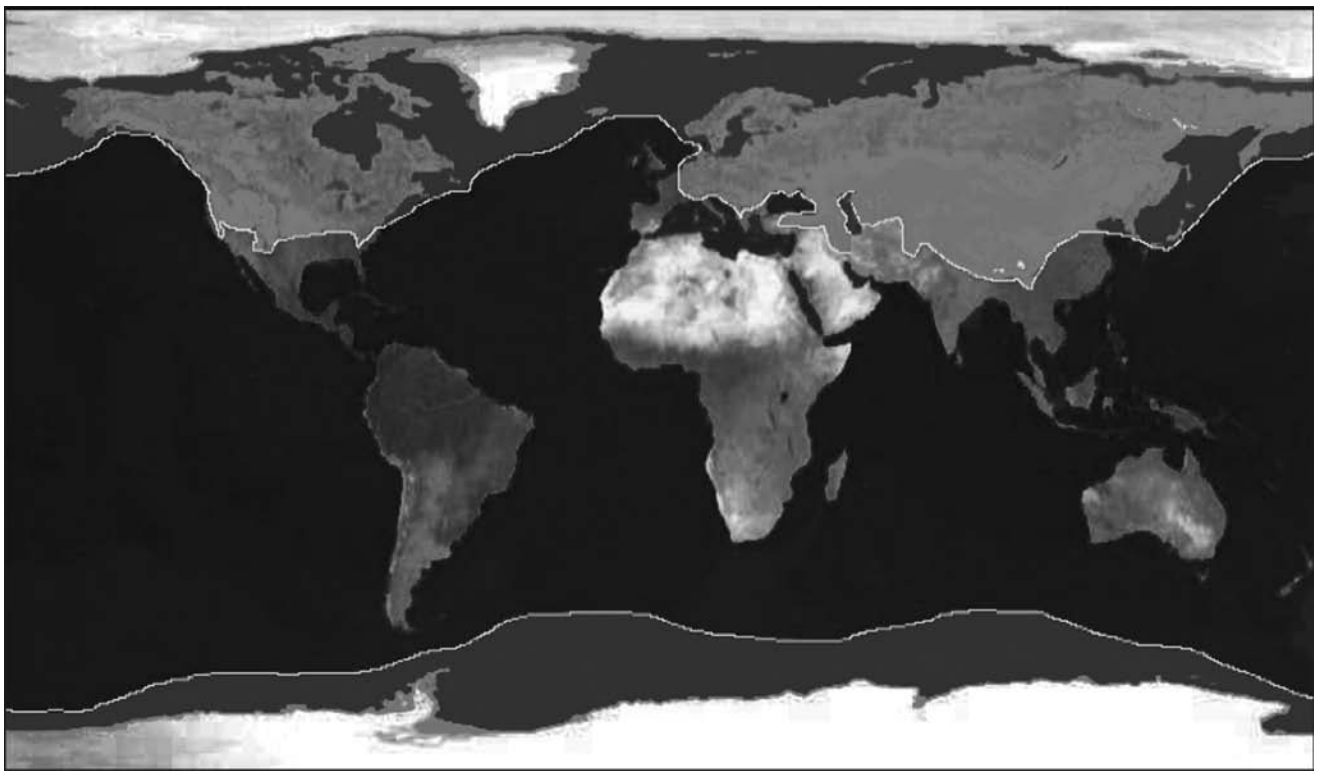

Figure 1 Approximate distribution of frost and ice effected regions. The terrestrial cryosphere comprises land areas shaded light blue or white (north of the yellow line in the northern hemisphere, and Antarctica), and most mountainous regions with elevations over 1000 m. These regions exhibit a 0 °C mean monthly temperature during the coldest month, and approximately 0.25 m of frost penetration one year in ten (after Cline, *et al.*, 1999; based on figure provided courtesy of the US Army Engineer Research and Development Center-Cold Regions Research and Engineering Lab). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

The timing of seasonal freeze/thaw transitions generally defines the duration of seasonal snow cover, frozen soils, and the timing of lake and river ice breakup and flooding in the spring (Kimball *et al.*, 2001, 2004a). The seasonal nonfrozen period also bounds the vegetation growing season, whereas annual variability in freeze/thaw timing has a direct impact on net primary production and net CO_2 exchange with the atmosphere (Vaganov *et al.*, 1999; Goulden *et al.*, 1998).

Landscape freeze/thaw state strongly influences the seasonal amplitude and partitioning of surface energy exchange, with major consequences for atmospheric profile development and regional weather patterns (Betts *et al.*, 2001a). At high latitudes, for example, the onset of seasonal thawing in spring is coincident with snowmelt and large decreases in surface albedo from approximately 80% over snow to less than 20% over vegetation, soil, and open water surfaces (Lafleur *et al.*, 1997; Harazono *et al.*, 2003). Over forests, the albedo remains relatively low (~20%) even in winter (Betts and Ball, 1997), but drops below 10% following seasonal snowmelt. Prior to thaw in the early spring, frozen soils, low evaporation rates, and high incident solar radiation and sensible energy loading promote a relatively warm, dry atmospheric boundary layer as indicated by seasonally low relative humidity (Figure 3). The timing of this transition from predominantly frozen, high albedo conditions to thawed, low albedo conditions coincides with an abrupt increase in surface net radiation. With the decrease in albedo, the additional absorption of incident solar radiation causes surface air and soil temperatures to rise dramatically, often 3–5 °C within a few days. The new abundance of liquid water causes a transition of the surface energy balance from a sensible energy dominated system to a latent energy dominated system with associated increases in surface humidity. An increasing trend in relative humidity continues throughout the growing season with the availability of adequate moisture for vegetation canopy growth and evapotranspiration. In the autumn, the land surface is generally warmer than the air, and atmospheric boundary layers are shallow and moist until the onset of freezing temperatures dramatically reduces available moisture, causing an abrupt seasonal decline in relative humidity. Betts *et al.* (1998) found that numerical weather prediction

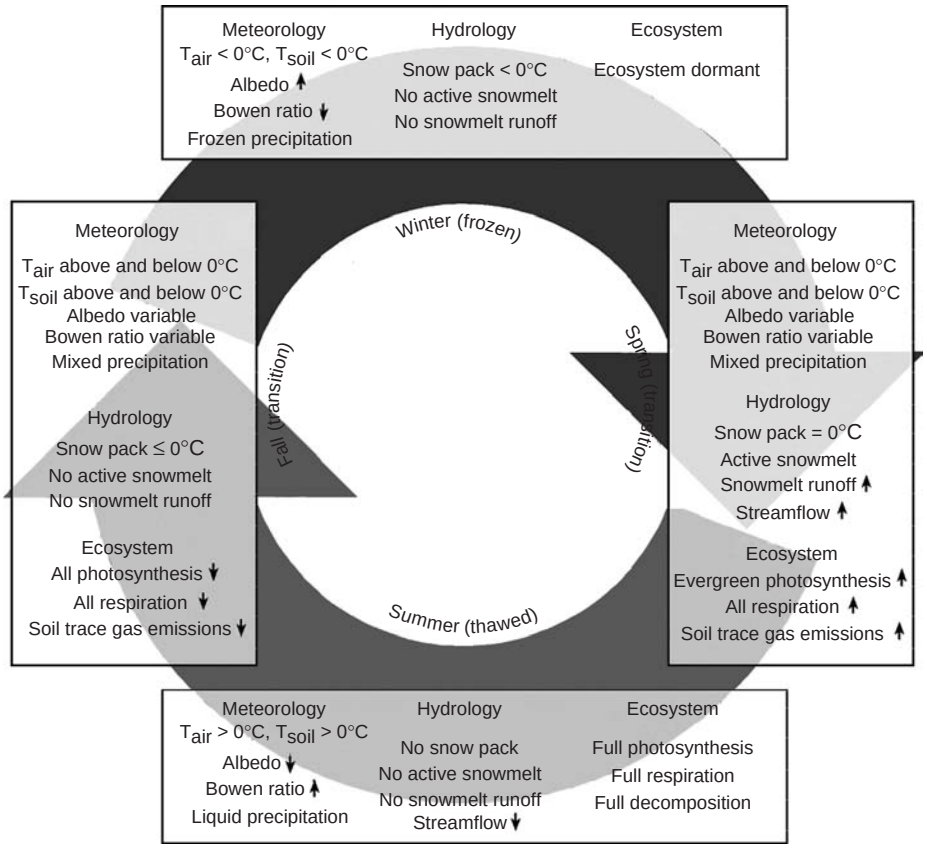

Figure 2 Conceptual diagram showing the general effects of freeze/thaw status and snow on meteorological, hydrological, and ecosystem processes throughout the year (Cline *et al.*, 1999). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

models that do not correctly account for the contrast between frozen and thawed surfaces overestimate springtime latent energy fluxes, leading to forecast errors of up to 5 °C in lower tropospheric temperatures. These errors then propagate throughout the planetary boundary layer and above.

The ability of regional monitoring networks to capture spatial and temporal patterns in landscape freeze/thaw state is severely limited because of the remote locations, large regional extent, and adverse weather conditions that characterize much of the cryosphere. The density of reporting surface weather and hydrological stations in these regions is extremely sparse, on the order of 1 station per million km^2, and has been deteriorating further because of station closures, limited funding, and embargoes on national data (Karl, 1995; Lanfear and Hirsch, 1999). Satellite-borne optical-infrared remote sensing methods provide regional information regarding snow-covered area, surface albedo, and land-surface temperature (LST) that can be used to infer surface freeze/thaw state. For most of the cryosphere, however, frequent cloud cover, low solar elevation angles, shadowing, and reduced illumination restrict regional monitoring from these sensors to relatively coarse 8–16 day temporal composites necessary to mitigate atmospheric effects (Running, 1998; Cihlar *et al.*, 1997). These effects are particularly acute during winter, early spring, and late fall when seasonal freeze/thaw transitions are most likely to occur.

Satellite-borne remote sensing at microwave wavelengths has unique capabilities that allow near real-time monitoring of numerous landscape processes associated with a single measure, freeze/thaw state, without many of the limitations of optical-infrared sensors. These properties include a strong sensitivity to the pronounced contrast in the dielectric constant of frozen and liquid water, the ability of microwaves to penetrate cloud cover, and their independence from solar illumination. Major landscape hydrological processes embracing the remotely sensed freeze/thaw signal include timing and spatial dynamics of seasonal snowmelt and associated soil thaw, runoff generation and flooding, ice breakup in large rivers and lakes, and timing and length of vegetation growing seasons and associated productivity and trace gas exchange. This paper summarizes the physical principles of microwave sensitivity to landscape freeze/thaw state, recent progress in applying these principles toward satellite remote sensing

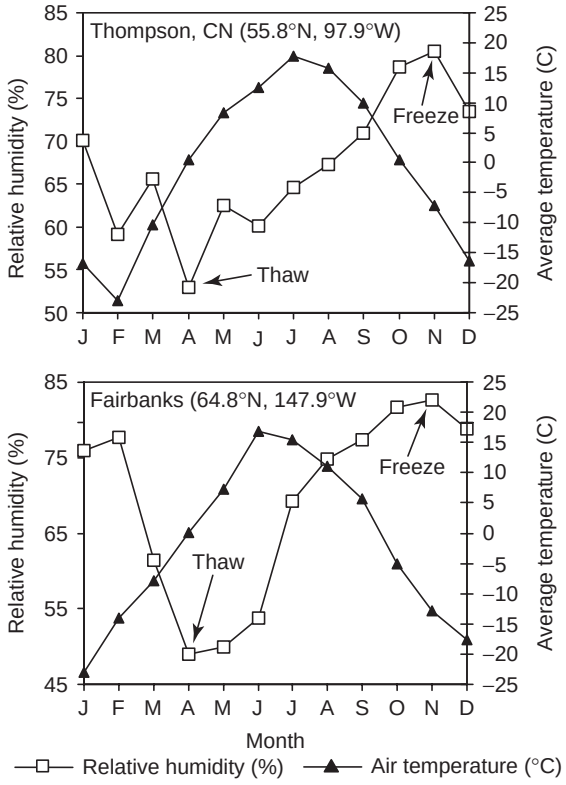

Figure 3 The seasonal cycle of mean monthly relative humidity and air temperature at 2 sites in Northern Canada and Alaska illustrates the large control seasonal surface freeze-thaw dynamics have on boreal climate. Monthly mean relative humidity is at a minimum in April, just prior to spring thaw, because of increased solar irradiance and a general lack of liquid water available for evaporation under frozen conditions. Relative humidity is at a maximum in autumn, when the ground, not yet frozen, is warmer that the air. The consequence is a deep, warm boundary layer in spring, and a very shallow, stratocumulus capped boundary layer in autumn (after Betts *et al.*, 2001b)

of freeze/thaw processes over broad regions, and potential for future global monitoring of this key phenomenon of the global cryosphere.

PRINCIPLES OF MICROWAVE REMOTE SENSING FOR FREEZE/THAW DETECTION

Microwave remote sensing signatures of natural terrain are controlled by the dielectric properties and the structure (shapes, sizes, and spatial arrangement) of the landscape constituents (Elachi, 1987). Radars are active sensor systems that observe a target, providing their own illumination source and measuring the scattered energy returned to the sensor (backscatter). Radiometers are passive sensor systems that observe the target's natural emission (emissivity). Microwave sensors operate at much longer wavelengths than optical sensors, allowing observations day and night throughout the year, regardless of cloud cover, solar zenith angle, and reduced solar illumination that are particularly problematic for optical-infrared remote sensing of the high latitudes. While continuous coverage of surface state conditions is possible, actual coverage is defined by sensor configuration and orbit design.

Freeze/thaw transitions may be spatially and temporally heterogeneous, with the landscape commonly experiencing several thaw and refreeze events in a season, underscoring the need for mapping with combined high spatial resolution and high temporal revisit (Running *et al.*, 1999). Both radiometer and radar measurements have been shown to be sensitive to landscape freeze/thaw state. The effects of vegetation characteristics on these measurements is complex and for the active (radar) case, is influenced by the shapes, sizes, and orientations of the vegetation components to a greater extent than for the passive (radiometer) case. Radars, on the other hand, generally allow measurements with a higher spatial resolution than do radiometers. In general, low spatial resolution, high temporal revisit microwave radiometers (e.g. SSM/I, AMSR-E) and scatterometers (e.g. SeaWinds) are well-suited for quantifying the timing of freeze/thaw transitions across broad regions, whereas high spatial resolution, low-to-moderate revisit Synthetic Aperture Radars (SARs) (e.g. JERS, RADARSAT) are better able to resolve spatial heterogeneity in freeze/thaw transitions in regions of complex topography and land cover. The techniques described here are applicable to both radars and radiometers.

Permittivity and Dielectric Constant

The ability of microwave remote sensing instruments to observe freezing and thawing of a landscape has its origin in the distinct changes of surface dielectric properties that occur as water transitions between solid and liquid phases. A material's permittivity describes how that material responds in the presence of an electromagnetic field (Kraszewski, 1996). As an electromagnetic field interacts with a dielectric material, the resulting displacement of charged particles from their equilibrium positions gives rise to induced dipoles that respond to the applied field. A material's permittivity is a complex quantity (i.e. having both real and imaginary numerical components) expressed as

$$\varepsilon = \varepsilon' - j\varepsilon'' \tag{1}$$

and is often normalized to the permittivity of a vacuum (ε_0), and referred to as the relative permittivity, or the *complex dielectric constant*:

$$\varepsilon_r = \frac{\varepsilon'}{\varepsilon_0} - \frac{j\varepsilon''}{\varepsilon_0} = \varepsilon_r{}' - j\varepsilon_r{}'' \tag{2}$$

The real component of the dielectric constant, $\varepsilon_r{}'$, is related to a material's ability to store electric field energy.

The imaginary component of the dielectric constant, ε_r'', is related to the dissipation or energy loss within the material. At microwave wavelengths, the dominant phenomenon contributing to ε_r'' is the polarization of molecules arising from their orientation with the applied field. The dissipation factor, or *loss tangent,* is defined as the ratio

$$\tan(\delta) = \frac{\varepsilon_r''}{\varepsilon_r'} \tag{3}$$

Consisting of highly polar molecules, liquid water exhibits a dielectric constant that dominates the microwave dielectric response of natural landscapes. Graphed in Figure4, the Debye equation describes the dielectric constant of pure liquid water (Ulaby *et al.*, 1986, pp. 2022–2025). As liquid water freezes, the molecules become bound in a crystalline lattice, impeding the free rotation of the polar molecules and reducing the dielectric constant substantially. Figure 4 compares ε_r of liquid water at 0 °C with ε_r of pure ice across the microwave spectrum.

Brightness Temperature and Backscatter

In general, landscapes of the terrestrial cryosphere consist of a soil substrate that may be covered by some combination of vegetation and seasonal or permanent snow. The sensitivity of radar and radiometer signatures to these landscape features is affected strongly by the sensing wavelength, as well as landscape structure and moisture conditions. The composite remote sensing signature represents a sampling of the aggregate landscape dielectric and structural characteristics, with sensor wavelength having a strong influence on the sensitivity of the remotely sensed signature to the various landscape constituents.

In the microwave region of the electromagnetic spectrum, vegetation canopies may be considered to be weakly scattering media (i.e. media characterized by volume absorption that is much larger than volume scattering), with the first-order approximation to canopy emission and scattering being applicable. In this case, diffuse scattering effects may be ignored and first-order emissivity and scattering model approaches utilized to interpret emissivity and backscatter (Ulaby *et al.*, 1986, vol. II). Figure 5 depicts the first-order contributions to landscape emissivity and backscatter. At higher frequencies, scattering effects of the vegetation are increasingly significant. The dependence of the microwave signatures on vegetation characteristics is complex, with vegetation structure influencing radar signatures to a greater extent than radiometer signatures.

For the passive microwave case, a material's radiometric *brightness temperature*, T_B, is characterized by its emissivity e, as $T_B = e \cdot T$, where T is its physical temperature (K). Emissivity is a unitless variable ranging from 0 for a perfectly nonemitting material, to 1 for a perfect emitter (blackbody) (Ulaby *et al.*, 1986, vol. I). First-order contributions to the landscape brightness temperature (Figure 5a) are (i) emission by the underlying surface that is attenuated

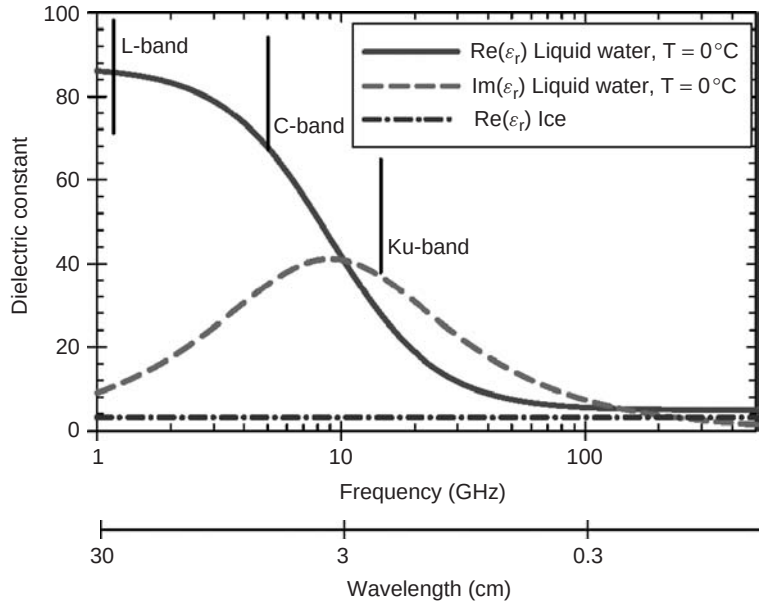

Figure 4 Comparison of the dielectric constants of liquid water at 0 °C and ice shows the contrast across the microwave spectrum. The dielectric constant of water is described by the Debye equation. For pure ice, $\varepsilon_r \approx 3.15 - j\,0.001$ and is independent of temperature and frequency in the microwave region (Ulaby, *et al.*, 1986, p. 848; Kraszewski, 1996). As liquid water possesses a relatively high dielectric constant, its presence or absence and freeze/thaw state strongly influences backscatter and emissivity. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

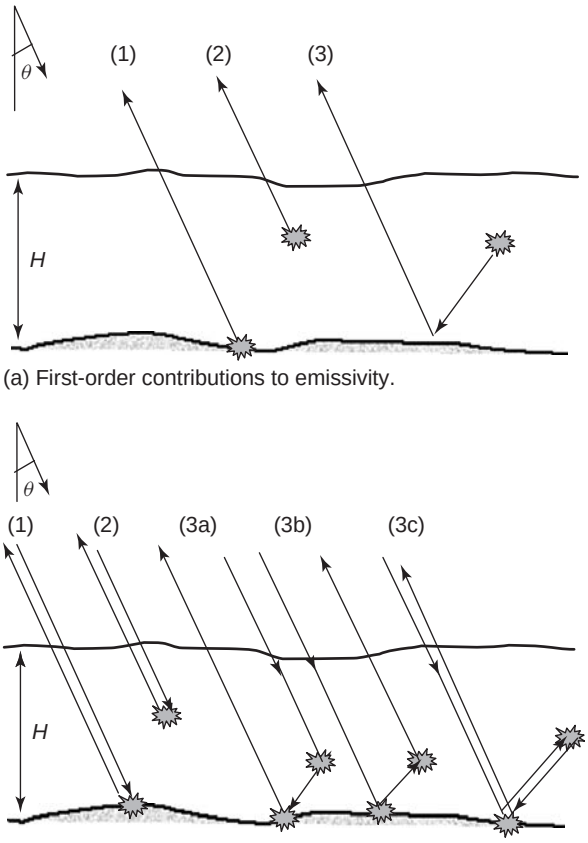

Figure 5 First-order emissivity and scattering contributions to emission (a) and scattering (b) for a land surface covered by a vegetation canopy of height H. The angle θ represents the look angle of the sensing instrument. First-order contributions to landscape emissivity are: (1) emission by the underlying soil and snow that is attenuated by the vegetation, (2) upward-propagating emission by the vegetation itself, and (3) downward-propagating emission by the vegetation that is reflected by the snow-soil surface toward the sensor, attenuated by the vegetation. First-order contributions to backscatter are: (1) backscatter from the underlying snow-soil surface that is attenuated by two-way propagation through the vegetation, (2) backscatter from the vegetation itself, and (3) backscatter arising from multiple scattering between the vegetation and snow-soil surface. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

by upward propagation through the vegetation canopy, (ii) vegetation volume emission propagating in the upward direction, and (iii) vegetation volume emission propagating in the downward direction that is reflected back through the vegetation volume by the underlying surface. These first-order relationships between the landscape physical characteristics and the observed brightness temperature T_{Bp} at polarization p (vertical or horizontal) can be expressed as (Ulaby *et al.*, 1986, vol. II, p. 889):

$$T_{Bp} = T_s e_p \exp(-\tau_c) + T_c(1-\omega)[1-\exp(-\tau_c)] + T_c(1-\omega)[1-\exp(-\tau_c)] r_p \exp(-\tau_c) \quad (4)$$

where T_c and T_s are the physical temperatures (K) of the vegetation canopy and the underlying surface, respectively, τ_c is the vegetation opacity along the slant path defined by the radiometer look angle (θ) and canopy height (H), ω is the single-scattering albedo of the vegetation medium, and r_p is the soil reflectivity at look angle θ. The surface reflectivity is related to its emissivity by $r_p = (1 - e_p)$.

For the active microwave case, the total copolarized backscatter from the landscape at polarization p is the sum of three components (Figure 5b):

$$\sigma^t_{pp} = \sigma^s_{pp} \exp(-2\tau_c) + \sigma^{\text{vol}}_{pp} + \sigma^{\text{int}}_{pp} \quad (5)$$

The first term is the surface backscatter, σ^s_{pp}, modified by the two-way attenuation through a vegetation layer of opacity τ_c along the slant path. The second term represents the backscatter from the vegetation volume, σ^{vol}_{pp}. The third term represents the interaction between the vegetation and soil surface, σ^{int}_{pp}, and includes contributions from terms (3a), (3b) and (3c) of Figure 5(b) (Ulaby *et al.*, 1986 vol II, pp. 860–875; Ulaby *et al.*, 1990; Kuga *et al.*, 1990).

The response of T_{Bp} and σ^t_{pp} to freeze/thaw dynamics is affected by surface roughness, topography, and vegetation and snow cover. The relative contribution of the three terms in each of equations (4) and (5) is influenced strongly by the canopy opacity, τ_c. Opacity, volume scattering, and emission all vary significantly with frequency. For bare surface or sparsely vegetated conditions, the surface terms dominate the received signal, with T_{Bp} and σ^t_{pp} being influenced primarily by contributions from the soil surface and snow cover. Because of the high dielectric constant of liquid water, microwave penetration of the vegetation decreases as biomass moisture levels increase. In general, τ_c increases with increasing frequency, vegetation density, and dielectric constant. High-frequency, short-wavelength energy (e.g. Ku-band) has higher τ_c and does not penetrate as significantly into vegetation canopies as lower-frequency, longer-wavelength energy (e.g. L-band). Hence, higher-frequency sensors are generally less sensitive to properties of surfaces underlying dense vegetation canopies. However, the dependence of T_{Bp} and σ^t_{pp} on snow characteristics is also complex, with snow pack wetness, density, crystal structure, and depth influencing both brightness temperature and backscatter. The effect of snow cover on brightness temperature and backscatter is more significant at higher frequencies because of the increased scattering albedo of the snow pack at short wavelengths relative to longer wavelengths (e.g. Ulaby *et al.*, 1986; Raney, 1998). These phenomena lead to notable differences in the

temporal response of emission and backscatter to landscape freeze/thaw processes with sensor wavelengths (e.g. Way *et al.*, 1994; Way *et al.*, 1997; Frolking *et al.*, 1999; Kimball *et al.*, 2001).

ALGORITHMS

Common approaches employing satellite microwave remote sensing to classifying landscape freeze/thaw state involve temporal change detection schemes applied to time-series radar backscatter or radiometric brightness temperature. The general approach of these techniques is to identify landscape freeze/thaw transition sequences by exploiting the dynamic temporal response of backscatter or brightness temperature to differences in the aggregate landscape dielectric constant that occur as the landscape transitions between predominantly frozen and nonfrozen conditions. These techniques assume that the large changes in dielectric constant occurring between frozen and nonfrozen conditions dominate the corresponding backscatter and brightness temperature temporal dynamics, rather than other potential sources of temporal variability such as changes in canopy structure and biomass or large precipitation events. This assumption is generally valid during periods of seasonal freeze/thaw transitions for most areas of the cryosphere.

Seasonal Threshold Approach

Seasonal threshold approaches examine the time-series progression of the remote sensing signature relative to signatures acquired during a seasonal reference state or states. These techniques are well-suited for application to data with temporally sparse or variable repeat-visit observation intervals and have been applied to ERS and JERS Synthetic Aperture Radar (SAR) imagery (*e.g.* Rignot and Way, 1994; Way *et al.*, 1997; Gamon *et al.*, 2004; Entekhabi *et al.*, 2004). A seasonal scale factor $\Delta(t)$ may be defined for an observation acquired at time t as:

$$\Delta(t) = \frac{\sigma(t) - \sigma_{\mathrm{fr}}}{\sigma_{\mathrm{th}} - \sigma_{\mathrm{fr}}} \tag{6}$$

where $\sigma(t)$ is the measurement acquired at time t, for which a freeze/thaw classification is sought, and σ_{fr} and σ_{th} are measurements (backscatter or brightness temperature) corresponding to the frozen and thaw reference states, respectively. In situations where only a single reference state is available, for example, σ_{fr}, $\Delta(t)$ may be defined as a difference:

$$\Delta(t) = \sigma(t) - \sigma_{\mathrm{fr}} \tag{7}$$

A threshold level T is then defined such that

$$\begin{aligned} \Delta(t) &> T \\ \Delta(t) &\leq T \end{aligned} \tag{8}$$

define the frozen and thawed landscape states, respectively. Whereas equation (6) accounts for differences in the dynamic range of the remote sensing response to freeze/thaw transitions driven by variations in land cover, equation (7) does not scale $\Delta(t)$ to account for the dynamic range in the seasonal response.

The selection of parameter T may be optimized for various land-cover conditions and sensor configurations. In situations where the wintertime microwave signature is not dominated by the snow pack volume, for example, for radar measurements at lower frequencies (e.g. L-band) and where shallow dry snowpacks are common, $\sigma_{\mathrm{fr}} < \sigma_{\mathrm{th}}$ and $\Delta(t) > T$ defines the thawed state. In situations where the wintertime signature is dominated by the snow pack volume, for example, at high frequencies (e.g. Ku-band) and where deep, wet snowpacks are common, the microwave seasonal response to landscape freeze/thaw is more complex, and defining the frozen and thawed landscape state in terms of a single threshold may not adequately represent these processes. In some applications, multiple threshold values may be employed to delineate multiple freeze/thaw events occurring during seasonal transitions.

Moving Window Approach

Moving window techniques classify freeze/thaw transitions based on changes in the radiometric signature relative to the temporally averaged signature computed over a moving window of specified duration. These approaches are useful when applied to temporally consistent data sets consisting of frequent (e.g. daily) observations, and for identifying multiple freeze/thaw transition events. For a measurement $\sigma(t)$ acquired at time t, the difference $\delta(t)$ relative to a moving window mean may be defined as

$$\delta(t) = \sigma(t) - \sigma_{av}(t - L \leq t_0 \leq t - 1) \tag{9}$$

where $\sigma_{av}(t - L \leq t_0 \leq t - 1)$ is the average measurement (backscatter or brightness temperature) acquired over a window of duration L extending over the time interval $(t - L \leq t_0 \leq t - 1)$. The difference $\delta(t)$ may be compared to various thresholds, as in (8), to define the timing of critical freeze/thaw transitions. These approaches have been employed using both NSCAT and SeaWinds scatterometer data for a variety of regions (Frolking *et al.*, 1999; Kimball *et al.*, 2001, 2004a,b; Rawlins *et al.*, 2004). Principal distinctions in the application of equation (9) have been the duration L of the moving window and the selection of thresholds applied to infer transition events.

Temporal Edge Detection Approach

Temporal edge detection techniques classify freeze/thaw transitions by identifying predominant step edges in time-series remote sensing data that correspond to freeze/thaw

transition events. As freeze/thaw events induce large temporal changes in landscape dielectric properties that tend to dominate the seasonal time-series response of the microwave radiometric signatures for the terrestrial cryosphere, edge detection approaches are suitable for identification of these events using time-series microwave remote sensing data. These techniques are based on the application of an optimal edge detector for determining edge transitions in noisy signals (Canny, 1986). The timing of a major freeze/thaw event is determined from the convolution applied to a time series of backscatter or brightness temperature measurements $\sigma(t)$:

$$CNV(t) = \int_{-\infty}^{\infty} f'(x)\sigma(t-x)\,\mathrm{d}x \qquad (10)$$

where $f'(x)$ is the first derivative of a normal (Gaussian) distribution. The occurrence of a step-edge transition is then given by the time when *CNV(t)* is at a local maximum or minimum.

Seasonal transition periods may involve multiple freeze/thaw events. This technique accounts for the occurrence of weak edges, or less pronounced freeze/thaw events, as well as larger seasonal events indicated by strong edges, and can distinguish the frequencies and relative magnitudes of these events. The variance of the normal distribution may be selected to identify step edges with varying dominance, that is, selection of a large variance identifies more predominant step edges, while narrower variances allow identification and discrimination of less pronounced events. This approach has been applied to daily time-series brightness temperatures from the Special Sensor Microwave/Imager (SSM/I) to map primary springtime thaw events annually across the pan-Arctic basin and Alaska (McDonald *et al.*, 2004).

HYDROLOGICAL APPLICATIONS OF SATELLITE FREEZE/THAW DETECTION

The ability of satellite-borne microwave remote sensing instruments to detect freeze/thaw transitions over broad landscapes has been well established. Initial radar studies were carried out from ground-based observations of bare soils and croplands, followed by aircraft campaigns over boreal landscapes, and more recently at regional and continental scales using a variety of satellite-based platforms. Studies using truck-mounted scatterometers have demonstrated the sensitivity of radar backscatter to soil and vegetation frozen and thawed conditions (Wegmuller, 1990; Ulaby *et al.*, 1986). Freeze/thaw transitions in boreal forest landscapes were first observed with imaging radar in a series of L-band (1.1 GHz, 23-cm wavelength) synthetic aperture radar (SAR) images acquired during March 1988 over boreal forests of central Alaska by the NASA/JPL AIRSAR instrument flown onboard a DC-8 aircraft. As air temperatures ranged from unseasonably warm (up to 9 °C) to well below freezing (−8 to −15 °C), a corresponding 4–6 dB decrease in landscape backscatter resulted (Way *et al.*, 1990). An intensive study of the fall freeze transition was carried out for the same region using a temporal sequence (August to November 1991) of European Remote Sensing (ERS-1) satellite C-band (5.2 GHz, 5.7 cm) SAR images processed at a 200-m spatial resolution (Rignot *et al.*, 1994; Rignot and Way, 1994). ERS SAR imagery showed an approximate 3 dB decrease in radar backscatter as the landscape froze, corresponding to *in situ* vegetation, soil, and air-temperature measurements of freezing conditions within mature black spruce, white spruce, and balsam poplar stands. ERS-1 SAR data were also used to assess spring thaw processes within the BOREAS region of central Canada (Way *et al.*, 1997; Gamon *et al.*, 2004). These results were limited to a coarse 3–168 day temporal repeat because of the narrow (100 km) swath width and varying orbital geometry of the ERS SAR sensor. Results showed a two-stage 1–2 dB temporal increase in radar backscatter, relative to midwinter frozen values, corresponding to surface measurements of initial snow pack and soil thaw in March followed by forest canopy thaw in May.

At continental scales, Wismann (2000) mapped spatial and temporal behavior in the surface spring thaw transition across much of Siberia using a temporal change detection analysis of ERS-1 C-band scatterometer data. These data were collected from March to July 1993, processed to a 50-km spatial resolution and an approximate 3-day temporal fidelity. Moderate, 25-km spatial resolution data from the Ku-band NASA scatterometer (NSCAT; 14.0 GHz, 2.1 cm) and SeaWinds-on-QuikSCAT scatterometer (13.4 GHz, 2.2 cm) have been used to assess freeze/thaw cycles over broad boreal, Arctic, and subalpine landscapes of North America (Frolking *et al.*, 1999; Kimball *et al.*, 2001, 2004a,b). Daily backscatter data from these scatterometers show a 5 to 8 dB temporally dynamic response that coincides with landscape springtime freeze/thaw processes as identified by daily snow cover, air, vegetation, and soil temperature measurements from regional surface station networks. The primary thaw transition has been found to be generally coincident with the arrival of maximum surface wetness in spring associated with rising air temperatures, seasonal snowmelt, soil active layer thawing and growing season onset (Kimball *et al.*, 2004a).

Studies using coincident satellite-borne remote sensing and surface network measurements of freeze/thaw processes demonstrate that these seasonal transitions are spatially heterogeneous and that landscapes undergo multiple thaw and refreeze cycles in a season. Figure 6 shows the seasonal progression of daily mean radar backscatter from a mature boreal black spruce forest site in northern Manitoba,

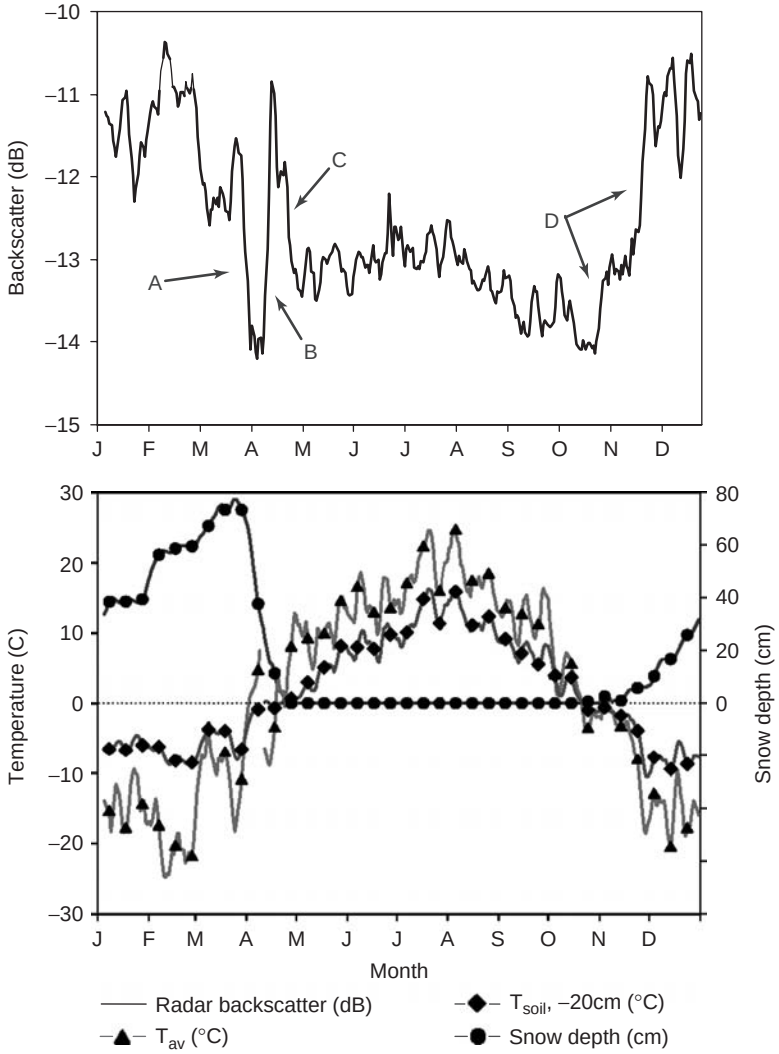

Figure 6 Satellite-borne Ku-band mean daily radar backscatter from the outer beam of the SeaWinds scatterometer flown onboard QuikSCAT measured for a mature boreal black spruce forest in Northern Manitoba, Canada in 2001. Also shown are daily site surface air and soil temperature data from the NSA-OBS Ameriflux site and snow depth data from nearby Thompson, Manitoba, both located within the SeaWinds sensor footprint. These results highlight the large sensitivity of Ku-band radar to landscape seasonal freeze-thaw state transitions as indicated by seasonal changes in snowcover, and air and soil temperatures. Surface state transitions between frozen and thawed conditions are associated with large (1–3 dB) temporal changes in radar backscatter. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Canada measured with the SeaWinds scatterometer. These results demonstrate the pronounced sensitivity of Ku-band radar backscatter to seasonal landscape freeze-thaw state transitions as identified by surface snow cover and air and soil temperature measurements located within the sensor footprint. Surface freeze/thaw state transitions are associated with large (1–3 dB) temporal changes in radar backscatter. A major thaw event in early spring (A) coincides with a 2-dB decrease in radar backscatter, followed by a brief refreezing event (B) corresponding to a 3-dB backscatter increase, final spring thawing (C) and a large backscatter decrease. In the autumn, freezing air and soil temperatures and the arrival of seasonal snow cover coincide with large increases in radar backscatter (D). These time-series backscatter data have been shown to identify spring thaw and autumn freeze processes that coincide with seasonal shifts in boreal ecosystem carbon exchange from a source to sink of atmospheric CO_2. This effectively identifies the seasonal boundaries of the vegetation growing season (Frolking *et al.*, 1999; Kimball *et al.*, 2004b).

Studies utilizing passive microwave radiometry have also demonstrated a capability for distinguishing freeze/thaw cycles with both ground-based and spaceborne systems (England, 1990; Judge *et al.*, 1997; Judge *et al.*, 2001;

Zhang *et al.*, 2003). Data from both the Nimbus 7 Scanning Multichannel Microwave Radiometer (SMMR) and the Special Sensor Microwave/Imager (SSM/I) have been used to identify and monitor snow cover and the freeze/thaw status of prairie soils across the Northern Great Plains region of North America (England, 1990; Zuerndorfer and England, 1992; Judge *et al.*, 1997). Though these sensors have lower spatial resolutions than active microwave sensors, they have been successful at monitoring thaw processes and snow properties in prairie regions with gentle topography, shallow snow, dry soils, and low vegetation densities (e.g. Josberger *et al.*, 1998).

Availability of multiyear global data sets allows investigation of trends and variability in freeze/thaw transitions. SeaWinds-on-QuikSCAT provides consistent global coverage beginning summer, 1999. Figure 7 shows maps of the primary springtime thaw date across the pan-Arctic basin and Alaska as derived from SeaWinds data for years 2000–2003. The multiyear SSM/I time series has also been used to assess seasonal freeze-thaw dynamics at high latitudes and associated linkages to vegetation growing seasons and atmospheric CO_2 concentrations (Mognard *et al.*, 1998; McDonald *et al.*, 2004). These data have proven to be a useful tool for global change monitoring at high latitudes. Analysis of daily time-series SSM/I data for the pan-Arctic basin and Alaska, for example, shows evidence of an approximate 8-day advance in the timing of spring thawing and initiation of seasonal growing seasons at high latitudes from 1988 to 2001, with generally positive impacts to regional vegetation productivity (McDonald *et al.*, 2004). This finding is generally consistent with other observations of a trend towards earlier onset of the growing season and higher vegetation productivity at high latitudes derived from the NOAA AVHRR Pathfinder record (Myneni *et al.*, 1997). Unlike NOAA AVHRR, however, satellite-borne microwave sensors such as SSM/I and SeaWinds provide more consistent, daily observations of the cryosphere without significant signal degradation from atmosphere and illumination effects, allowing improved temporal fidelity and potentially better detection and monitoring of global change.

The global coverage and daily temporal repeat observations of landscape freeze/thaw conditions available from moderate resolution, active/passive microwave sensors such as SeaWinds and the SSM/I have direct application to hydrological monitoring (Running *et al.*, 1999; Kimball *et al.*, 2001; Rawlins *et al.*, 2004). The timing of seasonal ice breakup and the spring flood pulse is the

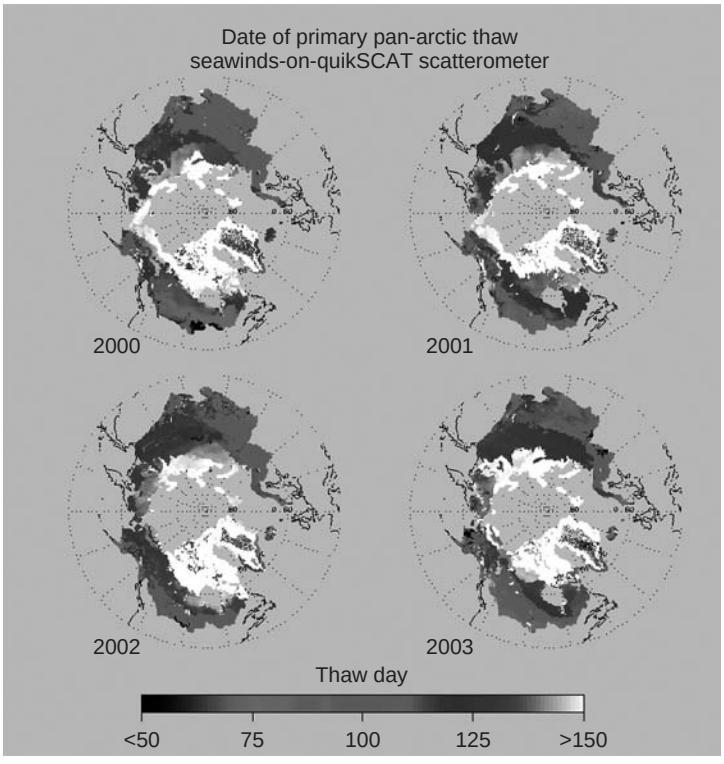

Figure 7 Day of the primary spring thaw event across the pan-arctic drainage basin for 2000–2003. Maps were derived using daily SeaWinds-on-QuikSCAT outer beam data posted to a 25-km grid. The edge detection scheme of equation (10) was applied to derive primary thaw day. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

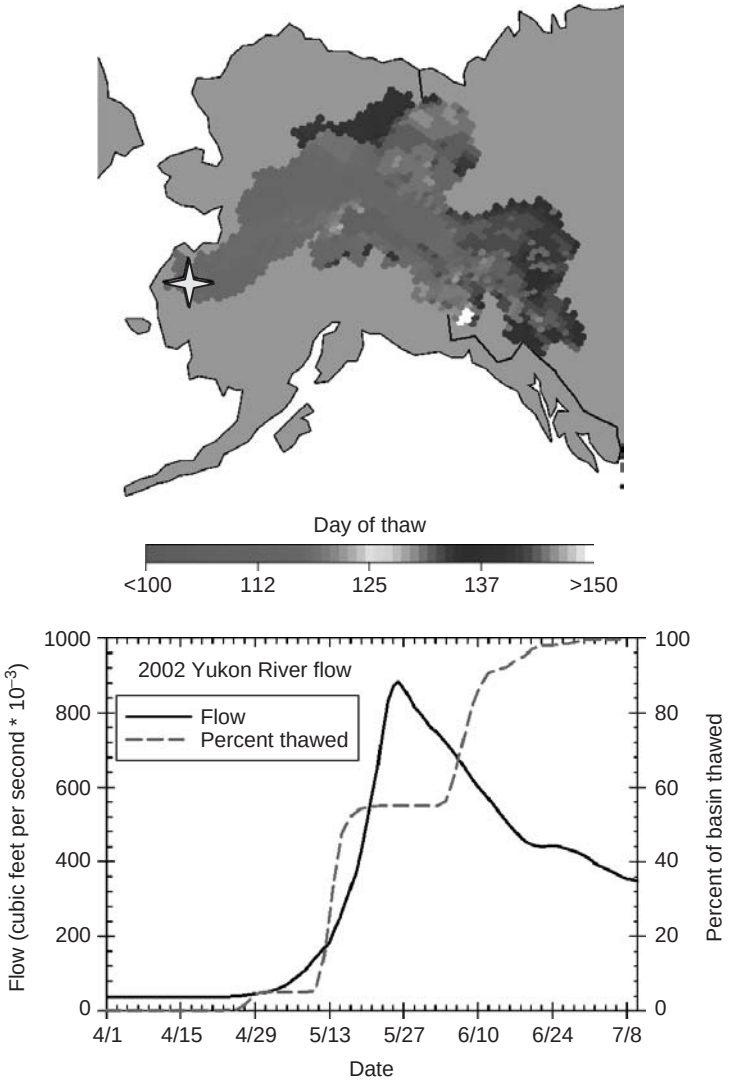

Figure 8 The map at top shows the day of primary thaw during 2002 for the Yukon River basin of Alaska and Yukon Territory. Primary thaw day was derived using the edge detection scheme of equation (10) applied to the SeaWinds-on-QuikSCAT Ku-band scatterometer data. The graph at bottom compares the percent of the Yukon River basin having undergone the primary thaw to daily mean river flow during 2002 measured near the mouth of the Yukon River. The Yukon River drains 831 391 km^2 of boreal NW Canada and Alaska. Yukon River daily flow records were obtained for Pilot Station, Alaska (location indicated by the yellow cross) courtesy of the US Geological Survey. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

dominant annual hydrological event for major rivers of the cryosphere. The rate, location, and extent of thawing and snowmelt in spring have major impacts on runoff and potential for flooding. While stream gages provide accurate measurements of past and current flow conditions, they provide little information on future flows or advanced warning of potential flooding. Figure 8 shows a map of the day of the primary spring thaw event as derived from a temporal classification of SeaWinds daily radar backscatter observations for the Yukon River basin of Alaska and Yukon Territory. The Yukon River drains an area of approximately 840 000 km^2 and is one of the 3 longest rivers in North America. The graph in Figure 8 shows the relationship between stream flow and the spring flood pulse, and the relative proportion of basin area having undergone the primary springtime thaw as determined from the SeaWinds data. Together, the map and associated graph show that for 2002 seasonal thawing of the basin initiated at lower elevations prior to April 30 and progressed to higher elevation areas over an approximate 3-week period. A major thaw event began on May 12, extended over a 2-day period and encompassed approximately 50% of the basin. This event coincided with the timing of major ice breakup and arrival of the primary spring flood pulse for the river. A second

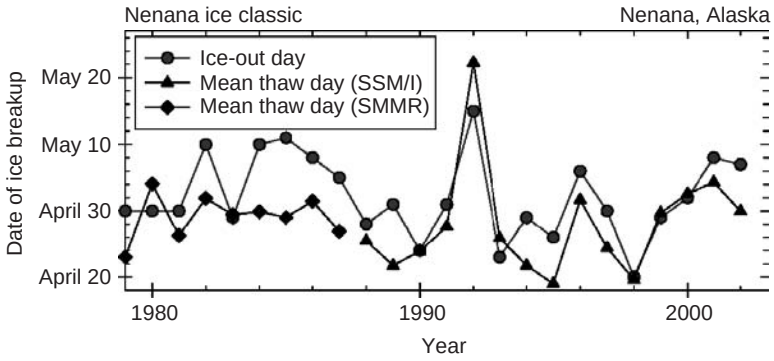

Figure 9 Comparison of mean primary thaw day for the Yukon River basin of Alaska and Yukon Territory with ice breakup day measured on the Tanana River at Nenana, Alaska (http://www.nenanaakiceclassic.com/BreakupLog.htm). Primary thaw day was derived from SSMI and SMMR passive microwave pathfinder data (Armstrong *et al.,* 1994; Armstrong and Brodzik, 1995; Knowles *et al.,* 2002). The relationship between mean thaw day and ice breakup day yields $r^2 = 0.52$ and $P = 7.2 \times 10^{-5}$ (JERS Images Copyright © 1992–1998 NASDA/MITI. Courtesy of the Global Boreal Forest Mapping (GBFM) project). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

major thaw event is also evident, beginning in early June and is associated with thawing of higher elevations. This secondary event does not contribute to the seasonal peak flow, but extends the period of flood recession.

The timing of seasonal ice breakup of major rivers and lakes in spring has important implications for navigation and potential for flooding. Additionally, long-term changes in the timing of these events have been found to be an important indicator of hydrological responses to global change (Magnuson *et al.*, 2000). As the previous example indicated, satellite microwave remote sensing of the timing of regional thawing in spring is closely associated with the timing of the seasonal ice breakup for major rivers. Long-term monitoring of freeze-thaw processes from spaceborne sensors has the potential for enhanced regional monitoring of this important variable. Figure 9 shows the relationship between the timing of ice breakup for the Tanana River at Nenana, Alaska and the average annual spring thaw date for the surrounding Yukon basin as derived from a temporal classification of SMMR and SSM/I time-series T_b observations for the region (McDonald *et al.*, 2004). These results illustrate the strong correspondence between seasonal ice breakup for the river and regional thawing as observed from the passive microwave record. This graphic also highlights the substantial annual variability in both the timing of spring thawing and seasonal ice breakup that characterizes much of the global cryosphere, with the standard deviations in mean thaw day and ice breakup day being 6.7 and 6.2 days, respectively.

While moderate resolution sensors such as SeaWinds and SSM/I provide relatively high temporal fidelity, their capability to distinguish subgrid scale (i.e. $<\sim$25 km resolution) freeze/thaw processes is limited. These limitations can be problematic for distinguishing complex freeze/thaw patterns over landscapes with variable topography and other spatially heterogeneous features. Techniques have been applied to improve spatial resolution of these data with demonstrated success (Early and Long, 2001), though these methods generally sacrifice temporal fidelity in order to enhance spatial resolution. Satellite-borne synthetic aperture radars such as JERS-1, ERS and Radarsat time-series data provide relatively fine scale (e.g. $\leq$200 m) spatial resolution and have been useful for monitoring freeze/thaw transitions, albeit with less temporal fidelity than the moderate resolution sensors. While the relatively coarse temporal fidelity (3–168 day) of these data has limitations for global monitoring, they can provide an accurate means for assessing subgrid scale spatial variability in freeze-thaw processes over complex landscapes. As Figure 10 shows, 100 m resolution JERS-1 L-band SAR data have the capability to accurately distinguish spatial variability in freeze-thaw processes associated with differences in landscape slope, aspect, and vegetation within a complex boreal landscape of central Alaska. While coincident Ku-band daily backscatter time-series data from SeaWinds capture the predominant seasonal freeze/thaw pattern of the 25-km region, these data do not capture the subregional complexity of freeze/thaw spatial patterns associated with variable vegetation canopy conditions and topography.

SUMMARY AND FUTURE DIRECTIONS

We have presented an overview of the development, physical basis, current techniques, and selected hydrological applications of satellite-borne remote sensing of landscape freeze/thaw states. The ability of satellite-based microwave remote sensing to detect freeze/thaw status over broad landscapes has been well established, first through focused ground-based and aircraft observations, and extending to

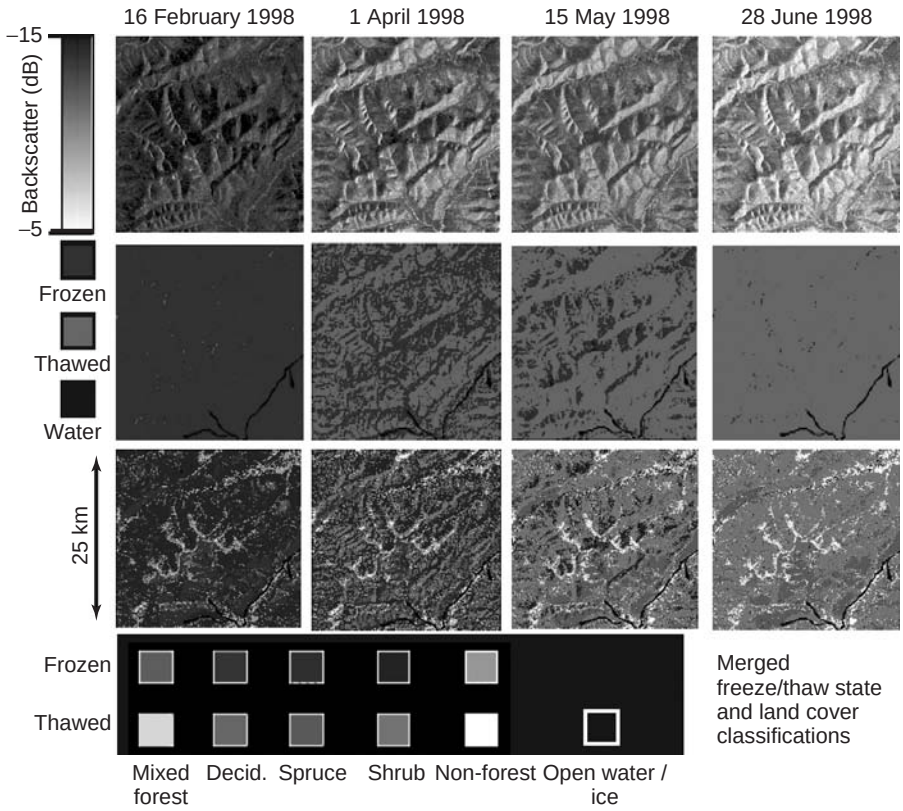

Figure 10 Time series of JERS-1 L-band SAR imagery is applied to assess the spatial complexity in freeze/thaw transition for a boreal landscape. The top series of four images shows backscatter for a 25 km × 25 km region of boreal forest near Fairbanks, Alaska. The middle series shows the corresponding classified freeze/thaw maps. In the bottom series, the freeze/thaw maps have been merged with a land-cover classification map to illustrate the variability of thaw transition with land cover. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

regional and continental scale observations from a variety of satellite-borne active and passive microwave sensors. Application of this information ranges from studies of global change and growing season dynamics to regional monitoring of snowmelt timing and seasonal flooding. Though a variety of current satellite-borne microwave sensors are capable of quantifying landscape freeze-thaw transitions, most are not optimized for this purpose and lack the optimal combination of measurement wavelength, spatial resolution, temporal repeat, and global coverage.

The large range of seasonal and annual variability of freeze/thaw transitions within the cryosphere and the broad ranging impact of this state variable on regional and even global climate, hydrology, and biogeochemistry would suggest that regular, accurate monitoring be a priority in global change research. However, at high latitudes and high elevations the number density of reporting surface weather stations and of hydrological monitoring stations is very low. While optical satellite data suffer from cloud contamination and seasonal solar illumination problems, satellite-borne active and passive microwave remote sensing of landscape freeze/thaw processes may have increased scientific and policy significance for the future. A variety of current satellite-borne microwave sensors are useful for detecting freeze/thaw processes. Development is also under way for a new combined active-passive microwave sensor system with more optimal spectral, spatial, and temporal sampling capabilities for dedicated monitoring of freeze-thaw processes for the global cryosphere. The Hydrosphere State Mission (HYDROS) is currently being developed under NASA's Earth System Science Pathfinder (ESSP) program. This planned satellite mission will provide active and passive L-band observations of the Earth's soil moisture and land surface freeze/thaw conditions for improving our understanding of the linkages between global energy, water, and carbon cycles (Entekhabi *et al.*, 2004). Other missions are also being developed specifically for improved hydrological monitoring of snow and freeze-thaw processes over cold land regions (Cline *et al.*, 1999). Thus regional assessment and monitoring of the freeze/thaw variable will continue, as will the application of this variable for hydrological and global change research.

Acknowledgments

We thank Erika Podest (California Institute of Technology and the University of Dundee, Scotland) for her assistance with the JERS SAR Bonanza Creek data set. We thank Michael Rawlins (University of New Hampshire) for his assistance with the Yukon River catchment data processing. We are grateful to Dr. Donald Cline (National Oceanic and Atmospheric Administration) and Dr. Alan Betts for their helpful input. SeaWinds data were provided by the NASA Ocean Vector Winds Science Team and the Physical Oceanography Distributed Active Archive Center (PO.DAAC) at the Jet Propulsion Laboratory, Pasadena, CA. Nimbus-7 SMMR daily EASE-Grid brightness temperatures and NOAA/NASA Pathfinder SSM/I Level 3 EASE-Grid Brightness Temperatures were obtained from the EOSDIS NSIDC Distributed Active Archive Center (NSIDC DAAC), University of Colorado at Boulder. This work was carried out at the Jet Propulsion Laboratory, California Institute of Technology, and at the University of Montana, Missoula, under contract to the National Aeronautics and Space Administration.

54: Estimation of Surface Soil Moisture Using Microwave Sensors

THOMAS J JACKSON

USDA ARS Hydrology and Remote Sensing Lab, Beltsville, MD, US

Soil moisture has been particularly difficult to measure and map using conventional ground-based point sampling. Microwave remote sensing–based soil moisture retrieval has been demonstrated using tower and aircraft instruments. The translation of this approach to satellites and the implementation in hydrologic applications has been limited by both the technology and the satellite systems that were available. Recent developments in both science and associated technologies now make the exploitation of the microwave region for soil moisture mapping feasible. A number of new and potential satellite missions are reviewed and evaluated for soil moisture applications.

INTRODUCTION

Improvements in hydrological modeling can be achieved through observation of the current status of soil moisture. More accurate predictions from these models will lead to better forecasts of floods and other hydrological phenomena. Soil moisture products are now feasible using a new generation of microwave remote sensing satellites. The quality of these products will continue to improve over time as new sensors are launched.

Leese *et al.* (2001) concluded that the optimal approach to monitoring soil moisture would be a combination of model derived estimates using *in situ* measurements and estimates derived from remote sensing data as input data for assimilation (Houser *et al.*, 1998). In this regard, each method produces soil moisture values that are both unique and complementary. These satellite products, combined with existing *in situ* observations, should be exploited in hydrological monitoring, assessment, and prediction.

Remote sensing has been a valuable tool in some aspects of hydrological modeling. Advantages include synoptic coverage, temporal repeat, and in most situations the unrestricted collection and distribution of information.

Microwave sensors are of particular value in hydrology because they respond to the amount of moisture in the soil. There are several methods that have been shown to be capable of providing soil moisture information. Each has unique capabilities (i.e. temporal coverage, spatial resolution) that must be matched with specific types of applications. In the past, options have been limited by available satellite systems. Investigators have demonstrated the potential of these data in hydrologic studies using ground and aircraft systems. However, efforts to use the less than optimal available satellite systems have had very limited success. In recent years, and continuing over the coming decade, a wide range of new and significantly improved satellites will be launched that will offer new opportunities. A description of alternative techniques will be presented along with a review of current and future satellite systems and products.

MICROWAVE REMOTE SENSING OF SURFACE SOIL MOISTURE

Microwave remote sensing provides a direct measurement of the surface soil moisture for a range of vegetation cover conditions within reasonable error bounds. Two basic approaches are used, passive and active. In passive methods, the natural thermal emission of the land surface (or brightness temperature) is measured at microwave wavelengths, using very sensitive detectors. In active methods or radar, a microwave pulse is sent and received. The power

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

of the received signal is compared to that which was sent to determine the backscattering coefficient.

Portions of the microwave region of the electromagnetic spectrum are often referred to as bands, which are identified by a lettering system. Some of the relevant bands that are used in Earth remote sensing are: K (18–27 GHz), X (8–12 GHz), C (4–8 GHz), and L (1–2 GHz). Within these bands, only small ranges exist that are protected for scientific applications, such as radioastronomy and passive sensing of the Earth's surface. There is evidence that there is increasing radio frequency interference (RFI) occurring throughout the world as a result of communications networks.

Microwave sensors operating at very low microwave frequencies (<6 GHz) provide the best soil moisture information. At low frequencies, attenuation and scattering problems associated with the atmosphere and vegetation are less significant, the instruments respond to a deeper soil layer, and have a higher sensitivity to soil water content variations.

Active and passive sensors provide different types of measurements, which are determined by various physical phenomena. However, both types of sensors provide information on the surface reflectivity. The essential relationship needed to utilize microwave remote sensing, is a link between reflectivity and soil moisture. The Fresnel reflection equations are generally used for this purpose (Ulaby *et al.*, 1986). These equations predict the surface reflectivity (r) as a function of dielectric constant (k) and the viewing angle (θ), based on the polarization of the sensor (horizontal-H or vertical-V).

$$r^{\mathrm{H}} = \left| \frac{\cos\theta - \sqrt{k - \sin^2\theta}}{\cos\theta + \sqrt{k - \sin^2\theta}} \right|^2 \tag{1}$$

$$r^{\mathrm{V}} = \left| \frac{k\cos\theta - \sqrt{k - \sin^2\theta}}{k\cos\theta + \sqrt{k - \sin^2\theta}} \right|^2 \tag{2}$$

From the reflectivity, the dielectric constant of the soil can be estimated. The dielectric constant of soil is a composite of the values of its components: air, soil, and water. The basic reason microwave remote sensing is capable of providing soil moisture information is that there is a large difference between the dielectric constants of water (~80) and the other components (~4). On the basis of an estimate of the mixture dielectric constant derived from the Fresnel equations and soil texture information, volumetric soil moisture can be estimated using an inversion of the model. The depth of soil measured is approximately one-fourth the wavelength (wavelength~29.6/frequency (GHz)).

Passive Microwave Techniques

Passive microwave remote sensing utilizes radiometers that measure the natural thermal radio emission within a narrow band centered on a particular frequency. The measurement provided is the brightness temperature in degrees Kelvin, T_{B}, which includes contributions from the atmosphere, reflected sky radiation, and the land surface. Atmospheric contributions are negligible at frequencies <10 GHz, and the following section assumes this to be the case. Galactic and cosmic radiations contribute to sky radiation and have a known value that varies very little in the frequency range used for observations of soil water content ($T_{\mathrm{sky}} \sim 4$ K). The observed brightness temperature of a surface is equal to its emissivity (e_{obs}) multiplied by its physical temperature (T). The observed emissivity is equal to 1 minus the reflectivity, which provides the link to the Fresnel equations and soil moisture for passive microwave remote sensing.

On the basis of the above and neglecting atmospheric contributions, for a specific frequency (f), polarization (p), and viewing angle (θ), the equation for T_{B} is

$$T_{\mathrm{B}_{fp\vartheta}} = \mathrm{e}_{\mathrm{obs}_{fp\vartheta}} T + (1 - \mathrm{e}_{\mathrm{obs}_{fp\vartheta}}) T_{\mathrm{sky}} \tag{3}$$

The second term of equation 3 is about 2 K. A typical range of response for a soil is 60 K; therefore, the reflected sky contribution can be dropped for computational purposes. Equation 3 can be rearranged as follows:

$$\mathrm{e}_{\mathrm{obs}_{fp\vartheta}} = \frac{T_{\mathrm{B}_{fp\vartheta}}}{T} \tag{4}$$

If the physical temperature is estimated independently, the emissivity can be determined from T_{B}. The physical temperature can be estimated using surrogates based on satellite surface temperature, air-temperature observations, or forecast model predictions. As noted above, the derived emissivity is for a specific instrument configuration (frequency, polarization, and viewing angle).

For natural conditions, varying degrees of vegetation type and density are likely to be encountered. The presence of vegetation has a major impact on the microwave measurement. Vegetation reduces the sensitivity of the retrieval algorithm to changes in soil water content by attenuating the soil signal and by adding a microwave emission of its own to the microwave measurement. This attenuation increases with increasing microwave frequency, which is another important reason for using lower frequencies. Attenuation is characterized by the optical depth of the vegetation canopy (Jackson and Schmugge, 1991). A widely used correction for these effects uses information on the vegetation type (parameter b) and the vegetation water content (W_{veg}) as follows:

$$\mathrm{e}_{\mathrm{surf}_{fp\vartheta}} = 1 + [\mathrm{e}_{\mathrm{obs}_{fp\vartheta}} - 1] \exp[-2bW_{\mathrm{veg}} \cos\theta] \tag{5}$$

The corrected emissivity represents that of the soil surface (e_{surf}). Methods have been developed for estimating vegetation type parameter (typically derived from land cover) and vegetation water content using visible/near-infrared remote sensing.

One of the key concepts in passive microwave remote sensing is the effect of frequency on the retrieval capabilities. To illustrate this, sensitivity will be used as defined by the change in T_B for a 1% change in soil moisture. A good system design seeks to maximize sensitivity for a wide range of vegetation conditions. Using simple radiative transfer models (Jackson, 1993), it is possible to simulate the relationship between soil moisture and T_B for different levels of vegetation and frequencies. The slope of these relationships represents the sensitivity. Sensitivity as a function of frequency is presented in Figure 1 for bare soil and a vegetation canopy with a nominal vegetation water content of $1\,kg\,m^{-2}$. Although the contributing depth changes, the sensitivity for bare soil is high and fairly constant. The effect of frequency is clearly seen in the vegetation curve. At high frequencies ($\sim$19 GHz), there is essentially no sensitivity to soil moisture under these vegetation conditions. However, if we could implement a 1 GHz system, there would be good sensitivity over a wide range of vegetation conditions.

Most research and applications involving passive microwave remote sensing of soil moisture have emphasized low frequencies (L-band). In this range, it is possible to develop soil moisture retrievals based on a single H polarization observation (Jackson, 1993). This approach relies on providing ancillary data on temperature, vegetation, land cover, and soils. Other algorithm approaches are described in Njoku *et al.* (2000, 2003).

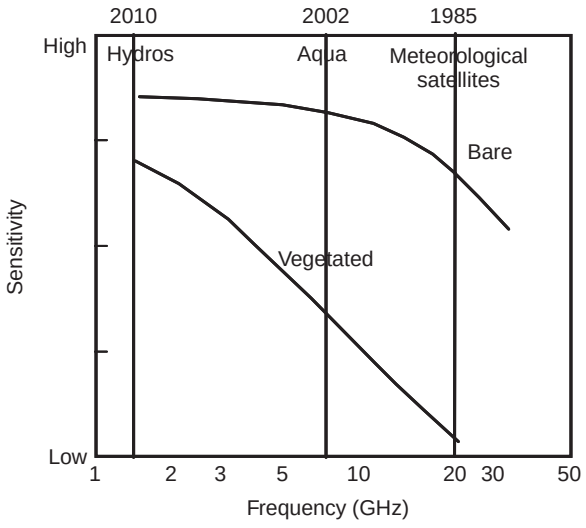

Figure 1 Sensitivity of brightness temperature to soil moisture as a function of frequency

Active Microwave Methods

Active microwave sensors or radars measure the transmitted and received power to yield a variable called the *backscattering coefficient* (σ^o), which can be related to the surface reflectivity (Ulaby *et al.*, 1986). As described previously, the reflectivity can then be used to determine surface soil moisture. For active techniques, the link between the measurement of the backscattering coefficient and the surface reflectivity is a bit more complex than for passive methods. The geometric properties of the soil surface and vegetation have a greater effect on these measurements and simple correction procedures are difficult to develop.

The two most common types of radars are scatterometers and synthetic aperture radars (SAR). Scatterometers are nonimaging radars. In the case of a SAR, the received microwave signal is further processed to produce an image. A SAR uses the phase history of the returned signal to synthesize a very large antenna, and thus significantly improve resolution in the azimuth direction (on the order of 10–100 m even from satellites).

The signals sent and received by a radar system are usually linearly polarized, either horizontal (H) or vertical (V). Transmitter and receiver can each have a different polarization. Possible combinations are HH, VV, HV, and VH. Advanced multipolarization systems can make all of these measurements simultaneously.

Estimating soil water content from radar backscatter is easier where the soil is bare. When there is a vegetation cover, establishing soil water under the canopy is much more difficult. Microwaves transmitted will interact with the vegetation cover. These will be scattered and attenuated by the vegetation. In addition, the energy scattered back towards the sensor is a combination of scattering directly from the canopy and directly from the soil, as well as multiple scattering that results from the signal interacting with both the soil and the canopy. Estimating soil water content under a vegetation canopy is difficult and requires unraveling the contribution of the soil itself from that of vegetation.

The most common approach to estimating soil moisture from backscatter has been linear regression (Brown *et al.*, 1993). This of course does not result in a robust retrieval algorithm. More theoretical approaches have limited applicability and can be difficult to implement. A more promising technique involves semiempirical models. These involve multiple polarization observations and restrictions on the range of applicability. Algorithms incorporating this approach for bare soils are presented in Dubois *et al.* (1995). A robust approach to account for vegetation has not yet been developed and validated.

Table 1 Microwave satellite systems

Satellite Instrument	Period of coverage	Frequency (GHz)	Polarization	Horizontal resolution (km)	Repeat frequency (days)
Passive					
SSM/I	1987–present	19.4, 22.2 37.0, 85.5	H and V	70 to 5 km	1–2
TMI	1998–present	10.7, 19.4, 21.3, 37.0, 85.5	H and V	60 to 6 km	1
AMSR-E (NASA)	2002–present	6.9, 10.7, 18.7, 23.8, 36.5, 89.0	H and V	75 to 7 km	2 – 3
AMSR (Japan)	2002	6.9, 10.7, 18.7, 23.8, 36.5, 89.0	H and V	70 to 6 km	2 – 3
Windsat	2003–present	6.8, 10.7, 18.7, 23.8, 37	H and V (U in some channels)	50 to 10 km	2–3
SMOS	(2007)	1.4	H and V	50 km	2–3
Hydros	(2010)	1.4	H and V (passive) HH, VV (active)	3 to 40 km	2–3
Active					
ERS	1991–present	5.3	VV	30 m	35
Radarsat-1	1995–present	5.3	HH	7 to 100 m	24
ASAR	2002–present	5.3	HH and VV, or HH and HV, or VV and VH	30 to 1000 m	35
Radarsat-2	(2005)	5.3	HH, VV, HV and VH	3 to 100 m	24
Palsar	(2005)	1.27	HH or VV and HV or VH	10 to 100 m	46

LARGE-AREA MULTITEMPORAL AIRCRAFT MAPPING

Key advances in soil moisture remote sensing include not only algorithms and sensors but also the demonstration of the value and potential of the data in a hydrological context. This has been achieved using experimental sensors on aircraft over well-instrumented sites as part of comprehensive field experiments. Many of these have taken place in Oklahoma.

One of the most important of these experiments was Washita'92. Washita'92 was a large-scale study of remote sensing and hydrology, conducted over the Little Washita watershed in southwest Oklahoma (Jackson *et al.*, 1995). Data collection during the experiment included passive and active microwave observations. Data were collected for nine days in June 1992. The watershed was saturated with a great deal of standing water at the outset of the study. During the experiment there was no rainfall, and surface soil water content observations exhibited a dry-down pattern over the period. These fortunate circumstances allowed the examination of post-rainfall hydrologic phenomena over an extended period. Surface soil water content observations were made at sites distributed over the area. Significant variations in the level and rate of change in surface soil water content were noted over areas dominated by different soil textures.

Another unique aspect of Washita'92 was the use of a new aircraft instrument called the *Electronically Scanned Thinned Array Radiometer* (ESTAR). ESTAR represented a breakthrough approach to solving the spatial resolution problem of low frequency passive microwave remote sensing from space. Passive microwave observations were made on eight days. The ESTAR data were processed to produce brightness temperature maps of a 740-km^2 area on each of the eight days. Using the single-channel soil water content algorithm described in Jackson (1993), these data were converted to soil water content images. Gray-scale images for each day are shown in Figure 2. These data exhibited significant spatial and temporal patterns. Spatial patterns were clearly associated with soil textures, and temporal patterns with drainage and evaporative processes. Relationships between the ground sampled soil water content and the brightness temperatures were consistent with previous results.

An aspect of spatial scaling of soil water content sensing was investigated using this data set. All of the soil water content samples collected on a given day were averaged for the study area. This same procedure was used for the brightness temperature, which was then converted to an emissivity estimate by normalizing with the averaged soil temperature data. This results in one pair of emissivity and soil water content values for each of the eight days. When compared with the Fresnel-based predicted relationship, there was very good agreement (standard error of estimate $<5\%$) which indicated that the data interpretation algorithms apply within this region, and that large-scale averaging (740 km^2) does not degrade their predictive ability.

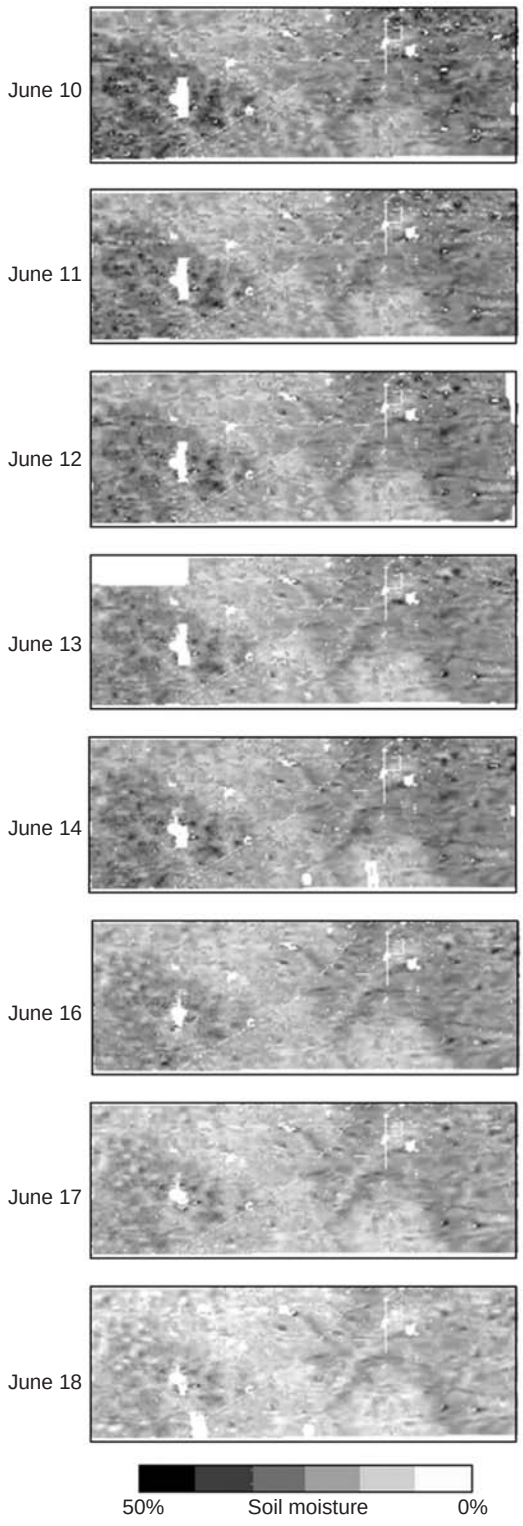

Figure 2 Washita'92 soil moisture

Numerous hydrologic analyses resulted from the Washita'92 soil moisture data sets. These included analysis of scaling (Rodruigez-Iturbe *et al.*, 1995; Dubayah *et al.*, 1997), hydraulic property derivation (Mattikalli *et al.*, 1998a,b), geostatistical relationships (Cosh and Brutsaert, 1999; Lin *et al.*, 1997), and energy balance (Kustas and Jackson, 1999).

Using the model developed in Washita'92, larger and more diverse experiments were conducted in this same region in 1997 and 1999. The 1997 experiments expanded the spatial domain an order of magnitude and the temporal period to one month (Jackson *et al.*, 1999). With these expanded datasets it was possible to further develop concepts established in Washita'92 (Kustas *et al.*, 2001; Kim and Barros, 2002; Crow and Wood 2002) and explore the development of soil moisture data assimilation schemes (Reichle *et al.*, 2001; Margulis *et al.*, 2002). In the 1999 experiment (Jackson *et al.*, 2002), simulators of near future C-band satellite instruments were used. The focus in 1999 was on current and near future satellite instruments.

HYDRAULIC PROPERTIES OF SOILS

One of the most significant findings from the Washita'92 experiment described above was not part of the initial experiment plan. This result involved using the microwave observations to derive soil properties. Soil physical and hydraulic properties are of value for water balance studies and simulations. Although it is possible to obtain these data at the field point scale, the data are not available over large areas, do not take into account spatial variability, and are costly and difficult to measure.

Temporal observations of soil moisture were used in the work of Ahuja *et al.* (1993), Mattikalli *et al.* (1998a), Hollenbeck *et al.* (1996), and Burke *et al.* (1998). These studies constrained the problem by minimizing the role of the surface flux, or by specifying it, in order to estimate the hydraulic properties of the integrated soil profile.

A few studies have employed ground-based passive microwave remote sensing and physical models for the estimation of the saturated hydraulic conductivity (Camillo *et al.*, 1986; Van de Griend and O'Neill, 1986). In these studies, the soil properties at the plot scale were derived through an iterative process of matching remotely sensed T_B with values generated by a microwave simulation model. This approach requires detailed inputs describing the profile soil water content and temperature that will not be available over large areas.

Ahuja *et al.* (1993) hypothesized that the change in soil surface moisture followed a wetting event and two days later could be used to determine the profile average hydraulic conductivity. Using simulations for soils of different textures, they found that a strong relationship existed. This was highest for sandy soils and decreased as clay content increased. In addition, they found that a measurement of the 0–5-cm layer provided as much information as a 0–30-cm observation.

These relationships were affected by evaporation; however, it was more significant for soils with lower hydraulic conductivity and with a shallow depth of observation. Tests using observations showed R^2 values that were generally greater than 0.6. Chen *et al.* (1993) followed up on this approach and utilized a time series of soil moisture to estimate hydraulic properties of macropore soils, which are difficult to be characterized on the basis of readily available soils data.

Hollenbeck *et al.* (1996) explored the use of passive microwave observations, 1.4 GHz, for identifying areas of relatively slow or fast drainage in a region. These differences were interpreted as heterogeneity of the soil hydraulic properties in the region. In this study, the responses were correlated with soil type and geomorphic features. The authors noted that antecedent conditions and the timing of the observations will impact the value of the data in retrieving soil properties.

Mattikalli *et al.* (1998a,b) took the approach presented by Ahuja *et al.* (1993) a step further by utilizing remotely sensed data to provide soil moisture information on a spatial basis. They hypothesized that surface soil moisture changes could be used to identify soil texture classes over an area. An important point that the authors made is that even if this method was not highly accurate for each and every sensor resolution element (pixel), the information provided would significantly improve the definition of the spatial domain of the soil hydraulic properties. In their opinion this was more valuable than a few accurate point estimates.

Mattikalli *et al.* (1998b) used microwave remote sensing data from the Washita'92 experiment described earlier, to obtain spatial and multitemporal soil water content data over the Little Washita watershed in Oklahoma. Analysis of the multitemporal water content maps with the soil maps suggested that the remotely sensed soil moisture and its temporal changes could be used to identify soil texture and to estimate soil hydraulic properties as hypothesized. Validations of the technique indicated that this could be accomplished with acceptable accuracy.

SATELLITE OBSERVING SYSTEMS AND PRODUCTS

Satellite-based sensors offer the advantages of large-area mapping and long-term repetitive coverage. Revisit time can be a critical problem in studies involving rapidly changing conditions, such as surface soil water content. With very wide swaths it is possible to obtain twice daily coverage with a polar orbiting satellite. For most satellites, especially if constant or narrow ranges of the viewing angle are important, the revisit time can be much longer. Optimizing the time and frequency of coverage is a critical problem for studies of soil water content.

Current Passive Systems

Special Satellite Microwave/Imager

Currently, all passive microwave sensors on satellite platforms operate at high frequencies (>6 GHz). Of particular note, due to the longevity of its data record, is the Special Satellite Microwave/Imager (SSM/I) package on the Defense Meteorological Satellite Platforms. These satellites have been in operation since 1987, and provide high frequencies and two polarizations (see Table 1) except 22 GHz (V only).

Interpreting data from the SSM/I to extract surface information requires accounting for atmospheric effects on the measurement (Drusch *et al.*, 2001). When one considers the atmospheric correction, the significance of vegetation attenuation, and the shallow contributing depth of soil for these high frequencies, it becomes apparent that the data are of limited value for estimating soil water content. However, data from the SSM/I can be used under some circumstances, such as in arid and semiarid areas with low amounts of vegetation. Spatial resolution of the SSM/I is very coarse, as shown in Table 1. The SSM/I utilizes conical scanning, which provides measurements at the same viewing angle at all beam positions on a swath. This makes data interpretation more straightforward and simplifies image comparisons. There have been as many as four SSM/I satellites in operation during any given period. Therefore, frequent and even multiple daily passes are typical for most regions of the Earth. Data from the SSM/I are publicly available.

Value-added products from the SSM/I sensors include a wide range of atmospheric and ocean variables. However, for reasons noted above there have been few attempts at generating standard land surface products. NOAA (Basist *et al.*, 1998) utilizes SSM/I data to produce an experimental data product called the Soil Wetness Index (SWI). The key point to recognize with regard to this index is that it is intended to provide information on significantly wet soil conditions (areal extent of flooding), which can be more reliably detected than variations at lower levels of soil moisture. In most cases, these will involve some standing surface water, which will result in a large decrease in brightness temperature.

The SWI uses the difference between the 85 GHz and 19 GHz horizontally polarized brightness temperatures from the SSM/I instrument. These differences are scaled to enhance the extremely wet to flooded soil conditions. Data are composited as temporal five day averages in order to identify flooded areas, which may otherwise be obscured by precipitation. Spatial resolution is 0.3 degrees. For each 0.3-degree pixel, the current SWI is compared to the historic mean and standard deviation (1987–present) as follows

$$\mathrm{SWIZ}_i = \frac{(\mathrm{SWI}_i - \mathrm{Mean}(\mathrm{SWI}_i))}{\mathrm{Sigma}(\mathrm{SWI}_i)}, \qquad (6)$$

where:

i = the ith five-day period: $i = 1, 2, \ldots, 73$
Mean (SWI_i) = the average pixel level SWI for the ith period
Sigma (SWI_i) = the standard deviation of SWI for the ith period.

As a flood index, only the positive anomalies of the SWI are important. These are on a scale of 1 to 3. SWIZ values in the range 1–2 are associated with wet surface conditions; 2–3 are indicative of extremely wet conditions; and >=3 have the potential for flooding. Standard products include daily, five-day composite, and an anomaly product for the continental US and globally.

A few studies have attempted to extract actual soil moisture from SSM/I data (Jackson, 1997; Lakshmi *et al.*, 1997; Vinnikov *et al.*, 1999; Owe *et al.*, 1992). In Jackson (1997), the single channel/ancillary data approach described in Jackson (1993) for L-band, was extended to the higher frequencies of the SSM/I instrument. For the limited validation data set available, the approach performed relatively well with a standard error estimate of 5.3%. It is likely that the success of the approach was related to the limited conditions and light vegetation conditions evaluated.

Tropical Rainfall Measurement Mission Microwave Imager

Another option is the Tropical Rainfall Measurement Mission Microwave Imager (TMI) on the TRMM satellite (Kummerow *et al.*, 1998). It is a five-channel, dual-polarized, passive microwave radiometer. The lowest TMI frequency is 10 GHz (see Table 1), about half that of the SSM/I. The TMI has a higher spatial resolution as compared to the SSM/I. Tropical Rainfall Measurement Mission or TRMM only provides coverage of the tropics, which includes latitudes between 38 °N and 38 °S for the TMI instrument. However, a unique capability of the TMI is its ability to collect data daily, and in many cases more often, within certain latitude ranges. This could facilitate multitemporal and diurnal analyses. Jackson and Hsu (2001), and Wen and Su (2003) demonstrated the potential of using these data to retrieve soil moisture. Bindlish *et al.* (2003) have developed and validated a five-year data set for the Southern United States based upon the TMI data. These studies show the potential of the improved spatial resolution, higher temporal repeat coverage, and lower frequency as compared to the SSM/I. Figure 3 illustrates the difference in the spatial resolution and density of observations between the SSM/I and the TMI instruments. The enhanced information of the TMI results in images with increased spatial detail and structure.

Advanced Microwave Scanning Radiometer

Several new multifrequency passive microwave satellite systems were launched in 2002 and 2003. As opposed to the previously available systems, these offer a lower frequency channel operating at C-band, which should provide a more robust soil moisture measurement. These satellites are the NASA Aqua, Japanese ADEOS-II, and the US interagency Coriolis satellite.

Aqua and ADEOS-II included an instrument called the Advanced Microwave Scanning Radiometer (AMSR). AMSR is multifrequency (Table 1) and includes a 6.9 GHz (C-band) channel with a nominal 60-km spatial resolution. AMSR holds great promise for estimating soil water content in sparsely vegetated regions and is the best source of data in the near term for mapping soil water. On the basis of published results and supporting theory (Njoku and Li, 1999), this instrument should be able to provide information about soil water content in regions of low vegetation cover, less than 1 kg m^{-2} vegetation water content. There are some small differences in the spatial resolution of AMSR and AMSR-E. The most important difference between the two satellites is the time of day of the overpasses. Aqua is 1:30 am and pm local time and ADEOS-II is 10:30 am and 10:30 pm. The orbits result in 2–3 day coverage in the mid-latitudes. Unfortunately, communications with the ADEOS-II satellite were lost in October 2003.

As opposed to previous passive microwave satellite missions, the Aqua project includes soil moisture as a product. The algorithm planned for use with Aqua is a variation of the multiple channel approach described in Njoku and Li (1999), and Njoku *et al.* (2003). Several types of soil moisture products will be produced. These include a daily swath product and a global composite. The swath products include a retrieval of soil moisture for each pixel observed. Results will be composited to a standard grid to generate a global map of surface soil moisture with a nominal spatial resolution of 25 km. After a period of calibration/validation, the soil moisture products should be available on a daily basis.

A somewhat parallel program is being conducted by the Japanese Aerospace Exploration Agency (JAXA) using the AMSR-E and AMSR data. In this program, soil moisture is considered to be a research product. Four algorithms are under consideration (Koike *et al.*, 2000). All algorithms are being evaluated and compared as part of the calibration/validation program. If one of these is considered acceptable, it will be adopted as a standard product algorithm.

Preliminary studies indicate that there is widespread RFI in the C-band channels. Therefore, it is likely that the most useful channels for soil moisture will be those operating at the slightly higher X band.

The Coriolis satellite includes the Windsat instrument, which is a multifrequency passive microwave radiometer system. It is similar to AMSR with some differences in frequencies and more polarization options (Table 1). It is a prototype of one component of the next generation of

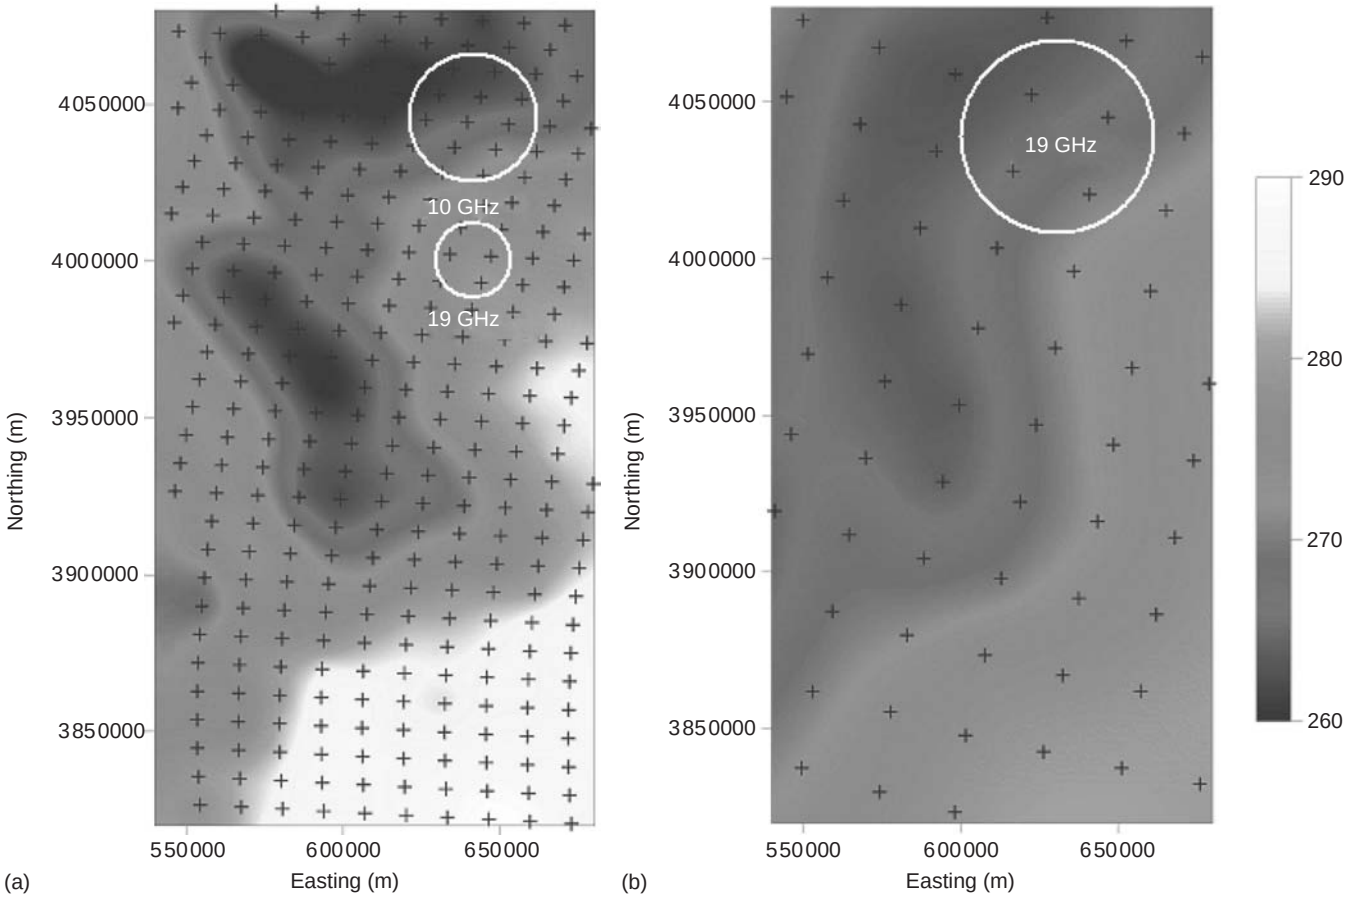

Figure 3 Spatial features of the (a) TMI and (b) SSM/I compared for an area in Oklahoma. The footprint density (+) and size (circles) are shown on interpolated brightness temperature images for one pass. The two TMI footprints shown are approximately 20 km and 40 km, and the SSM/I footprint is 70 km

operational polar orbiting satellites that the United States will implement at the end of this decade. Experience gained using these science missions will provide the basis for future operational products.

Future Passive Systems

Research programs are underway to develop and implement space-based systems with a 1.4 GHz channel that would provide improved global soil moisture information. Toward that goal the European Space Agency (ESA) is developing a sensor system called the *Soil Moisture Ocean Salinity* (*SMOS*) *mission* (Wigneron *et al.*, 2000), and NASA will launch the Hydros mission (Entekhabi *et al.*, 2004).

SMOS will utilize two-dimensional synthetic aperture radiometry at L-band and will provide H and V polarization observations. The data collected during one integration period can be thought of as an image consisting of lines and pixels. A key concept for SMOS is that the incidence angle of each pixel varies on the basis of its position relative to the spacecraft track. For a given data take, it is possible to select a subset of the available pixels within a specific incidence angle range, say 50°. This process can yield a pseudoconical scanned product. It is also possible to select all pixels at another individual incidence angle, which would yield a different subset of observations. By using this idea it is then possible, over selected portions of the swath and data take, to obtain observations of an area on the ground at different incidence angles by using sequential data takes. As described in Wigneron *et al.* (2000), the multiple incidence angle observations of the surface is the key element of the soil moisture retrieval algorithm that is proposed for the mission. The launch of the mission is anticipated in 2007. A minimum temporal coverage of three days is proposed depending on the latitude.

Hydros is an exploratory mission that will provide global measurements of soil moisture and surface freeze/thaw, focusing on regions where these are primary environmental controls. The sampling will be continuous, over the minimum mission duration of three years. Hydros would use an active and passive L-band instrument design for mapping at resolutions ranging from 3 to 40 km depending

upon the product. Hydros data will be merged with data from *in situ* networks and other satellites in a land data assimilation framework, providing value-added end products that will deliver the most comprehensive view yet of Earth's land hydrosphere. Soil moisture will be estimated by Hydros using the radiometer and radar data separately and in combination, taking advantage of the simultaneous, coincident, and complementary nature of the measurements. Both measurement types are sensitive to soil moisture directly. Radiometer measurements currently provide more accurate soil moisture estimates than radar under vegetated conditions because of the maturity of the radiometer-based algorithms compared to those for radar. Radar measurements provide a higher resolution capability and subpixel roughness and vegetation information within the radiometer footprint. The combination of simultaneous radar and radiometer data has the potential to improve the accuracy of soil moisture estimates over heterogeneous surface conditions. Soil moisture will be obtained using both absolute and relative change estimation approaches. Hydros is currently scheduled for 2010.

Current Active Systems

At present, several radar satellites are in orbit (Table 1). The ESA has operated a satellite SAR series called *ERS* since 1991, which provides C-band VV. This satellite includes both a SAR and a scatterometer. Although numerous investigations have been conducted that attempt to utilize ERS-SAR data, few results have been reported in the area of soil moisture estimation. This paucity is due to the limitations of using a single mid-frequency channel-single polarization SAR with an exact repeat cycle of 35 days. With this kind of temporal coverage, the data are of little value in process studies. However, with enough assumptions and effort, it is possible to develop site-specific soil moisture information from the single-channel radar data.

The next satellite in the ERS series is called Envisat and it has C-band Advanced Synthetic Aperture Radar (ASAR) with multiple polarization capabilities. It also offers the option of varying the incidence angle to allow for different viewing angles and more frequent coverage if angle is not a critical parameter in the application. Data from ASAR are just beginning to be made available to investigators.

The Canadian Space Agency operates a C-band satellite SAR called *Radarsat*. Radarsat offers HH polarization and has more flexibility in its data-collection modes. Options include a variable viewing angle and a wide swath (large range of incidence angles). These choices offer more frequent temporal coverage of a particular region of the Earth if angle is not important.

There have been a number of attempts at using the single-channel SAR data to retrieve soil moisture. The general consensus from these studies is that there are too many physical variables that have to be known in order to derive soil moisture (Verhoest *et al.*, 1998; Satalino *et al.*, 2002). These variables include the soil moisture, surface roughness, and vegetation. Site-specific studies and creative selection of data sets have resulted in some degree of success (Altese *et al.*, 1996; Verhoest *et al.*, 1998; Wagner *et al.*, 1999; Le Hegarat-Mascle *et al.*, 2002; Moran *et al.*, 2002; Satalino *et al.*, 2002).

Future Active Systems

Japan will include an L-band SAR called *PALSAR* on an upcoming satellite, the Advanced Land Observing System (ALOS). The lower frequency will offer information that is different from that offered by other satellite SAR systems operating at C-band. PALSAR will have a multipolarization mode as well as varying incidence angles, the advantages of which have been described.

Canada is developing Radarsat-2, which will be similar to Radarsat-1. As with the ASAR, it will be fully polarimetric and consequently, any possible polarization (including, but not limited to HH, VV, HV, and VH) can be generated along with phase information. The satellite will include a mode in which the spatial resolution is 3 m. The expected launch is in 2005.

As noted above, progress in SAR soil moisture mapping has been limited by the available data, single channel. The new generation of multipolarization SAR systems will provide at least one additional measurement. There is hope that more robust soil moisture retrieval methods can be developed as these data become available.

SUMMARY

Soil moisture products based upon satellite microwave remote sensing have become a viable source of information for hydrologic modeling and analysis. New opportunities and improved products will be available within the next five years. Key issues to consider for applications are trade-offs between desired temporal coverage and spatial resolution that are related to active and passive microwave systems.

Currently, passive microwave remote sensing offers more robust and well-validated retrieval algorithms. However, it is limited by spatial resolution at satellite altitudes. Active microwave techniques can provide high spatial resolution data, but suffer from weak soil moisture algorithms. There are many new satellite opportunities within the coming decade that will significantly advance satellite-based soil moisture remote sensing. As these become available, each needs to be evaluated and exploited for hydrological applications.

55: Estimation of Snow Extent and Snow Properties

DOROTHY K HALL[1], RICHARD EJ KELLY[2], JAMES L FOSTER[1] AND ALFRED TC CHANG[1†]

[1]NASA/Goddard Space Flight Center, Greenbelt, MD, US
[2]University of Maryland, Baltimore, MD, US
[†]Deceased May 26, 2004

Important advances have been made in the measurement of seasonal snow cover since the advent of satellite remote sensing in the mid 1960s. Data from the visible, near-infrared, infrared, and microwave portions of the electromagnetic spectrum have proven useful for measuring different properties of snow. In terms of snow mapping, sensors employing visible and near-infrared wavelengths are now capable of accurately and reliably measuring snow-cover extent with a spatial resolution of up to 250 m on a daily basis, and even higher resolution for less-frequent coverage. Passive-microwave data, available since the 1970s, have been utilized for measuring snow extent, depth and snow-water equivalent (SWE), though at a coarse spatial resolution compared to visible data, while active-microwave sensors such as scatterometers, provide valuable information on snowpack ripening. Capabilities of synthetic-aperture radar (SAR) data for snow-cover studies are still being explored, however, bands on current satellite SAR sensors are not ideal for measuring snow cover. Remote sensing data of snow cover are now well suited for use in hydrologic and general-circulation models. Inclusion of remotely-sensed data significantly enhances our understanding of the Earth's weather and climate, and decadal-scale climate change. Future improvements include refinement of snow-cover extent measurements, minimizing SWE errors, and improving our ability to ingest remote sensing data of snow into models.

INTRODUCTION

Satellite remote-sensing technology has virtually revolutionized the study of snow cover. The high albedo of snow presents a good contrast with most other natural surfaces (except clouds), and therefore is easily detected by many satellite sensors. Weekly snow mapping of the Northern Hemisphere using National Oceanographic and Atmospheric Administration (NOAA) satellite data began in 1966 and continues today in the United States, but with improved resolution and on a daily basis (Matson *et al.*, 1986; Ramsay, 1998; Carroll *et al.*, 2001). In addition, using Earth Observing System (EOS) Moderate Resolution Imaging Spectroradiometer (MODIS) data, beginning in early 2000, global snow cover has been mapped on a daily basis at a spatial resolution of up to 500 m (Hall *et al.*, 2002a).

In addition to the visible/near-infrared data, from MODIS and NOAA satellite sensors, both passive and active microwave data have been useful for mapping snow and determining snow wetness and snow water equivalent (SWE) (Ulaby and Stiles, 1980) since the early 1970s. Using passive microwave data, snow extent, and SWE may be estimated globally on a daily basis since the launch of the Nimbus-7 Scanning Multichannel Microwave Radiometer (SMMR) (Chang *et al.*, 1987), and continuing with the May 2002 launch of the Advanced Microwave Scanning Radiometer (AMSR) (Kelly *et al.*, 2003). Active-microwave sensors, such as from the NASA scatterometer (NSCAT), are especially useful for detecting snowpack ripening (Nghiem and Tsai, 2001).

The geographical extent of snow cover over the Northern Hemisphere varies from a maximum of $\sim 46 \times 10^6$ km^2 in January and February to a minimum of $\sim 4 \times 10^6$ km^2 in

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

August; between 60 and 65% of winter snow cover is found over Eurasia, and most midsummer snow cover is in Greenland (Frei and Robinson, 1999). Numerous studies have shown the importance of accurate measurements of snow and ice parameters as they relate to the Earth's climate and climate change (for example, see Martinelli, 1979; Dewey and Heim, 1981 and 1983; Barry, 1983, 1984, and 1990; Dozier, 1987; Ledley *et al.*, 1999; Foster *et al.*, 1987 and 1996; Serreze *et al.*, 2000; Dozier and Painter, 2004). Measurements have become increasingly sophisticated over time. In addition, as the length of the satellite record increases, it becomes easier to determine trends that have climatic importance.

Three of the most important properties of a snow cover are depth, density, and water equivalent (Pomeroy and Gray, 1995). If the snow depth and density are known, then the SWE may be calculated. SWE is a hydrologically important parameter as it determines the amount of water that will be available as snowmelt.

After introducing snow as a medium, and reviewing its optical and microwave properties, we will show how remote sensing is used to study snow-covered area, SWE, snow wetness and snow albedo, and discuss the parameterization of snow in hydrologic and general circulation models (GCMs).

INTRODUCTION TO SNOW CRYSTALS AND DEVELOPMENT OF A SNOWPACK

Snow is a porous, permeable aggregate of ice grains (Bader, 1962). Snow crystals nucleate and begin their growth in clouds where the temperature is below 0 °C. Snow crystals can occur in a variety of relatively flat hexagonal or six-sided shapes (Figure 1), however, they can also occur as elongated columns and needles. Differences in snow crystals are a result of variations in the temperature and humidity of the atmosphere at the time of their formation and the action of the wind during their descent to the ground (Male, 1980). As a result, there is a myriad of possible shapes that can form depending primarily on the cloud temperature at the time the water vapor freezes.

Freshly fallen snow almost immediately begins to compact and metamorphose, initially preserving the original shape of the snow crystal. The constant jostling and rubbing of crystals against each other causes protuberances to become chipped and broken. As the snow settles under its own weight, melts and refreezes, and is buffeted by the wind, individual crystals are further altered such that after a few days they have little resemblance to their original shape. A seasonal snowpack might have grain radii ranging from 0.1 to 0.5 mm throughout the season.

In the absence of a temperature gradient in the snowpack, snowflakes undergo "destructive metamorphism" and become more rounded over time, with typically slower

Figure 1 This image of a newly fallen hexagonal plate snow crystal was taken with an Electron Scanning Microscope and shows a classic dendritic snow crystal, having a central hexagonal plate, but lacking sharp edges. Because of the air temperature at the time of collection (close to 0 °C), this crystal may have undergone some sublimation (Wergin *et al.,* 1996)

growth rates being more characteristic of the more-rounded crystals. "Constructive metamorphism," when large grains grow at the expense of small grains, occurs when there is a thermal and vapor gradient in the snowpack and snow grains at the base of the pack grow at the expense of smaller grains, hence the crystals develop distinctive shapes (Colbeck, 1982). Faster growth rates give rise to the faceted crystals. Dry snow will metamorphose into large depth-hoar grains when subjected to a strong temperature gradient, and grain growth and dry-snow metamorphism control the movement and redistribution of mass, chemical species, and isotopes in the snowpack (Sturm and Benson, 1997). Depth-hoar crystals may grow to 1 cm in size (Trabant and Benson, 1972).

Seasonal snowpacks develop from a series of winter storms and are often created by various forms of precipitation such as rain and freezing rain. Diurnal melting and refreezing, and wind action are also important in the ultimate development of a snowpack. Thus, seasonal snow cover usually develops a layered structure in which ice layers alternate with layers of a coarser texture (Male, 1980).

FUNDAMENTALS OF THE REMOTE SENSING OF SNOW

Introduction With optical remote sensing, there is a potential to determine the extent and albedo of a snow cover, and some inference as to snow depth can be made based on the ability of a snow cover to cover existing vegetation of known height. Infrared sensors can provide snow

surface temperature, which may be a useful parameter for hydrologic modeling. Microwave measurements have the capability to respond to the bulk properties of a snowpack as well as to variations in other surface and subsurface features because microwaves can penetrate the snowpack and thus provide information on snow depth and SWE when the snowpack is dry. Additionally, the microwave part of the spectrum allows remote observation of snow cover under nearly all weather and lighting conditions. SWE is of critical importance for water resources and hydrologic and GCM modeling. In short, use of optical, infrared, and microwave sensors provides synergy that allows extraction of important snowpack properties for use in models.

Optical Properties The spectral albedo of a surface is the upflux divided by the downflux at a particular wavelength (Warren, 1982). The spectral albedo of fresh snow in the visible region of the spectrum remains high but decreases slowly as snow ages, but in the near-infrared, the spectral albedo of aging snow decreases considerably as compared to fresh snow (O'Brien and Munis, 1975; Warren and Wiscombe, 1980; Wiscombe and Warren, 1980).

The broadband albedo is the reflectance across the reflective part of the solar spectrum. Broadband albedo decreases when grain size increases as the snow ages (Choudhury and Chang, 1979), and melting causes snow grains to grow and bond into clusters (Dozier *et al.*, 1981; Grenfell *et al.*, 1981; Warren, 1982). Snow albedo may decrease by $>25\%$ within just a few days as grain growth proceeds (Nolin and Liang, 2000). For example, Gerland *et al.* (1999) measured a maximum albedo $>90\%$ on Svalbard, Norway, before melt onset, and $\sim 60\%$ after melt had progressed in the spring when the snow was considered old, but still clean. The albedo of a snow cover is also influenced by the albedo of the land cover that it overlies, especially when the snowpack is thin.

Grain size may be estimated using remotely sensed data (Dozier, 1984; Nolin and Dozier, 1993). With the onset of surface melting and associated grain size increase, the near-infrared reflectance decreases dramatically (Warren, 1982) (Figure 2). The near-infrared albedo of snow is very sensitive to snow-grain size while visible albedo is less sensitive to grain size, but is affected by snow impurities. Modeling by Warren and Wiscombe (1980) demonstrates that small but highly absorbing particles can lower the snow albedo in the visible part of the spectrum by 5–15% compared to pure snow. Hansen and Nazarenko (2004) report that anthropogenic soot emissions have reduced snow and ice albedos by 3% in Northern Hemisphere land areas to yield a climate forcing of $+0.3\,\mathrm{W\,m^{-2}}$ in the Northern Hemisphere, thus contributing to global warming.

Though the reflectance of freshly fallen snow is nearly isotropic (Dirmhirn and Eaton, 1975), as snow ages, the specular reflection component increases, especially in the forward direction and with solar zenith angle (SZA) (Salomonson and Marlatt, 1968), and the anisotropic nature of snow reflectance increases with increasing grain size

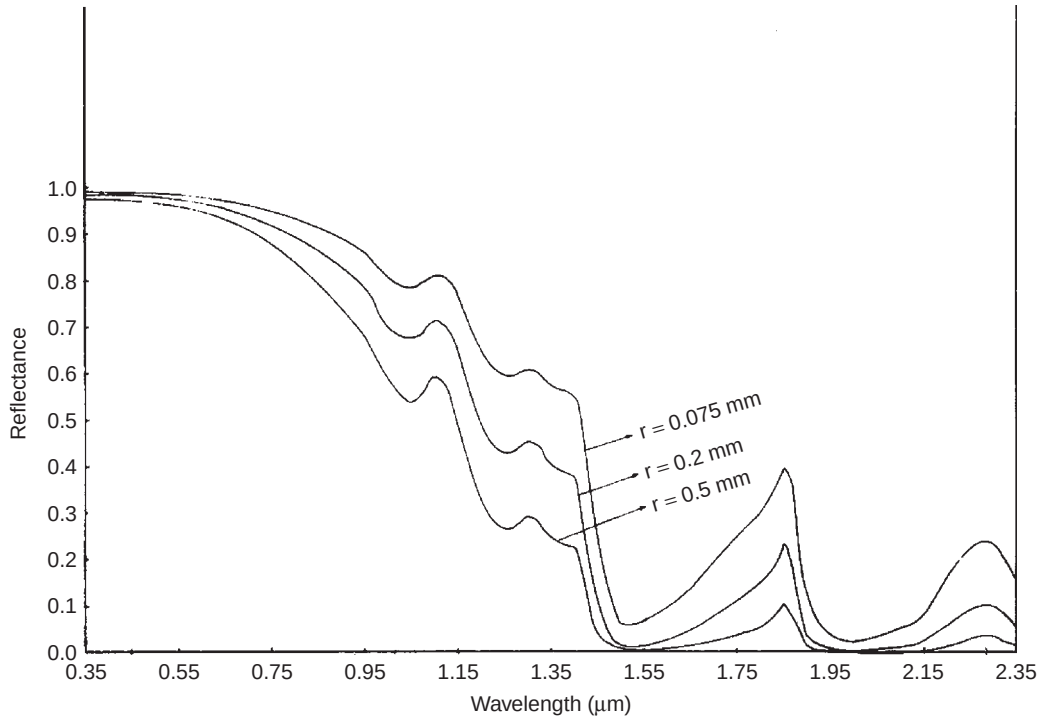

Figure 2 Illustration of the effect of different snow crystals on snow reflectance (From Choudhury and Chang, 1979)

(Steffen, 1987). Effective snow-grain radii typically range in size from ~50 μm for new snow, to 1 mm for wet snow consisting of clusters of ice grains (Warren, 1982).

Snow albedo increases at all wavelengths with the SZA. Additionally, cloud cover normally causes an increase in spectrally integrated snow albedo due to multiple reflections caused by clouds (Grenfell and Maykut, 1977; Warren, 1982).

Microwave Properties In the microwave part of the spectrum (300 to 1 GHz, or 1 mm to 30 cm wavelength), remote sensing can be accomplished either by measuring emitted radiation with a radiometer or by measuring the intensity of the return (in decibels) of a signal sent by a radar.

Microwave emission from a layer of snow over a ground surface consists of contributions from the snow itself and from the underlying ground. Both contributions are governed by the transmission and reflection properties of the air-snow and snow-ground interfaces, and by the absorption/emission and scattering properties of the snow layer.

The dielectric properties of snow at a given microwave frequency are generally dependent on the relative proportion of liquid and solid water in the snow by volume. Even at temperatures <0 °C, liquid-like water exists in thin films surrounding, and bound to, ice crystals (Hobbs, 1974), but is considered to be dry since it contains no "free" liquid water (Leconte *et al.*, 1990). However, snow that contains a large amount of liquid water (>5% by volume) has a high dielectric constant (>35 below 20 GHz) relative to that of dry snow.

Theoretically, the dielectric constant of snow consists of the sum of a real and an imaginary part. Snow is a mixture of air and ice, the dielectric constant of air being 1.0 and ice 3.17 ± 0.07 for frequencies from 1 MHz to well above the microwave region (Evans, 1965). Snow has a dielectric constant between l.2 and 2.0 when the snow densities range from 0.1 to 0.5 g cm^{-3} (Hallikainen and Ulaby, 1986).

If a dry snowpack contains ice and snow layers, specular reflection at the interfaces between layers may occur resulting in strongly enhanced backscatter in the case of active-microwave remote sensing (Mätzler and Schanda, 1984). Or, if the grain sizes of a dry snowpack are large enough relative to the microwave wavelength, volume scattering will occur. Otherwise, the signal is returned mainly from the ground/snow interface.

Longer wavelengths, in general, travel almost unaffected through dry snow. X-band (2.4–3.75 cm, 8.0–12.5 GHz) or lower frequencies (longer wavelengths) are not generally useful for detecting and mapping thin, dry snow because the size of snow particles is much smaller than the size of the wavelength. Thus, at these longer wavelengths, there is little chance for a microwave signal to be attenuated and scattered by the relatively small ice crystals comprising a snowpack (Waite and MacDonald, 1970; Ulaby and Stiles, 1980, 1981). Wavelengths longer than ~10–15 cm are not impeded as they move through most dry seasonal snowpacks (Bernier, 1987).

For snow crystals of a radius >~0.1 mm, scattering dominates emission at higher (>15 GHz) microwave frequencies (Ulaby *et al.*, 1986). Absorption is determined primarily by the imaginary part of the refractive index. In dry snow, the imaginary part is very small, several orders of magnitude smaller than for water (Ulaby and Stiles, 1980).

The backscatter received by a synthetic-aperture radar (SAR) antenna is the sum of surface scattering at the air/snow interface, volume scattering within the snowpack, scattering at the snow/soil interface, and volumetric scattering from the underlying surface (if applicable). Most techniques developed for mapping snow cover using SAR data show promise for mapping only wet snow (see, for example, Rott and Nagler, 1993; Shi *et al.*, 1994). This is because it is difficult to distinguish dry snow from bare ground using SAR data at the X-band and lower frequencies that are currently flown in space. Volume scattering from a shallow, dry snow cover (SWE <20 cm) is undetectable at C-band (5.3 GHz, 5.6 cm), for example, because the backscatter is dominated by soil/snow scattering. Volume-scattering in dry snow results from scattering at dielectric discontinuities created by the differences in electrical properties of ice crystals and air, and by ice lenses and layers. Atmospheric scattering is usually very small and can be neglected (Ulaby and Stiles, 1980; Leconte *et al.*, 1990; Leconte, 1995).

In the case of wet snow (Stiles and Ulaby, 1980; Ulaby and Stiles, 1980; Rott, 1984; Ulaby *et al.*, 1986), when at least one layer of the snowpack (within the penetration depth of the radar signal) becomes wet (4–5% liquid water content), the penetration depth of the radar signal is reduced to about 3–4 cm (or one wavelength at X-band) (Mätzler and Schanda, 1984). Thus, there may be high contrast between snow-free ground and ground covered with wet snow, thus making it possible to distinguish wet and dry land or snow when imaged with C-band SAR from space.

Volume scattering increases with snow-grain size and internal layering, and with amount of snow. Radiation at wavelengths comparable in size to the snow crystal size (about 0.05–3.0 mm, or greater if depth hoar is present) is scattered in a dry snowpack according to Mie scattering theory. (Mie scattering predominates when the particles causing the scattering are larger than the wavelengths of radiation in contact with them.) Currently, only passive microwave sensors operate at these wavelengths from satellites.

In the microwave part of the spectrum, the radiation emitted from a perfect emitter is proportional to its physical temperature, T. However, most real objects emit only a fraction of the radiation that a perfect emitter would emit at its physical temperature. The equivalent temperature of

the microwave radiation thermally emitted by an object is called its *brightness temperature*, T_B, expressed in Kelvins. This fraction defines the emissivity, E, of an object (Chang *et al.*, 1976). In the microwave region,

$$E = \frac{T_B}{T} \tag{1}$$

Microwave emission from a layer of snow over a ground medium consists of two contributions: (i) emission by the snow volume and (ii) emission by the underlying ground. Both contributions are governed by the transmission and reflection properties of the air-snow and snow-ground interfaces, and by the absorption/emission and scattering properties of the snow layer (Stiles *et al.*, 1981), and a myriad of physical parameters that affects the emission (Derksen *et al.*, 2002). As an electromagnetic wave emitted from the underlying surface propagates through a snowpack, it is scattered by the randomly spaced snow particles in all directions. As the snowpack grows deeper, there is more loss of radiation due to scattering, and the emission of the snowpack is reduced, thus lowering the T_B. The deeper the snow, the more crystals are available to scatter the upwelling microwave energy, and, thus, it is possible to estimate the depth and water equivalent of the snow using passive-microwave remote sensing.

Snow grains scatter the electromagnetic radiation incoherently and are assumed to be spherical and randomly spaced within the snowpack. Although most snow particles are generally not spherical in shape, using Mie theory, their optical properties can be simulated as spheres (Chang *et al.*, 1976). We will discuss the scattering power of a variety of different snow crystal shapes and their effect on the microwave emission of a snowpack in a later section.

A wet snowpack radiates like a blackbody at the physical temperature of the snow layer, and is therefore indistinguishable from snow-free soil using microwave remote sensing (Kunzi *et al.*, 1982). The dielectric constants of water, ice, and snow are different enough so that even a little surface melting causes a strong microwave response (Schanda *et al.*, 1983; Foster *et al.*, 1987). The scattering loss decreases drastically with increasing liquid water content (free water) and becomes negligible for values above about 1% (Hallikainen, 1984).

SNOW MAPPING

Early attempts to forecast runoff from the areal extent of snow cover used terrestrial photographs (Potts, 1937). Other observations from aircraft were also undertaken such as locating and mapping snow-cover extent and mapping the location of the snowline. Along with volume, the areal extent of snow cover has been used to predict snowmelt runoff and to forecast floods.

Because of its high albedo, snow was easily observed in the first image obtained from the Television Infrared Operational Satellite-1 (TIROS-1) weather satellite in 1960. Data from meteorological satellites and manned spacecraft were useful in determining snowline elevation, delineating snow boundaries, and observing changes in snow conditions due to rising temperatures and rain-on-snow events (Singer and Popham, 1963), and later, seasonal streamflow could also be estimated (Rango and Salomonson, 1977). Data from Environmental Science Services Administration (ESSA) operational satellites were used as early as the mid-to-late 1960s to determine areal extent of snow cover.

A major step forward in snow mapping came with the advent of the Landsat series of sensors beginning in 1972. Landsat-1 carried a Multispectral Scanner (MSS) sensor with 80-m spatial resolution. With Landsat data came the ability to create detailed basin-scale snow-cover maps on a regular basis when cloudcover permitted. At first, the repeat-pass interval for the Landsat satellite was 18 days, but this was decreased to 16 days with the launch of Landsat-4 in 1982. Landsats-4 and -5 carried a Thematic Mapper (TM) sensor with 30-m resolution, and Landsat-7 carries an Enhanced Thematic Mapper Plus (ETM+) with spatial resolution of 30 m, except in the panchromatic band where the resolution is 15 m. As of this writing, the TM onboard the Landsat-5 satellite is still operating. (Landsat-6 was lost after it failed to reach orbit in 1993.) Though the Landsat series has provided high-quality, scene-based snow maps, the 16- or 18-day repeat-pass interval of the Landsat satellites is not adequate for most snow-mapping requirements, especially during spring snowmelt.

Operational Snow-cover Mapping in the United States The NOAA National Environmental Satellite, Data, and Information Service (NESDIS) began to generate Northern Hemisphere Weekly Snow and Ice Cover analysis charts derived from NOAA's Geostationary Operational Environmental Satellite (GOES) and Polar Orbiting Environmental Satellite (POES) visible satellite imagers in November 1966. Maps were manually constructed, and the spatial resolution of the charts was 190 km. Since 1997, the Interactive Multi-sensor Snow and Ice Mapping System (IMS) has been used by analysts to produce products daily at a spatial resolution of about 25 km, and utilizes a variety of satellite data to generate the maps (Ramsay, 1998). This snow-cover record has been studied carefully (Robinson *et al.*, 1993; Robinson, 1997, 1999) and has been reconstructed following adjustment for inconsistencies that were discovered in the early part of the data set (Robinson and Frei, 2000; Frei *et al.*, 1999). Results show that the Northern Hemisphere annual snow-covered area has decreased (Robinson *et al.*, 1993; Brown and Goodison, 1996; Hughes and Robinson, 1996; Hughes *et al.*, 1996; Armstrong and Brodzik, 1998, 2001; Frei *et al.*, 1999;

Brown, 2000); satellite data show a decrease of about 0.2% per year from 1979–1999 (Armstrong and Brodzik, 2001).

The National Operational Hydrologic Remote Sensing Center (NOHRSC) snow-cover maps, generated by National Weather Service NOHRSC hydrologists, are distributed electronically in near real time to local, state, and federal users during the snow season (Carroll, 1987 and 1995; Cline *et al.*, 1998; Carroll *et al.*, 2001). The NOHRSC 1-km maps are generated primarily from the NOAA polar-orbiting satellites and GOES satellites to develop daily digital maps depicting the areal extent of snow cover for the coterminous United States and Alaska, and parts of southern Canada.

Other Snow Maps Landsat data have been used for measurement of snow-covered area over drainage basins (Rango and Martinec, 1979, 1982). The Landsat TM and ETM+ have been especially useful for measuring snow cover because of the short-wave infrared band – band 6(1.6 μm), which allows snow/cloud discrimination. The reflectance of snow is low and the reflectance of most clouds remains high in that part of the spectrum. Various techniques, ranging from visual interpretation, multispectral image classification, decision trees, change detection, and ratios (Kyle *et al.*, 1978; Bunting and d'Entremont, 1982; Crane and Anderson, 1984; Dozier, 1989; Romanov *et al.*, 2000; Hall *et al.*, 2002a; Romanov and Tarpley, 2003) have been used to map snow cover. Other spectral and threshold tests are also used.

The MODIS was first launched in December 1999 on the Terra spacecraft. MODIS data are now being used to produce daily and eight-day composite (Figure 3) snow-cover products from automated algorithms **`http://modis-snow-ice.gsfc.nasa.gov`** at Goddard Space Flight Center in Greenbelt, Maryland (Hall *et al.*, 2002a). The products are transferred to the National Snow and Ice Data Center (NSIDC) in Boulder, Colorado, where they are archived and distributed via the Earth Observing System Data Gateway (EDG) **`http://nsidc.org`** (Scharfen *et al.*, 2000). The Aqua satellite was launched in 2002 with a second MODIS instrument that enables snow-covered area measurements to be extended farther into the future (Riggs and Hall, 2004).

The MODIS maps provide global, daily coverage at 500-m resolution, and the climate-modeling grid (CMG) maps are available at 0.05 °resolution, which is ~5.6 km at the Equator. The CMG map, designed for climate modelers, provides a global view of the Earth's snow cover in a geographical projection with fractional snow cover reported in each cell. The automated MODIS snow mapping algorithm uses at-satellite reflectances in MODIS bands 4 (0.545–0.565 μm) and 6 (1.628–1.652 μm) to calculate the normalized difference snow index (NDSI) (Hall *et al.*, 2002a). Other threshold tests are also used, including the Normalized Difference Vegetation Index (NDVI) together with the NDSI to improve snow mapping in forests (Klein *et al.*, 1998). Mauer *et al.* (2003) compared MODIS and NOHRSC data for the Columbia River Basin, USA, and found that the maps were comparable, but the MODIS maps generally provided more cloud-free data than did the NOHRSC maps. Other studies have also shown the MODIS snow maps to represent an advance in global snow mapping.

Fractional Snow Cover or Subpixel Snow Mapping Fractional snow cover (FSC) utilizing Landsat and MODIS data has been derived to exploit subpixel information. Much of this work has relied on spectral-mixture modeling (see Nolin *et al.*, 1993; Rosenthal and Dozier, 1996; Vikhamer and Solberg, 2002; Dozier and Painter, 2004), and neural networks (Simpson and McIntire, 2001) but does not provide global coverage. Painter *et al.* (2003) couple

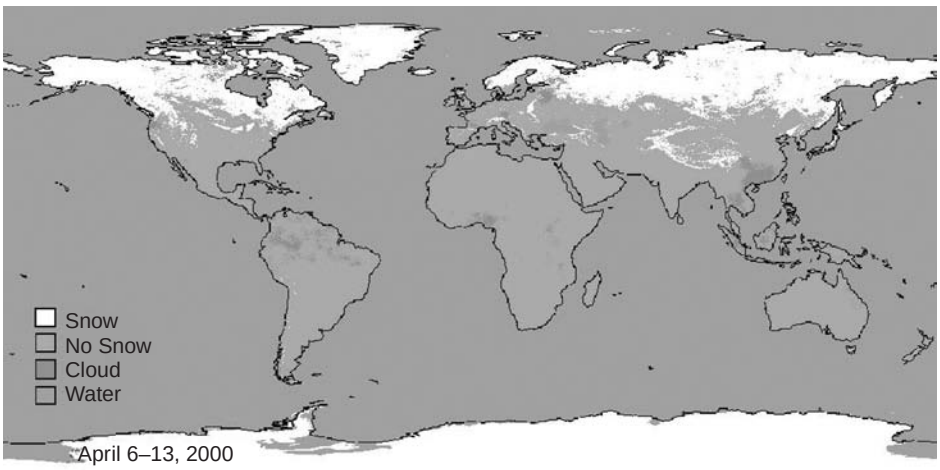

Figure 3 MODIS 8-day composite CMG global snow-cover map. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

spectral-mixture analysis with a radiative transfer model to retrieve subpixel snow-covered area and effective grain size from Airborne Visible/Infrared Imaging Spectrometer (AVIRIS) data.

Recently, Salomonson and Appel (2004) have extended the use of the NDSI to provide FSC globally with absolute errors of 0.1 or less over the whole range of FSC from 0 to 100%. In the near future, percent snow cover or fractional snow cover in each pixel (Salomonson and Appel, 2004) will be provided in the 500-m products. Other work using MODIS data (Kaufman *et al.*, 2002) has also developed algorithms to map FSC globally.

The Norwegian Water Resources and Energy Directorate (NVE) and the Tromso Satellite Station (TSS) produce snow maps from Advanced Very High Resolution Radiometer (AVHRR) data using band 2 (0.7–1.1 μm) for snow mapping, and bands 3 (3.6–3.9 μm), 4 (10.3–11.3 μm), and 5 (11.5–12.5 μm) for snow/cloud discrimination (Anderson, 1982; König *et al.*, 2001). An upper limit of 100% snow cover is determined from a glacier or 100% snow-covered region and a lower limit of 0% is determined from water or land areas, and percentage of snow cover is interpolated linearly, thus deriving FSC (König *et al.*, 2001).

Snow Mapping Using Microwave Sensors For dry snow, the naturally emitted microwave radiation of a snowpack is related to several physical properties of the snow as discussed earlier. These properties include the number of snow grains along the emission path (the snow depth in cm), the size of grains (grain radius in mm), and the packing of the grains (volume fraction in % or density in $\mathrm{kg\,m^{-3}}$). Such components control the propagation of radiation, especially at higher frequencies (e.g. 36 GHz) but affect the microwave response less at lower frequencies (e.g. 18 GHz). The brightness temperature difference between 18 GHz and 36 GHz ($T_B18 - T_B36$) is used to minimize the effect of snow temperature on the microwave emissivity. This is the principle that has been used to estimate SWE and snow depth from passive microwave instruments (Chang *et al.*, 1976, 1982; Kunzi *et al.*, 1976, 1982; Goodison and Walker, 1994; Goodison *et al.*, 1986; Grody and Basist, 1996; Foster *et al.*, 1997; Kelly and Chang, 2003). Experiments and applications have shown that:

$$SD = a(T_B18\mathrm{H} - T_B36\mathrm{H}) \qquad (2)$$

where SD is the snow depth in cm, a is constant of 1.59 for SMMR and is derived from radiative transfer experiments (Chang *et al.*, 1982), and $T_B18\mathrm{H}$ and $T_B36\mathrm{H}$ are the horizontally polarized brightness temperatures measured by the spacecraft at 18 and 36 GHz, respectively. If SWE is desired, a is set to a value of 4.8. Research into estimation of SWE and snow depth from passive microwave instruments has used this principle and an example of its application to AMSR-E data is shown in Figure 4 (Kelly *et al.*, 2003).

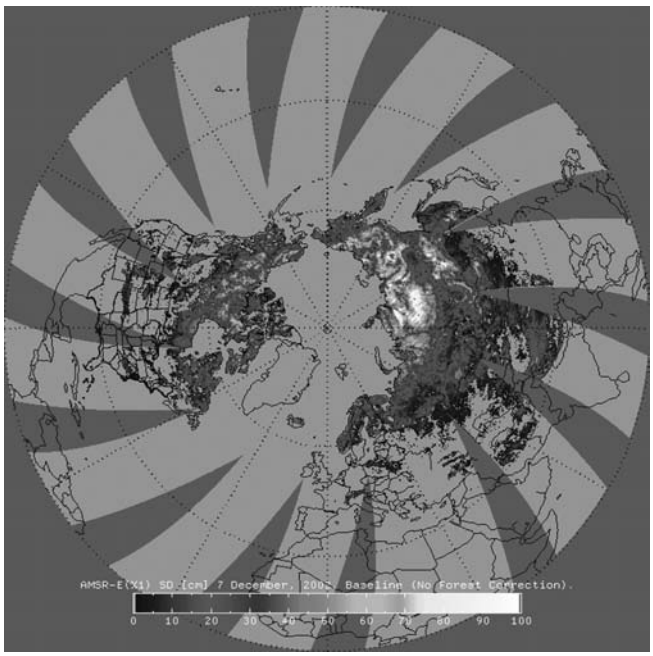

Figure 4 Estimated snow depth for the Northern Hemisphere from AMSR-E data for 7 December 2002 (From R.E.J. Kelly and A.T.C. Chang, unpublished data). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Rott and Nagler (1995) developed a threshold-based algorithm to map the extent of melting snow areas in mountainous regions on glaciers using ERS-1 SAR data. The classification is based on the ratio of the backscatter of the image with wet snow cover *versus* the backscatter of the reference image. They determined a threshold value of −3 dB by comparison with field observations. Using a single-layer backscatter model, seasonal variations as well as day/night changes in snow-covered alpine areas are shown by Nagler and Rott (2000) to be largely due to changes of the liquid water content of the snowpack and the snow surface roughness. They showed the same threshold of −3 dB for identifying wet snow using C-band HH Radarsat SAR and C-band ERS SAR data. Comparison of SAR-derived snow maps with Landsat-derived snow maps showed generally good results, but with a systematic underestimation of the snow extent at the edges of the snowpack using the SAR data.

In alpine regions, Shi *et al.* (1994) used single-pass SAR imagery with polarization to map wet snow cover, finding it difficult to distinguish dry snow cover from bare ground and short vegetation. Further work using single-pass, multifrequency (SIR-C/X-SAR) data (Shi and Dozier, 1997) showed that the coherence between two passes provides a useful measurement and allows development of

algorithms to map both wet and dry snow under specific circumstances.

MODIS snow maps were compared with SSM/I-derived snow maps over the prairie and boreal forest region in western Canada by Bussières *et al.* (2002); generally good correspondence was found in the taiga region in eastern Canada, however, the accuracy of the SSM/I maps was reduced in the fall and spring. As the snow deepens during the winter, snow-grain sizes increase and the temperatures become consistently colder, the ability of the SSM/I to map snow improves, and the agreement between the visible and passive microwave maps improves (Basist *et al.*, 1996). This is because the passive microwave data are not able to effectively map wet snow cover since the penetration of the microwave signal upward through the snowpack is extremely low when the snow is wet.

Snow Albedo

Early attempts to measure snow albedo remotely were conducted from aircraft (Bauer and Dutton, 1962; Hanson and Viebrock, 1964; McFadden and Ragotzkie, 1967; Salomonson and Marlatt, 1968; Dirmhirn and Eaton, 1975). More recently, however, detailed field, aircraft, and satellite studies have been undertaken to derive quantitative measurements of snow reflectance and albedo (for example, see Steffen, 1987; Hall *et al.*, 1989; Duguay and LeDrew, 1992; Winther, 1993; Knap and Oerlemans, 1996; Stroeve *et al.*, 1997; Winther *et al.*, 1999; Greuell *et al.*, 2002).

Some researchers have measured the albedo of snow-covered lands using satellite data on a hemispheric scale (e.g. Kukla and Robinson, 1980; Robock, 1980; Robinson and Kukla, 1985; Robinson *et al.*, 1992; Robinson, 1993). Both Robinson *et al.* (1986) and Scharfen *et al.* (1987) constructed basinwide albedo maps and observed differences in the timing of the melt between years. Robinson and Kukla (1985) used Defense Meteorological Satellite Program (DMSP) imagery (spectral range – 0.4–1.1 μm) to derive a linear relationship between the brightest snow-covered arctic tundra and the darkest snow-covered forest, which were assigned albedos of 0.80 and 0.18, respectively. Scene brightness was then converted to surface albedo by linear interpolation. The surface brightness is a function of the type and density of vegetation and the depth and age of snow (Robinson and Kukla, 1985). The derived "maximum" surface albedo values were useful for climate modeling (Ross and Walsh, 1987).

Surface albedo has also been derived from Landsat MSS and TM data. One approach, based on exact solutions of the radiative transfer equation for upwelling intensity, requires known albedo values derived in each Landsat scene at different points (Mekler and Joseph, 1983). Other approaches rely on a narrowband to broadband conversion to derive albedo (Brest and Goward, 1987; Hall *et al.*, 1989; Duguay and LeDrew, 1992; Knap *et al.*, 1998; Winther *et al.*, 1999). Knap and Reijmer (1998) used Landsat data to derive the Bidirectional Reflectance Distribution Function (BRDF) to describe the complete distribution of the anisotropic reflectance of snow, and Greuell and de Ruyter de Wildt (1999) used BRDF to correct for anisotropic reflectance. The BRDF is the physical property that determines the amount and angular distribution of reflected radiance from a surface (Nicodemus *et al.*, 1977).

AVHRR data have been used to map changes in albedo over the Greenland Ice Sheet during the spring and summer months (Knap and Oerlemans, 1996; Nolin and Stroeve, 1997; Stroeve *et al.*, 1997). While Stroeve *et al.* (1997) found a good correspondence with satellite-derived and surface-measured albedo before snowmelt, after snowmelt began, melt-water ponding on the ice surface precluded accurate comparisons between the satellite-derived and surface-measured albedo.

A near-surface global algorithm has been developed to map snow albedo using MODIS data (Klein and Stroeve, 2002). In deriving albedo, atmospherically corrected MODIS surface reflectances in individual MODIS bands for snow-covered pixels located in nonforested areas are adjusted for anisotropic scattering effects using a discrete ordinates radiative transfer (DISORT) model and snow optical properties. Currently, in the algorithm, snow-covered forests are considered to be Lambertian reflectors. The adjusted spectral albedos are then combined into a broadband albedo measurement using a narrow-to-broadband conversion scheme developed specifically for snow by Shunlin Liang (written communication, 2003) (Liang, 2000; Klein and Stroeve, 2002). A near-global snow albedo product (Figure 5) is available from February 2000 to the present and validation of this product is ongoing.

Snow-water Equivalent

To derive the SWE using passive microwave data, a radiative transfer approach is used in which, for example,

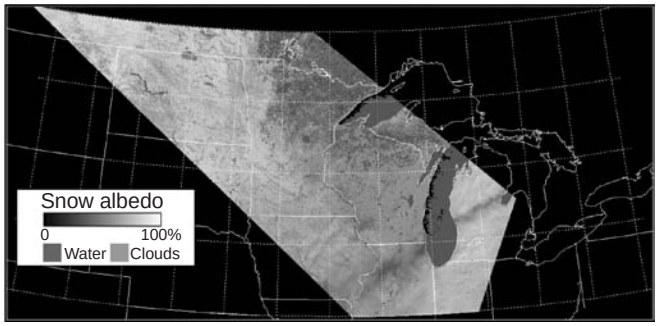

Figure 5 MODIS snow albedo product – north central United States and southern Canada – February 16, 2001. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

an average crystal size of 0.3 mm (radius), a density of 300 kg m^{-1}, and a spherical shape are assumed. It is also assumed that the crystals scatter radiation incoherently and independently of the path length between scattering centers. These quantities are then used in radiative transfer equations to solve the energy transfer through the snowpack (Chang *et al.*, 1976, 1987). Equations 1 and 2 are derived from this work and reasonable results are obtained from its implementation. However, if the crystal radii and snow density differ significantly from the averages and assumptions, then poor SWE values may result. Current efforts are aimed at improving the methods to estimate SWE by incorporating more dynamic parameterizations of these variables.

When viewed with an electron microscope, the detail is so great that individual crystals (Figure 1) can be assigned a specific shape, but the variation between even adjacent crystals can be substantial (Rango *et al.*, 1996; Wergin *et al.*, 2002). While crystal size and effective crystal size (Mätzler, 1997) are strongly related to microwave brightness temperature, it appears from modeling results that the shape of the snow crystal is of little consequence in accounting for the transfer of microwave radiation (at least at 0.81 cm) from the ground through the snowpack (Foster *et al.*, 1999, 2000; Tsang *et al.*, 2000).

Currently, SWE of a dry snowpack can be estimated with passive microwave sensors such as the SSM/I, and the AMSR (see Table 1), which was launched on the Aqua satellite in May of 2002. In Canada, SSM/I data are used to provide operational SWE map products (Figure 6) for the Canadian prairie region.

Forest cover can adversely affect the SWE retrieval accuracy by reducing the characteristic scattering response from snow by suppressing the $T_B18\mathrm{H} - T_B36\mathrm{H}$ signal (Tiuri and Hallikainen, 1981; Hall *et al.*, 1982; Hallikainen, 1984; Kurvonen and Hallikainen, 1997). Foster *et al.* (1997) attempted to correct for this effect by incorporating forest fraction into equation (1) such that:

$$SD = \frac{a(T_B18\mathrm{H} - T_B36\mathrm{H})}{(1-ff)} \qquad (3)$$

where *ff* is the per pixel forest fraction (expressed as a unit percent) that ranges from 0% to 50% (fractions greater than 50% are set to 50%). This approach improved the retrieval accuracy in forested regions.

Snow-grain size is another important parameter that influences the microwave brightness temperature. A model was developed to study the growth of the depth-hoar layer at the base of the snowpack on the Arctic Coastal Plain of Alaska during winter and compared to brightness temperature as derived from the SMMR by Hall *et al.* (1986). Results showed that an approximately 20 K lower T_B was found at inland sites with a comparable snow depth, but a thicker depth-hoar layer than was present at coastal sites. Thus, it is necessary to characterize snow-grain size on a regional basis to enhance the accuracy of snow retrievals using passive microwave data. Using SSM/I data, Mognard and Josberger (2002) modeled seasonal changes in snow grain size using a temperature gradient approach. This information was then used to parameterize the retrieval of snow depth in the northern Great Plains during the 1996–1997 winter season. Taking this approach further, Kelly *et al.* (2003) have recently developed a methodology to estimate snow-grain size and density as the snowpack evolves through the season using SSM/I and simple statistical growth models. These estimated variables are then coupled with a dense media radiative transfer (DMRT) model, described in Tsang and Kong (2001) and Chang *et al.* (2003), to estimate SWE.

As early as 1972, Meier (1972) was able to map the snowline on Mt. Rainier in Washington State in the US, using the 270 K-T_B line and a single channel (19.35 GHz) of an airborne radiometer. Since then, many different algorithms to map snow cover and SWE using passive microwave data have been developed and tested (e.g. Rott *et al.*, 1981; Kunzi *et al.*, 1982; Chang *et al.*, 1982; Goodison, 1989; Goodison and Walker, 1994; Mätzler, 1987; Hallikainen and Jolma, 1992; Grody and Basist, 1996 and Derksen *et al.*, 2002; Pivot *et al.*, 2002; Walker *et al.*, 2002). Some appear to work better under certain conditions than others, and it is now well accepted that there is no algorithm that is ideal globally.

Table 1 Comparison of characteristics of passive microwave sensors (from Foster *et al.*, 2005)

	SMMR	SSM/I	AMSR-E
Platform	Nimbus-7	DMSP F-8, 11, 13	Aqua
Period of Operation	1979–87	1987 to present	2002 to present
Data Acquisition	every other day	daily	daily
Swath Width	780 km	1400 km	1600 km
Frequency (GHz)	18.0 37.0	19.35 37.0	18.7 36.5
Spatial Resolution (km)	60 × 40 (18 GHz) 30 × 20 (37 GHz)	69 × 43 (19.4 GHz) 37 × 29 (37 GHz)	28 × 16 (19.7 GHz) 14 × 8 (36.5 GHz)

Orbital Timing (equation Crossing) (for minimum temperature)	midnight	6:00 a.m.	1:30 a.m.

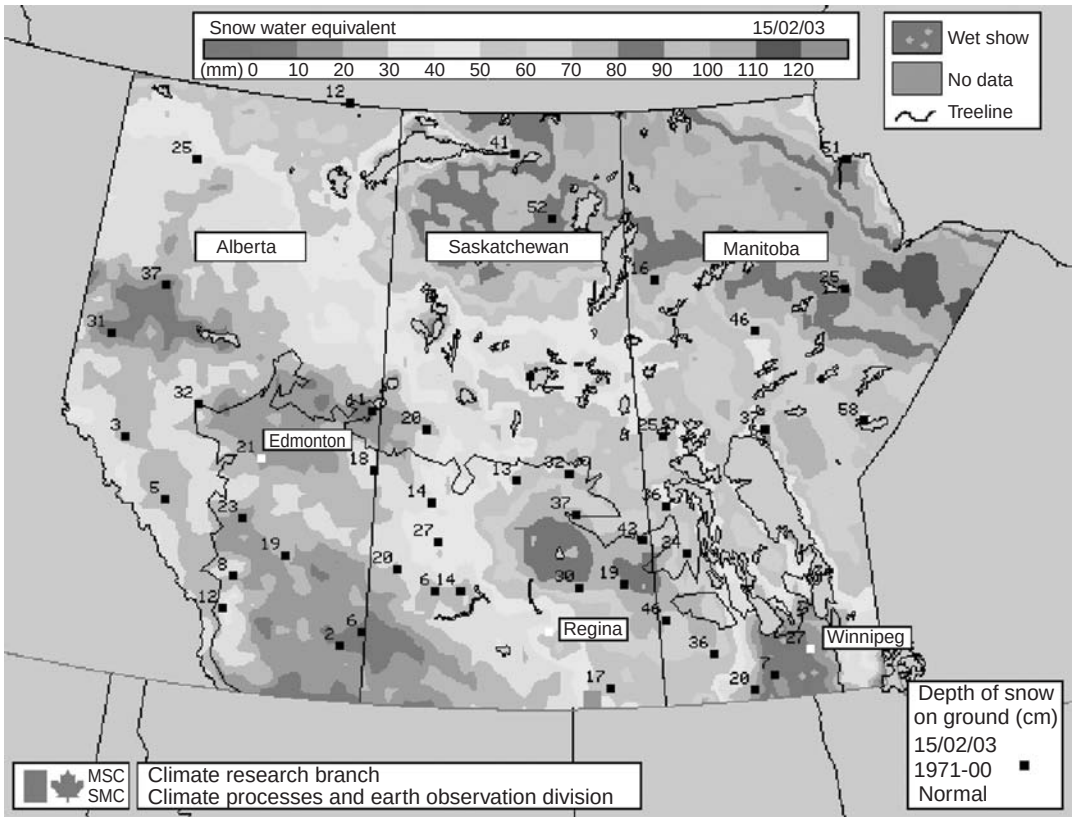

Figure 6 Snow water equivalent (in mm) over the Canadian Prairie region, derived from DMSP SSM/I data for 15 February, 2003. Areas of highest snow water equivalent generally correspond to the areas where the snow cover is deepest (Courtesy of the Climate Research Branch, Meteorological Service of Canada, Environment Canada). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

The basic algorithm must be tuned to individual land-cover types (Walker and Goodison, 2000). Walker and Goodison (1993) developed a wet snow indicator using the SSM/I 37 GHz polarization difference for the Canadian Prairies, and Goita *et al.* (2003) developed separate algorithms, both based on the vertically polarized difference index using 18 and 37 GHz data from SSM/I to map SWE in deciduous and coniferous forest types, respectively.

The differences between the day and night brightness temperatures indicate the presence of liquid water in the snowpack. Early in the snow season, the difference is small, indicating the absence of liquid water in the snowpack. As spring approaches, the difference increases, indicating the presence of liquid water during the day, and then the pack refreezes at night. When liquid water does not refreeze at night, the difference again becomes small, and the snowpack is ripe and will soon begin to melt (Josberger *et al.*, 1993). Ramage and Isacks (2002) used SSM/I-derived diurnal-amplitude variations to detect early melt on snow-covered icefields in southeast Alaska, and found that melt timing correlates well with nearby stream hydrographs.

Climate-data-record (CDR) quality data sets of SWE are difficult to derive. The development of long-term CDR quality datasets may be influenced by difficulties related to calibration between sensors. Derksen *et al.* (2003) produced a time series for central North America for the winter season from 1978 through 1999, using both SMMR and SSM/I data. They found evidence of systematic SWE underestimation during the SMMR years, and overestimation of SWE during the SSM/I years. Previous work by Armstrong and Brodzik (2001) also suggested inconsistencies between the SMMR and SSM/I datasets.

Many other researchers have developed algorithms that use multiple sensors to map snow cover and SWE (e.g. Basist *et al.*, 1996; Armstrong and Brodzik, 1998, 2001, 2002; Standley and Barrett, 1999; Tait *et al.*, 2000 and, 2001; Kelly, 2001; Hall *et al.*, 2002b), and in different land covers (Hall *et al.*, 2001). Visible/near-infrared data, with good spatial resolution, provide excellent snow-covered area determination under cloud-free conditions, while passive microwave data provide all-weather day/night snow maps, but with coarser resolution. In addition, problems arise in wet snow and thin, dry snow when using passive microwave data alone.

There are conflicting results showing the sensitivity of radars to SWE. Ulaby *et al.* (1977) found that radar

sensitivity to total SWE (for wet snow) increased in magnitude with increasing frequency (or shorter wavelength) and is almost independent of angle for angles of incidence $>30°$, particularly at higher frequencies. Goodison *et al.* (1980) found little or no relationship between radar return and snowpack properties under either wet or dry snow conditions using L-band airborne SAR. A uniform, low return was found for a given area under both snow-free and snow-covered conditions. However, using X-band, in their study area near Ottawa, Ontario, nonforested areas exhibited higher backscatter when snow cover was present. Areas of ice and dense snow were observed to produce relatively higher radar returns using the X-band SAR (Goodison *et al.*, 1980).

Bernier *et al.* (1999) established a relationship between the backscattering ratios of a winter (snow covered) image and a fall (snow-free) image to estimate the snowpack thermal resistance using the Radarsat SAR. They then estimated the SWE from the thermal resistance and the measured mean density. In related work, Gauthier *et al.* (2001) used Radarsat C-band ScanSAR data to derive SWE in the La Grande River Basin in northern Québec, where they found ScanSAR-derived SWE values to be similar ($\pm 12\%$) to those derived from *in situ* snow measurements in January and March 1999.

SNOW WETNESS

A study of wet snow using C-, L- (1.25 GHz), and P-band (440 MHz) (see Table 2) polarimetric SAR of a mountainous area in Austria (Otzal), Rott *et al.* (1992) showed the importance of surface roughness at C- and L-band frequencies, and the increasing importance of the snow volume contribution with the longer wavelength P-band sensor. Radar polarimetry allows simultaneous measurement of the radar backscatter from a given surface at a number of different polarizations. Using European Remote Sensing Satellite (ERS)-1 images acquired before, during and after the melt period, Koskinen *et al.* (1997) successfully mapped wet snow with C-band SAR in unforested and sparsely forested regions in northern Finland.

Table 2 Band designations, wavelength, and frequency ranges for Earth-sensing radars (Long, 1975)

Band	Wavelength range (cm)	Frequency range (GHz)
Ka-band	0.75–1.1	26.5–40.0
K-band	1.1–1.67	18.0–26.5
Ku-band	1.67–2.4	12.5–18.0
X-band	2.4–3.75	8.0–12.5
C-band	3.75–7.5	4.0–8.0
S-band	7.5–15.0	2.0–4.0
L-band	15.0–30.0	1.0–2.0
P-band	30.0–100.0	0.3–1.0

Extensive aircraft and ground measurements were obtained by the Canada Centre for Remote Sensing (CCRS) over agricultural areas in southern Québec, Canada, in 1988–1990 (Bernier and Fortin, 1998). It was concluded that, at C-band, volume scattering from a shallow dry snowpack (SWE <20 cm) is not detectable. The backscatter using a C-band SAR emanates from the snow/soil interface when the snowpack is dry. Earlier, Mätzler and Schanda (1984) and Mätzler (1987) had concluded that the backscatter change between an unfrozen bare soil and a dry snow cover over unfrozen soil was small – on the order of 1.5 dB at X-band. Rott and Mätzler (1987) found no significant difference between snow-free and dry-snow-covered regions at 10.4 GHz. However, there may be a potential for detecting shallow, dry snow cover with C-band SAR data when the soil beneath the snow is frozen (Bernier and Fortin, 1998).

Though the main scattering contribution from a dry snow cover is from the ground/snow interface, small changes in the snow can be detected using tandem pairs from repeat-pass interferometric synthetic-aperture radar (InSAR) data. Using the coherence measurement of repeat passes, Shi and Dozier (2000) found that both wet and dry snow can be mapped as evidenced by comparison of snow mapped using Landsat imagery. Refraction of microwaves in dry snow was shown to have a significant effect on the interferometric phase difference and a relationship between changes in SWE and the interferometric phase was derived. Using three tandem pairs of InSAR data, Guneriussen *et al.* (2001) found that a snow density of $0.2\,\mathrm{g\,cm^{-2}}$ at 23° incidence angle gives phase wrapping for changes in snow depth of 16.4 cm and equals a SWE of 3.3 cm.

A promising technology for measuring snow cover is scatterometry. A Ku-band (14.6 GHz) scatterometer operated for three months from July to September 1978 on the Seasat satellite, and results show that some of the glacier facies could be mapped using derived backscatter images (Long and Drinkwater, 1994). The NASA Scatterometer (NSCAT) operated on the Advanced Environmental Observation Satellite (ADEOS) from September 1996 to June 1997 and also permitted study of melt zones on Greenland (Long and Drinkwater, 1999). Timing of melt onset was detected by Nghiem *et al.* (2001) on the Greenland Ice Sheet by a sharp decrease in backscatter, and verified with *in situ* measurements, using the SeaWinds scatterometer on the QuikSCAT satellite.

For seasonal snow cover, Nghiem and Tsai (2001) show that NSCAT backscatter patterns reveal boundaries that correspond to various snow classes as defined by Sturm *et al.* (1995). Additionally, they show rapid changes in the backscatter over the northern plains of the United States and the Canadian prairies that led to the major spring 1997 floods in the mid-western United States and southern Canada (Figure 7).

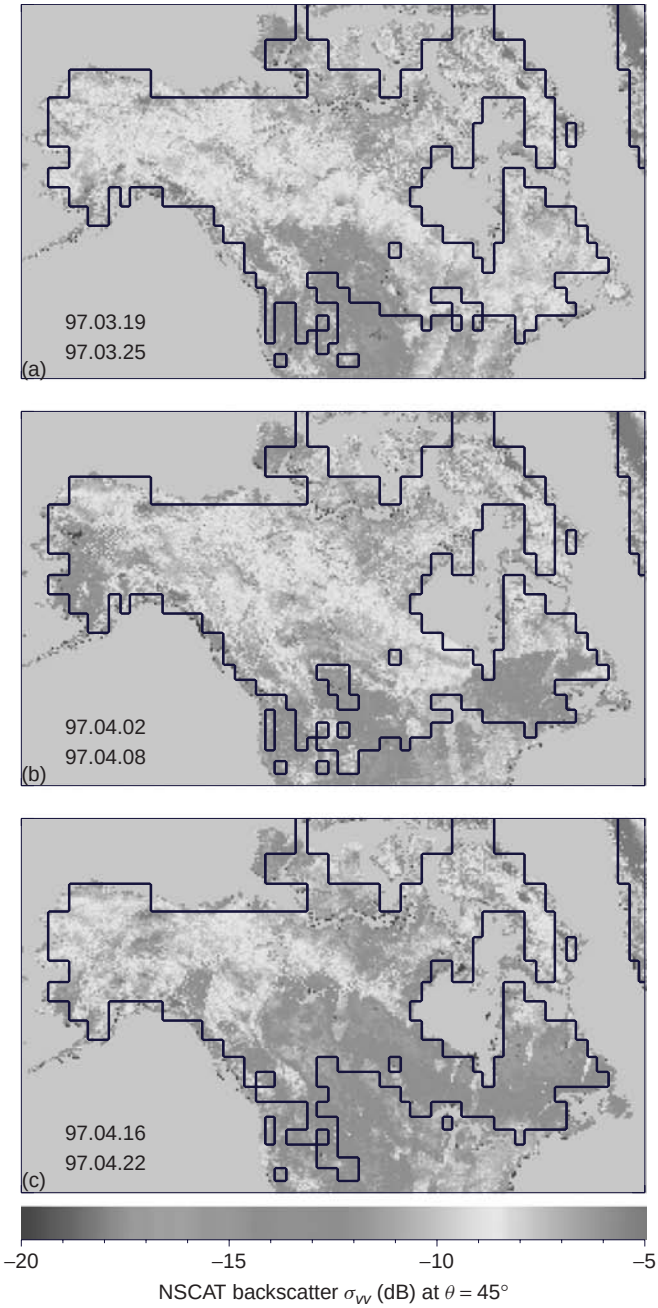

Figure 7 NSCAT backscatter signatures over snow cover corresponding to snow events leading to the 1997 flood in the northern plains of the United States and the Canadian prairies: (a) period of snowmelt from March 19 to March 25, 1997; (b) period of the blizzard from April 2 to April 8, 1997; and (c) period of rapid snow retreat from April 16 to April 22, 1997 (Nghiem *et al.*, 2001). Future Directions and Conclusions

Mapping snow cover areal extent using satellite observations is relatively mature and well validated (see, e.g., Robinson, 1993, 1999; Hughes *et al.*, 1996; Frei *et al.*, 1999; Hall *et al.*, 2002a; Brown *et al.*, 2003; Mauer *et al.*, 2003). Recent global water and climate system studies have begun to examine the link between snow cover areal extent and atmospheric dynamics. For example, Cohen and Entekhabi (1999) investigated the link between early season snow extent in Eurasia and the dynamics of the Siberian high. Saunders *et al.* (2003) show a link between summer snow extent and the winter North Atlantic Oscillation. These studies are important for our understanding of the role of snow in the Earth's hydrological cycle and how it affects human sustainability, especially in regions that are heavily dependent on snowmelt runoff for water supply.

The methodology to map global SWE from remote-sensing instruments is less mature. While microwave remote-sensing observations are helping to advance our ability to effectively characterize water storage in snowpacks, there remain uncertainties about the retrievals from these instruments. Historically, the frequency configurations of space borne active radar systems have produced measurements that are sensitive to the presence or absence of wet snow only and little or no direct information about SWE can be determined from these instruments. Satellite passive microwave measurements now have a 25- year record from which SWE can be estimated. However, with the characteristically large instantaneous fields of view that characterize these instruments (tens of kilometers), the uncertainties associated with SWE estimates are difficult to quantify, and, therefore, are still under investigation. Studies have shown that in noncomplex terrain with low-stand vegetation, reasonable estimates of SWE can be obtained from passive microwave measurements. In other terrain types, however, larger uncertainties persist.

In order to characterize snow water storage, new and improved satellite instrument measurement techniques need to be developed, especially for instruments in the microwave part of the electromagnetic spectrum that are sensitive to snow volume. Ku-band radar measurements are sensitive to SWE and could be developed to resolve fine spatial variations of SWE (tens of meters) through SAR technology. For passive microwave measurements, the relatively low spatial resolution is a key cause of uncertainties in the estimation of SWE. Only through technology improvements in antenna design can instantaneous fields of view be significantly improved, thus increasing the spatial resolution (e.g. Doiron *et al.*, 2004).

With improvements in microwave instrument and measurement techniques of SWE, the uncertainties and errors in SWE estimates will be reduced providing more confidence in our ability to estimate snow water storage throughout the year. If these technology developments come to fruition and new, "more SWE-capable" microwave missions overlap with the current and planned global multidisciplinary instruments, such as the available AMSR-E and the proposed Conical Scanning Microwave Imager/Sounder (CMIS) planned for National Polar-orbiting Operational Environmental Satellite System (NPOESS), the benefits could be great (Kelly *et al.*, 2004). Local scale SWE characterization would be possible; the prospect of combining high spatial resolution-accurate SWE measurements with sophisticated numerical land surface models may then be possible, and is a very exciting one from the water resource management perspective.

Satellite remote sensing has been used to map snow cover for nearly 40 years. Decade-scale CDR-quality records of snow-covered area are already in existence for the Northern Hemisphere (Robinson and Frei, 2000) and are useful in climate models, however, problems exist in developing a CDR for SWE (Armstrong and Brodzik, 2001; Derksen *et al.*, 2003), as discussed above. We can now extend the snow-covered area record using SMMR, SSM/I MODIS, and AMSR data to the global scale, and provide CDR-quality maps of snow-covered area, and continue to study the development of CDR-quality datasets of SWE and snow albedo using visible, near infrared, and passive microwave sensors such as the MODIS and AMSR.

The trend has been toward increasingly automatically processed quantitative maps with error bars provided. Automated processing is necessary so that consistent products can be derived from the observations and long duration data sets might ultimately be available for long-term water-cycle studies. The error estimates associated with snow products are also essential if the products are to be used effectively in combination with catchment-based land surface or climate models. This is because models that require snow-state parameters often require the errors associated with the estimated snow states, especially if data assimilation techniques are used to generate blended products. Whether the snow products are used for initial conditioning or as a forcing variable in a model, or whether the products are used in their own right, the role of remotely sensed observations of snow will continue to be important and is set to play an increasingly important role in climate and hydrological forecasting.

Future sensors will permit automated algorithms to be used to create maps that are consistent with existing maps so that the confidence level of the long-term (~40 year) record is high. The quality allows them to be amenable to comparison with long-term records of other geophysical parameters such as global sea ice, and for input to general circulation models.

Acknowledgments

The authors would like to thank Dr. Andrew G. Klein of Texas A & M University for helpful comments on parts of the manuscript.

Past satellite missions have demonstrated the utility of spaceborne remote sensing in studies of polar ice. Because of their ability to "see" into polar ice without regard to cloud cover or solar lighting, microwave remote sensing instruments have played and will continue to play an increasing role in such studies and in long-term monitoring the polar regions. Microwave sensors can be either active radars which transmit and receive, or receive-only radiometers. Spaceborne microwave sensors such as radiometers and scatterometers offer wide-area, frequent coverage but at lower resolution and a longer historical database. The historic data sets are particularly important since they provide a baseline for studies of global change. Synthetic aperture radar systems possess high resolution capability but have restricted spatial and temporal coverage. Microwave sensors are sensitive to snow and ice structure and are particularly sensitive to freeze/thaw conditions. Optical sensors can also be active (Lidars) or passive. Laser altimeters are an example of an active optical sensor. They provide accurate ice sheet topography information. Passive optical sensing is useful in change detection and infrared ice temperature sensing. In this chapter, essential background in microwave and optical remote sensing of sea-ice, glaciers and ice sheets is provided, along with application examples.

INTRODUCTION

Snow, sea ice, and land ice exert a profound influence not only on the local climates but also on the global climate through their high albedos and thermal and radiative properties. A common feature of climate model projections is that largely due to albedo feedbacks involving snow and sea ice, the effects of greenhouse gas (GHG) loading will be observed first, and will be most pronounced in the polar regions. Thus, long-term, internally consistent datasets are required to detect any climate-change-related trends that may be occurring in these regions.

Remote sensing utilizing instruments spanning the visible through microwave portion of the electromagnetic spectrum have found many applications for mapping sea and land ice. The advantages of satellite remote sensing in mapping snow and ice cover is that large and inaccessible areas such as the polar regions can be studied even under darkness and through fog, cloud, or rain. This latter point is particularly important in the polar regions that are frequently cloud-covered and undergo six months of darkness. This article discusses applications of different satellite sensors to the studies of ice sheets, glaciers, and sea ice. Here, we address passive and active microwave and optical remote sensing as well as infrared observations. We begin the discussion by reviewing the relevant physical properties of sea ice and snow that affect the satellite signal.

PHYSICAL STRUCTURE AND TEMPORAL EVOLUTION OF SEA ICE AND ICE SHEETS

Using remote sensing data is essential to the study of sea ice and ice sheets because of the difficulty in accessing these large and inhospitable remote areas. Remote sensing

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

in the microwave wavelength region is particularly useful because of the ability of microwave instruments to collect data through cloud cover and polar darkness. This section discusses some of the basic physical properties of sea ice, land ice, and snow that affect the satellite signal.

Sea Ice

Sea ice is a complex structure consisting of a variably aged ice matrix with inclusions of brine, air, and solid salts. Scattering and emission of microwave radiation is very sensitive to small variations in the structure and composition of the sea ice. Snow cover on top of the sea ice acts as an insulating blanket for the sea ice since it has a thermal conductivity that is approximately 10 times lower than that of the underlying sea ice and therefore reduces the conductive flux between the ocean and the atmosphere. Snow cover significantly alters the microwave emission of the sea ice as well as the surface albedo and will be discussed later. Next we discuss the cycle of formation and deformation of sea ice. The process can be broken down into four steps: (i) formation, (ii) growth, (iii) deformation, and finally (iv) disintegration.

Formation and Growth

Sea ice tends to form first in shallow waters (i.e. waters of small depths cool faster), in areas of reduced current (i.e. bays and inlets), and also in areas near the mouths of rivers (i.e. areas of low salinity). The greater the depth of high-salinity water, the later (longer) the time until freezing. At the first signs of freezing, an oily appearance occurs on the water caused by the formation of needle-like crystals or plates of about 10 mm, made up of pure ice (no salts). This is called *frazil ice*. As freezing continues, these needle-like crystals increase in number and form a thin layer of slushy ice (or *grease ice*).

The salt in the ocean does not initially become part of the crystals that form, and thus the nearby water becomes saltier. This denser water sinks, and as more crystals form, the salts eventually become frozen to one another in such a way that tiny spaces or pockets remain between groups of crystals. Some of the residual brine will become trapped in those pockets, which are called *brine cells*. Depending on the rate of freezing, the remaining brine will diffuse downward into the water (if freezing is slow), or become trapped in the brine cells (if freezing is rapid). Thus, ice that forms rapidly is saltier than ice that forms slowly with consequent impacts on the ice's material properties.

If the air temperature is very low, a thin sheet of ice will grow quickly in a short span of time, but as the ice becomes thicker (e.g. 8–10 cm), the growth rate slows as the ice thickens further. Since the snow cover acts as a blanket, a few centimeters of snow on top of the ice will drastically slow down the rate of ice thickness growth. Under appropriate conditions, *frost flowers* may form on the ice surface. Frost flowers form directly from water vapor. Salt flowers are caused by the channeling of brine into frost flowers. These intricate crystal forms are important because they can cover large areas and can significantly alter the microwave signature, increasing backscatter and decreasing emission (Rankin *et al.*, 2003).

Deformation

Sea ice changes shape through the movement of winds and currents, by thermal expansion and contraction of the ice, or by contact with converging ice or shorelines. Ice expands rapidly when it first forms and will continue to expand until a critical temperature is reached, after which it contracts slightly: the greater the salinity of the ice, the greater the expansion. The following describes some of the various ice formations caused by deformation:

- **Pressure ridges** form on the ice surface because of thermal expansion or from the pressure exerted on the ice by wind or currents. Pressure ridges can extend downward four to five times as far as they extend upward.
- **Hummocks** are small hills of broken ice that have been forced upwards by pressure. They are less salty than pressure ridges and have a melting point close to 0 °C.
- **Ice floes** are formed by the cracking and breaking of a solid ice layer into separate pieces.
- **Rafting** occurs when two floes are pressed together so that one lies on top of the other.
- **Cracks or Leads** occur when the ice layer breaks open because of the action of winds and/or currents and the floes separate, or because of contraction.

Disintegration

Sea ice disintegrates by:

- *Melting.* Absorption of sun's radiation by snow and ice (after the snow melts off) and conduction of heat from surrounding air, water, and land contribute to the loss of ice due to melting. Once there is open water, such as leads or cracks close to the ice, or water on top of the ice (ponds), melting is accelerated.
- *Conduction.* When warm air is in contact with the liquid water on the ice, heat is transferred from the air to the water. Heat is conducted down into the water, which in turn accelerates the melting of the ice underneath.

Glacial Ice and the Major Ice Sheets

Because of the distinct differences in temporal scale, this section will not be broken down into formation, deformation, and disintegration sections, as was done in the previous

text. It is important to note that glacial ice generally originates as snowfall, which accumulates over hundreds to tens of thousands of years and eventually begins to flow under its own mass. Snow deposition and seasonal melting continually modify the surface. Aeolian processes produce snow drifts and small dunes known as *sastrugi*. Some megadunes in Antarctica are many kilometers in size, with lengths up to 100 km and wavelengths of 5 km. Under appropriate conditions, surface meltwater can percolate down into the snow layer creating ice lenses and other structures that can greatly affect the microwave signature of the ice. Movement of the ice creates crevasses and surface expressions of basal topography greatly modifying the surface of flowing glaciers. Frost flowers and hoar can also form on the ice surface or in the near-surface layers.

On the Greenland ice sheet, a wide range of snow and ice zones are found (Benson, 1962). The boundaries between the facies are sensitive indicators of seasonal climate characteristics (Long and Drinkwater, 1994; Jezek *et al.*, 1994). The dry snow facies are located at the highest elevations of an ice sheet (or glacier), where there is little or no surface melt. The percolation facies, where some melt occurs but meltwater percolates into the snowpack and refreezes, is just below the dry-snow zone in elevation. It is not easily distinguished from the wet snow facies, where complete annual accumulation of snow may experience melt and refreezing. However, at the lower elevations of the wet snow facies there are melt ponds and areas of slush. Still lower is the superimposed ice facies, which represents the zone of refrozen melted snow. Because superimposed ice is created by the melting and refreezing of this year's snow, this zone is still considered part of the ice-sheet accumulation area. The lowest elevation zone is the ice facies, which represents the ablation region. In this region, the annual accumulation of snow and ice is fully melted and ice from the previous years can be removed. Melt is critically important to the Earth's radiation budget, as wet snow can absorb 45% more incoming solar radiation than dry snow (Abdalati and Steffen, 1995). The equilibrium line altitude on a glacier or ice sheet is defined as the boundary between the accumulation area and the ablation area. This line is where the annual mass balance is zero. The firn line is the minimum elevation of firn lying on a glacier surface. Each year's firn line marks a glacier or ice sheet's annual equilibrium line.

Snow metamorphism, and the resulting stratigraphy of the snow and firn (snow that is older than one year), is enhanced by the thermal regime during seasonal change as well as the presence of meltwater. In Greenland, the general evolution in the dry-snow zone closely follows thermal forcing within the upper few meters of the snowpack. Diagenetic changes in the snow and firn can take place over time without melt, but are accelerated with higher temperatures. When summer temperatures in the upper snowpack increase above $-10\,^{\circ}C$, the vapor pressure increases, leading to increased vapor transport and sublimation. The net result is the destruction of original precipitated snow crystals, increased grain sizes, and increased bonding between grains. These changes in snow and firn are common to the spring and summer months in the dry-snow zone at elevations that are too high to experience actual melting.

Further downslope, as summer surface air temperatures increase, diagenesis takes place much more rapidly and dramatically as snow and ice melts (Echelmeyer *et al.*, 1992). Below the dry-snow line lies the percolation zone, where meltwater can percolate downward to form pipes and channels. When meltwater encounters obstructions or snow below the freezing point, it moves laterally to form layers or buried ice lenses and glands (Pfeffer *et al.*, 1990), parallel to the strata. As meteorological conditions vary, the pipes that feed these hard ice layers with melt water may also freeze, resulting in vertically extended ice masses. At lower altitudes where melting is significant, the seasonal snowpack typically becomes isothermal and may melt away to reveal bare glacial ice.

Layering develops in the accumulation zone of ice sheets because of snow precipitation and redistribution patterns and the changes affected by seasonal weather. Such stratigraphy is preserved over time and can be often correlated using passive microwave data over scales of tens or even hundreds of kilometers (Shuman and Alley, 1993). Stratigraphic discontinuities such as hoar layers form because of seasonal changes such as a strong thermal gradient in the near-surface along with low accumulation and wind speed that are characteristic of the austral summer in Greenland. In addition, a discrete boundary in the snow pack often produces a coarse-grained, low-density layer, overlain by a finer-grained, harder layer of higher density, slightly above the previous summer's surface melting. Benson (1962) observed the formation of this sequence under strong negative temperature gradients in mid- to late August during the fall season. In the percolation zone, stratigraphic horizons such as ice firn or ice lenses are seasonal markers. In bare ice zones, stratigraphic markers are effectively removed.

MICROWAVE REMOTE SENSING APPLICATIONS

Remote sensing utilizing instruments in the microwave portion of the electromagnetic spectrum is well suited for large-scale sea ice, ice sheet, and snow studies, including the estimation of the fraction of sea ice, snow accumulation on ice sheets, and snowmelt. Microwave sensors can be divided into two classes: passive (radiometers) and active (radars). Radiometers are passive, receive-only sensors that measure the thermal emission (brightness temperature) of the target in the microwave band. Radars transmit pulses of

microwave energy towards the Earth's surface and measure the reflected energy (Ulaby *et al.*, 1981).

Data from passive microwave instruments now span nearly three decades; active sensors cover somewhat lesser time period. Data from passive microwave radiometers have been available since December 1972 with the launch of the Nimbus-5 Electrically Scanning Microwave Radiometer (ESMR). This early sensor provided the first synoptic overview of the polar ice masses that were not affected by weather or polar darkness for five years. The Nimbus-7 Scanning Multichannel Microwave Radiometer (SMMR) provided the first multifrequency passive microwave observations for almost a decade, from 1978 to 1987. The operational mode Special Sensor Microwave/Imager (SSM/I) onboard a series of Defense Meteorological Satellite Program (DMSP) satellites has continued the satellite passive microwave observations since 1987. Now, with the launch of the Advanced Microwave Scanning Radiometer (AMSR) onboard the Aqua platform, these multidecadal time series will be continued and enhanced through the additional spectral channels, enhanced resolution, and improved instrument performance offered by AMSR.

Active microwave sensors include synthetic aperture radars (SARs), scatterometers, and altimeters (Ulaby *et al.*, 1981). SARs are imaging radars that measure the surface backscatter at fine resolution (Henderson and Lewis, 1998), but have only limited coverage and are typically less well calibrated than scatterometers. Microwave scatterometers were originally designed to measure winds over the ocean but have also been found to be very useful in cryospheric studies (Long *et al.*, 2001). Scatterometers have low spatial resolution, but offer wide-area and frequent coverage. Altimeters are designed to measure surface topography and have very narrow swaths.

The first SAR and scatterometer flew in 1978 aboard Seasat and operated for 3 months. Later active sensors include the European Remote Sensing (ERS) 1 and 2, Active Microwave Instrument (AMI), which included both scatterometer and SAR modes operating at C-band, the Ku-band NASA Scatterometer (NSCAT), and the Ku-band SeaWinds scatterometer series. ERS-1 operated from 1992 through 1996, while ERS-2 operated from 1996 through 2000, with limited current operation to the present. NSCAT operated for 9 months in 1996–1997. The first SeaWinds was launched aboard QuikSCAT in 1999 and continues operation into 2005. The second SeaWinds operated for 10 months aboard the Japanese ADEOS-II spacecraft after its launch in December 2002. Several Space Shuttle-based SAR missions have been flown, including SIR-A, SIR-B, SIR-C, and SRTF. Other orbital SARs include the Japanese JERS-1, the Canadian RADARSAT-1, and the European EnviSAT. Interferometric SAR uses phase information collected from two different antennas on the same spacecraft (SRTF) or from two different orbits (other sensors) to infer surface topography (Ulaby *et al.*, 1981). The RADARSAT Antarctic Mapping Project (RAMP) collected interferometric SAR data and created the first high-resolution topographic map of Antarctica in 1997 (Jezek, 1999; Jezek *et al.*, 2000). A second map was created in 2000. Interferometric SAR data measure ice sheet and glacier velocities (e.g. Kwok and Fahnestock, 1996; Rignot, 1996; Young and Hyland, 2002).

A number of satellite altimeter missions have been flown, including Seasat-A, TOPEX, GEOSAT, ERS-1/2, and JASON-1. These have been used to map ice-sheet topography and study changes in the major ice sheets (e.g. Zwally and Bindschadler, 1983; Zwally *et al.*, 1987; Davis and Zwally, 1993; Bamber, 1994). In the following, we primarily concentrate on radiometer and scatterometer observations. SAR sensing is considered in more detail elsewhere, for example, Henderson and Lewis (1998), Tsatsoulis and Kwok (1998).

Relevant Microwave Electromagnetic Properties of Ice and Snow

Passive microwave sensors observe the radiometric brightness temperature of the surface, which is a function of the physical temperature and the dielectric constant, which is dependent on the wavelength, on the amount of snow and ice, as well as on the structure of the snow and ice (i.e. grain size, shape, etc). The dielectric constant is closely related to the permittivity. Active microwave sensors rely on measurements of the normalized radar backscatter, also termed the *normalized radar cross section* (NRCS) (Ulaby *et al.*, 1981). The backscatter is a function of the permittivity and the roughness of the surface as well as the subsurface structure, with the volume contribution depending on various characteristics of the volume snow and ice properties. The microwave signature of snow and ice are dependent on the backscatter and emission from the surface, emission volume scattering from within the snow and ice, and scattering from layers within the snow and ice.

Since there is a large emissivity difference between ice and open water, sea ice is easily distinguished in the microwave wavelength region depending on the proportion of water and ice in the sensor footprint. The reflectivity of sea ice depends upon the bulk dielectric properties, which is dependent on the distribution of brine, air, and solid salts within the ice. Scattering on the other hand is largely influenced by the surface roughness and the inhomogeneities within the ice, as well as the bulk dielectric constant. Knowledge of small-scale surface roughness across the footprint is essential for the correct interpretation of microwave data. In addition, air pockets, brine inclusions, and depth and type of snow cover in sea ice significantly change the permittivity and hence the backscatter observed by radar instruments.

Dry snow has a low relative permittivity (~1.5–2.5) that increases dramatically in the presence of moisture, resulting in a strong melt signature. Thus, snowmelt can be detected in the microwave wavelength region as liquid water inclusions form around and between snow grains (Colbeck, 1986). Since the permittivity of liquid water is approximately 40 times that of ice crystals (Tiuri *et al.*, 1984), even small amounts of liquid water will affect snow dielectrics. For instance, as moisture bonds to snow grains overlying sea ice, microwave emission is largely due to the snow, rather than the underlying ice (Onstott *et al.*, 1987), and closely resembles a blackbody (Eppler *et al.*, 1992). Microwave brightness temperatures increase rapidly at frequencies greater than 10 GHz during melt onset (Thomas *et al.*, 1985), with greater increases at higher frequencies. As seasonal melt continues, liquid water begins to flow freely around the snow grains (Colbeck, 1986), and microwave emissivities tend to approximate an infinitely thick, wet, snow pack (Onstott *et al.*, 1987). Once ponding and drainage begin, the surface becomes a complex mixture over typical sensor footprint scales (several to tens of km), and typically displays a range of brightness temperatures (Grenfell and Lohanick, 1985).

Rapid changes in passive microwave signatures have been used to detect snowmelt over sea ice (e.g. Anderson, 1997; Smith, 1998) and ice sheets (e.g. Mote and Anderson, 1995; Abdalati and Steffen, 1995; Fahnestock *et al.*, 2002). Meltwater, however, causes passive microwave sea-ice algorithms to significantly underestimate summer ice concentration (e.g. Fetterer and Untersteiner, 1998; Comiso and Kwok, 1996). Partington *et al.* (2003) compared the Arctic sea-ice concentrations from the NASA Team sea-ice algorithm and manual ice charts from the US National Ice Center (NIC) and reported average differences of 23% in early August.

On ice sheets, the freeze-up period marks the end of freshwater input into the ocean and an increase in surface albedo. Over land ice, the diurnal difference in microwave brightness temperatures increases sharply when near-surface air temperatures approach 0 °C (Forster and Baumgras, 2000). Although Winebrenner *et al.* (1994) used active microwave data to identify the continuous melt period, and Parkinson (1992, 1994) used passive microwave data to calculate the time period between melt onset and freeze-up, little work using passive microwave data to distinguish the continuous and advanced melt stages has been done to date (see Fahnestock *et al.*, 2002). Smith (1998) utilized a combination of 19 and 37 GHz vertical brightness temperatures to recognize the start of the freeze-up period. Comiso and Kwok (1996) also showed that freeze-up could be determined on the basis of latitudinal-averaged SSM/I data, but they did not attempt to systematically map spatial and temporal variations.

The change in radar backscatter due to melt as measured by radar sensors is very dramatic and thus is a very powerful tool for mapping melt extent over both sea ice and ice sheets (e.g. Long and Drinkwater, 1999; Wismann, 2000). Nghiem *et al.* (2001) used diurnal variations in backscatter to map melt extent. Figure 1 illustrates two NSCAT backscatter images before and after melt onset.

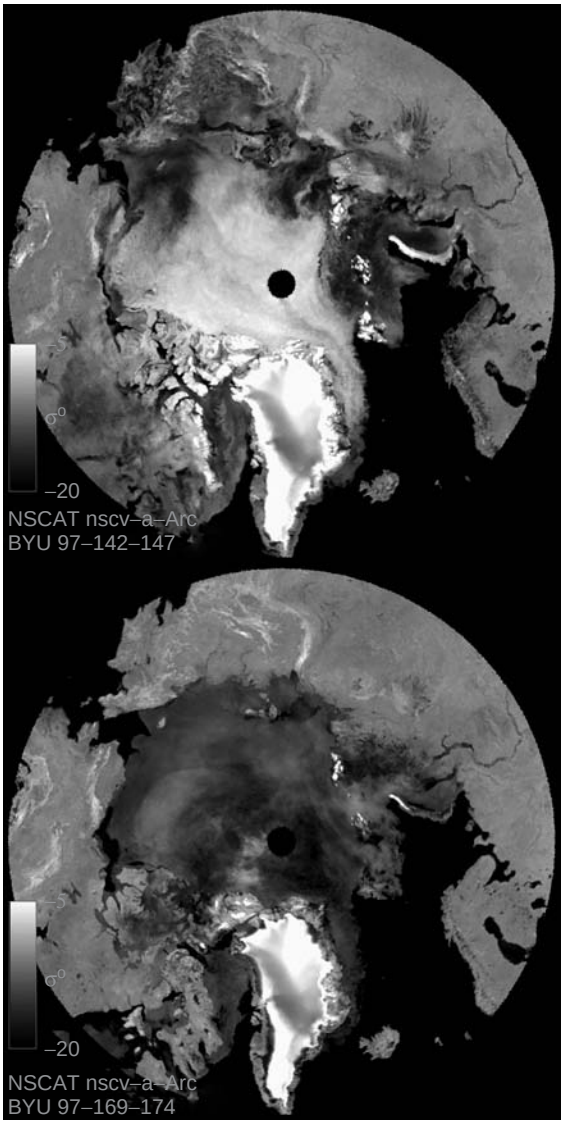

Figure 1 Two NSCAT enhanced-resolution backscatter images. The 13.9 GHz normalized radar cross section at 40° incidence angle (in dB) is shown before (a) and after (b) a major melt event. Note the dramatic change in backscatter over the sea ice and along the periphery of the Greenland ice sheet (from the Scatterometer Climate Record Pathfinder **http://www.scp.byu.edu**). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Electromagnetic Scattering and Emission Models

The relationship between the EM signature of ice and its geophysical characteristics is complicated. While much progress has been made in the methods for estimating geophysical parameters from microwave observations, more remains to be done. A common approach is to use inverse modeling techniques. In inverse modeling, a forward EM model is formulated, which predicts the microwave response as a function of the geophysical properties of the ice. Then, given a measured response, we try to infer or estimate the geophysical parameters that give rise to (or explain) the observed response (see, for example, Remund *et al.*, 2000).

While techniques for modeling the interaction of electromagnetic signals with natural surfaces have advanced significantly, the highly inhomogeneous nature of sea and glacial ice on a variety of spatial scales complicate modeling of snow and ice. Further, multiple combinations of geophysical parameters can give rise to similar microwave responses. An extensive review of ice emission and scattering models and inverse techniques is outside the scope of this article; however, we consider a number of important models (see also, Ulaby *et al.*, 1981).

Early modeling results have been based on simplified geophysics and electromagnetic interaction. As models have developed, the geophysics they incorporate have become more complicated. Drinkwater (1989) and Livingstone and Drinkwater (1991) used simple EM scattering models based on simplified volume backscatter from individual ice crystals, air bubbles and brine pockets, and rough surface scattering. They compared their modeling results with actual observations from both spaceborne and shipborne instruments. By incorporating snow and ice layering, this model has been extended to glacial ice in Greenland (Long and Drinkwater, 1994). However, no existing models adequately incorporate temporal evolution of the ice.

Several models have been developed to compute microwave emission for sea ice, which can be useful to help understand the evolution of passive microwave signatures of the ice pack. One method for the calculation of sea-ice reflectivity is performed using the "many-layer-strong fluctuation theory" approach of Stogryn (1987). This model treats interference between waves reflected and transmitted through the various layer planar interfaces coherently. Microwave emissivities are computed on the basis of Kirchoff's law, which relates emissivity to reflectivity. The model describes the emissivity of isothermal layers of snow and ice. For each type of surface (snow or ice), different parameters are used to describe its structure and constituents. The layer structure is used to calculate the dielectric properties and the emissivity of the sea ice. This modeling approach has been found to work well for sea ice without snow cover. For example, Figure 2 compares

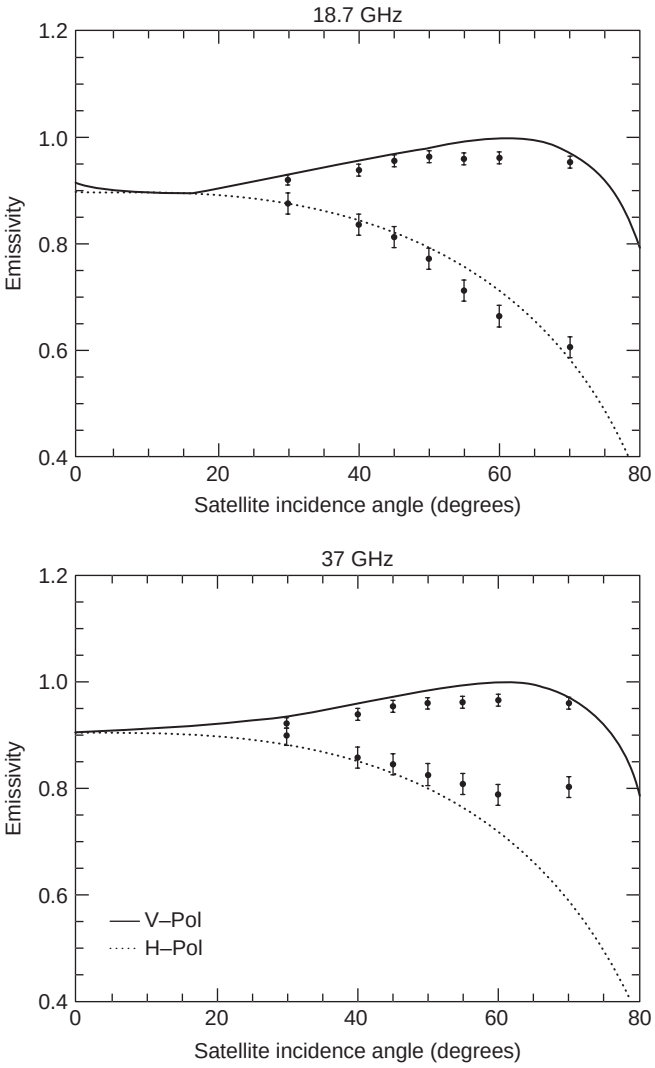

Figure 2 Comparison between modeled and measured emissivities as a function of incidence angle at 18.7 and 37 GHz for a thin gray ice sheet without snow cover

modeled emissivities with observations for a thin (4 cm) gray ice sheet without snow cover using the many-layer-strong fluctuation theory to model the microwave emissivity at 18.7 and 37 GHz. A model specifically designed for the emission of snowpacks has been developed by Wiesmann and Maetzler (1999) and is currently widely used to model the microwave emission of snowpacks.

Nghiem *et al.* (1995) introduced a composite polarimetric model for sea-ice scattering. This model is designed to calculate the effective sea-ice permittivity and the backscattering covariance matrices to compute the polarimetric signature. While emphasizing polarimetric modeling, they provide a good description of the general process of EM modeling of sea ice, including the effects of the ocean/ice interface, surface roughness, temperature, brine inclusions, air bubbles, and solid salt. Frost flowers and dynamic ice

effects such as ridging need further consideration as does the spatial variability of these phenomena relative to the sensor footprint.

A disadvantage of the geophysical modeling approach discussed so far is the significant amount of geophysical information required to compute the EM scattering model. The large number of parameters makes inverting such a comprehensive model difficult, particularly for large footprint sensors such as scatterometers (although the problem is not much simplified for higher-resolution sensors such as SAR.). Complicating this is the (often) wide spatial variation in parameters over the microwave sensor footprint, termed *footprint inhomogeneity*. Each forward model essentially estimates the radiances or backscatter at a single point defined by the set of input conditions. Satellites observe mixtures of such "pure pixels". Relating the satellite measurement to the ice state in practice requires some understanding of how the combinations of various surface types contributes to the set of observations recorded by the satellite sensors. A key component of forward modeling work will therefore require investigation of the contribution of individual snow and ice characteristics to area-averaged sets of radiances comparable to the footprint size of different sensors.

An alternate approach is to reduce the number of model parameters using simplifying assumptions. Swift (1999) uses a very simple model for ice scattering based on just three key parameters based on a bulk parameterization of the backscatter response. While overly simple, Remund *et al.* (2000) successfully used this model to classify ice types in the seas around Antarctica. Similar approaches can be applied to EM modeling of glacial ice. For example, Ashcraft and Long (2005) used a simplified scattering model to study wind-induced roughness on the Greenland ice sheet, which has been remarkably successful.

Application of EM Models to Modeling Ice Sheet Facies

Radar can detect the bare ice zone, the firn line (which does not necessarily coincide with the equilibrium line), the percolation zone, the wet snow zone, and the dry-snow zone. Passive microwave instruments are more limited spatially and can only detect broad changes, primarily the differences between regions of surface melt and dry snow in part because of their significantly coarser resolution. Because of the significant differences between the ice conditions in each facie, different EM modeling approaches have been used traditionally.

Dry-Snow Zone The EM response in the dry-snow zone contains both a surface and volume scattering component. Absorption and scattering losses within the firn are generally small for fine-grained firn and low frequencies (Mätzler and Hüppi, 1989); however, as the ratio of the grain size to wavelength increases, the scattering loss can become significant. While actual firn particles are irregular, they are often modeled as spheres or ellipsoids (Ulaby *et al.*, 1981). Bingham and Drinkwater (2000) propose multilayer scattering and emission models that include the scattering loss.

Until recently, on the basis of the high transmissivity of dry-snow surfaces at microwave frequencies, the air–snow interface roughness has been considered to have only a limited impact on the observed microwave signatures, particularly in the dry-snow zone. Thus, models have primarily addressed the volume scattering from firn crystals (e.g. Long and Drinkwater, 1994). However, Long and Drinkwater (2000) and Ashcraft and Long (2005) showed that an observed anisotropic scattering due to aligned roughness elements in Antarctica and Greenland is caused by the wind-driven roughness in the bedding structure and the annual layering of accumulated and wind-redistributed snow, suggesting links between the firn layer characteristics, wind-induced bedding structures, and the thermodynamic processes linking these physical attributes to the atmospheric conditions on the ice sheet. Understanding this linkage could provide insight into the evolution of the major ice sheets and improve microwave monitoring capabilities; thus, future modeling activities must include this effect.

Percolation Zone Swift *et al.* (1985) considered volume scattering mechanisms in simulations of the backscatter from the percolation zone by using an unbounded halfspace of scatterers. However, it is not necessary to invoke a strong volume scattering layer to simulate the bright levels of backscatter observed at Ku-band. Jezek *et al.* (1993) suggest that dominant stratigraphic features regulate short-wavelength percolation zone scattering. Longer wavelengths such as L-band (21-cm wavelength) penetrate deeper, possibly penetrating the multiple layers found in this glacial regime (Echelmeyer *et al.*, 1992). Such signals are scattered off the ice glands and lenses found up to a few meters beneath the surface. X-band (3-cm wavelength) measurements by Forster *et al.* (1991) indicate that the strongest returns come from annual layers beneath the surface that are shallower than 3 m. Jezek and Gogineni (1992) found that the largest proportion of backscattered returns occurs from an ice layer just beneath the annual snow accumulation. Long and Drinkwater (1994) formulated a simple 2-layer ice/snow model where the primary response from the upper layer is formulated in terms of a nonstratified Rayleigh layer upon an ice horizon of finite thickness, based on Mader (1991) and Jezek *et al.* (1993).

Geophysical Inversions: Sea-ice Concentration and Extent

The goal in this section is to present a few methods to derive the fraction of ice cover and extent from both passive

and active microwave remote sensing. It is important to remember that several other algorithms exist besides the ones described here. Future sea-ice retrieval algorithms will likely focus on blending passive and active methods for more accurate estimates of sea-ice cover.

Passive

Since passive microwave emission is relatively unaffected by the frequent and extensive cloud cover in the polar regions, one of the most important parameters provided by passive microwave data is sea-ice concentration. Sea-ice concentration maps are used to track ice edges, estimate ice extent, ice type, actual ice area, and the amount of open water within the ice pack for both climatological and more pragmatic (i.e. shipping) purposes. The latter is in turn needed to monitor occurrence, impact, and persistence of polynyas, to calculate heat and salinity fluxes between the ocean and the atmosphere in the polar regions, in addition to many other applications.

Several techniques have been developed to obtain ice concentration from passive microwave data (Markus and Cavalieri, 2000; Svendsen *et al.*, 1983; Cavalieri *et al.*, 1984; Swift *et al.*, 1985; Comiso, 1986; Smith, 1996). Steffen *et al.* (1992) and Smith (1996) provide a review of some of these techniques and a comparison of ice concentration from some of the most commonly used sea-ice algorithms. Ice concentration differences between algorithms result from the use of different sets of channels in the algorithms: different responses to changes in atmospheric conditions, surface temperatures, and emissivities; different algorithm tie points (reference brightness temperatures); and from the ways in which the tie points are selected (Smith, 1996). Radiative transfer (RT) modeling suggests that differences may also result from the ways in which the algorithms respond to variations in snowpack conditions such as hoar layers, snow depth/density, ice lenses, flooding at the snow/ice interface, and so on.

Two widely used sea-ice algorithms are the NASA Team (Cavalieri *et al.*, 1984) and the Bootstrap (Comiso, 1986) algorithm. The NASA Team algorithm is based on two ratios, the polarization (PR) and the spectral gradient ratios (GR) defined by:

$$\mathrm{PR} = \frac{[\mathrm{TB}(19\ \mathrm{V}) - \mathrm{TB}(19\ \mathrm{H})]}{[\mathrm{TB}(19\ \mathrm{V}) + \mathrm{TB}(19\ \mathrm{H})]} \quad (1)$$

$$\mathrm{GR} = \frac{[\mathrm{TB}(37\ \mathrm{V}) - \mathrm{TB}(19\ \mathrm{V})]}{[\mathrm{TB}(37\ \mathrm{V}) + \mathrm{TB}(19\ \mathrm{V})]} \quad (2)$$

where TB is the observed brightness temperature at the indicated frequency and polarization. From these two parameters, the first-year ice concentration (CF) and the multiyear ice concentration (CM) are derived, and thetotal ice concentration (CT) is computed as the sum of CF and CM.

The Bootstrap algorithm uses two microwave channels (37 H and 37 V) and selects the slope and offset of the consolidated ice line in the scatter plots of these two channels. An inherent assumption in the algorithm is that there are large regions in the Central Arctic during winter with ice concentrations of 100%. The 37 H versus 37 V scatter plot shows very high correlation for consolidated ice. However, in the seasonal sea-ice regions where first-year ice dominates, as in the waters surrounding the Antarctic, the sole use of the 37 H and 37 V channels does not provide consistent identification of consolidated ice data points. Sometimes, consolidated ice is difficult to distinguish from mixtures of ice and water because of the presence of snow cover, flood, or roughness effects. Under these conditions, the 19 V and 37 H TBs and the Bootstrap algorithm are considerably more consistent and accurate. These channels are thus used primarily in the seasonal ice region, including the Antarctic region.

Comiso *et al.* (1997) compared the NASA Team and the Bootstrap sea-ice algorithms. Results from comparison studies such as this one show significant qualitative and quantitative differences between the NASA Team and Bootstrap algorithms. For example, differences in monthly means as large as 30% were observed in the Southern Hemisphere. Changes were made to the Bootstrap algorithm in order to help reduce the large differences noticed in the Southern Hemisphere. However, large differences also occurred in the Northern Hemisphere. For example, Figure 3 shows a comparison of ice concentrations on September 14, 1998 near the SHEBA ice camp. The image in Figure 3(a) shows ice concentrations from the Bootstrap algorithm, and ice concentrations in (b) are from the NASA Team algorithm. Differences as large as 40% in ice concentrations are observed between the two algorithms. Results from the enhanced NASA Team algorithm (Markus and Cavalieri, 2000), which is used to derive Northern Hemisphere sea-ice concentrations from the AMSR instrument

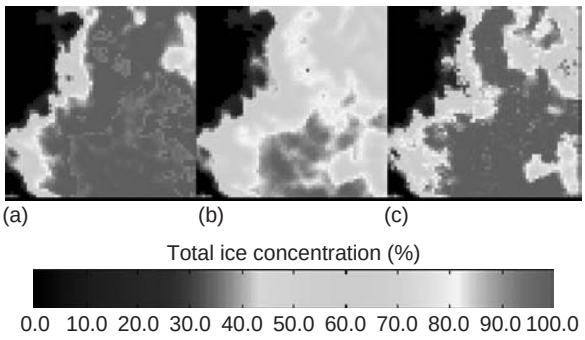

Figure 3 Bootstrap (a), NASA Team (b) and enhanced NASA Team (c) sea-ice concentrations on 14 September, 1998 near the SHEBA ice camp. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

are shown in Figure 3(c). This algorithm appears to correct some of the underestimation of the fraction of ice cover in the NASA team algorithm, but areas of large differences between the Bootstrap ice concentrations are still observed. Time series of ice concentrations near the SHEBA ice camp from September 1997 to September 1998 (not shown) also show large differences among the three algorithms. Many of the differences observed have a stable quality that do not appear to be related to atmospheric effects, but rather as a result of differences in how the algorithms respond to the sea-ice surface characteristics.

Comparative studies with optical satellite imagery, such as Landsat, have not yielded conclusive evaluation of the merit of each technique. However, current work with SAR data may provide new insights about the discrepancies. Some of the observed large discrepancies have led to improvements in the Bootstrap sea-ice algorithm (Comiso *et al.*, 1997), where the Bootstrap algorithm tie points have been adjusted to match ice concentrations derived from SAR during the melt period. However, even though ice concentrations may differ substantially among all the various techniques, they all do tend to be consistent in finding the location of the ice edge.

Active

Sea-ice extent is readily identified with ERS-1/2 scatterometer (ESCAT), using a normalized measure of the isotropy of sea ice relative to ocean (Cavanié and Gohin, 1995; Early and Long, 1997), and with NSCAT and QSCAT, by comparing the response of VV (vertical transmit – vertical receive) and HH (horizontal transmit – horizontal receive) polarizations over ice and water (e.g. Remund and Long, 1999; Haarpainter *et al.*, 2004; Anderson and Long, 2005). Haarpainter *et al.* (2004) suggests that scatterometer polarization ratios can be used to infer sea-ice concentration. The dual-polarization capability of QuikSCAT data can make it more effective in monitoring the decay of sea ice than SAR data (Howell *et al.*, 2005).

The onset of seasonal surface melt and then freeze-up provides a significant contrast to winter, colder conditions over sea ice in the polar regions. Melt onset defines a significant transition in the radiative budget of the ice-covered region, while autumn freeze-up is a key period during which the residual fraction and characteristics of perennial sea ice can be assessed and the initial conditions for winter sea-ice dynamics is established via the distribution and orientation of newly forming ice in leads. Most recently, algorithmic approaches to use scatterometer data to determine melt onset and freeze-up have been examined, including those in Antarctica over a period of several years (Drinkwater and Liu, 2000; Forster *et al.*, 2001; Winebrenner *et al.*, 1998).

Observations and Results

In this section, we provide a brief summary of selected results from the literature. The goal is to provide a starting point for those pursuing research in the field.

Passive Observations of Sea Ice

Sea-ice time series derived from multichannel, passive microwave data are among the longest, continuous, satellite-derived, geophysical records. These climatological data sets extend across nearly three decades. The predominant variability in Arctic sea-ice time series is seasonal, with a typical late winter (March) maximum ice extent $\sim 15 \times 10^6\,\mathrm{km}^2$, compared to a late summer (September) minimum $\sim 6 \times 10^6$ in the Arctic, although the absolute values may vary from study to study because of operational differences and time period sampled (Figure 4). The satellite passive microwave sensor record is augmented by active sensors, though there is some seasonal sensitivity difference between the two sensors, see Figure 5 (Anderson and Long, 2005; Haarpainter *et al.*, 2004).

The first trend analysis based on SMMR data found a slight negative trend in the Arctic sea-ice extent from 1978 to 1987 (Gloersen and Campbell, 1991). The $3.2 \times 10^4\,\mathrm{km}^2\,\mathrm{year}^{-1}$ decrease (2.4% per decade) was found to be statistically significant. Data from the subsequent SSM/I sensors has provided the basis to follow up the SMMR trends. The Johannessen *et al.* (1995) analysis of SMMR and SSM/I records taken separately revealed a greater reduction in the Arctic sea-ice area and extent during the SSM/I period – decreases from 1987 to 1994 were ~4% per decade compared to ~2.5% per decade from 1978 to 1987. However, large interannual variability coupled with the brevity of the individual SMMR and SSM/I records compelled researchers to produce longer time series for more robust trend estimation. Merged SMMR–SSM/I time series have since been produced and analyzed, establishing the trends more robustly (Bjørgo *et al.*, 1997; Cavalieri *et al.*, 1997). The merging of SMMR and SSM/I data involves intercomparison and adjustments (i.e. "intercalibration") based on the 6-week overlap period in 1987, when both types of sensor operated. Two independent analyses of merged SMMR–SSM/I data established the trend in the Arctic ice area and extent (1978–1995) to be about $-3.0 \times 10^5\,\mathrm{km}^2$ per decade, corresponding to ~3% per decade (Bjørgo *et al.*, 1997; Cavalieri *et al.*, 1997; Comiso, 2000; Comiso, 2003).

Parkinson *et al.* (1999) identified the seasonal and geographic patterns of variability and trends in the ice concentration data, 1979–1997, finding winter reductions to be concentrated in the Barents and Greenland seas, with summer reductions more pronounced in the Siberian seas. Maslanik *et al.* (1996) investigated reductions in the Arctic ice cover using SMMR–SSM/I data (1979–1995), with ice reductions in the 1990s found to be most pronounced in

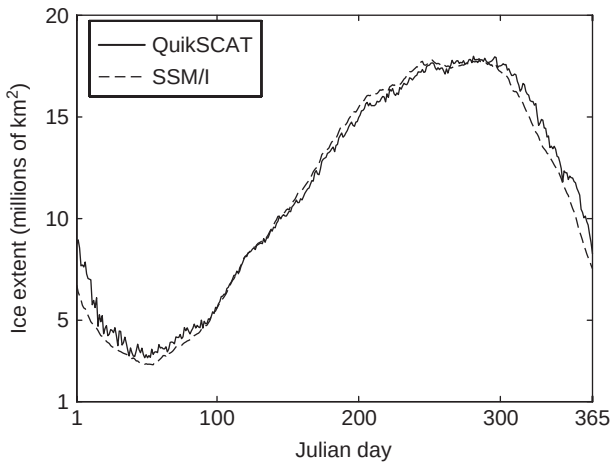

Figure 5 Seasonal Antarctic sea-ice extent in square kilometers derived from active (NSCAT) and passive (SSM/I) data for Antarctica. The differing sensitivities of the active and passive sensing to seasonal melt are apparent (Reproduced from Remund and Long, 1999 by permission of the American Geophysical Union)

the Siberian sector in summer, with record low Arctic ice minima in 1990, 1993, and 1995. Summer 2002 set the 25-year record for minimum ice extent and area (Serreze *et al.*, 2003), with essentially no ice in the Greenland Sea. The situation repeated itself again in 2003 and 2004, strongly reinforcing the downward trend in the Arctic ice cover (Stroeve *et al.*, 2005). Figure 6 shows the time series of monthly ice extent anomalies for the Arctic from November 1978 through September 2002, highlighting the record low ice concentrations observed in September 2002. Although early summer 2003 did not appear to be unusual in terms of ice extent, the September 2003 ice extent nearly reached the 2002 record low, again with no ice in the Greenland Sea. The September trend is $(-0.54 \pm 0.11) \times 10^6\,\mathrm{km}^2$ per decade at a 99% confidence interval (or $-7.7\% \pm 3\%$ per decade), when data through September 2004 is included (Stroeve *et al.*, 2005). These dramatic declines have led to predictions of a seasonally ice-free Arctic Ocean by $\sim$2050.

Antarctic sea ice tells a different story, however, during this time frame. Satellite records of sea ice around Antarctica indicate that the Southern Hemisphere ice cover has increased slightly since the late 1970s, while at the same time that the Arctic sea ice has declined (Figure 7). The upward trend in the Antarctic sea-ice cover is not statistically significant and conflicts with photographic ice core estimates that suggest that the sea-ice cover has receded by about 45% since 1951 (Wolff, 2003). However, detection of long-term change is masked by decadal-scale variability and these decadal fluctuations have produced the apparent short-term increases in ice extent during the satellite era.

Passive Observations of Greenland Melt

Combined, the Greenland and Antarctic ice sheets contain enough water to raise the global mean sea level by

Today 57(8), 38–44, 2004. ©2004 American Institute of Physics)

approximately 70 m, with the Greenland ice sheet comprising around 7 m of that estimate (Warrick *et al.*, 1996). Given detectable ice-sheet elevation changes in Greenland (Krabill *et al.*, 2000, and updates), this area warrants continued monitoring. Microwave remote sensing offers a key tool that can assess broad areas rapidly, for example, melt extent from passive microwave sensors shows an overall increase in total melt area of the Greenland ice sheet since 1978 (Abdalati and Steffen, 2001). Figure 8 shows the interannual variations in mean melt extent from 1979 through 2003. Only the average melt area for the months of June, July, and August of each year are shown. Results show an increase in melt area of 0.62% per year since 1979.

In 2002, the spatial extent of melt on the ice sheet reached a new record, surpassing the previous record spatial melt extent by more than 9% (K. Steffen, personal communication). This is not reflected in Figure 8, however, since only the months of June through August were used to compute the mean melt. In 2002, melt was observed to begin earlier than it had over the past 24 years and extended up to higher elevations, resulting in an overall greater area of melt during 2002, but not necessarily more melt volume. The decline in 1991 Greenland melt extent is thought to be associated with cooling across the region associated with the Mt. Pinatubo eruption that sent aerosols into the atmosphere, which reflected solar radiation and resulted in cooler temperatures and less melt; in other words, a short-term "anomaly" in the upward melt trend (Shuman *et al.*, 2001; Abdalati and Steffen, 1997a).

Active Observations of Glacial Ice, Antarctica

A variety of techniques for observing melt extent have been developed (see bibliography), which are compared in Ashcraft and Long (2004b) for both active and passive measurements. Initial results are encouraging, but further work is required to validate the technique.

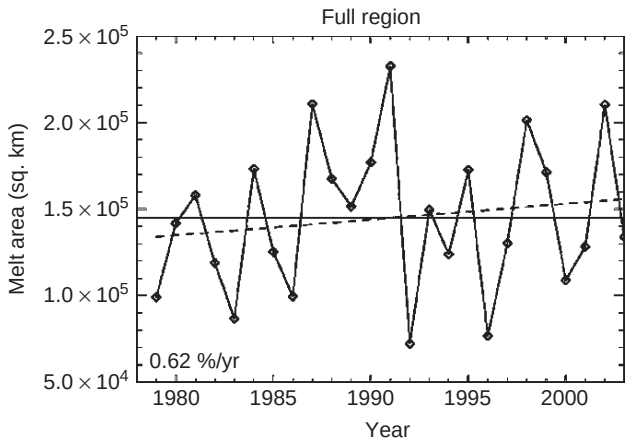

Figure 8 Interannual variations in mean melt extent (average area for June, July, and August). Statistically significant slope is 0.62%/year. Image provided by W. Abdalati from NASA GSFC

The recent collapse of the Larsen-A ice shelf has been conclusively linked to local warming (Scambos *et al.*, 2000, 2003). Surface warming causes additional meltwater formation which saturates the permeable firn and which then fills crevasses in the ice shelves where it can refreeze. Additionally, this flowing meltwater can also enlarge or propagate these large cracks through the thickness of the ice shelf that may be thinning by submarine melting as well. By using microwave sensing, melt on ice shelves can be monitored and shelves of highest risk can be identified. Resolution plays a key role in the effectiveness of this approach. As a demonstration, Fahnestock *et al.*, 2002 and Kunz and Long (2005) have used SSM/I and QuikSCAT data to observe melt onset and duration over a multiyear period. Their results suggest that microwave sensors can be effective for such monitoring.

SAR Applications

Owing to their high resolution, SARs have been used extensively for the study of ice sheets and glaciers. Because of space limitations, we cannot do due justice to the many SAR applications. We are limited to a few introductory references. Some examples include: SAR data has been used to map sea-ice thickness (Kwok *et al.*, 1999b), studies of the Greenland and the Antarctic ice sheet and associated glaciers (Jezek *et al.*, 1993; Fahnestock and Bindschadler, 1993; Fahnestock *et al.*, 1993) such as mapping of ice-sheet topography (Jezek *et al.*, 2000), glacier motion (Kwok and Fahnestock, 1996; Rignot, 1996; Young and Hyland, 2002), estimates of snow accumulation (Munk *et al.*, 2003), and melt onset dates (Kwok *et al.*, 2003), among many, many others! An introductory review of SAR and its applications to ice observation is contained in Henderson and Lewis (1998) with a more extensive summary of SAR applications in the polar regions given by Tsatsoulis and Kwok (1998).

Optical Observation of Ice Sheets and Sea Ice

In this section, we also briefly consider optical sensors, including laser altimetry.

Like microwave sensors, optical sensors can be divided into passive and active sensors. Active optical sensors include laser altimeters such as the ICESat Geoscience Laster Altimeter System (GLAS) (Zwally *et al.*, 2002). Designed for precision ice-sheet elevation measurement, this sensor uses infrared and green lasers to transmit light energy to the surface and to measure the time of flight of the return echo. This is converted to an elevation value based on the orbit trajectory. Passive optical sensors include conventional cameras and precision optical radiometers. The latter can be used for measuring surface skin temperature and surface albedo, though only under cloud-free conditions. Optical ice sensors operate in the visible, near-infrared, and

infrared portions of the electromagnetic spectrum. Here we discuss optical observations of the Earth's polar regions at various frequencies. We first consider passive visible and near-infrared, then infrared observations. Finally, a brief summary of active optical sensing is provided.

Visible and Near-infrared Imaging

The ability of satellite-based visible and near-infrared sensors (VNIR; making measurements in the 400–1600 nm range) to rapidly acquire data over remote regions has led to wide applications in mapping and in the measurement of polar ice. Beginning in 1972, with the launch of the first Landsat (and even sooner in the world of intelligence satellite mapping such as CORONA), images of Antarctica and Greenland were systematically acquired, largely to provide basic mapping data on coastlines, mountain ranges, and ice flow. Over time, with a larger range of sensors available and with a record of past images to review and compare, the use of VNIR images has expanded to include tracking movement and detection of changes, such as velocity mapping, melt-extent mapping, snow cover, and grain-size changes, surface albedo, fracturing and calving, and a host of other processes.

In an outstanding series of volumes, the US Geological Survey has demonstrated the remarkable range of information that may be obtained about glaciers and ice sheets simply by looking at their images (Williams and Ferrigno, 1988–2002). Inmaps produced by US, European, and Australian groups from both Landsat and SPOT (Systeme Probatoire pour l'Observation de la Terre), VNIR sensors revealed the outline and structure of several large ice systems for the first time (e.g. Swithinbank *et al.*, 1988); such work is still important even in the new century in some areas (e.g. Skvarca and De Angelis, 2002). But a further realization of the potential of satellite images came in the late 1980s and early 1990s, when computer technology and data storage systems reached the point where large images could be readily reprocessed and enhanced digitally. Suddenly, a wealth of detail was revealed in the interior of ice sheets, as subtle topographic features almost invisible in the photographic renditions of the satellite data became enhanced by simple digital techniques such as high pass filtering (e.g. Orheim and Lucchitta, 1987; Bindschadler and Vornberger, 1990). The value of vast amounts of weather-satellite image data in the visible and near-infrared range also came to be appreciated, particularly for those sensors with greater radiometric sensitivity (e.g. the NOAA Advanced Very High Resolution Radiometer (AVHRR), see following section on infrared temperature mapping; Comiso, 2000; Hastings and Emery, 1992). This led to the first image maps of the great ice sheets in which the interior topographic detail was shown (e.g. USGS, 1991), rather than the "blank white" areas of earlier maps (AGS, 1971). Since then, VNIR digital image mapping of ice has advanced rapidly, permitting seamless images of both high resolution and wide spatial coverage (e.g. the Moderate Resolution Imaging Spectroradiometer (MODIS) Mosaic of Antarctica (MOA), Bohlander *et al.*, 2004).

As researchers realized the topographic detail present in VNIR satellite images through improved digital processing, they began to strive to include that detail quantitatively in topographic models of the ice via "shape-from-shading" or photoclinometry. In a few cases, multi-image data "stacking" or "data cumulation" has been used to push spatial and spectral resolution of subtle ice features for specific areas beyond what a single image from a given sensor can achieve (Fahnestock *et al.*, 2000). In addition to mapping the extent and surface shape of glacial and sea ice, researchers have also sought to use satellite VNIR images to map important surface properties of snow and ice. Chief among these are albedo, grain size, and surface roughness or backscatter. In these cases, particularly, good radiometry and spectral resolution is favored over spatial detail. Most studies to date have used moderate-spatial-resolution VNIR imagers such as AVHRR, MODIS, and the Multiangle Imaging SpectroRadiometer (MISR) (Stroeve *et al.*, 1997; Nolin *et al.*, 2002), with a few exceptions (Landsat; Bourdelles and Fily, 1993).

Investigators have pushed past the basic objectives of mapping and towards detecting and mapping *changes* in the ice, thus offering the hope of connecting these mapped changes to dynamic or climate causes. Change detection in the coastlines is currently being addressed in a series of new maps from the USGS (Ferrigno *et al.*, 1994), and for glaciers, in large satellite projects designed to monitor the ice-covered regions throughout the planet(the GLIMS project, Bishop *et al.*, 2004). More broadly, recent efforts have assembled long time series of VNIR data over both poles, suitable for a host of change detection and seasonal- or interannual process studies (the Polar Pathfinder AVHRR data set; Maslanik *et al.*, 1997). Huge collections of Antarctic and Greenland Landsat 7 data now exist for the ice-sheet areas, archived by USGS (**`http://edcsns17.cr.usgs.gov/EarthExplorer`**), and MODIS data from both Terra and Aqua are also readily available (**`http://acdisx.gsfc.nasa.gov/data`**).

A major advance in the late 1980s and early 1990s was the development of methods to map ice flow velocity from satellite (and for sea ice, ice drift velocity). Initially, these used standard manual photogrammetric techniques (Lucchitta and Ferguson, 1986), but evolved to use digital correlation to track movement (Bindschadler and Scambos, 1991; Scambos *et al.*, 1992; Emery *et al.*, 1991). As the time series of Landsat, SPOT, and ASTER images has grown, several studies now report changes in glacier ice velocity on the basis of VNIR image pair sequences (e.g. Stearns and Hamilton, 2003; Berthier *et al.*, 2004; Scambos *et al.*, 2004).

Satellite VNIR data will continue to be used to track and monitor the evolution of the polar regions. Further details on recent advances in visible and near-infrared image mapping of glaciers, snow, and sea ice have been published in reviews by Massom (1995), Bindschadler (1998), and Konig (2001).

INFRARED ICE TEMPERATURE OBSERVATION

Surface temperatures have been recorded in parts of the polar regions for as long as a century. The locations of these records are, however, sparsely distributed and do not provide good representation of the large-scale distribution of surface temperatures over ice-covered areas. Because of the vast expanse and general inaccessibility of ice sheets and sea ice, the only practical way to produce spatially detailed maps of surface temperature is through the use of satellite remote sensing. Among the currently proven techniques are those which make use of thermal infrared channels. Thermal infrared is quite useful for this purpose because the emissivity of snow and ice surfaces is uniform and close to unity (Comiso, 1994). The use of passive (or active) microwave systems has been cited as alternatives, (Shuman and Comiso, 2002) but while the microwave systems have some advantages, namely, their ability to penetrate thick clouds, the application is limited because they require the knowledge of the emissivity (or backscatter) of the surface almost on a pixel-by-pixel basis owing to large spatial variability of these parameters at the microwave frequencies. One of the main issues with the use of infrared sensors is that they can provide the desired surface temperatures only during cloud-free conditions. An effective cloud masking technique is thus required, which sometimes is not easy to implement because signatures of clouds can be difficult to distinguish from those of snow and ice-covered areas. While clouds are persistent at times, the frequency of observation by polar orbiting satellite sensors over the Earth's ice-covered regions is very high and with clouds always moving, the chance of getting surface measurements for a particular area is relatively high. Weekly and monthly averages of the data have been generated with practically no gaps over ice-covered areas. Because of the "clear-sky" sampling bias, the resulting maps are regarded as surface temperature maps for these conditions only. However, comparative studies using continuous and cloud-free data recorded by meteorological stations indicate that the biases in the monthly average data are typically small, ranging from 0.5 to 1 K.

The first system that has been used for large-scale studies of surface temperature in the polar region was the Temperature Humidity Infrared Radiometer (THIR) which was onboard the Nimbus-4, Nimbus-5, Nimbus-6, and Nimbus-7 research satellites. The Nimbus-7 system was different from those earlier in the series in that data were digitized on board the spacecraft. Thus, the Nimbus-7 THIR was the only system that provided consistently good quality data that could be used for polar studies (Comiso, 1994). The THIR sensor was a two channel system (6.7 and 11.5 μm) with a resolution of 6.7 km and 20 km for the 11.5 μm and 6.7 μm channel, respectively, and provided reasonably good data from 1978 to 1985. The system, however, did not provide enough channels to allow for accurate cloud masking and atmospheric corrections. The advent of the NOAA AVHRR enabled a significant improvement in the accuracy of the retrieved surface temperature data in terms of spatial and radiometric resolution and the ability to resolve and mask clouds. The sensor has five channels from the visible to infrared wavelength, two of which are window channels in the thermal infrared region. The basic resolution is 1 km at nadir but because of very large storage requirements (considering mass storage technology limitations in the 1980s), only a 5 by 4 km subset, called *GAC* (Global Area Coverage), is automatically stored and archived for global and continuous coverage, while the 1 km data set, called *LAC* (Local Area Coverage), is available only on a limited basis. It is the GAC data that has been used mainly for seasonal and interannual variability studies (e.g. Comiso and Parkinson, 2004). Other systems (e.g. ENVISAT/AATSR and EOS/MODIS) provide improved capabilities and more accurate retrievals, but these data sets began in the late 1990s.

All these infrared sensors measure the temperature of the top layer (usually referred to as *skin depth*) of the ice surface. Comparative analysis of surface temperatures derived from AVHRR data with co-registered and coincident *in situ* measurements confirms that the thermal infrared data captures the same variability in surface temperature as the ground values (Comiso, 2000; Comiso and Parkinson, 2004). Errors associated with the retrieval of surface temperatures have been evaluated and estimated to range from 2 to 3 K (Steffen *et al.*, 1993; Key and Haefliger, 1993; Comiso, 2000; Shuman and Comiso, 2002). The main concern associated with the development and analysis of a long-term temperature record is the relatively short lifespan (typically 5 years) of each AVHRR sensor. The archived composite record is actually a collection of data from several AVHRR sensors with no overlap coverage between sensors. The lack of overlap has made it difficult to compare the performance and compatibility of the different AVHRRs. For lack of a better solution, *in situ* data have been used to improve calibration and ensure consistencies in the derived temperatures from the different sensors.

The AVHRR sensor series data have been used to generate monthly average temperature maps of high latitude regions of the Northern and Southern Hemisphere from August 1981 to the present. The data is gridded at a

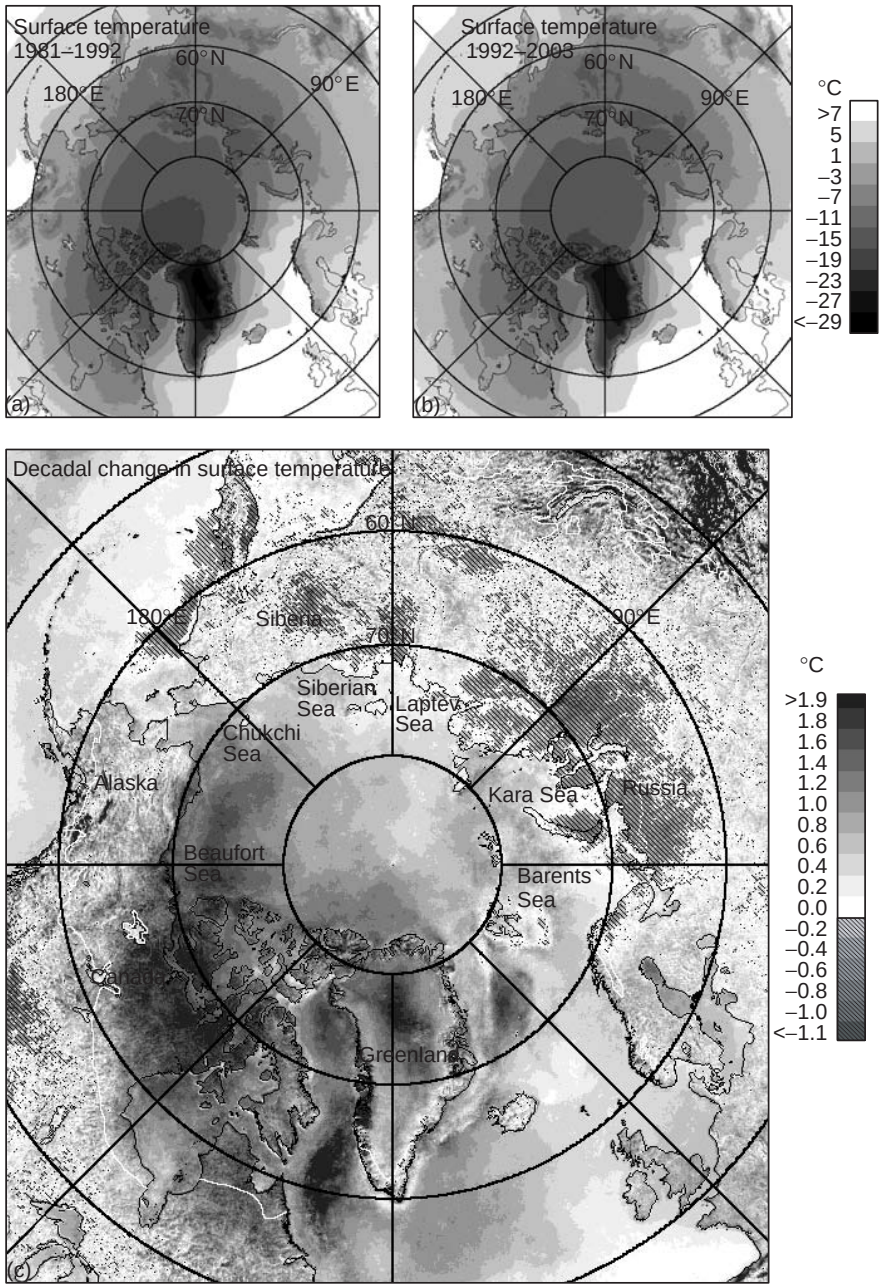

Figure 9 (a) average surface temperature from August 1981 to July 1992; (b) average surface temperature from August 1992 to July 2003; and (c) difference of the first set of data and the second set of data (from Comiso and Parkinson, 2004). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

resolution of about 6 km in polar stereographic format. Compared to other sources of regional surface temperature data (e.g. NCEP or ECMWF), the infrared data provide more realistic representations of the spatial distribution of surface temperatures in areas where there are no *in situ* measurements. For example, the retrieved data are coherent with the expected variations in surface temperature with elevation in Antarctica and in Greenland, whereas models reflect spatial temperature patterns poorly over the ice sheets. Some unique surface features over land and sea ice that are not in other data sources have also been identified.

To illustrate the value of the AVHRR data set, Figure 9(a) shows averages of surface temperature in the Arctic region from August 1981 to July 1992, while Figure 9(b) is a similar average, but for the period from August 1992 to July 2003. The two images appear to be almost identical except for slight shifts in the temperature contours. The

consistency of the images in reproducing distinct surface features is an indication that the cloud masking technique is basically effective, and the data represents mean surface temperatures over these time periods. The difference map shown in Figure 9(c) allows evaluation of decadal changes in the Arctic (i.e. from one 11-year period to the next). Positive changes are represented by warm (light gray shades) colors, while negative changes are represented in cool (black and dark gray shades) colors. The map indicates that the changes are overwhelmingly positive, indicating warming, with the most positive located in the western Arctic (e.g. Beaufort Sea) and North American region. An unexpected result is the detection of large areas of cooling in parts of Russia, which have subsequently been verified using *in situ* data. This indicates that global monitoring is important and that trend studies should not rely solely on measurements from ground stations especially if the latter are sparsely distributed. As a check on the difference map, a trend map has been generated using the same set of data, but with regressions done on a pixel-by-pixel basis. The result was very similar to the difference map shown in Figure 9(c). For the whole area, on the average, the warming trend over the entire Pan–Arctic region during the study period is estimated to be 0.5 K per decade. The maps thus provide the basis to assess the temperature state of different regions of the cryosphere and enable evaluation of vulnerabilities of these regions to melt, ice breakup, permafrost thawing, or iceberg calving. The temperature maps are also useful for specific polar process studies. For example, they have been used to verify that the temperature changes in the Antarctic Peninsula are anomalous and are closely associated with the region (King and Comiso, 2003). Studies of this type also show that the temperature variability is highly correlated with the southern oscillation as well as with the Southern Hemisphere Annular Mode (Kwok and Comiso, 2002; Schneider *et al.*, 2004). In short, these evolving data sets enable a much greater understanding of the spatial and temporal nature of climate variability across the Earth's sea ice and ice sheets.

ICESat (LASER ALTIMETRY)

As the first operational satellite laser altimeter in early 2003, NASA's Ice, Cloud, and land Elevation Satellite (ICESat) has provided precise surface elevation data from 86° N to 86° S latitude (Zwally *et al.*, 2002). The data have been acquired in a discrete series of observational periods and over two repeated track patterns using all three of ICESat's GLAS lasers. Surface elevation data is collected over most of Antarctica and all of Greenland as well as smaller ice caps and glaciers in accordance with the primary mission goal of improving ice-sheet elevation change and ice mass balance assessments (Scambos *et al.*, 2004; Thomas *et al.*, 2004). In addition, ICESat provides precise elevation data across most of the Arctic Ocean and the icy waters surrounding Antarctica, which can be converted into remote sensing–based estimates of sea-ice thickness (Kwok *et al.*, 2004). As the mission enters its third year, particular efforts are on to ensure that the most precise elevation data is derived from the ICESat laser information obtained to date. This section summarizes ICESat's utility for research across the Earth's polar regions.

The GLAS instrument on ICESat is a novel, "active" remote-sensing instrument. Its lasers operate continuously and emit pulses of 1064 and 532 nm (infrared and green light, respectively), at 40 Hz throughout each orbit. The light energy spreads as it travels from the spacecraft and reflects from approximately 70 m "spots" separated by about 170 m along track back to the GLAS detectors. The timing information, after adjustment for travel through the Earth's atmosphere, is then converted into an elevation value for each measurement location. This is based on precise knowledge of where ICESat/GLAS was when the pulse was sent and received as well as where the laser was pointing relative to the stellar background (Brenner *et al.*, 1999).

The resulting elevation values, although subject to refinement as pointing or orbital position information is improved, are capable of centimeter-level precision (Figure 10). This plot shows an ICESat track that has been repeated in late 2003 and early 2004 across Lake Vostok's relatively smooth surface in East Antarctica. ICESat's precision can be visually assessed by comparing the actual elevation profile values to an 11 point ($\sim$1.9 km) running mean derived from them. The differences between the actual and the smoothed elevation profiles has a standard deviation of less than 3 cm for both Laser 2a and Laser 2b over this portion of Lake Vostok. The absolute accuracy of ICESat is more difficult to quantify, given that the ice-sheet surface is not absolutely known and may change with time depending on snow accumulation or ablation as well as ICESat-specific factors such as pulse saturation that are not fully addressed at this time. In addition, ICESat profiles do not usually repeat the same coordinates exactly; therefore any cross track slope over the distance between the profiles, generally less than 100 m, may cause an apparent elevation difference. Despite these uncertainties, ICESat's accuracy is estimated at better than 20 cm for repeat track observation conditions like the ones shown here.

Elevation data of this precision and accuracy has never before been obtained across the polar regions from space. Although compromises have been made to the spatial and temporal density of data acquisition to accommodate laser problems, and reprocessing improvements continue, ICESat is proving that the risks of this novel mission are worth the return. ICESat data is defining a "baseline" shape of the ice sheets and detailing their rapidly changing margins (Scambos *et al.*, 2004; Thomas *et al.*, 2004) as well as

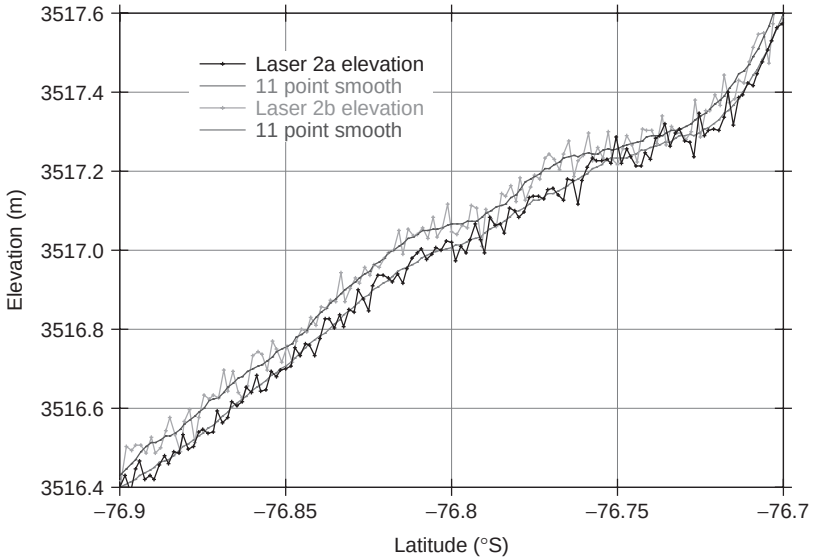

Figure 10 Sample ICESat repeat-track elevation plot over Lake Vostok, East Antarctica. The low slope and relatively low accumulation across this area makes it a useful area for assessment of ICESat precision and accuracy. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

providing extensive data on other ice-sheet phenomena such as ice shelf margins and internal rifts, ice streams, and the broad interior plateaus.

ICESat data over the Arctic Ocean has been used to identify and measure the elevations of the ice pack including thin ice or open water as well as the surface relief of old and first-year ice (Kwok *et al.*, 2004). Uncertainties in the knowledge of sea surface topography or "sea level" across the area require the development of surface references that allow estimation of local freeboard – the height of the air-snow surface above sea level. This can be achieved by using the relative reflectivity signature in the ICESat data of thin ice and open water to identify areas suitable for use as sea-level reference. If snow is absent, laser returns from thin ice in newly opened areas typically have a lower reflectivity than the surrounding ice cover. Returns from open water or very thin ice, however, are frequently saturated and unreliable for direct surface height estimation, so challenges remain. These results are validated by analysis of near-coincident ICESat data and openings in RADARSAT imagery (Kwok *et al.*, 2004).

By determining improved sea-level elevations from open water reference points, an estimate of the sea surface elevation relative to the ellipsoid can be derived. Using this reference surface, the state of the sea-ice pack can be determined relatively consistently, and the distributions of sea-ice thickness can be obtained over spatial scales of about 50 km by 50 km across the Arctic Ocean. Thickness distributions allow the mean sea-ice thickness and the ratio of thicker multiyear ice to thinner ice types to be determined by comparing these estimates at adjacent tracks and crossovers within the grid cell. Variable thickness snow cover can impact the freeboard height conversion to ice thickness. Currently, sea-ice thickness can be estimated using snow-cover climatology and approximate densities.

ICESat's multiple operational periods in 2003 into 2005 thus can generate sea-ice freeboard datasets to allow the study of the interannual as well as seasonal behavior of the freeboard. Maps of sea-ice thickness show similarities to those from satellite radar altimetry, and spatial distributions similar to passive microwave and scatterometer retrievals. The spatial distributions of sea-ice thickness in the Arctic Ocean for the winters (February/March) of 2003 and 2004 show significant variations. In 2004, thicker ice is more compacted adjacent to the Canadian Arctic than it was in 2003, with a larger area of thinner ice in the Beaufort and Chukchi Seas where the summer ice cover has been rapidly decreasing. In 2003, the multiyear ice pack extends farther to the south near the 45° East longitude than is typical. Additional comparisons will be enabled following the launch of ESA's CryoSat in mid-2005.

57: Land-cover Classification and Change Detection

MATTHEW C HANSEN[1] AND SCOTT J GOETZ[2]

[1]Geographic Information Science Center of Excellence, South Dakota State University, Brookings, SD, US
[2]Woods Hole Research Center, Woods Hole, MA, US

Various multispectral data sets and tools are available for mapping land cover and land-cover change for inputs to hydrologic applications. The best choice is often a function of the specific application. New sensors offer increased capability in mapping spatial detail and temporal variation of land-cover categories. Algorithms have advanced in robustness and include distribution-free methods that are superior to traditional approaches in terms of modeling the multispectral distributions of reference data. Advanced subpixel methods of mapping land cover offer greater thematic coherency and the possibility of using consecutive land-cover characterizations to map change. The success of deriving a meaningful result, such as deriving a relationship between aquatic biotic indices and land-cover change, relies on a high-quality land-cover reference map. By choosing the most appropriate data sources, constructing a defensible land-cover definition set, and employing robust algorithms, analysts allow for the meaningful incorporation of land-cover map information into hydrological studies.

INTRODUCTION

Land cover is defined as the observed biophysical state of the earth's surface, and is largely described by the presence or absence of various vegetation types. Land-cover information is an important parameter for many hydrological studies. Vegetation type and density affect rainfall interception, evapotranspiration, runoff estimation, water quality, and stream flow, among other parameters (Gorte, 2000). The uses of land-cover information in hydrological applications are varied. Broad categories include operational hydrologic modeling, climate modeling, and water quality assessments. Concerning hydrologic modeling, land-cover information can be used to help determine runoff coefficients and to characterize infiltration, erosion, and evapotranspiration for distributed models (Dubayah *et al.*, 2000; Liang *et al.*, 1999). When land-cover conditions change, so do the runoff, soil moisture, and groundwater characteristics of the land. For example, Foley *et al.* (2003) have shown the effects of land-cover change, namely, the increasing dominance of agriculture on water resources across the Mississippi River basin. An advantage of remotely sensed land-cover characterizations is the spatially explicit nature of derived land-cover information. Schumann and Schultz (2000) point out the need to have spatial and temporal detail concerning land-use changes in relation to other river basin characteristics such as soil type. Concerning climate studies, land cover is an important boundary condition in parameterizing soil–vegetation–atmosphere transfer schemes, which can be incorporated into general circulation models. Such models include the Biosphere–Atmosphere Transfer Scheme (BATS) (Dickinson *et al.*, 1986), the Simple Biosphere (SiB) model (Sellers *et al.*, 1986), and the Land–Atmosphere Transfer Scheme (Pauwels and Wood, 1999). Land-cover characteristics govern many variables, including surface roughness for energy transfer, albedo for solar absorption, moisture from canopies and soils, and mechanisms for water runoff (Dickinson, 1995). Land cover is also a critical variable in determining water quality (Nilsson *et al.*, 2003) and for assessing pollution risk and watershed health (Wickham *et al.*, 2000). Remotely sensed data sets offer the opportunity to efficiently quantify various land-cover components over large areas repeatedly through time, enabling researchers to

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

easily incorporate land-cover information into hydrological studies.

This chapter reports methods for characterizing land cover and land-cover change using remotely sensed data sets. In strict terms, it is a primer for technical approaches to land-cover mapping from multispectral data sets. However, using land-cover information as an input to hydrologic applications requires knowing the strengths and limitations of such data sets regarding map accuracy, spatial scale, and thematic content. For example, Pauwels and Wood (2000) report that land-cover classification accuracy had a greater effect on their land–atmosphere model uncertainty than the spatial detail of the land-cover depiction, and that overall uncertainty attributable to land cover was relatively small compared to that of meteorological forcing data (*see* **Chapter 201, Land-Atmosphere Models for Water and Energy Cycle Studies, Volume 5**). An example of varying uncertainty related to thematic content is shown in climate modeling science (*see* **Chapter 32, Models of Global and Regional Climate, Volume 1**). Dickinson (1995) advocated the use of subpixel estimates of proportional land cover, as opposed to discrete land-cover classifications, in improving climate model parameterization. Bonan *et al.* (2002) concurred in showing that uncertainty in climate and ecosystem models for such variables as ground temperature and ground evaporation was reduced when continuous representations of vegetation were used in place of discrete biome maps. These studies emphasize the need to understand the interplay of map characteristics and their potential effects on modeling outputs.

This chapter outlines the use of visible (0.4–0.7 μm), near-infrared (0.7–1.3 μm) and middle-infrared (1.3–3 μm) reflected energy, and emitted energy from the thermal infrared (3–14 μm) wavelengths, in mapping land cover. Energy reflected and emitted by the earth in this spectral region is captured by many earth observing satellite sensors. In recent years, significant advances in land-cover mapping using such satellite data have been made. First, improved satellite data sets have become available. Data from new sensors with superior spectral and spatial characteristics have allowed for more accurate depictions of land cover and land-cover change. Algorithms new to remote sensing have been successfully implemented with satellite imagery and found to be both robust and user-friendly. Improvements in thematic depictions including the increased use of subpixel fractional cover estimates have advanced mapping spatial detail and land-cover change over time. This chapter outlines the available data sets, algorithms, thematic outputs, and change detection techniques available to potential users of multispectral remotely sensed data sets. A case study using the addressed techniques for a hydrological application mapping impervious surface and tree cover is also provided.

FINDING APPROPRIATE DATA FOR MAPPING LAND COVER

In attempting to characterize land cover using multispectral remotely sensed data sets, a number of considerations must be taken into account. These considerations lead to the selection and acquisition of data from specific satellite sensors and include requirements concerning the spectral, spatial, and temporal dimensions of the problem. The initial step is to define the thematic content to be mapped. This definition set dictates the level of spatial and spectral detail required for successfully mapping the land-cover theme of interest. For most purposes, definition sets consist of a classification scheme made up of two or more land-cover categories. Less frequently employed are continuous representations of land-cover categories or basic vegetation traits. Instead of discrete land-cover types, these products depict each mapping unit as proportional estimates of a land-cover category or attribute, such as percent vegetative cover.

Whichever approach to characterizing land cover is taken, the analyst must first determine if optical remotely sensed data sets are appropriate for mapping the land-cover variable of interest. Available spectral information captured by a sensor should relate to the absence or presence of the land-cover theme of interest, and this leads ultimately to the selection of a specific data set for inclusion in the study. While multispectral data sets are commonly used for mapping general land-cover categories, researchers should be aware of limitations to using these data. For example, optical data have been found to be of limited value in mapping forested wetlands, and researchers have employed radar data (DeGrandi *et al.*, 2000) or a combination of optical and radar data sources (Townsend and Walsh, 1998) to map flooded forests. Radar data have been shown to be more sensitive to variations in fundamental wetland attributes such as standing water and soil moisture than optical data sets (Ramsey, 1999).

Table 1 shows land-cover features discernible within different regions of the visible and infrared parts of the electromagnetic spectrum. Visible and near-infrared reflected energy have long been used to map the presence and types of vegetation cover as well as nonvegetated surfaces such as bare soils or impervious surfaces (Jensen, 1996). A very useful measure, the Normalized Difference Vegetation Index (NDVI), has been shown to be positively correlated with vegetation greenness (Tucker, 1979). The NDVI is a normalized ratio near-infrared and red reflected energy and takes the following form:

$$\mathrm{NDVI} = \frac{(\mathrm{NIR} - \mathrm{RED})}{(\mathrm{NIR} + \mathrm{RED})} \tag{1}$$

The change of vegetation cover through time, or its phenology, is captured using repeated images of derived NDVI. The depiction of phenology with satellite data has

Table 1 Principal spectral divisions and associated utility in observing surface conditions

Blue (400–500 nm): Highly influenced by atmospheric scattering and absorption. Provides penetration into water bodies and strong absorption by green vegetation.
Green (500–600 nm): Positively correlated with presence of healthy vegetation.
Red (600–700 nm): Strongly absorbed by green vegetation. Extinction of red light occurs in complex vegetation canopies. Used to derive Normalized Difference Vegetation Index (NDVI), which correlates strongly with presence of green vegetation. Sensitive to turbidity levels of water.
Near-infrared (700–1100 nm): Responsive to abundance of green vegetation. Used with red reflectance information to create NDVI. Useful in differentiating land from water. Sensitive to leaf geometry (needleleaf/broadleaf) and leaf water content.
Mid-infrared (1100–3000 nm): Used to differentiate clouds, snow and ice. Sensitive to soil moisture levels and related to plant vigor and drought stress. Water is absorbed very strongly. Important in identifying geologic features.
Thermal infrared (3000–30 0 000 nm): Useful in monitoring drought and water stress in plants, allowing for the mapping of drought deciduous woodlands. Also used for land-surface temperature calculations that, in conjunction with NDVI, have been used to measure land-cover change.

significantly enhanced the ability to discriminate many vegetative cover categories (Justice *et al.*, 1985). Visible and near-infrared energy have also proven useful in mapping water bodies and water clarity (Lillesand and Kieffer, 1994; Harrington *et al.*, 1992). Emitted energy in the thermal region has been related to surface temperature (Price, 1984) and has also been used in ratio form with NDVI to predict soil moisture status (Nemani *et al.*, 1993). Studies using both NDVI and surface temperature in concert have shown their utility in documenting both short and long-term environmental variation as well as land degradation (Lambin and Ehrlich, 1996).

The second consideration in defining the land-cover mapping problem is to outline the spatial requirements of the study in terms of areal extent and required spatial detail. For this discussion, areal extents of study can be divided into site level studies ($<100\,km^2$), local scale studies (100 to 10 000 km^2), regional scale studies (10 000 to 1 000 000 km^2), and continental to global scale studies ($>1\,000\,000\,km^2$). The use of specific remotely sensed data sets in land-cover mapping is usually a function of the spatial extent of the area of study. Spatial resolution is generally inversely related to image swath size (ground area captured by the sensor in a single scene), meaning sensors with higher spatial detail cover smaller areas than sensors with lower spatial resolution. So, depicting fine spatial detail over large areas requires the use of multiple images and a higher order of data processing requirements. Cost is often a determining factor in study feasibility and the costs of imagery increase with increasing spatial detail. As a consequence, studies examining detailed landscape features such as individual tree crowns or fine-scale drainage features are going to be limited in areal scale, most probably at the site level, due to the increased costs of the very high-resolution data required for such research. Table 2 shows the various characteristics for selected sensors.

When the spatial extent of the study area is larger than the footprint of desired input imagery, then the mosaicking of images acquired at different times is required. Land-cover characterizations using mosaicked images are performed in one of two ways. Either each image is separately characterized and the resulting products are stitched together, or all images are radiometrically normalized and an algorithm is run on a single mosaiced image. Radiometric normalization is the process by which images of varying illumination geometries and/or atmospheric conditions are made directly comparable. Thus, the use of individual images has significant advantages given that the study area fits within a single orbital swath. In general, less work is involved in preprocessing if the area of study fits within the footprint of a single image.

Third, the temporal scale of the mapping exercise must be defined. Is the study a single-date characterization for use with concurrently collected *in situ* data sets, or are multiple characterizations sought with the goal of performing a land-cover change detection study? In many cases, the simple identification of a land-cover category requires the use of multiple images in order to identify a characteristic vegetation phenological profile. Land-cover mapping using multitemporal image inputs is more commonly performed with coarse resolution sensors that have shorter repeat coverage intervals than fine-resolution sensors. As with areal scale considerations, the required temporal frequency of image capture will govern which sensor's data are most appropriate to the study. Table 2 shows the repeat coverage interval for available optical remote sensors.

A particular advantage of high temporal resolution sensors is the ability to composite data over time. Compositing algorithms preferentially select clear-sky pixels via an algorithm that operates on multitemporal data. Hand-selecting only cloud-free imagery for inputs is highly impractical for large regional and continental-scale study areas. The most commonly used method is a maximum-value compositing approach employing the NDVI (Holben, 1986). The NDVI is a ratio measure of near-infrared to red reflectance and is positively correlated with vegetation greenness. As such, it is a measure used to reduce the inclusion of cloud-contaminated data in time series imagery. Compositing

Table 2 Spectral, spatial, temporal and radiometric characteristics for commonly used multispectral sensors

		Spectral resolution	Spatial resolution (m)	Temporal resolution	Radiometric resolution (bits)	Swath width (km)
Very high spatial resolution	IKONOS	445–516 nm (blue) 506–595 nm (green) 632–698 nm (red) 757–853 nm (nir)	4	pointable	11	11

Moderate spatial resolution	MERIS	5 bands from 400 to 1050 nm	300	3 days	12	1150
	MODIS	620–670 nm (red) 841–876 nm (nir)	250			
		459–479 nm (blue) 545–563 nm (green) 1230–1250 nm (swir) 1628–1652 nm (swir) 2105–2155 nm (swir)	500	daily	12	2330
		29 other surface/atmosphere/ocean bands	1000			
Coarse spatial resolution	VEGETATION	430–470 nm (blue) 610–680 nm (red) 780–890 nm (nir) 1580–1750 nm (swir)	1000	daily	10	2250
	AVHRR	580–680 nm (red) 725–1100 nm (nir) 3550–3930 nm (thermal) 10 300–11 300 nm (thermal) 11 500–12 500 nm (thermal)	1100	daily	10	2399

reduces the volume of the data, while still retaining the temporal variability of the land-cover signal, given an appropriate compositing period. However, compositing requires significant preprocessing such as the application of an atmospheric correction algorithm in order to create radiometrically normalized images (Cihlar, 2000). Using composited data sets becomes the clearer choice as study areas increase from regional to continental in size. The ability to find individual cloud-free images is less probable as the area of study increases, and compositing becomes a practical solution to reducing cloud contamination. However, compositing can introduce noise as well as reduce spatial fidelity (Justice *et al.*, 1989; Moody and Strahler, 1994) when compared to optimum single-date images.

The aforementioned information domains of spectral, spatial, and temporal characteristics, are shown in Table 2, and are classified by spatial detail into four generic categories: very high resolution (<5 m), high resolution (5–100 m), moderate resolution (100–500 m), and coarse resolution data (>500 m) (*see* **Chapter 47, Sensor Principles and Remote Sensing Techniques, Volume 2**).

INDEPENDENT AND DEPENDENT VARIABLES

The independent variables input to any algorithm are the remotely sensed data. The number of inputs typically equals the number of satellite bands times the number of images (dates). Composites are another source of image inputs representing nominally clear-sky conditions over a fixed period of time and are available only for moderate and coarse resolution data sets. Ancillary data such as digital elevation models (DEMs) can also be used as inputs to mapping exercises. Some algorithms can also ingest categorical information such as soil type as independent variables.

Defining the dependent variable of land-cover type is an important and often overlooked part of classifying land cover. Some classification schemes developed by the modeling and remote sensing communities have significant problems that limit their utility. It is paramount to use a clear set of class labels and definitions for each label when developing a classification legend. These labels and definitions constitute the classification scheme and must be (i) mutually exclusive and (ii) totally exhaustive (Congalton and Green, 1999). It is important to avoid using legends that have holes or overlaps in their classification schemes. This is of particular importance when it comes to validating a land-cover map. If the legend does not hold to these two rules, then it is virtually impossible to validate the map. In addition, hierarchies within the classification scheme should be included to nest classes into categories of increasing/decreasing thematic detail. This affords the analyst to represent various confidence levels for greater- or less-generalized map products. This is useful for showing algorithm limitations by nesting classes in different ways, especially those with low accuracies. Sensitivity to the needs and desires of the user community must also be met by including all classes that can feasibly be mapped. For mapping exercises that produce per-pixel continuous-cover estimates, the same rules for producing a set of mutually exclusive and thematically exhaustive definitions apply.

When mapping using satellite data, a physiognomic-structural vegetation characterization scheme is advocated. First, land cover, defined as the observed biophysical state of the earth's surface, lends itself most unambiguously to a physiognomic definition set (DiGregorio and Jansen, 2000). Second, the signal, being mapped in multispectral and multitemporal space, is highly correlated with vegetation structure and phenology in terms of life form and cover. Third, physiognomic-structural definition sets based on measurable traits such as cover and height allow for validation exercises that can measure these same traits.

SUPERVISED AND UNSUPERVISED CLASSIFIERS

The most general distinction between classifiers is that of supervised versus unsupervised. The former requires training data, a set of land parcels of known cover types that are used to calibrate a classification algorithm. These parcels are identified in the imagery as groups of pixels that are used to develop per class spectral signature statistics. These signatures in turn drive the assignment of the remaining unlabeled pixels in the image. Unsupervised methods, on the other hand, use numerical algorithms to exhaustively cluster the image into spectrally similar groups of pixels. Each pixel in the image is assigned to one of the clusters automatically. These clusters are subsequently labeled by image analysts on the basis of their geographic distribution (Jensen, 1996). In each case, a paramount goal is to minimize the analyst's input. By creating a more repeatable product, the ability to develop baselines for future reference is increased.

The following discussion compares these two fundamental approaches. The first difference is the role of the analyst. A classification is not an automatic procedure. By definition, it relies on an interpreter's skills in labeling either training sites, in the case of supervised classifications, or clusters, in the case of unsupervised classifications. However, the potential to minimize the analyst's role is greatest with the supervised approach. Ideally, the analyst's input for a classification procedure is needed only once. The same training sites can be used repeatedly for successive classifications. For unsupervised approaches, new interpreter input is necessary for each successive clustering, limiting the reproducibility of the map product as compared to the supervised approach. However, the high-quality training needed to perform successive supervised classifications requires significant analysis and data gathering prior to running the algorithm. As a result, many researchers believe

that as the area of study increases, so does the suitability of using an unsupervised classifier because of the difficulty in acquiring reliable training data for larger areas to be used as inputs to a supervised classifier (Cihlar, 2000). Thus, land-cover mapping projects that use moderate and coarse resolution data sets have employed unsupervised techniques more frequently. Exceptions to this include Hansen *et al.* (2000) and Friedl *et al.* (2002), who created global-scale supervised land-cover classifications.

The second difference regards the thematic reference information used in training and labeling for both approaches. For any classification scheme, there are implied spectral boundaries, even if not explicitly stated, which when crossed represent the migration from one class to another. It is the accurate delineation of these boundaries that is sought. For example, if a classification has the goal of mapping tree cover, there is a range of canopy values associated with different tree cover classes. Unsupervised algorithms are based on various clustering regimes around "natural" groupings in multispectral space. In an unsupervised approach, the spectral ranges of these clusters may or may not consistently coincide with the physiognomic-structural limits as represented in the land-cover class legend. The resulting classes yield separable, but not necessarily meaningful classes (Rees, 1990). On the other hand, training data can be delineated that correspond directly to the classes as defined in the land-cover legend. In other words, the supervised approach allows the researcher to delineate training data that correspond to the chosen classification scheme, and does not have to rely on the "natural" spectral groupings to mimic that construct. An example of a "natural" grouping that usually corresponds to a unique multispectral signature is clear water. Few other land-cover classes can be confused with clear water. However, a classification system that breaks up a "natural" grouping along its spectral continuum, such as the example of tree canopy into forest, woodland, and parkland classes, lends itself poorly to a clustering algorithm. The main limitation for the supervised approach is the acquisition of training data, especially for large areas of study. If robust training data exist, a supervised approach is clearly more suitable for characterizing land cover. In the absence of reference data, unsupervised techniques are very useful as a data mining tool that can reveal the underlying distributions in multispectral and map space.

A final consideration is the sensitivity of the algorithm to noise in the data. An algorithm that, in effect, ignores or minimizes the impacts of noise is preferred. Supervised procedures such as classification trees use only the spectral information germane to separating the defined classes. For example, data with cloud contamination will be ignored if other spectral information allows for a separation of the classes in question. The inputs to a clustering algorithm must be preprocessed to eliminate as much noise as possible since all of the data are used in deriving the clusters. If cloudy pixels are left in the inputs of an unsupervised classifier, clusters of this spectral class may well be created. The analyst is left to interpret how to label such classes. Also, some classes, such as bare ground, are highly spectrally variable and an unsupervised classifier will create multiple clusters for what in a given class legend is a single class. Cihlar *et al.* (1998) have shown a way to reduce this problem by creating a parsimonious set of clusters. For many supervised classifiers a simple threshold or two will allow for the characterization of a spectrally variable, yet distinct class such as bare ground (Hansen *et al.*, 1996).

DISTRIBUTION-FREE ALGORITHMS

Parametric classifiers employ assumptions concerning the shape and distribution of decision volumes in multispectral space (Skidmore and Turner, 1988). The assumption of multivariate normality exists for the most used remote sensing classification algorithms, including maximum likelihood and linear discriminant functions. While these classifiers are optimal under conditions of normality, this assumption is rarely valid. As shown in Figure 1, a single class can be represented by a series of spectrally distinct subclasses. Thus, a model of a single data distribution is inappropriate. Distribution-free classifiers, which do not operate under any assumptions of data distributions, can capture the complex intraclass multispectral variability typical of most land-cover types. One of the reasons that normal probability density functions were used to estimate the histograms of training sites originally was that computers were not capable of computing probabilities across all digital counts in the actual histograms (Swain and Davis, 1978). This is not the case today, and classifiers that examine each and every digital number have provided new opportunities to calculate class extent in multispectral space. Advances in algorithm development and computing power have made previously infeasible distribution-free approaches more accessible (Hardin and Thomson, 1992; Paola and Schowengerdt, 1993; Foody, 1995; Ito and Omatu, 1997).

For land cover categories that feature high intraclass spectral variability, unsupervised approaches are superior to heritage supervised parametric algorithms such as maximum likelihood. A useful feature of unsupervised classifiers is the ability to make multiple clusters for a single class. Figure 1 shows a typical problem in characterizing a single land-cover class. An unsupervised algorithm can likely produce clusters that, when aggregated, capture this land-cover type. For a traditional parametric classifier to work, training data for each subcategory must be acquired and distinctly labeled. If all of these spectral subcategories are labeled as a single class, then the assumptions regarding normally distributed data will likely have been violated, leading to suboptimal performance in mapping this or other

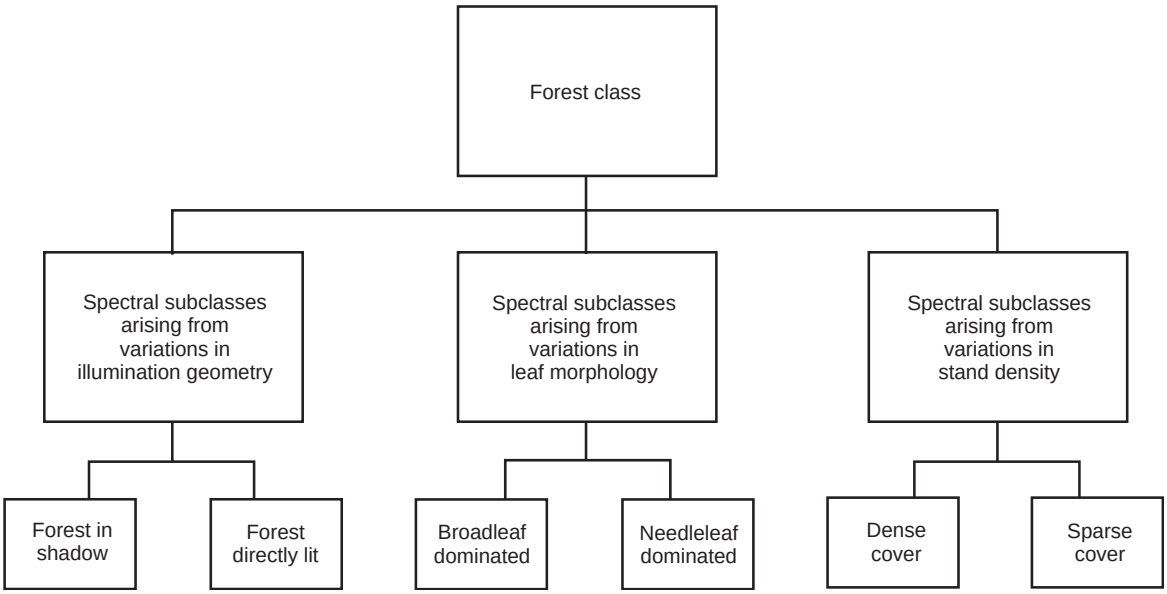

Figure 1 Theoretical intraclass spectral variability of a forest land-cover class, adapted from Campbell (2002)

cover types. However, distribution-free supervised classifiers, such as decision trees and artificial neural networks exist that enforce no distribution assumptions for the input classes. In the training phase, all of the subcategories in Figure 1 can be labeled forest.

A number of comparisons have been made between distribution-free methods and the historically favored parametric techniques. The majority of these comparisons show that no penalty is paid in using distribution-free techniques and that they usually yield higher accuracies. Ince (1987) and Hardin (1994) showed that nearest-neighbor classifiers were superior to parametric methods. Hansen *et al.* (1996) and Friedl and Brodley (1997) found comparable performance between a classification tree approach and a maximum likelihood one. Key *et al.* (1989), Bischof *et al.* (1992) and Gopal *et al.* (1999) tested maximum likelihood versus neural network classifiers and found similar or superior accuracies when using the neural nets.

Three commonly used methods are k-nearest neighbor, decision trees, and neural networks. The generic k-nearest neighbor method assigns each unknown pixel of a satellite image to the cover type of the most spectrally similar k reference training sites using a simple Euclidean or Mahalanobis spectral distance measure (Franco-Lopez *et al.*, 2001). The number k should be large enough to minimize the probability of misclassification and small enough to ensure that the k-nearest neighbors are in fact in close proximity to the candidate pixel. Cross-validation is recommended for finding a suitable value of k (Bishop, 1995). A distance criterion is often added to the algorithm to favorably weight those samples that are closest in spectral space to the candidate pixel.

Figure 2 shows an example of a two-class training set and how different values of k change the decision boundary in a two-dimensional spectral space. As k is increased, the decision boundary is correspondingly generalized. With a k value of 1, each training pixel is used to delineate

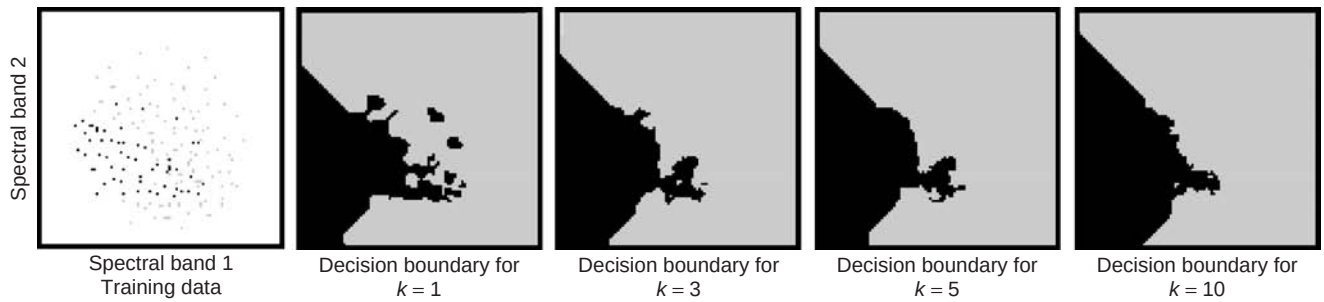

Figure 2 Two-class spectral training data and resultant partitioning of two-dimensional spectral space using a k-nearest neighbor algorithm

the decision boundary. This illustrates not only the great flexibility of distribution-free classifiers in classifying data but also the danger in overfitting the classifier to potential noise or errors in the training data. Choosing the best method to generalize the classifier is often an iterative process and greatly depends on the quality and quantity of reference information.

Decision tree theory (Breiman *et al.*, 1984) has previously been used to classify remotely sensed data sets (Hansen *et al.*, 1996; Friedl and Brodley, 1997; Hansen *et al.*, 2000; Friedl *et al.*, 2002), and offers some advantages over other classification methods. Trees are a hierarchical classifier that predicts class membership by recursively partitioning a data set into more homogeneous subsets. This splitting procedure is followed until a perfect tree (one in which every pixel is discriminated from pixels of other classes, if possible) is created with all pure terminal nodes or until preset conditions are met for terminating the tree's growth. One approach is that of the S-PLUS statistical package (Clark and Pergibon, 1992), which employs a deviance measure to split data into nodes that are more homogeneous with respect to class membership than the parent node. The reduction in deviance (D), is defined as:

$$D = D_s - D_t - D_u \tag{2}$$

where s is the parent node, and t and u are the splits from s. Right and left splits along the digital counts for all data are examined. When D is maximized, the best split has been found, and the data are divided at that digital count and the process repeated on the two new nodes of the tree. The deviance for nodes is calculated from the following:

$$D_i = -2\Sigma n_{ik} \log p_{ik} \tag{3}$$

where n is the number of pixels in class k in node i and p is the probability distribution of class k in node i.

Neural networks are an artificial intelligence technique that transforms feature space into class space and have been employed in many land-cover mapping exercises (Yoshida and Omatu, 1994; Gopal *et al.*, 1999; Kavzoglu and Mather, 2003). Many versions of neural network algorithms exist. A commonly used form is the multilayer perceptron that connects input feature vectors to output class assignments via a series of hidden layers (Atkinson and Tatnall, 1997). The training pattern is fed forward through the network architecture and output labels assigned. Comparisons of the output and input reference labels allow for computing the error, which is then used to adjust the weights of the various connections in an iterative manner to increase the network's accuracy. Increasing the number of hidden layers allows for a more complex network to be derived, but risks losing the ability to successfully generalize feature-label relationships (Foody, 1995). Like the nearest neighbor and classification tree algorithms, overfitting of the model is a potential problem (Abuelgasim *et al.*, 1996).

ALGORITHM COMPARISONS

To illustrate the algorithmic differences between traditional approaches and distribution-free methods, an example data set was analyzed for an area in Colorado, USA. Figure 3 shows a comparison for a set of forest and nonforest training data and examples of how unsupervised clustering, supervised maximum likelihood, and decision tree algorithms vary in partitioning a data set. If classifying only forest and nonforest, the unsupervised clustering approach creates many categories not germane to the task of separating the two land-cover classes. Without training data or a set of *a priori* rules that guide the clustering process, the production of superfluous clusters is often unavoidable. Otherwise, a series of cluster-busting operations must be undertaken to delineate the most accurate decision boundary (Jensen, 1996). The supervised maximum likelihood algorithm, on the other hand, creates a generalized decision boundary related to the assumed normal distributions of the two classes of interest. This creates a rather inflexible model of the actual boundaries between the two multispectral distributions. The distribution-free decision tree algorithm creates what might be called *supervised clusters*, which capture the areas of high and low class membership purity. The strength of this approach is that the clusters or nodes are directly related to the classes of interest, and areas of confusion are well delineated.

The simplest answer as to why superior results have been found using distribution-free classifiers is that a great deal of training data distributions do not conform to the assumptions of multivariate normality. Maximum likelihood classifiers are based on statistics of central tendency and are in many cases poorly suited to delineating class boundaries. Identifying the core area for any given class is, in most cases, the easy part, but correctly characterizing the limits of class memberships is considerably harder. Thus, classifiers that offer the possibility of calculating the edges between classes are most useful. Having a tool that is flexible along these boundaries and conforms to the actual multivariate distributions of the training data often yields superior results.

For distribution-free methods, individual pixels in multispectral space can be identified and included in creating a classification rule set. Thus, the major limitation in using these techniques is the possibility of overfitting the algorithm to the training data. For nearest-neighbor techniques, parameters such as k in the k-nearest neighbor algorithm are used to ensure that isolated and possibly mislabeled reference sites do not adversely affect output map products. The methods of pruning or bagging when using decision tree classifiers (Chan *et al.*, 2001) are also used to

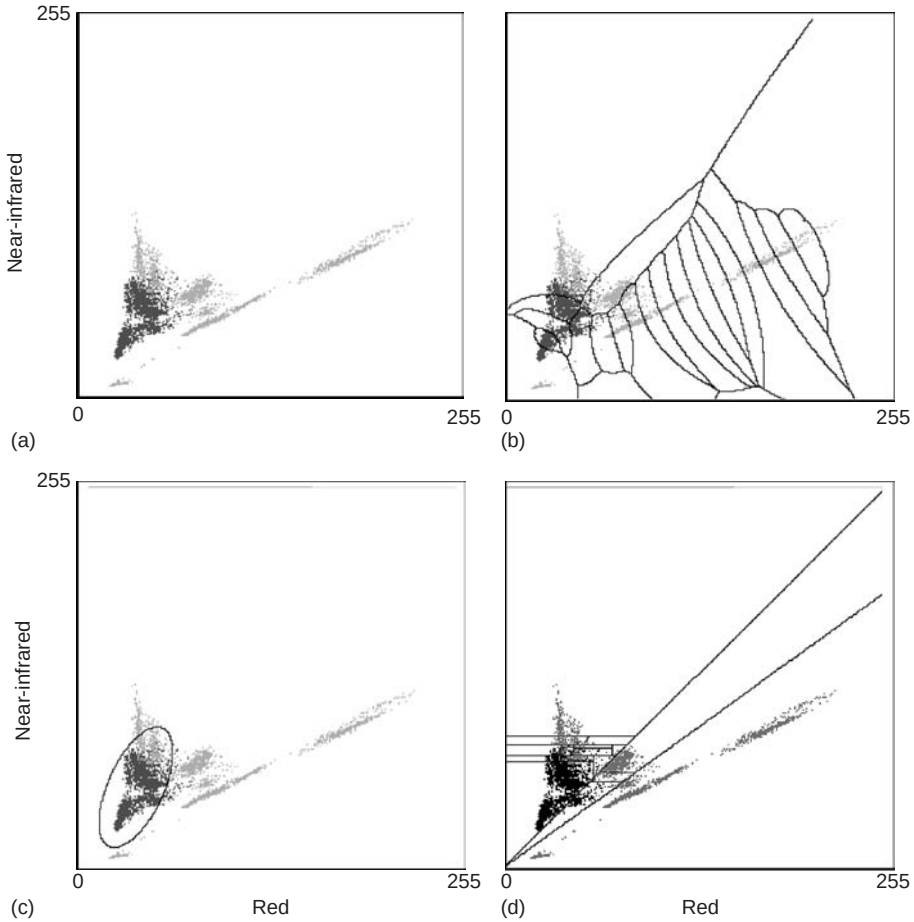

Figure 3 Training data and resultant partitioning of spectral space for data derived using a Landsat Enhanced Thematic Mapper Plus (032/035) image in western Colorado, United States, (a) is the spectral distribution of training data for forest and nonforest classes, where forest consists of broadleaf and needleleaf forests and woodlands of varying illumination conditions and nonforest consists of water, crops, parklands, shrublands and bare ground, (b) is the result of an unsupervised clustering of the data, yielding 20 clusters, with a maximum likelihood rule applied, (c) is the result of a maximum likelihood classifier applied to the training data, and (d) is a decision tree classifier applied to the training data, set to yield 20 terminal nodes

create a generalized output that avoids overfitting. For neural networks, limiting network training times or reducing the number of "hidden" layers (those sets of nodes between the input spectral and output class layers) can help in producing generalized results that best predict unseen cases (Atkinson and Tatnall, 1997).

In choosing which distribution-free methods are the best, there are a few important concerns, foremost of which is performance. Numerous studies have found that there is no single algorithm that is superior in all cases (Curram and Mingers, 1994). For many data sets, there may be a functional equivalency between algorithms with performance being primarily limited by quality of training data. The second concern is ease of use. While algorithms such as nearest neighbor and decision trees have a few, easily understood input parameters, neural networks have a number of obscure and difficult-to-assign input parameters that reduce ease of use (Paola and Schowengerdt, 1993). Another concern is ease of interpretation regarding algorithm outputs. Clearly, establishing the links between the input satellite data and the land-cover assignments is not always easily achieved. The most transparent of the commonly used distribution-free methods is the decision tree. Clear linkages between the splitting rules and class assignments are created, allowing for a ready interpretation from a biophysical standpoint.

CONTINUOUS REPRESENTATIONS OF LAND COVER

Continuous representations of land-cover features are layers in which the percent cover for a given vegetation trait is estimated on a per-pixel basis. These types of maps hold many advantages over land-cover classifications.

Continuously varying depictions of cover provide greater spatial detail than do discrete classifications. Ecotones or highly disturbed and fragmented areas are more accurately depicted by subpixel characterizations that fully exploit the inherent variability found in imagery. This greater thematic detail allows for a better ability to parameterize modeling efforts (DeFries *et al.*, 1995). Unlike classifications, continuous-cover maps allow for the use of consecutive products to measure change. They also allow users to define their own thresholds for land-cover classes. This avoids the common problem of shoehorning one classification legend into another. A major drawback for some methods is the need for precise training data at the subpixel scale. Also, instead of capturing all thematic content in a single map layer, continuous depictions of subpixel cover require data layers for each cover trait of interest.

Much work has been done in calibrating remotely sensed data to fractional vegetation cover. The techniques include (i) using end-member linear mixture modeling (Settle and Drake, 1993; Adams *et al.*, 1995; DeFries *et al.*, 1999); (ii) using fuzzy sets to estimate forest cover (Foody and Cox, 1994); (iii) estimating likelihoods of class membership using logistic regression methods; (iv) empirically estimating percent cover based on calibrating coarse resolution data with high-resolution data (Iverson *et al.*, 1994; Zhu and Evans, 1994; DeFries *et al.*, 1997; Hansen *et al.*, 2002); (v) using high-resolution data to calibrate coarse resolution cover estimates while incorporating the spatial arrangement of the fine-resolution cover estimates (Mayaux and Lambin, 1997); and (vi) employing isolines in scatterplots of red/near-infrared space to map plant density (Jasinski, 1996).

The various approaches can be divided into two general categories, those that rely on exemplar categorical reference data to model the intercategory variation and those that require calibration data along the entire range of mixtures. Examples of the former type include linear mixture models, fuzzy classifiers, and logistic regression approaches. For linear mixture models, a set of spectral endmembers is used to estimate cover fractions for each pixel. The reflectance for any pixel is assumed to be the sum of the reflectances for each endmember within the pixel weighted by the respective proportional covers (DeFries *et al.*, 2000) and takes the following form:

$$R_i = \sum_{j=1}^{Q} r_{ij} x_j + e_i \tag{4}$$

Where R_i is the reflectance in band i, r_{ij} is the reflectance of endmember j in band i, and x_j is the fractional cover of endmember j, e_i is the error term and i is the number of endmembers. The model is further constrained so that the sum of fractional cover estimates sum to 1.

Figure 4 shows an example of a linear mixture model application for monitoring change in coastal wetlands for the Chesapeake Bay area of the Mid-Atlantic United States. For this approach, which employed Landsat Thematic Mapper data, two normalized indices were used to create a transformed spectral space that enabled the labeling of three distinct spectral endmembers: water, vegetation, and soil. The image dates were chosen to account for sources of false change, including phenological and tidal variations. The normalized inputs also accounted for interscene variation in illumination conditions. This enabled the mixture model to detect changes in ponding in coastal marshlands and the derivation of a measure depicting the severity of marshland loss (Kearney *et al.*, 2002).

Limitations to the linear mixture modeling approach include the difficulty in successfully identifying endmembers in multispectral space (Roberts *et al.*, 1998). Also, imputing a linear model upon subpixel, land-cover spectral interactions can often oversimplify the complex spectral relationships of land-cover mixtures, especially at regional and continental scales. It is generally accepted that for small study areas with robust spectral data, usable endmembers can be found for mapping purposes. For larger areas, image stratification can be employed to map regions individually using linear models (Zhu and Evans, 1994). For larger areas where stratification is not possible or not desired, nonlinear models are often preferred.

Fuzzy approaches use classification routines to derive a strength-of-class membership per pixel. The result is a continuous output analogous to posterior probabilities of class membership where the individual class fuzzy membership functions vary from 0 to 1 and sum to 1 for all classes. Fuzzy approaches have been shown to perform comparably to linear mixture models (Foody and Cox, 1994), but have many of the same limitations.

Logistic regression models allow for the use of categorical inputs to create continuous outputs of class likelihoods per pixel. Logistic regressions are a nonlinear transformation of a standard linear regression that employs an *S*-shaped distribution function to constrain estimated output probabilities to between 0 and 1. For remote sensing applications, the dependent variable of class proportion is run against the independent variables of multispectral imagery. The probability of class membership is found by transforming the standard linear regression model with an intercept of a and a slope of b using this function:

$$p = \frac{1}{[1 + \exp(-a - bx)]} \tag{5}$$

where b is now the change in the log odds as a function of x. Figure 5 shows a logistic regression output for mapping intensive mechanized agriculture in an area of Brazil experiencing rapid agro-industrial development. For this method, pixels labeled *crop* and *not crop* are input to the

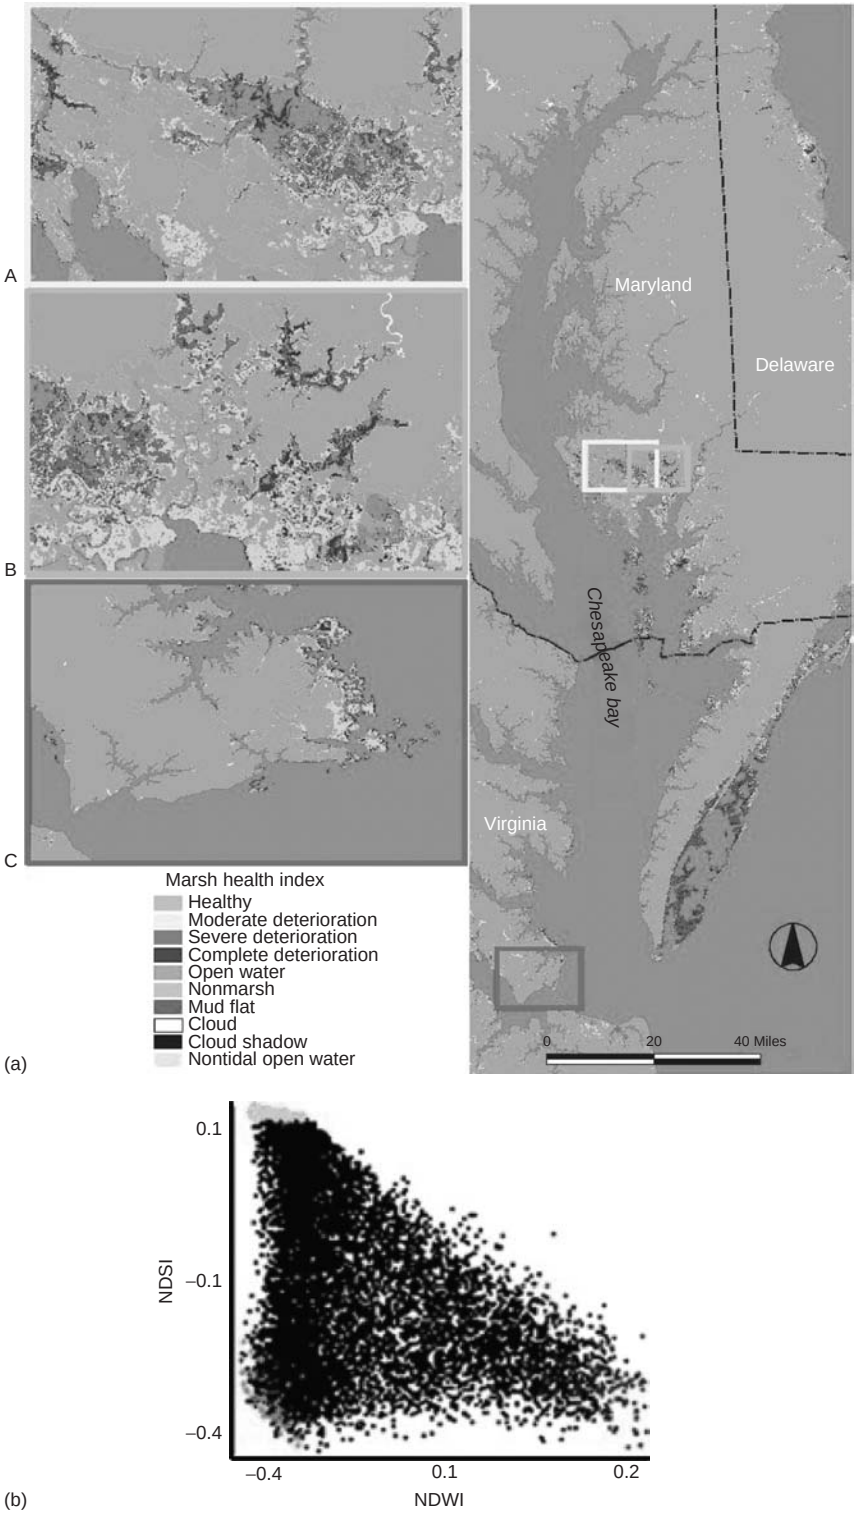

Figure 4 Results of a linear mixture model applied to measure water presence in a coastal marshland environment of the Chesapeake Bay, Mid-Atlantic, United States. (a) Multitemporal application of the model yielded a measure of change in coastal marshlands. (b) Two normalized difference indices, the Normalized Difference Wetness Index ($NDWI = (TM3 - TM5)/(TM3 + TM5)$) and the Normalized Difference Soil Index ($NDSI = (TM5 - TM4)/(TM5 + TM4)$) were used to identify water, vegetation, and soil spectral endmembers as shown (Reproduced from (Kearney *et al.*, 2002) by permission of American Geophysical Union). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

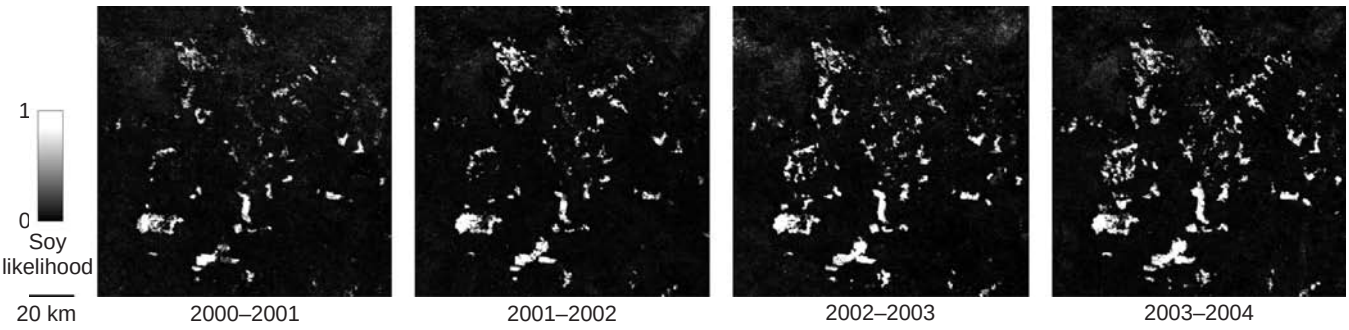

Figure 5 Application of a logistic regression model to map the likelihood of first crop soybean for an area of northeastern Brazil (Tocantins, Maranhao, and Piaui states) experiencing rapid expansion of mechanized agriculture

logistic regression model and a set of regression estimators are derived. These can then be used to derive a likelihood of crop class membership and monitor cropping patterns over time. Logistic regression approaches, like the other aforementioned methods, do not incorporate intermediate cover values in model calibration.

Methods that rely on calibration data at the subpixel level are empirical in nature and include linear techniques such as multivariate linear regression models and nonlinear approaches such as tree-based models. Calibrating empirical models requires significant up-front work using subpixel scale ancillary data sets to create training data over the continuum of cover mixtures. By deriving such a training data set, the true ability to map subpixel cover can be better tested regardless of algorithm choice. However, models that exploit the subpixel information directly in the calibration process should perform better than those that only model subpixel cover variation.

Regression tree models have been used in numerous applications for mapping continuous variables using remotely sensed data (Michaelson *et al.*, 1994; DeFries *et al.*, 1997; Prince and Steininger, 1999; Hansen *et al.*, 2002). The regression tree is a nonlinear tool that recursively splits a continuous training variable into subsets, called *nodes*, that minimize the overall residual sum of squares. The regression tree algorithm takes the form of the following equation:

$$D = \sum_{cases(j)} (y_j - u_{[j]})^2 \qquad (6)$$

where D is the deviance as measured by the corrected sum of squares for a split. This is calculated from all j cases of y and the mean value of those cases, u. The split that minimizes the residual sum of squares is chosen as the best split. For regression trees, the relationship between the independent and dependent variables is not monotonic and nonlinear. This allows for a flexible subsetting of the multispectral image space not feasible with many other methods.

CHANGE DETECTION

Land use and land-cover change includes both the conversion from one land-cover category to another (Riebsame *et al.*, 1994) and the modification, or subtle within-class change, that affects the character of the land cover without changing its overall classification (Coppin *et al.*, 2004). Mapping such changes using remotely sensed data sets offers a unique and powerful tool for measuring land-surface transformations. For hydrological applications, such change can include deforestation mapping within a watershed, or increased ponding within a marshland. The ability to detect land-cover conversions or modifications is a function of the mappability of the classes themselves, the spatial extent of change, and the temporal context in which the change occurs (Singh, 1989). Addressing what cover change dynamics are to be detected is the first order of business. Remote sensing system characteristics, including temporal, spatial, spectral, and radiometric resolutions, dictate which sensors may be of use to a given change detection study. In the temporal domain, change events can vary in terms of persistence, ranging from ephemeral, to interannual, to permanent change. Ephemeral changes are short-term changes in cover such as floods, or seasonal burning in a savanna setting, which do not permanently alter the dominant vegetation cover distribution of the landscape. Interannual changes are variations in land cover largely due to long-term climatic variability such as change in the annual extent of grasslands semiarid regions, or the reduction of woodland canopy cover for an area experiencing long-term drought. Semipermanent/permanent changes are wholesale land-cover conversions and include new construction of impervious surface, deforestation events, or the expansion of agricultural lands. Land-cover modifications, as compared with land-cover conversions, are a form of semipermanent/permanent change within a given land-cover category. This is a more subtle form of change and includes examples such as rangeland degradation due to overgrazing, or forest thinning due to selective logging.

As stated before, the temporal resolution of a sensor is typically inversely related to its spatial resolution. Change events sought on a short-term basis require data from sensors with high temporal revisit rates, which typically have coarse spatial resolutions. Thus, the opportunity to measure change at fine spatial resolutions is governed by a longer interval from time 1 to time 2, as compared with spatially extensive change events. Understanding land-cover change dynamics in the context of sensor capabilities is critical and allows the analyst to construct a defensible land-cover change type definition set. An undeveloped research area is the use of techniques that incorporate multiple sensors in change detection studies. Multiresolution and multitemporal data fusion techniques offer the greatest potential for operational land-cover change monitoring.

The basic principle behind spectral change methods is that variation in spectral signatures between images of different dates indicates land-cover change. However, such variation is not necessarily indicative of land-cover disturbance, and a number of complicating factors must be addressed prior to assigning disturbance using spectral change methods. If data from different sensors are used to find change, then complications arise from differing spectral bandwidths, radiometric, and spatial resolutions. Therefore, it is often recommended to use data from a single sensor. For a given sensing system, spectral variability between dates is often a function of the changes in viewing geometry. Variation in sun-sensor-target geometry can be partially accounted for by obtaining data on anniversary dates from a sensor in a sun-synchronous orbit. In this manner, data are acquired at approximately the same time of day with the same viewing and illumination geometries (Jensen, 1996), minimizing interscene spectral variation unrelated to change. However, for many applications such data are unavailable and these variations must be accounted for by other means, such as the application of an at-sensor or at-surface reflectance correction.

In addition to interscene variations related to sun-sensor-target geometry, atmospheric variability between time periods represents another source of potential error in using spectral change methods. Performing atmospheric corrections for the various effects of water vapor, aerosols, ozone, and Rayleigh scattering is typically not possible unless standard datasets exist that include preprocessed corrections (Vermote *et al.*, 2002). Other procedures to normalize data from multiple images exist, including dark target normalization, histogram matching, and band-to-band regression procedures (Richards, 1993; Teillet and Fedosejevs, 1995; Jensen, 1996). However, many atmospheric effects vary not only between scenes but also within scenes, and this must be considered in evaluating image data for possible use in change detection studies.

Analysts must also recognize the impact of surface environmental factors, wholly unrelated to land-cover change that may alter the spectral character of the surface. Such influences include interscene soil moisture and phenological variation. Apparent land-cover change between dates may simply be the result of images acquired at times of the year when the same vegetation has different spectral properties. For example, mapping deciduous forest in high latitudes requires the acquisition of data from a narrow window of peak cover conditions in July and August. If any of the input images are from other times of the year when the canopy is not exhibiting mature leaf-flush, then spectral change methods will likely lead to false change detection results related to offsets in phenological timing. In most cases, making sure that the input imagery represents common interdate phenological variability is paramount to detecting land-cover conversion events.

There are various approaches to delineating change using remotely sensed data sets. The two general categories of change methods are spectral change and postcharacterization approaches. Spectral change methods use imagery as inputs to detecting land-cover change events, while postcharacterization approaches use derived land-cover map classifications or fractional cover maps as inputs. Commonly used spectral change methods include image algebra, multidate composite, and change vector analyses. Image algebra methods include image ratioing and image differencing, where change pixels are found as outliers in the resultant probability distributions. Since NDVI represents a compression of two bands of spectral information and is a strong correlate with the presence/absence of green vegetation, NDVI image differencing has proven an effective method for identifying land-cover change (Lyon *et al.*, 1998). Identification of change is often performed by thresholding the tails of the differenced image's histogram (Borak *et al.*, 2000).

Multidate composite approaches include algorithms such as Principal Components Analysis (PCA) or unsupervised clustering. If the input images are normalized for variations in environmental factors, then pixels representing change will be captured as unique statistical information. In the case of PCA, the majority of pixels in an image does not change, and as a result they are highly correlated across dates. These pixels represent the majority of the variance in the composite image and are transformed onto the first component, while the change pixels are identified in lesser components (Richards, 1984). Similarly, unsupervised clustering can be used to identify the unique spectral signatures of change pixels in composite images. The major limitation with these methods is the lack of information regarding the labeling of change types.

Change vector analysis incorporates multispectral information to calculate the magnitude and direction of pixel change over time. This approach uses all data layers concurrently and allows for an examination of all change information in multitemporal imagery. As such, it detects both

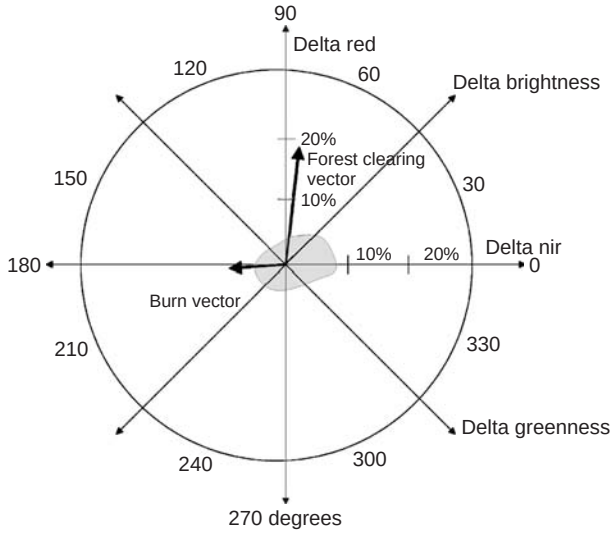

Figure 6 Example of change vector analysis for red and near-infrared spectral bands. Grey area represents time 1 and time 2 interscene spectral variation due to phenological and illumination effects. Vectors extending beyond this area represent actual land-cover change events. In this example, deforestation and burn examples are shown (Reproduced from Zhan *et al.*, 2000 with permission from Taylor & Francis Ltd., `http://www/tandf.co.uk/journals`)

actual land-cover change information as well as interscene background environmental variation. Users of this approach need to account for confounding spurious change classes with actual change classes of interest. Figure 6 shows two change scenarios for the removal of forest canopy cover in change vector space. By accounting for a limit-of-interscene phenological variation for successive images, a threshold of change magnitude and direction can be used to identify specific forest clearing dynamics. For a two band case, as is used in the MODIS change detection algorithm for the 250-m red and near-infrared bands (Zhan *et al.*, 2000), the change vector is calculated as follows:

$$M = \sqrt{(\Delta\rho_{\text{red}})^2 + (\Delta\rho_{\text{nir}})^2} \text{ and } \theta = \arctan\left(\frac{\Delta\rho_{\text{red}}}{\Delta\rho_{\text{nir}}}\right) \quad (7)$$

where M is the change magnitude, θ is the change direction, $\Delta\rho_{\text{red}}$ is the difference in time 1 and time 2 red reflectance and $\Delta\rho_{\text{nir}}$ is the difference in time 1 and time 2 near-infrared reflectance.

Postcharacterization methods compare consecutive land-cover maps to identify change sites. For hard classifications, limitations to the method are a function of the individual time 1 and time 2 classification accuracies. Since change is often a minority occurrence within a given study area, then errors in mapping accuracy confound the ability to delineate actual change. A better approach to detecting change is the use of comparisons of consecutive subpixel

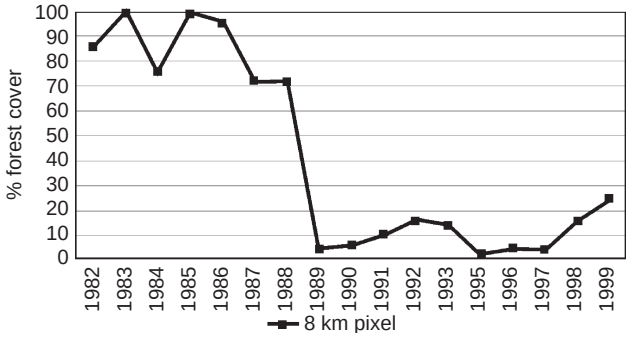

Figure 7 Multitemporal estimates of percent forest cover for an 8-km pixel from the Pathfinder Advanced Very High Resolution Radiometer data set from 1982–1999. Canopy removal due to fire is evident in 1988 within the time series forest cover estimates for this area of Yellowstone National Park, Wyoming, United States (Reproduced from Hansen and DeFries, 2004 by permission of Springer-Verlag)

cover estimates, as shown in Figure 4. Change estimates using fuzzy measures of land cover have been shown to be superior to simple postclassification change detection strategies (Foody, 2001). Since continuous estimates of fractional cover have the same statistical properties of images, approaches such as image differencing can be applied. Figure 7 shows an example of a percent forest cover application that identifies the extensive fire of 1988 in Yellowstone National Park, Wyoming, United States. Here, the biophysical trait of interest, forest cover, is directly characterized and mapped repeatedly through time. Change is found by measuring the ability of the algorithm to map unchanging areas. This measure of algorithm noise is then used with a difference image of consecutive cover estimates to derive a threshold beyond which actual biophysical change in forest area has occurred (Hansen and DeFries, 2004). An advantage of this approach is that the land-cover characterizations can be derived from time-integrated, multitemporal data sets while the change analysis can exploit simple, bitemporal difference image calculations based on the cover estimates.

CASE STUDY–MAPPING LAND COVER FOR ASSESSING STREAM HEALTH IN THE CHESAPEAKE BAY WATERSHED

The links between land cover and water quality, including stream health, have long been known, but not until recently have analyses over large areas emerged as a feasible area of ecohydrological research (Nilsson *et al.*, 2003). Impervious surface areas (ISAs) (like buildings, roads, parking lots) increase the amount of pollutants within and the temperature of runoff reaching streams (*see* **Chapter 117, Land Use and Land Cover Effects on Runoff Processes: Urban and Suburban Development, Volume 3**). Forested riparian buffers, on the other hand, preserve or increase stream

quality by contributing leaf litter, regulating temperature and sunlight, deterring erosion, and resorbing nutrients. In past studies, land cover was developed using aerial photography, but this analysis employs high-resolution satellite imagery and a supervised classification procedure to automatically classify land cover.

The objective in this case study was to utilize fine-resolution land-cover information for a range of small watersheds in suburban Maryland to explore the relationship between stream health and land-cover metrics. The stream health rankings were derived from a combination of physical measurements and macroinvertebrate and fish biological indices developed by state and county collaborators. The land-cover data included ISA and tree cover maps created from very high-resolution satellite data. We used logistic regression models of stream health rankings incorporating the heterogeneous land-cover types and topographic information, and examined the influence of spatial configuration of the landscape variables on predictions of stream health.

Montgomery County, Maryland is part of the Baltimore-Washington metropolitan area, extends over approximately 1300 km^2, and is home to 810 000 people. In this study we analyzed 284 small watersheds (20–47 km^2), which are used as management units (Van Ness *et al.*, 1997). Collaborators from the Montgomery County Department of Environmental Protection (MCDEP) and the Maryland-National Capital Park and Planning Commission (MNCPPC) provided stream health data for the watersheds. They used an Index of Biological Integrity (IBI) for macroinvertebrate species and for fish species based on the ecological assemblages found in reference streams, developed and measured by the Maryland Department of Natural Resources (MD-DNR) (Stribling *et al.*, 1998; Roth *et al.*, 2004). Of the 284 watersheds, 66 were omitted from further analysis due to incomplete assessments, spatial coverage, or excessive cloud cover at the time of satellite image acquisitions. The remaining 218 watersheds included 31 ranked as having excellent stream health, 77 good, 68 fair, and 42 poor (Figure 8).

Space Imaging IKONOS "precision georeferenced" imagery acquired between 6 April 2000 and 23 May 2001 were requisitioned through the NASA (National Aeronautics and Space Administration) Scientific Data Purchase program. The imagery covered a 1313-km^2 area including Montgomery County, at 4-m resolution in four multispectral wavelength bands (blue, green, red, and near-infrared). The images included a mixture of leaf-on (foliage expanded) and leaf-off (foliage absent) imagery acquired between early and late spring. Masks of clouds and cloud shadows for those areas affected were created manually by delineating affected areas in the imagery.

Maps of tree and impervious surface cover (Figure 8) were derived from the imagery using a decision tree classification based on the individual wavelength bands and spectral vegetation indices, to discriminate impervious and tree covered areas. The classification trees were created with S-PLUS statistical software, which uses a univariate algorithm to recursively threshold the training data into homogeneous groupings. The training data for the ISA classification were vector planimetric coverages from the MNCPPC, including building and road footprints. The training data for the tree cover map were forest areas (>60% tree cover) mapped in 1992 using a relatively large minimum mapping unit that captured densely forested areas. Both the training data sets were created from visual interpretation of aerial photography, and were preprocessed for accuracy to account for areas that had changed. The final tree and ISA maps capture changes in the land cover since 1992 and show more detail because of the fine spatial resolution of the imagery. Details on the creation and assessment of the tree cover and impervious surface maps from IKONOS imagery are reported by Goetz *et al.* (2003).

A DEM was created from a topographic map provided by Montgomery County. The vertical and horizontal resolution of the topographic map (<1 foot) was used to create a 4-m resolution DEM, from which a grid of the percent change in slope between the cells was derived. This and a vector hydrology layer provided by the county was used to create 30 m (100 ft) riparian buffers, since this is a common metric used for determining Chesapeake Bay restoration efforts. The tree cover map, the (4 m) ISA map, and the percent change in slope map were intersected with the buffer coverage to calculate for each watershed buffer zone, the proportion of tree cover, ISA, and mean slope (Figure 8). Spatial configuration metrics, such as the distance from the stream to ISA areas and land cover within flow paths, were also calculated and used in the statistical analyses.

Logistic regression models were developed to predict stream health rankings using the land-cover metrics within the watershed and the riparian buffer zones as the independent variables, and the stream health rankings (excellent, good, fair, poor) as the categorical dependent variables. Values in the logistic regression model are chosen using maximum likelihood to predict the probability of a given category (in our case stream health ranking). We allowed the logistic models to include in a stepwise fashion those variables most significant as predictors of stream health. Because ISA and tree cover relate to stream health in different ways, they were both included in the logistic models, but stepwise elimination tests were done to assess their relative importance.

The amount of ISA derived from the fine-resolution map (4 m) varied from 0 to 52%, while the percentage of tree cover varied from 0 to 94% (Figure 8). When the watersheds were grouped by stream health ranking, it was apparent that the average percent ISA increased from excellent to poor rankings, while the average percent tree cover

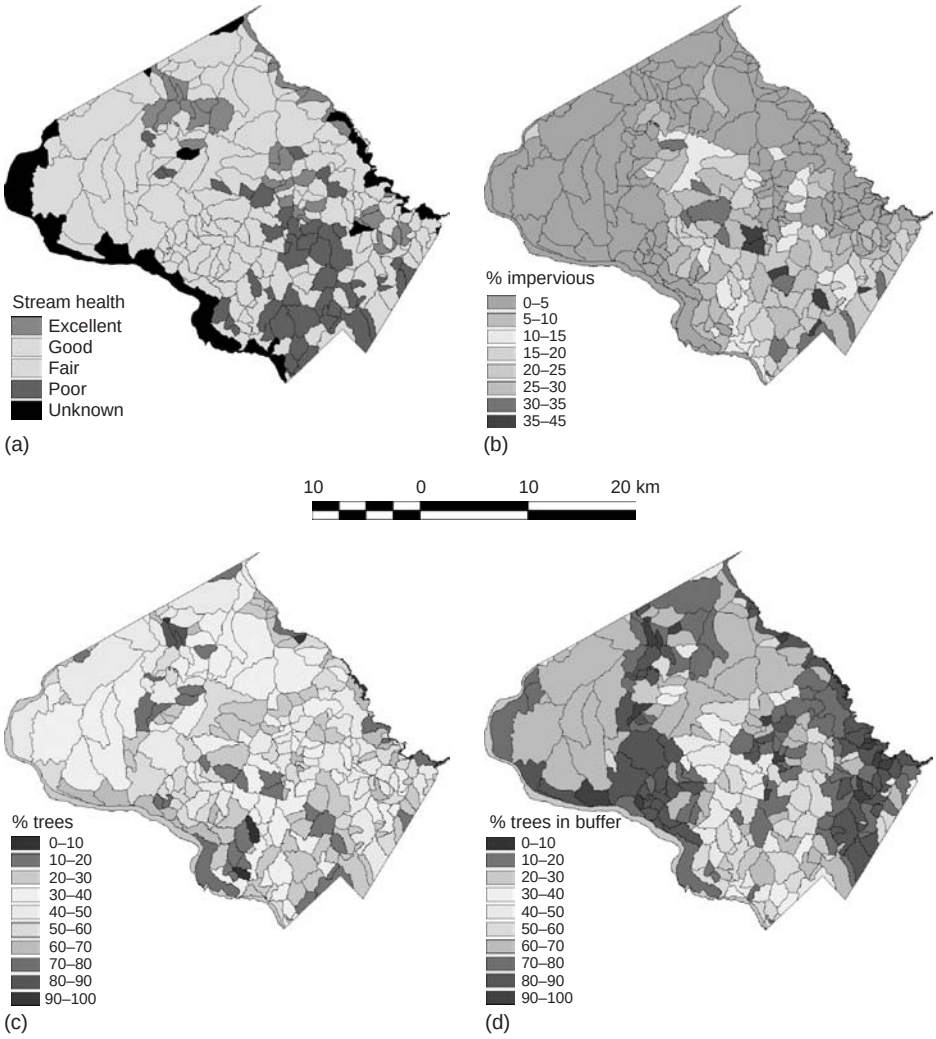

Figure 8 Maps of watershed aggregated values for: (a) stream health rankings, (b) impervious surface cover (%), (c) tree cover (%), (d) riparian buffer tree cover (%). Figures b, c and d were calculated using the IKONOS derived maps of these land-cover variables

Table 3 Small watershed sample size and average statistics by stream health rating category

Stream health rating	N	Area (km^2)	Impervious (%)	Tree cover(%)	Buffered (%)
Excellent	38	272	3.6	50.6	76.8
Good	81	658	4.9	44.6	71.3
Fair	76	451	13.9	37.0	63.2
Poor	50	356	19.5	29.6	56.3

decreased (Table 3). In the riparian buffer zone, tree cover ranged from 0 to 98%, the ISA varied from 0 to 32%, and the mean percentage slope from 3 to 26% (Table 3). The percentage of the buffer occupied by tree decreased and the percentage of ISA in the buffer increased with stream ranking, although a slight but insignificant decrease in percent ISA in the buffer occurred between the excellent and good rankings.

Measurements across scales were correlated, thus not independent estimators, including the percentage ISA in a watershed and in the buffer zone ($r = 0.79$) and the percent tree cover in the watersheds and in the buffer zones ($r = 0.74$). Moreover, the ISA and the tree cover area in the watersheds were inversely correlated ($r = -0.59$); thus as the percent ISA in a watershed increased, the percent tree cover decreased. Logistic regression minimizes these autocorrelation effects, however, and the percent ISA in the watersheds was consistently selected as the primary predictive variable ($r^2 = 0.33$, $p < 0.0001$). This was followed by the percentage tree cover in the buffer zone ($r^2 = 0.35$, $p = 0.04$), and then by other landscape variables such as slope and spatial configuration metrics. Note that r^2 terms from categorical logistic models are considered good fits when they exceed 0.2.

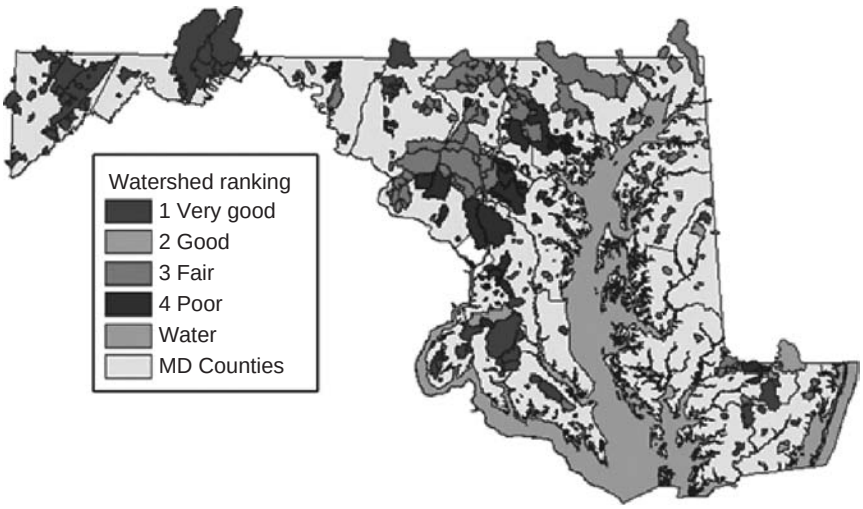

Figure 9 Predicted stream health ratings in some Maryland watersheds based on land-cover characteristics derived from Landsat imagery and the threshold criteria developed using the finer-scale IKONOS analysis results

Interpretation of the results indicates that the processes most affecting stream integrity in these watersheds are those that act primarily at the watershed scale. Several studies have noted that the effect of urbanization on biotic communities is evident between 10% and 15% ISA (Schueler, 1994; Arnold and Gibbons, 1996). The results indicate that watersheds in excellent health averaged less than 8% ISA, watersheds in good health averaged $<$10% ISA, those rated fair averaged $<$20% ISA, and those with a poor health ranking had $>$29% ISA. A few watersheds in this study had greater than 15% ISA but were still rated excellent, indicating that landscape configuration was probably important (the subject of work described by Snyder *et al.*, 2004). These ISA thresholds reflect statistically significant differences between rankings with some precision, as they were calculated from large sample sizes across a wide range of watersheds studied, at fine spatial resolution.

Many management agencies now have access to finer-resolution land-use data, and the analyses indicate that accurate impervious coefficients associated with land-use classes may provide a comparable level of predictive capability as the 4-m product developed and used here. For areas where an existing land-use map is not available, continuous 30-m Landsat land-cover maps of impervious and tree cover, like those recently produced for the Chesapeake Bay watershed (Goetz *et al.*, 2004) and elsewhere (Yang *et al.*, 2003), may be equally adequate. For example, using the continuous Landsat maps and the criteria developed in Montgomery County, the analysis assessed watersheds across the state of Maryland (Figure 9) and identified those that should be targeted for protection (excellent and good rankings) versus those that require restoration (fair or poor rankings). These results demonstrate the utility of impervious surface data for the development of guidelines relevant to stream health, and indicate that minimizing the amount of ISA in a watershed, or mitigating their negative impacts through various management practices, will aid the preservation, targeting, and restoration of stream health.

SUMMARY

Various data sets and tools are available for mapping land cover and land-cover change for inputs to hydrologic applications. The best choice is often a function of the specific application. New sensors offer increased capability in monitoring spatial detail and temporal variation of land-cover categories. Algorithms have advanced in robustness and include distribution-free methods that are superior to traditional approaches in terms of modeling the multispectral distributions of reference data. Advanced subpixel methods of mapping land cover offer greater thematic coherency and the possibility of using consecutive land-cover characterizations to map change. The success of deriving a meaningful result, such as deriving a relationship between aquatic biotic indices and land-cover change, relies on a high-quality land-cover reference map. By choosing the most appropriate data sources, constructing a defensible land-cover definition set, and employing robust algorithms, analysts allow for the meaningful incorporation of land-cover map information into hydrological studies.

Remote sensing observations increasingly are used to obtain the detailed information needed about land surface state required for hydrological analyses. However, many of the surface state parameters required for such analyses are related to the vertical structures of surface vegetation and topography, that are often difficult to measure using passive optical and radar remote sensing technologies. A new technology, lidar (light detection and ranging) remote sensing, has proven highly effective for characterizing land surface structure in great detail, including subcanopy topography, canopy height, foliar profile and biomass, among others. In this article, we review the theory and application of lidar remote sensing for characterizing land surface states for hydrological analysis. First we present a brief overview of lidar, and discuss similarities and distinctions between the small-footprint systems commonly used in commercial applications and large-footprint approaches used in research and space-based systems. We next describe common land surface variables that are often used in hydrological analysis and how these are related to vertical structures observable from lidar. Lastly, we present how lidar may be used to recover or parameterize these surface variables; in particular we focus on the observation of forest and topographic structures.

INTRODUCTION

Remote sensing data are used increasingly for the parameterization, initialization, and validation of hydrological models. The creation of consistent, long-term, global and regional scale remote sensing observational records, along with advances in remote sensing technologies, algorithms, and data assimilation methods have greatly advanced our ability to predict accurately hydrologic fluxes. However, many of the land surface state parameters required for such analyses are related to ground topography and the vertical structure of surface vegetation; yet these features are exceptionally difficult to recover using passive optical and radar remote sensing technologies. For example, aerodynamic roughness is generally parameterized as a function of canopy height, a parameter which conventional remote sensing methods have had little success in observing.

Lidar (light detection and ranging) or laser altimetry, in contrast, is a technology with great potential for characterizing the vertical structure of the land surface vegetation and the underlying ground topography because it directly measures such structure (Ackermann, 1999; Dubayah and Drake, 2000; Dubayah *et al.*, 2000; Lefsky *et al.*, 2002;). Lidar uses active laser energy to record the vertical distribution of canopy and ground surface components. From this distribution of energy, an impressive variety of vegetation features can be measured, inferred, or modeled, such as canopy height, foliar profiles, canopy cover, leaf area index (LAI), biomass, canopy volume, basal area, and stem density, among others. Furthermore, even in densely vegetated landscapes, lidar technology can produce "bare earth" topography, which can be constructed and is vastly more detailed than what is commonly available from conventional sources. From these observations, parameterization of variables needed for land surface models is greatly facilitated.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

In this chapter, we explore the potential of lidar remote sensing for characterizing land surface states for hydrological analysis. First we present a brief overview of lidar and laser altimetry. We discuss the distinction between small-footprint lidar commonly used in commercial applications and large-footprint approaches that are at the forefront of airborne and space-based systems. We next describe common land surface variables that are often used in hydrological analysis and how these are related to vertical structure observable from lidar. Lastly, we present how lidar may be used to recover or parameterize these surface variables; in particular, we focus on observations of forest and topographic structure.

LIDAR REMOTE SENSING

Lidar remote sensing is the optical laser analog of radar (light detection and ranging). With most systems, a pulse (or multiple pulses) of laser light is emitted from an airborne or space-based sensor towards a surface where the area irradiated by the laser pulse is referred to as a "footprint". An overview of the physical principles of lidar remote sensing as well as issues surrounding data collection, processing, and interpretation are provided in Wehr and Lohr (1999), Axelsson (1999) and Baltsavias (1999). Lidars that are designed to observe land surface features frequently operate in the near-IR as vegetation is highly reflective in this part of the electromagnetic spectrum. The incident energy is reflected off the surface and collected by a telescope back at the instrument. The roundtrip time of transit of the pulse is recorded from which the range or distance from the instrument to the surface can be calculated. For bare earth targets, for example, unvegetated ground, this distance from the sensor can then be converted to an estimate of topographic elevation relative to the Earth's geoid. For vegetated surfaces, the incident pulse reflects off canopy elements, providing a single range or a series of ranges to one or more portions of the canopy, depending on sensor design and configuration.

Lidar systems used for land surface observation may be distinguished by several characteristics, including footprint size, return signal digitization, pulse rate/scanning pattern, and wavelength.

There are two classes of footprint size in use, "small" and "large". By far, most lidar systems are small-footprint, where the incident beam has a diameter of centimeters to tens of centimeters at the surface. Almost all commercial systems collect such small-footprint data. In contrast, there are a few research systems, most notably the Scanning Lidar Imager of Canopies by Echo Recovery (SLICER, Harding *et al.*, 1994; Blair *et al.*, 1994), the Laser Vegetation Imaging Sensor (LVIS, Blair *et al.*, 1999), and the Geoscience Laser Altimeter System (GLAS, Schutz, 1998), that are large-footprint. With these instruments, footprint diameters are on the order of tens of meters, depending on configuration. For example, LVIS can operate at a variable footprint sizes, from about 5–50 m, whereas GLAS, a space-based lidar, has a large-footprint size of about 120 m.

Pulse rates and scanning patterns also vary with systems. Commercial small-footprint systems commonly operate at frequencies between about 1000 and 30 000 Hz, but have recently gone as high as 100 000 Hz. These instruments have variable scanning patterns (e.g. transect, gridded, or helical). Furthermore, these sensors are not imaging, instead they fire large numbers of pulses in close proximity to sample densely and recreate the surface being flown over. Generally, there is a trade-off between the sampling density required and the scanning width (or swath): high-density sampling will require a high-pulse-rate system and a tighter scanning pattern to reduce spaces between adjacent footprints. In well-vegetated landscapes, filtering algorithms are used to detect the bare earth signal in the data. Typically, significant overlap is needed in successive flight lines to obtain sufficient canopy penetration to characterize the bare earth topography.

The two large-footprint systems in use, LVIS and GLAS, are quite different. LVIS is an airborne scanning/imaging system, laying down adjacent-, along-, and across-track footprints within a 1–2 km wide swath. GLAS is space-based and has a pulse rate of 40 Hz with footprint spacing of 165 m along track, and variable across-track spacing as function of latitude (e.g. 15 km across track at the equator, with track separation decreasing towards the poles).

Return signal digitization is an important feature of lidar systems. Most commercial systems do not fully digitize the return signal, but rather record energy at various points. Common systems in use today are first-, last-, first-and-last-, and multiple-return systems. For example, a system that records first and last returns would provide a range to the surface for the first surface intercepted, say some portion of the canopy top, and the last surface intercepted, somewhere inside the canopy or possibly the ground below the canopy. Other systems, such as LVIS, digitize the entire record of reflected energy, resulting in what is commonly referred to as a *waveform*. The incident pulse fired from the laser is Gaussian in shape. As this Gaussian pulse is reflected off leaves and branches, the returned (non-Gaussian) waveform is fully digitized at some appropriate vertical resolution, for example, every 50 cm.

Small-footprint systems are used primarily to record topography but have also been employed extensively to map forest structure (Nelson *et al.*, 1984; Maclean and Krabill, 1986; Nelson *et al.*, 1988; Naesset, 1997; Nelson, 1997; Magnussen and Boudewyn, 1998; Gaveau and Hill, 2003). Small-footprint systems can be used in low flying airplanes or helicopters to obtain bare earth data density, which in grassy areas, is less than 1 point per square meter

continuously over large areas. Typically small-footprint systems record first and last return, although multireturn systems are becoming commercially available. In either large- or small-footprint systems, filtering algorithms must be used to distinguish true ground surface from vegetation. As mentioned later, much work is under way to develop filtering and classification algorithms (e.g. Barber and Shortridge, 2004; Sithole and Vosselman, 2004).

Figure 1 shows the measurement basis for multiple-return, small-footprint systems. A system designed to record more than one return may register multiple signals from a single tree crown; from a combination of crown material, woody material, and shrub layer, and/or from the ground. These returns from differing elevations can be analyzed statistically (e.g. through cluster analysis) to organize the data into canopy, understory, and ground.

Waveform digitization systems, regardless of footprint size, may improve ground detection because the entire signal is digitized. Furthermore, large-footprint systems, especially imaging systems such as LVIS, do not have the sampling issues present in the crown-detection problem mentioned above, that is, they completely map all portions of the canopy top so that no crowns are missed. However, in both large- and small-footprint systems, the sensitivity of the system is a critical parameter as it determines the minimum area perceivable by the sensor. In the case of large-footprint systems, this means that there must be sufficient leaf material at a particular height so that enough photons are returned above a background noise level. In both large- and small-footprint systems, the beam may penetrate a distance into the canopy before enough material is encountered to produce a strong enough reflected signal.

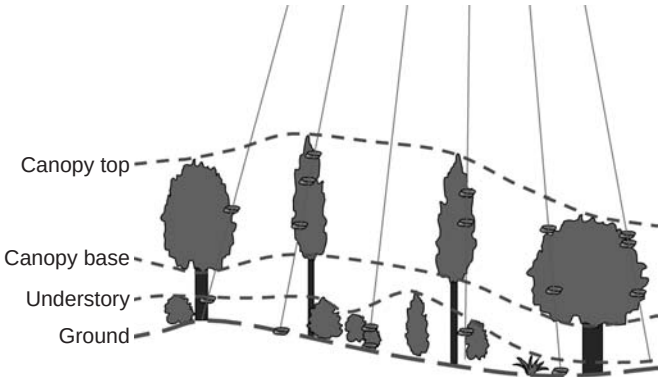

Figure 1 Schematic illustrating the basic principles behind a multiple-return, small-footprint system. The returns may register multiple signals from either a single crown; from a combination of crown, woody or shrub material; and/or from the ground. These returns can be analyzed statistically to organize the data into canopy, understory, and ground. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

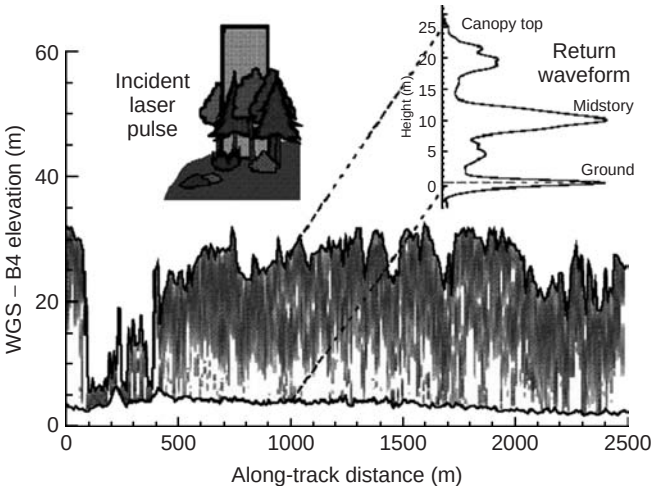

Figure 2 A conceptual drawing depicting the basic principles of large-footprint, waveform-digitizing lidar systems. The incident pulse of laser energy reflects off the canopy material and the ground beneath. The strengths of the amplitudes in the return waveform correspond to the amount of canopy material present at any given height in the canopy. The top of the canopy, the first-return above the background noise threshold, and ground location, the peak of the last return above the noise threshold, are also shown. Canopy height is the difference in elevation between the ground and the canopy top. The profile derived from actual lidar waveform data shows the organization of canopy material both horizontally and vertically; the darker shades correspond to areas with more canopy material, lighter shades to those with less, and clear areas with no canopy, such as in the subcanopy airspaces. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Figure 2 is a conceptual drawing illustrating the basic principles of large-footprint, waveform-digitizing lidar systems, that is, the strengths of the amplitudes in the waveform correspond to the amount of canopy material present at any given height in the canopy. The profile in Figure 2 clearly shows how the waveform data can be aggregated to provide a three-dimensional picture of the horizontal and vertical structure of the forest canopy.

DESIRED LAND SURFACE PARAMETERS FOR HYDROLOGICAL MODELING AND MONITORING

Land surface characteristics are important for hydrological modeling and predicate many of the parameters that control hydrological processes. Virtually every aspect of both the transfer of mass and energy transfer between the surface and the atmosphere, as well as the energy and water balance of the surface alone, is mediated by the characteristics of the land surface and its underlying topography. For example, evapotranspiration and turbulent transfer, short

and longwave energy fluxes, photosynthetic rates, rainfall interception, stemflow, throughflow, and runoff, are all affected by the characteristics of the vegetation and terrain of the area being modeled.

Most land surface structure characteristics are not easy to measure. Field sampling provides accurate data; however, the information gathered through field work is time consuming, expensive to obtain, and covers very limited areas. Remote sensing technology is frequently used to derive forest structure to avoid these issues. Lidar, in particular, is especially suited for the measurements of forest stand characteristics and is able to measure those characteristics from which the hydrological variables are derived. Dubayah *et al.* (2000), Dubayah and Drake (2000), and Lefsky *et al.* (2002) summarize much of this work for large-footprint systems.

Land surface parameters may be derived from lidar in one of three ways. First, some parameters, such as canopy height, may be obtained through direct retrievals from lidar signals. Second, other parameters may be retrieved through modeling, either statistically or using physics-based models such as radiative transfer models. For example, biomass is almost always retrieved through the creation of statistical relationships between ground-based measures of biomass and lidar returns. Third, other parameters may need a combination of data from various sensors, so-called *remote sensing fusion*, for retrieval. Table 1 lists various land surface characteristics that have been successfully obtained from lidar. In this review, we will focus on forest attributes most important for hydrological applications: canopy height, canopy height and foliar profiles, canopy cover and LAI, biomass, height to live crown (HTLC), large tree density, and basal area. In addition, we briefly review the retrieval of topographic structure from lidar.

FOREST STRUCTURE FROM LIDAR

Canopy Height

Canopy height is perhaps the most important land surface characteristic derivable from lidar not only because of its relevance for hydrological modeling, for example, aerodynamic roughness, but also because it is the most difficult to obtain through other remote sensing methods. Canopy height is a relatively direct and straightforward measurement for lidar systems. This is because canopy height is simply the difference between the ground elevation and the top of the canopy. For large-footprint waveform data, the top of the canopy is defined as the height of the first signal above the noise threshold of the waveform. The ground is defined as the peak of the last return (see Figure 2). Gridded height data from scanning large-footprint systems yield a unique view of canopy structure and increase the ability to distinguish between land cover types (Figure 3). Height estimation with small-footprint systems is somewhat more complex and generally requires the creation of interpolated ground and canopy surfaces created from first and last return signals. These two surfaces can then be differenced to calculate the canopy height. With sufficient sampling, individual trees and their heights can be determined (refer to Figure 1). If wall-to-wall sampling by a lidar system, either small- or large-footprint, is not available for an area, then integration of other remote sensing data with more extensive coverage may help extrapolate height information for a larger area (e.g. see Hudak *et al.*, 2002).

Both large- and small-footprint systems retrieve canopy height with errors of a few meters (Nelson *et al.*, 1988; Nilsson, 1996; Magnussen and Boudewyn, 1998; Means *et al.*, 1999; Lefsky *et al.*, 1999a; Hyde *et al.*, In press).

Table 1 Potential of lidar for deriving forest structure characteristics

Land surface characteristic	Lidar derivation
Canopy height	Direct retrieval
Vertical distribution of intercepted surfaces	Direct retrieval
Canopy cover / LAI	Direct and modeled
Canopy height profile	Modeled
Foliar height profile	Modeled
Biomass	Modeled
Height to live crown	Modeled
Large tree density/Basal area	Modeled

Figure 3 Image showing gridded height in Costa Rica in and around a portion of the La Selva Biological Station. The lighter shades indicate taller canopies, blues and greens short. In the image, one can detect a band of vegetation on both sides of the river running through the top portion of the image. The height data improve the identification of land use, especially in conjunction with ancillary data. The northwestern boundary of La Selva is visible where regenerating and secondary forests abut against fields and pasture land. The nearly rectangular area of taller vegetation along the eastern edge of the figure shows a privately owned old-growth forest stand. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Large-footprint systems in particular have been tested in a variety of forest conditions and have successfully recovered canopy height in deciduous, broadleaf forests (Lefsky *et al.*, 1999a), dense conifer forests (Means *et al.*, 1999), and more open conifer forests (Hyde *et al.*, In press). It has been suggested that for small-footprint systems, a combination of sampling density and sensor sensitivity (especially in broadleaf forests) are the dominant factors leading to height recovery biases, whereas for large-footprint systems, sensitivity alone is most important. Insufficient sensitivity can cause the laser energy to penetrate some depth into the canopy before registering a signal, thereby causing an underestimation of the canopy height (Gaveau and Hill, 2003). The sensitivity of the system also determines the likelihood of ground detection. In very closed canopies where closure approaches 99% or greater, systems must have sufficient power to penetrate to the ground with enough energy to provide a clear return pulse from the ground, but not so much that high-amplitude signals from the canopy saturate. Furthermore, height underestimation associated with large-footprint sensors can also be correlated with the location of the tallest trees relative to the footprint center (Hyde *et al.*, In press). Sensitivity may not be as strong at the footprint edges, causing the sensor to register a lower height, especially in sparse forests with conical crowns (e.g. conifers). Some of the additional biases that result from crown shape may be corrected through calibration efforts (Nelson, 1997).

Canopy and Foliar Height Profiles

The vertical distribution of canopy material affects mass and energy at and near the surface. The return waveform of fully digitizing lidar systems records the near-nadir reflections from the vertical distribution of intercepted surfaces (VDICS); indeed, this is the most basic measurement of such systems as shown in Figure 2. The relative strengths of the amplitudes of the return waveform may be used to infer the relative amount of canopy material (leaves and branches) that occur at any height (Harding *et al.*, 2001). However, as lidar energy passes through the canopy, it is attenuated so that there is less energy at lower levels in the canopy. Potentially, therefore, returns from the lower portion of the canopy may be smaller relative to the upper portion, not because of actual differences in canopy material but because of less incident energy. This effect can be adjusted for using the so-called MacArthur–Horn transformation (Means *et al.*, 1999; Lefsky *et al.*, 1999b; Harding *et al.*, 2001). The use of this transformation to increase the relative amplitude of lower portions of the signal is generally limited to canopies that meet relatively strict requirements of horizontal and vertical homogeneity. Once the transformation has been applied, the adjusted waveform is often referred to as *canopy height profile* (CHP), as opposed to the distribution of just the leaf material which is called the *foliar height profile* (FHP), neither one of which is necessarily identical to the VDICS. In retrieval of CHP in canopies that are clumped or relatively open, for example, coniferous stands, use of the MacArthur–Horn transformation is not well established. Derivation of the FHP is more difficult and is dependent on additional information about the canopy, including architectural variation, leaf and branch reflections, leaf orientation, as well as the shading effects mentioned earlier. Drake *et al.* (2002b) derived CHPs for lidar waveform data from Costa Rica and compared these to crown volume profiles calculated from field data. The two sets of profiles, representing different forest types, showed fairly good agreement, as did the metrics derived from both. In another study, Parker *et al.* (2001) demonstrate how lidar-derived CHPs can be used to infer light transmittance through a canopy.

Canopy Cover and LAI

Canopy cover and LAI are frequently used in hydrological modeling in deriving various aspects of the energy and mass balance and are also to infer rainfall interception rates by the canopy. Algorithms for determining canopy cover from large-footprint lidar are based on determining the relative amount of energy in the canopy portion of the return as opposed to the energy in the ground (Figure 4). For example, if the ground return contains 25% of the total energy in the waveform, then a canopy cover of approximately 75% may be assumed. Derivation of canopy

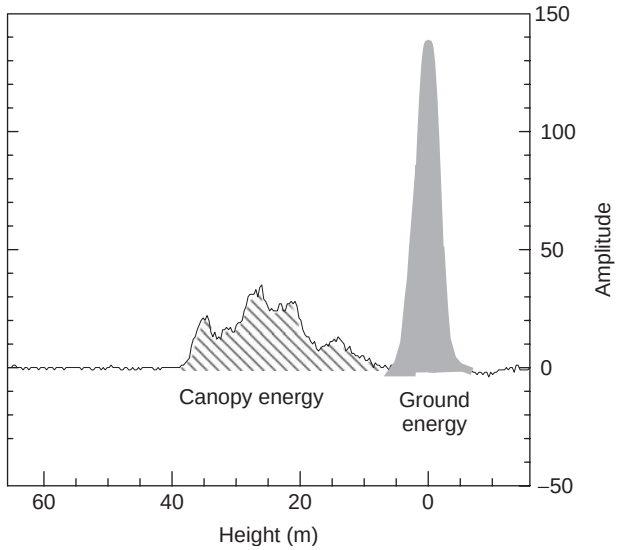

Figure 4 A diagram showing an individual lidar waveform. The waveform consists of a return from the ground (hatched) and from the canopy (grey). Canopy cover can be estimated by determining the ratio of the energy contained in the canopy return to the amount of energy in the ground return. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

cover in this way is dependent on knowing the relative reflectance of the ground and canopy in the wavelength region of the lidar. Retrieval of LAI requires further assumptions (e.g. see Lefsky *et al.*, 1999b).

Biomass

The study of the cycling of water and carbon through forested watersheds requires knowledge of both the current carbon status of the forest, as well as its successional state. Above-ground biomass (AGBM) is about 50% carbon. When this information is combined with successional status gleaned from the distribution of heights in the forest, it provides a powerful initialization of land surface state required for modeling energy, water and mass balances, including carbon.

Canopy height is the simplest lidar metric for predicting AGBM. Tree diameters generally increase as trees get taller, and there have been thousands of studies that have modeled the nonlinear allometric relationships between AGBM and tree diameter and height. Many small-footprint lidar studies have produced accurate predictions of biomass utilizing height alone. Other metrics derived from lidar waveforms may also be used (Lefsky *et al.*, 1999a,b; Drake *et al.*, 2002a; Hyde *et al.*, In press). For example, Drake *et al.* (2002a) used an energy metric, the lidar height of median energy (HOME) to explain almost 90% of variability in AGBM in a tropical forest (Figure 5) and to create a map of biomass (Figure 6). Other methods may use a combination of lidar metrics and other remote sensing and ancillary data. In any case, the prediction of biomass in high-biomass areas, where traditional remote sensing techniques have not fared well, is one of the most spectacular successes of lidar remote sensing.

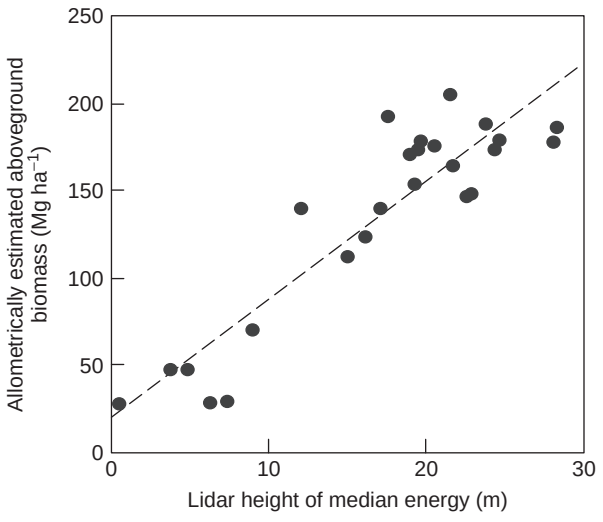

Figure 5 Results of a regression analysis using the LVIS HOME metric to predict AGBM for a series of plots in the rainforest at La Selva Biological Station in Costa Rica (Drake *et al.*, 2002a). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Height to Live Crown

HTLC is the height above the ground where the first living canopy material occurs. When combined with canopy height, it determines canopy depth and volume. It also delineates the subcanopy airspace, which is an important parameter in many land surface models. In theory, the lower edge of the canopy should be observable by lidar, provided it is a relatively sharp boundary, the canopy is relatively uniform, and there is sufficient energy in the waveform at that depth. In practice, this boundary may be difficult to detect, especially in closed forests or forests with a heterogeneous structure. For stands that are more dense and complex, it may be necessary to statistically model HTLC from lidar metrics. Furthermore, without ancillary information either from other remote sensing data or life form knowledge, lidar cannot distinguish between live and dead canopy material. A parameter closely related to HTLC, canopy base height (CBH), has been modeled from a combination of lidar metrics for a variety of forest types in the Sierra Nevada, comparing relatively well, to ground-based estimates ($r^2 = 0.59$) (Peterson *et al.*, 2003). These results are encouraging as they represent one of the few successful efforts to recover CBH from remote sensing. However, background noise, the presence of an understory, slope, as well as the architecture of the canopy itself can limit retrieval of both HTLC and CBH.

Large Tree Density and Basal Area

Tree density and basal area affect such hydrological parameters as aerodynamic roughness and overland flow, in addition to their ecological significance. Because lidar instruments provide measurements of canopy structure, it is possible to identify individual large or emergent tree crowns. Small-footprint systems that have sufficient sampling density can be used to visually identify individual crowns (Figure 7), or image segmentation methodologies may be employed to delimit tree crowns (Moorsdorf *et al.*, 2004). In contrast, large footprints may encompass several crowns, although histograms of canopy heights can be used to infer the frequency of large trees, especially emergent trees. However, other studies have shown good statistical relationships between large-footprint data and a variety of attributes related to tree density, including basal area and stem diameter (Drake *et al.*, 2002a; Lefsky *et al.*, 1999a,b; Means *et al.*, 1999). Drake *et al.* (2003), for example, found that the HOME metric alone accounted for up to 92% of variability of stem diameter and up to 70% of variability in basal area for two different tropical rainforest sites (Figure 8).

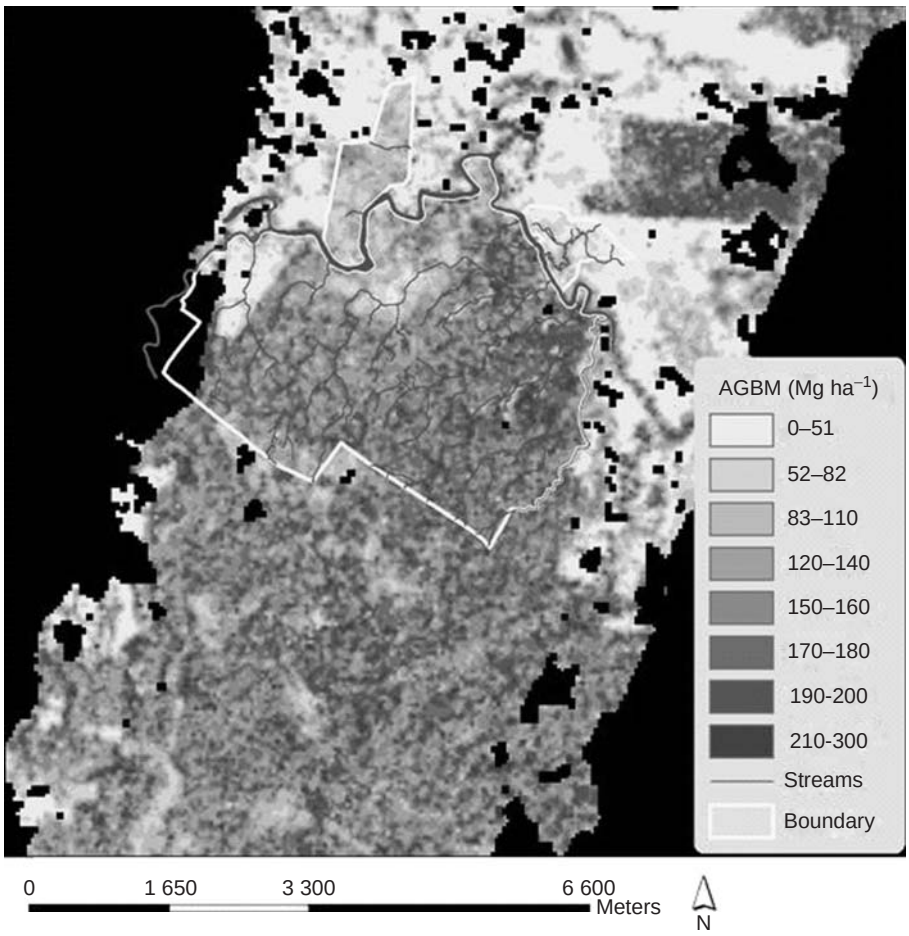

Figure 6 AGBM as derived from the HOME metric calculated from LVIS waveform data (from Drake *et al.*, 2002a). The image shows higher AGBM for the primary forest areas in the southern and eastern parts of La Selva and in Braulio Carrillo National Park to the south. The western parts of La Selva contain secondary and regenerating forests, with markedly lower AGBM values. Much of the land surrounding La Selva is agricultural and therefore also characterized by low AGBM values. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Radiative transfer methods may also be used to recover tree densities within large footprints (e.g. see Ni-Meister *et al.*, 2001). Waveform data can be input into a radiative transfer inversion model to calculate canopy structure characteristics such as stem density and LAI. This process is more complex than relying on statistical models to predict the structural characteristics of interest. However, the use of radiative transfer theory to infer canopy structure from lidar may result in the development of more generally or globally applicable models, thereby reducing the need for the ground-based data required to develop the more common statistical models.

GROUND TOPOGRAPHY FROM LIDAR

Small footprint, fixed-wing or helicopter-based laser swath mapping can provide elevation data of the ground surface over large areas with a spatial resolution of 1 m or better, a

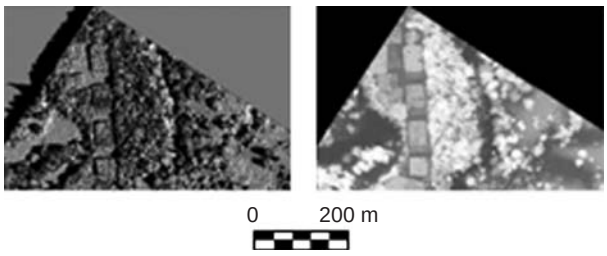

Figure 7 A small-footprint, first-return lidar system (FLIMAP, developed by John E. Chance and Associates, Louisiana) mapped a portion of the La Selva Biological Station in Costa Rica. The samples were gridded to a 1-m resolution. In this image, lighter tones signify higher elevations. Individual tree crowns are clearly recognizable. The rectangular features represent experimental agroforestry plots. A synthetic reflectance image (b) is created by illuminating the DEM on (a), and shows the remarkable canopy structure detail available from small-footprint systems

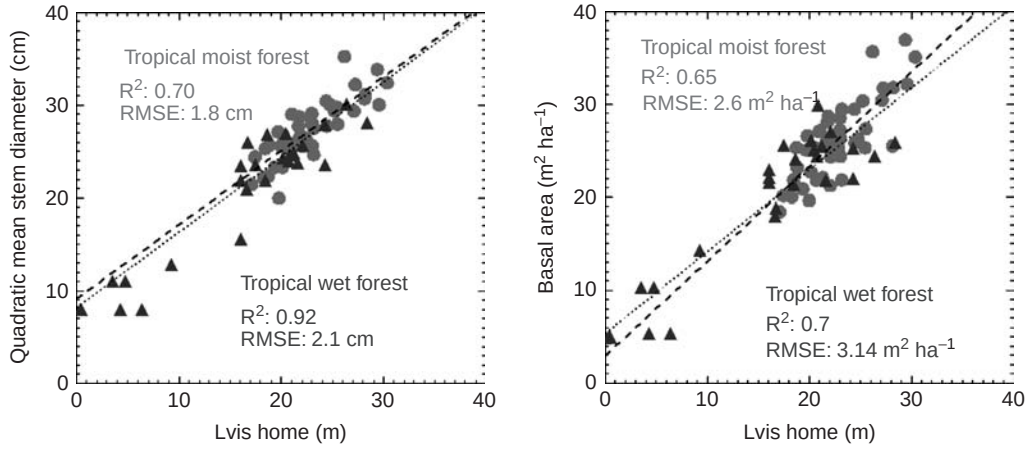

Figure 8 Results of regression analyses comparing lidar-derived HOME to quadratic mean stem diameter and basal area for two different topical rainforest study sites in Panama (circles, dashed line) and Costa Rica (triangles, dotted line) (Drake *et al.*, 2003). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

vertical accuracy of 5–10 cm, and a horizontal accuracy of 15–20 cm (Carter *et al.*, 2001). Such unprecedented topographic data promises to revolutionize the studies of hydrology and geomorphology (as well as all other fields that use ground topography). To obtain accurate high-resolution maps from such surveys, however, it is not simply a matter of installing a laser in a plane and flying it around, as considerable care and skill is involved in accurately tracking the plane and its motion (to provide the GPS-based elevation of the laser relative to the ground), calibrating the laser (which must be done for all surveys), and filtering the recovered data to remove vegetation, bridges, buildings, and other features that obscure the topography. Also, if systematically high-resolution data are to be acquired, especially in hilly or mountainous vegetated landscapes, flight lines must have considerable overlap (preferably at least 50%).

The greatest challenge in assembling a high-resolution topographic map from an airborne laser swath survey is the detection of bare earth data in the "point cloud" of all the return data acquired (Figure 9). Much research is under way to develop software that can remove vegetation, buildings, and other features without eliminating critical topographic attributes such as channel banks (e.g. Filin, 2004; Luzum *et al.*, 2004; Brovelli *et al.*, 2004). In areas with variable vegetation cover (e.g. combinations of hardwood, softwood, brush, agricultural fields, etc.), bare earth filtering procedures may be improved by conditioning them by the vegetation type. Included in the return data is the intensity of the signal, and this intensity varies with surface conditions, which may also be used to improve filtering strategies. Once the bare earth data have been generated, the resultant topography will depend on the procedure used for gridding the data. Hence, while high-resolution data fields can now be generated, there is still considerable art to optimizing the analysis of these data to get the most artifact-free realization of the surface topography. Given the challenges of obtaining high-resolution ground data under vegetation, low return-density and errors associated with rugged landscapes,

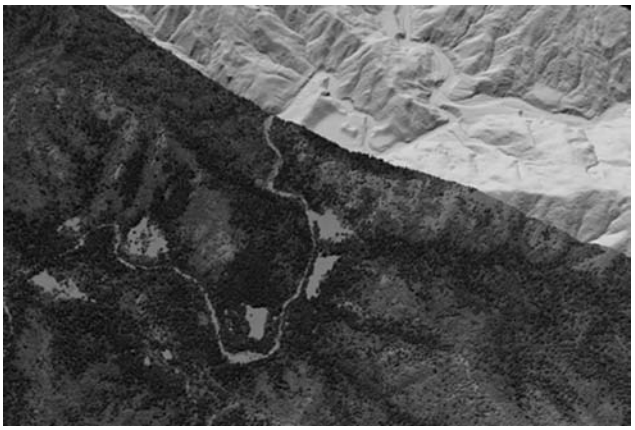

Figure 9 Digital image of the Angelo Reserve on the South Fork Eel River, California derived from data collected by the National Center for Airborne Laser Mapping in 2004 as part of a National Center for Earth-surface Dynamics study. Canopy surface and filtered ''bare earth'' data were computed and the difference in elevation between points was shaded: 1 m or less is light grey, from 1 m to 30 m, the shades are increasingly dark, representing greater differences. This accurately shows the spatial variation in vegetation from brush on the exposed hillslopes to Douglas-fir and Redwoods in the valley bottoms. The narrow brown sinuous line is the South Fork Eel River and adjacent to it our brown colored meadows. In the upper corner, the vegetation has been removed, revealing the bare earth topography in this shaded relief map. The diagonal distance from lower left to upper right corner is about 4 km. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

and the still-developing art of data analysis, it is essential that the potential user of such data be actively involved in data evaluation before using it in some project. Major artifacts are easily detectable by simple inspection of topographic maps, shaded relief maps, and plots of bare earth data distribution (ungridded) across the study area.

Of particular relevance to hydrology, high-resolution topographic maps from airborne laser swath maps provide for the first time the actual topography of the channel network over large areas. In nearly all digital elevation models used in hydrologic models, channels are defined as occurring in cells that drain some threshold area, and the size (width and bankfull depth) of the channel is specified by an assumed relationship between channel scale and drainage area (derived from hydraulic geometry observations, i.e. Leopold and Maddock, 1953). Even in the 10-m gridded United States Geological Survey maps, the valleys in which the finest scale channels occur are often not accurately shown (or are simply absent), and the relatively large channels are usually represented by two lines delineating the location of the channel banks. Drainage density affects runoff response (e.g. Beven and Kirby, 1993), and channel topography affects flow routing. Now, with high-resolution airborne laser swath mapping data, the channels on digital terrain maps are actual topographic features, with distinct heads, banks, and topography (Figure 10).

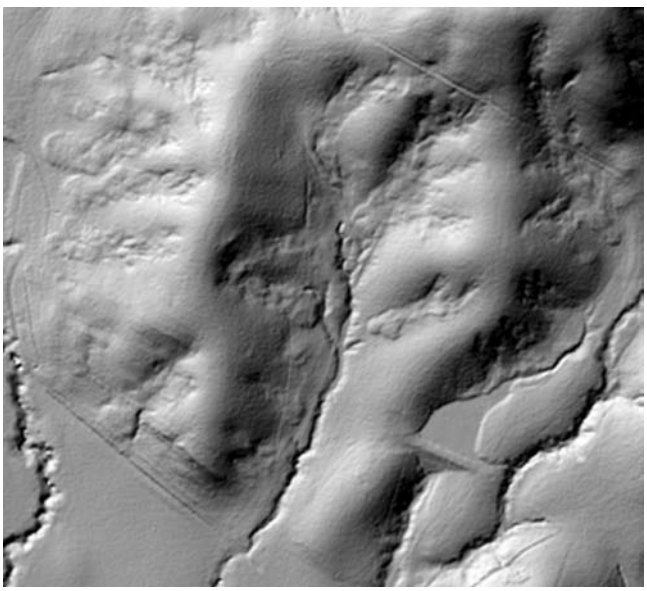

Figure 10 Shaded relief map of a portion of the Napa River watershed revealing landslides, roads, channels, channel heads, and reservoirs. High-resolution airborne laser swath mapping data are for the entire 1100 km^2 are available for download at **http://calm.geo.berkeley.edu/ncalm/index.html** as part of the National Center for Airborne Laser Mapping. Reservoir embankment is about 70-m long

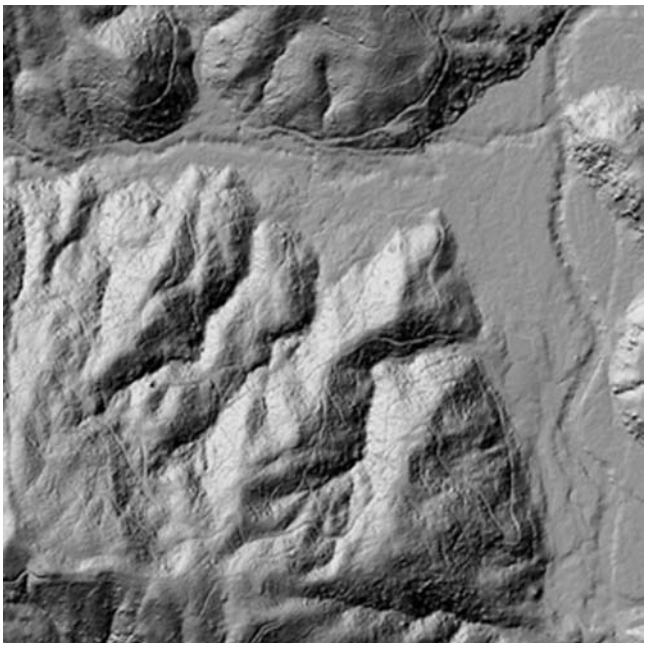

Figure 11 A shaded relief map showing a portion of the South Fork Eel River area outside the Angelo Reserve where a dense network of logging roads and skid trails have been cut across the landscape. Distance from top to bottom of the page is about 1 km. Such road densities may have a long lasting influence on runoff rates

Such high-resolution data detect the topographic presence of dams or even small agricultural reservoirs (Figure 10) and are ideal for accurately quantifying the extent and topography of roads and logging skid trials (Figure 11), which cumulatively in a watershed, may have long-term effects on peak flows (e.g. Jones and Grant, 1996) and sediment loading. A new challenge, however, is that this well-defined road network typically frequently crosses smaller channels via culverts. Lidar does not detect culverts (though the culvert location may be inferred from the adjacent of channel and elevated road bed in some cases) and consequently the roads breakup the channel network. Hence, to create an accurate channel network, either topographic connection across roads must be done by hand in the data, or software must be developed that does this automatically (Barber and Shortridge, 2004).

One of the most widespread applications of lidar in hydrology has been for floodplain mapping and there have been extensive areas overflown for this purpose (especially in Louisiana) (e.g. Pereira and Wicherson, 1999; Barber and Shortridge, 2004). In modeling floods on the River Severn, Cobby *et al.* (2003) found that lidar improved predictions with its more accurate topography because it enabled them to decompose a finite-element mesh to account for vegetation-dependent frictional properties.

Airborne laser swath mapping has enabled the testing and parameterization of theories for soil transport, hillslope evolution, and channel incision (Roering *et al.*, 1999; Stock and Dietrich, 2003). It may eventually lead to greatly improved landscape evolution models. Given the strong dependency of landslides on topography, high-resolution topographic data can greatly improve landslide potential maps (e.g. Dietrich *et al.*, 2001). Such topographic data are proving invaluable in detecting and tracing faults (e.g. Hudnut *et al.*, 2002; Sherrod *et al.*, 2004). These early accomplishments point to a large influence of airborne laser swath mapping on earth sciences.

High-resolution topography presents new challenges and opportunities to watershed runoff models. Should variable grid size models, or models based on irregular triangular networks, be further developed so that the fine-scale topography of critical features, such as channels, can be preserved while coarser scale cells can be used to characterize slowly varying topography, such as floodplains? How can the fine-scale topography be best exploited to improve hydrology modeling? Bates *et al.* (2003), in discussing numerical models of river flooding, have noted: "A newly emergent research area, therefore, is how to integrate such massive data sets with lower-resolution numerical inundation models in an optimum manner that makes maximum use of the information content available". French (2003) has argued that the high-resolution topographic data allows the modeler to focus on the physical mechanisms and parameterization by reducing geometric uncertainty. In the past, numerical models suffered from the crude topographic data available to them; now their use is made problematic because the resolution exceeds their abilities.

This article has focused on small-footprint lidar and the fine-scale topography it can provide. Large-footprint, waveform digitization lidar avoids some of the problems of filtering mentioned above. Such lidars measure topography under the canopy directly, provided there is sufficient energy in the ground return. Hofton *et al.* (2002) showed that LVIS successfully measured subcanopy topography at the La Selva Biological Station in Costa Rica where the canopy cover was often 99% or above. LVIS penetrated the dense canopy to measure the elevation of the surface beneath providing a unique picture of the highly variable terrain present beneath the canopy.

The coming years may produce a confluence of these two technologies, as large-footprint systems decrease their footprint size and small-footprint systems add waveform digitization. Ultimately, the choice of waveform versus multiple-return, and large versus small-footprint sizes will be determined by the particular topographic mapping application.

SUMMARY

Over the last three decades, remote sensing observations have been used to obtain the detailed information about land surface state required for hydrological analyses. During this time, land surface hydrological models have increased in complexity, in spatial and temporal resolution, and in areal extent, placing even greater demands on the accuracy and reliability of the land surface characterizations needed to both parameterize and drive them. Lidar remote sensing provides a new and revolutionary means of obtaining many of the surface descriptors, especially those related to the vertical structure of the canopy and high-resolution topography, which have proven difficult or expensive to derive by other means. The increased use of lidar in hydrological analysis will depend on many factors. First, because lidar is a new technology, its theoretical underpinnings must be further developed by more studies which link observations to physically based models of the radiative transfer of lidar energy through canopies (such as shown by Ni-Meister *et al.*, 2001; Sun and Ranson, 2000; Kotchenova *et al.*, 2004). Second, its efficacy must be further demonstrated across a gradient of environmental conditions and for a broader spectrum of applications. Third, an accompanying evolution of hydrological model structure as well as surface parameterization must be achieved. For example, virtually no model can ingest the vertical structure from lidar directly (because it has not been available). Hurtt *et al.* (2004) have shown how a model that is specifically height-structured could assimilate lidar data directly to initialize land surface states, and greatly extended model predictability. Similarly, model parameterizations need to be rethought. Aerodynamic roughness and infiltration potentially are much better parameterized using the actual profile of canopy material, rather than canopy height and LAI, respectively. Similar problems exist matching the current state of runoff models with the new high-resolution data in which to embed them. Last, the fusion of lidar observations with other, more readily obtained remote sensing data must be explored. Extensive spatial coverage on a regional basis, let alone on a continental or global scale, is probably at least a decade away. In the meantime, the development of algorithms that marry the vertical structure from lidar with a variety of spatially continuous data, such as multi- and hyperspectral, multiangle, and radar observations should be a priority.

Acknowledgments

The authors would like to thank J. Bryan Blair, Michelle Hofton, and Jason Drake for useful inputs included in this chapter, especially pertaining to the deployment and operation of the LVIS instrument and the collection and analysis of lidar data. Dubayah is supported through funding from the NASA Terrestrial Ecology Program. Dietrich

is supported by the National Center for Airborne Laser Mapping (NCALM) and the National Center for Earth-surface Dynamics (NCED).

59: Estimation of Soil Properties Using Hyperspectral VIS/IR Sensors

ALFREDO R HUETE

Department of Soil, Water and Environmental Science, University of Arizona, Tucson, AZ, US

Knowledge of soil properties and processes are crucial to the understanding of the terrestrial hydrologic cycle and the functioning of terrestrial ecosystems. In this paper, we present the current state and potential of hyperspectral remote sensing techniques for quantitative retrieval of soil properties. Remote sensing is used to detect chemical and physical soil properties either (i) directly from the bare soil pixels, (ii) through advanced spectroscopy methods in mixed "soil-vegetation-litter" pixels, and (iii) by measurements of the overlying vegetated canopy to infer soil properties and moisture status. Optical-geometric properties of soil surfaces reveal information on soil physical features, such as soil structure, crusting, and erosion. We also investigate the use of vegetation water indices to infer soil drying and wetting in the soil root zone. We conclude with a discussion on future needs and directions for remote sensing of soil properties.

INTRODUCTION

Soils are spatially variable, dynamic systems that develop from geologic parent materials under various climate regimes and biotic factors. Knowledge of soil surface properties and processes are crucial to our understanding of the terrestrial hydrologic cycle and the functioning of most terrestrial ecosystems. Relevant soil biotic and abiotic properties include organic matter and nutrient contents, mineralogy, texture and structure, albedo, and water holding capacity. These spatially variable properties form the *pedosphere* in which a complex suite of chemical, physical, and biological processes interacts with the biosphere, lithosphere, and atmosphere. The pedosphere serves as a *geomembrane*, influencing the movement and cycling of water, gases, nutrients, toxic compounds, and salts, with important consequences to water quality, energy balance, ecosystem health, wind and water erosion, and environmental health.

Upwelling reflected electromagnetic radiation in the visible (VIS, 400–700 nm), near-infrared (NIR, 700–1300 nm), and shortwave-infrared (SWIR, 1300–2500 nm) spectral regions provide quantitative information on terrestrial surface conditions of relevance to hydrology. The major factors influencing the interaction of electromagnetic energy with soil surfaces are (i) biogeochemical constituents such as primary and secondary minerals, organic compounds, and salts (Stoner and Baumgardner, 1981; Vitorello and Galvao, 1996); (ii) soil moisture (Bowers and Hanks, 1965; Baumgardner *et al.*, 1985); and (iii) optical-geometric effects involving texture, structure, crusts, and surface area (Irons *et al.*, 1992). The reflectance of a soil is dependent on the presence and amount of all absorbing constituents, including their interactions, for specific texture and structure conditions. Remote sensing of soil surfaces from aircraft and space-based platforms also involve more complex environmental factors such as atmosphere attenuation and scattering, topography and illumination variations, and the presence of litter and vegetation cover (Moran *et al.*, 1997). Early earth-observing satellite sensors provided only limited spectral information for remote sensing studies of soils. More recently, hyperspectral sensors and advanced spectroscopy and noise removal techniques offer much potential for quantitative retrieval of soil properties, for classifying soils, and for studying soil genesis processes and land degradation.

Remote sensing offers an easy method to collect spatial information on soil properties and vegetation canopy optical features, which provide indirect and integrated expressions of below-ground processes that can be used

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

to infer soil properties, as in the cases of geobotany and vegetation stress (Wessman, 1991; Ustin, 1999). In this paper, we discuss the uses of hyperspectral and optical-based remote sensing techniques for quantitative retrieval of soil properties. We then consider the spectral interactions and dynamics of water as it cycles through the soil surface, including the use of vegetation water indices to infer soil drying and wetting in the root zone. We also examine the optical-geometric properties of soil surfaces and their relationship to soil physical features, such as soil structure, crusting, and erosion, and conclude with a discussion on future needs and directions for remote sensing of soil properties.

SOIL BIOGEOCHEMICAL CONSTITUENTS

The most important constituents of the soil matrix are clay minerals, primary and secondary minerals, iron and aluminum sesquioxides, carbonates, gypsum, salts, humic substances, cellulose, and lignin. These chemical parameters affect the nature of the soil reflectance spectrum and are called "chromophores" by Ben-Dor *et al.* (1999). As examples, the type and relative amount of iron oxides in soils cause the red, brown, and yellow colors that are common in soils and used in soil classification (Baumgardner *et al.*, 1985). There are important iron absorption bands at 870 nm (ferric iron) and 1000 nm (ferrous iron) and there is decreasing reflectance in the 500- to 640-nm region with increasing iron contents. The iron mineral hematite has an absorption band extending to the 550-nm region and yields a reddish soil color while the iron mineral goethite gives the soil a yellowish appearance. The presence and type of iron oxides in soils are strongly related to soil weathering processes, climate regime, and the vegetation in which the soils develop. Latz *et al.* (1984) and Palacios-Orueta and Ustin (1998) found significant spectral variations due to iron oxide and organic matter content, which were useful in mapping erosion class and weathering condition.

Other mineral spectra of relevance in soils include kaolinite with a strong absorption feature at ~2200 nm attributed to hydroxyl ion that also yields absorption at 1450 nm. Gibbsite has an absorption feature at 2265 nm (Madeira Netto, 1996) and carbonates, such as calcite, have small absorption features at 2350 and 2360 nm (Ben-Dor and Banin, 1990). Most of these chemical chromophores in soil reflectance spectra are related to vibration of chemical bands and the charge transfer of ions (Ben-Dor *et al.*, 1999).

Soils, however, are generally complex mixtures of numerous mineral and organic constituents with overlapping absorption features making it very difficult to predict mineral and organic abundances based solely on spectral absorption features. Stoner and Baumgardner (1981) measured hundreds of soil samples in the laboratory and visually noted distinct spectral signature shapes, related to the iron oxide, organic matter, and textural attributes of the soils (see Figure 1). Soils devoid of appreciable amounts of iron and organic matter exhibited featureless and "convex" spectral signatures of increasing reflectance with wavelength. Soils with higher organic matter contents displayed "concave" spectral signatures, while soils with low and moderate quantities of iron oxides formed "sigmoidal" spectral signatures with strong absorption features in the blue–green part of the spectrum (Figure 1). The analysis of characteristic spectral signatures, however, yielded only a limited amount of knowledge on soil properties relative to the information content present (Kimes *et al.*, 1993). Huete and Escadafal (1991) found many variants even within one curve type, associated with selective absorptions in the visible spectrum caused by iron oxides.

Soil organic matter (SOM) influences the spectra of soils throughout the VIS to SWIR with numerous absorption features associated with vibration modes of organic functional groups (Henderson *et al.*, 1992; Ben-Dor *et al.*, 1999). The organic matter content in soils is composed of live and dead organisms, rootlets, and litter at varying stages of decomposition, and plays an important role in the water holding capacity, nutrients, and structural properties of a soil (Jenny, 1980). SOM contents range from trace amounts to 80% or more in peats and mucks. The overall behavior of SOM is to decrease reflectance throughout the optical portion of the spectrum, particularly in the VIS-NIR. Increasing amounts of organic matter coat soil particle surfaces and mask out mineralogic spectral features. When SOM exceeds 2%, they effectively mask mineralogic absorption features and may saturate soil particle surfaces, such that it becomes difficult to assess further variations in SOM contents. Dematte *et al.* (2003) showed that

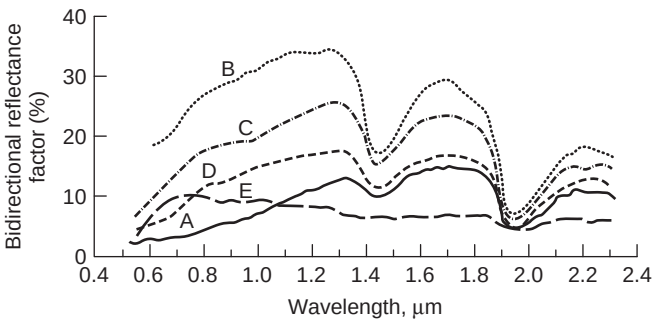

Figure 1 Five basic spectral reflectance curve shapes based on iron and organic matter contents. A – organic dominated soil, B – minimally weathered soil, C – iron-affected soil, D – organic affected soil, and E – iron dominated soil (Reproduced from Stoner and Baumgardner, 1981 by permission of Soil Science Society of America)

the removal of organic matter in soils caused reflectance increases in the VIS-NIR (450 to 1000 nm), with negligible changes from 1250 to 2400 nm. At the same time, other spectral features were observed with the greater exposure of goethite. Similar amounts of organic matter on different textures and particle surface areas will yield different spectral reflectance signatures.

Obukhov and Orlov (1964) and Baumgardner *et al.* (1985) distinguished among "fibric", "hemic", and "sapric" soil reflectance curves describing the stage of leaf litter decomposition and incorporation of plant material into the soil mineral horizon, with sapric being the most decomposed and fibric the least decomposed with recognizable plant material. There are a few spectral features present in undecomposed litter and other nonphotosynthetic vegetation (NPV) parts, associated with cellulose and lignins, including spectral absorptions at 1200 nm, 2175 nm, and 2300 nm with reflectance peaks at 2220 and 1648 nm (Gao, 1996; Asner and Lobell, 2000). In Figure 2, a set of soil and surface litter spectral signatures are shown for a field site in Brasilia National Park, Brazil. The subsoil spectra show a broad and intense iron absorption feature at 870 nm. This iron feature is present in the surface soil, but weaker, due to surface organic matter (5%) partially masking the iron feature. Also, one can see large differences in litter spectra in the SWIR region.

The presence of salts at the surface can be detected with remote sensing data either directly on bare soils, with salt efflorescence and crust, or indirectly through measures of the overlying and impacted vegetation (Mougenout *et al.*, 1993). Both the quantity and mineralogy of salts influence the spectral reflectance of the soil surface, but in manners dependent on soil moisture, color, and roughness (Metternicht and Zinck, 2003). In general, moderately to highly saline areas are easily detected, while low salinity levels and the initial stages of salinization are more difficult to discern. About 7% of the Earth's terrestrial surface and

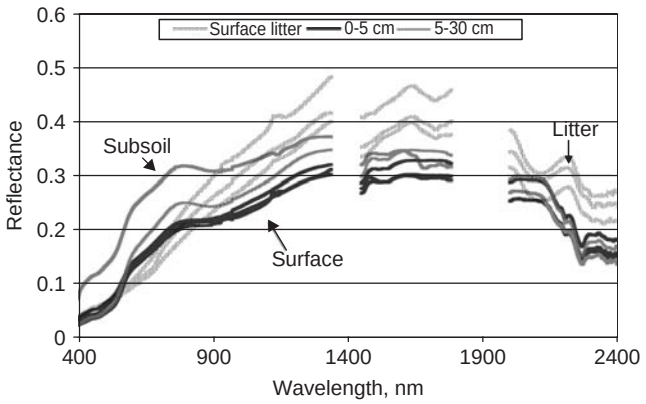

Figure 2 Sample spectral reflectance signatures of surface litter, surface soil (0–5 cm), and subsoil (5–30 cm) for a shrub cerrado site in Brasilia National Park, Brazil

20–30% of the world's irrigated lands are affected by salinity problems (Toth *et al.*, 1991) and soil salinity is a principal cause of soil degradation with negative impacts on water quality, soil structure, soil erosion, and vegetation production (Csillag *et al.*, 1993). Salinization occurs as salts (chlorides, sulfates, carbonates) of sodium, magnesium, or calcium accumulate in the root zone and move upward in the soil and are left at the surface as water evaporates.

For optical remote sensing, the possibility to identify salt-affected soils varies largely with moisture content, salt pureness, and spectral contrast with other spectral features. Salts generally have featureless spectra with no known narrow absorption bands linked specifically to salinity status (Ben-Dor and Banin, 1990; Csillag *et al.*, 1993). Crowley (1991) showed that many saline minerals exhibit diagnostic NIR absorptions mainly attributed to vibrations of hydrogen-bonded structural water, allowing the detection of minor hydrate phases within mineral mixtures dominated by halite. Dehaan and Taylor (2002) found salinized soils in the Murray-Darling Basin of Australia to have distinctive spectral features in the VIS-NIR related to combined water in the hydrated evaporite minerals, allowing discrimination of minerals such as gypsum and polyhalite. A reflectance high (shoulder) at 800 nm was observed in all soils containing halite with a slope reduction between 800 and 1300 nm. They also showed clay mineral absorption depths at 2200 nm (hydroxyl absorption feature) to be reduced as salinization increased in soils.

Surface salinity is a highly dynamic process, causing identification constraints derived from the spatial and temporal variable nature of soil drying (precipitated salts). Salt detection is easier at the end of the dry season, since salts will dissolve during the rainy season, and upon drying, salts tend to concentrate locally, in patchy spots, creating much heterogeneity within a pixel. In contrast to white saline surfaces, pure alkaline soils are usually dark at the surface, because excess sodium causes organic matter to disperse when the soil is moist (Metternicht and Zinck, 2003).

There are numerous remote sensing studies utilizing hyperspectral data to map and monitor salt-affected soils. Csillag *et al.* (1993) used a stepwise principal components analysis on a large set of salt-affected soils and found important spectral sensitivities to salt content in the visible (530–770 nm), NIR (900–1030 nm), and SWIR (2150–2310 and 2330–2400 nm) spectral regions. They also found that coarser bandwidths of 40 nm provided similar accuracies in discerning salinity status, suggesting that broader band sensors such as Landsat TM could provide comparable accuracies (Dwivedi and Rao, 1992). Shi *et al.* (2003) demonstrated the feasibility of detecting physicochemical properties of saline soils in reclaimed coastal areas in Zhejiang Province in China with hyperspectral lab spectra. Ben-Dor *et al.* (2002) have successfully demonstrated the use of advanced spectroscopy techniques in the

quantitative retrieval of soil properties based on their spectral absorption features, employing a "Visible and Near-infrared Analysis" (VNIRA) methodology to predict soil chemical constituents. The VNIRA approach assumes that a concentration of a given constituent is proportional to the linear combination of several absorption features, and is capable of generating empirical models for predicting soil properties using laboratory wet chemistry and spectral measurements on representative sets of "calibration" samples.

The utility of hyperspectral remote sensing of soils at the landscape scale has been demonstrated in numerous studies involving airborne and spaceborne imagery. NASA's Advanced Visible/Infrared Imaging Spectrometer (AVIRIS), a 224 band airborne imaging spectrometer with 10-nm nominal spectral resolution, has been applied to the detection and mapping of minerals, including clays and iron oxides (Clark *et al.*, 1990). Crowley (1993) mapped various hydrated chlorides and sulfates of sodium, potassium, calcium, and magnesium with AVIRIS. Palacios-Orueta and Ustin (1998) successfully applied lab soil spectra to train AVIRIS data in their mapping of organic matter and iron content levels in soils. Using airborne hyperspectral data in northern Israel, Ben-Dor *et al.* (2002) showed the capability of soil surface mapping with VNIRA, deriving quantitative maps of soil properties such as organic matter, clay content, moisture, and soil salinity. They employed similar methods to successfully predict carbonates from the SWIR region (Ben-Dor and Banin, 1990). Dehaan and Taylor (2002) showed that salinized soils could be mapped with airborne hyperspectral HyMap imagery using spectral matching techniques, such as the Spectral-Feature-Fitting (SFF) technique, of field spectra with airborne hyperspectral data. SSF is an absorption feature–based method that matches image spectra to reference spectra using a least-squares technique and continuum-removed data.

The Jet Propulsion Lab (JPL, **http://speclib.jpl.nasa.gov/documents/jpl_desc.htm**) and US Geologic Survey (USGS, **http://speclab.cr.usgs.gov/spectral.lib04/spectral-lib04.html**) maintain digital spectral libraries that provide laboratory measured mineral and organic spectra of a wide range of terrestrial surface constituents found in soils (Grove *et al.*, 2004; Clark *et al.*, 1993). Soil spectral libraries have been used to greatly aid in the characterization of soil properties (Shepherd and Walsh, 2002). Their utility is enhanced with the availability of chemicophysical information, descriptions of spectral variability for a given soil, and information on sampling location and soil genetic factors such as parent material, age, vegetation, topography, and climate.

SOIL MOISTURE

Soil moisture plays a critical role in the evaluation of terrestrial environmental conditions with important influences on hydrologic, pedologic, biogeochemical, ecologic, and atmospheric processes (Goward *et al.*, 2002). Soil moisture acts as an integrator of the occurrence, distribution, and amount of precipitation and its spatial and temporal patterns, in turn, affect the partitioning of surface available energy into sensible and latent heat fluxes, and precipitation into surface runoff, storage, and evaporation. The growth of terrestrial vegetation is largely sustained by the water supply in the soil with the subsoil supplying water to plants and respiring microbial organisms long after the surface has dried out. Despite its importance, there has been limited success in implementing remotely sensed soil moisture observations at the appropriate time and space scales needed for current hydrology, climate, and biogeochemical models (Sellers *et al.*, 1995). Accurate assessments of this variable have been difficult due to complex land cover conditions and extreme soil moisture variability across landscapes, with unknown scale dependencies (Wood, 1997). A fundamental limitation of remote sensing is that only the surface soil moisture which is a few millimeters (optical) or centimeters (microwave) deep is observed and near-surface soil moisture changes more quickly than soil moisture at greater depths, making it very difficult to infer soil wetness below a few centimeters.

The major effect of adsorbed water on soil reflectance is a decrease in reflected energy throughout the shortwave portion of the electromagnetic spectrum (see Figure 3a). Wet soils exhibit distinguishable spectral absorption features in the NIR and SWIR regions, despite the great variability in their signatures. Combination modes of three fundamental vibrations yield water absorption features at 950 nm (very weak), 1200 nm (weak), 1400 nm (strong), and 1900 nm (very strong) (Bowers and Hanks, 1965; Ben-Dor *et al.*, 1999). Generally, strong atmospheric water absorptions at 1400 and 1900 nm restrict the use of these spectral regions, and reflectance measurements at 1500–1730 nm and 2080–2300 nm are more commonly used for observations of surface soil moisture. Jacquemoud *et al.* (1992) found it difficult to model soil spectral reflectance spectra as a function of water content due to saturation at the 1900 nm absorption feature.

Angstrom (1925) attributed the effect of darkening to internal reflections within the water film adsorbed to the soil particle surfaces, where multiple reflections between water and soil particle surface cause increased absorption and decreased reflection,

$$\rho_{\text{wet}} = \frac{\rho_{\text{dry}}}{[n^2(1-\rho_{\text{dry}}) + \rho_{\text{dry}}]} \tag{1}$$

with 'n' as the index of refraction for the adsorbed water ($n = 1.33$ for pure water). The decrease in reflectance is proportional to the thickness of the water film around the soil particles and can be related to the gravimetric water

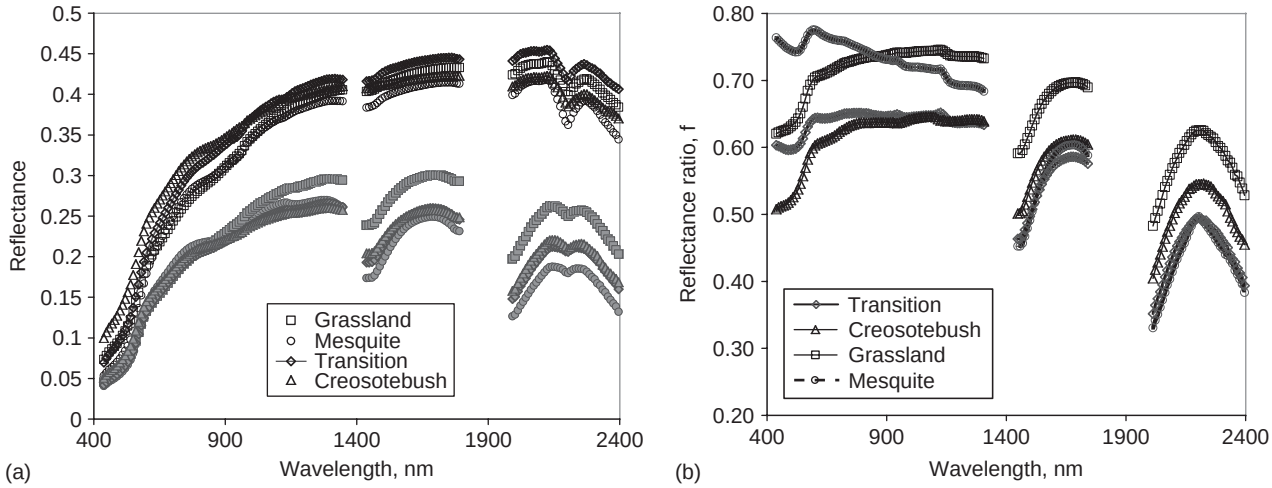

Figure 3 (a) Dry and wet soil spectral signatures for soils at Jornada Experimental Range, New Mexico for different land cover types and (b) the wet-to-dry reflectance ratios

content as well as energy status of the adsorbed water (Idso *et al.*, 1975).

Many controlled studies under laboratory conditions have shown an exponential decrease in reflectance with increasing soil water content (Bedidi *et al.*, 1992; Muller and Décamps, 2001). This nonlinear dependence on moisture varies with soil texture, but was found to be similar across soil types when moisture was expressed as degree of saturation, s,

$$s = \frac{\theta}{(1 - \rho_b/\rho_p)} \tag{2}$$

where θ is the volumetric water content and ρ_b, ρ_p are the bulk and particle densities of the soil respectively (Lobell and Asner, 2002). Lobell and Asner (2002) also applied the absorption depth at 2200 nm, in the more sensitive water-absorbing SWIR region, as a measure of moisture content using the relationship,

$$D = 1 - \frac{\rho_{2200}}{\rho_c} \tag{3}$$

where D is the continuum-removed band, ρ_{2200} is the measured reflectance at 2200 nm, and ρ_c is the value predicted from linear interpolation of reflectance at 2140 and 2260 nm.

Leger *et al.* (1979) studied the interactions of soil water with organic matter and iron oxides and concluded that the interactions among all three components were more important in determining the resulting soil spectra than considering each component individually. Ben-Dor *et al.* (1999) distinguished among the unique spectral influences of hydration water incorporated into the lattice of the mineral (e.g. gypsum), hygroscopic (air dry) water adsorbed tightly as a thin layer onto clays and humic colloids, and free water held in pore space. The absorption effects of hygroscopic water were governed by the relative humidity (vapor pressure deficit) of the atmosphere and, along with pore space water caused soil albedo to change drastically upon wetting.

In field-based measurements, Idso *et al.* (1975) found a linear function of reflectance measurements with the water content of the soil surface. They demonstrated three spatial/temporal stages of drying and were able to distinguish the transition points between the different stages of soil drying with the surface albedo measurements (Idso *et al.*, 1974):

- *Stage 1:* The wet soil surface is at potential evaporation and controlled by atmosphere conditions.
- *Stage 2:* Transition between wet and dry whereby the soil's hydraulic conductivity decreases to the extent that subsurface water is unable to move to the surface fast enough to meet evaporative demand of the atmosphere.
- *Stage 3:* Dry soil surface with low, nearly constant evaporation rate, controlled by the adsorptive forces of the soil.

Under conditions of high evaporative demand, a fairly wet soil may rapidly "dry" at the surface where optical measurements are made. Since the soil drying process is spatially nonuniform, all three stages of drying may contribute to the integrated response of reflected/ emitted energy from remotely sensed measurements. Thus, both linear and nonlinear reflectance variations are present under most soil wetting and drying conditions. The spatial and temporal variability of soil moisture is significant even at fine scales, making *in situ* soil measurements for calibration of remote sensing systems difficult.

Obukhov and Orlov (1964) noted that the spectral curves do not change in appearance with wetting and that the ratio

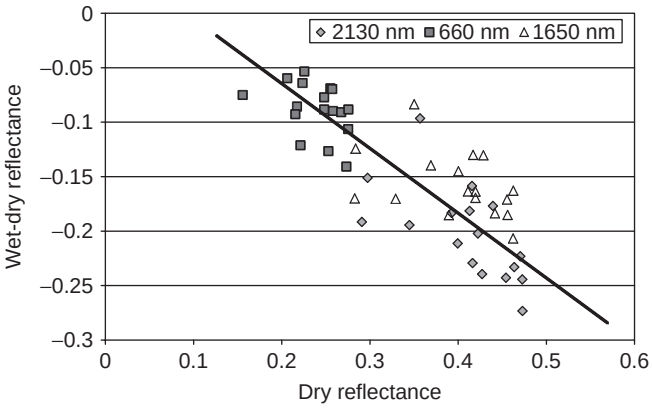

Figure 4 The difference in wet-to-dry soil reflectance plotted against dry soil reflectance for the Argentina and US sites over three wavelengths

of wet soil to dry soil reflectance remains fairly constant in the visible spectrum. The reflectance ratio between wet and dry soils, however, varies with soil type and decreases significantly in the SWIR region (see Figure 3b). The wet soil spectral signatures shown in Figure 3 were 25 to 60% lower in the VIS-NIR (ratios of 0.75 to 0.40) and 60 to 80% lower in the SWIR (Figure 3b). Baumgardner *et al.* (1985) showed that the wet to dry difference was greater in forest soils with low organic matter than in darker, grassland soils with higher organic matter contents. This is also seen in Figure 4, in which there is a linear change in wet–dry reflectance differences such that the brightest soils show the largest decrease in reflectance upon wetting. Knowledge of these changes is important in providing realistic soil albedo values, which are arbitrarily specified in almost all land surface energy and hydrology models.

Many earth-observing sensors have SWIR bands of potential use in surface moisture studies, including Landsat Thematic Mapper bands 5 and 7 (1550–1750 nm, 2080–2350 nm), MODIS (Moderate Resolution Imaging Spectroradiometer) bands 6 and 7 (1628–1652 nm, 2105–2155 nm), and SPOT-VEGETATION (1580–1750 nm), and offer potential soil water indicators. Water absorption in these bands can be expressed as a ratio or in linear combination and then related to soil water content for discrete soil textural classes (Levitt *et al.*, 1990). Huete and Warrick (1990), however, reported limitations in assessing soil moisture content at the surface (0–5 cm) with Thematic Mapper moisture bands, or with various "wetness" indicators under partial vegetation canopies with low (10–20%) vegetative covers.

SOIL PHYSICAL PROPERTIES

Geometric-optical variations of the soil surface yield important textural and morphological information relevant to hydrologic processes such as water infiltration, runoff, and moisture retention. Soil texture is important in modifying the movement of water within a soil, how much water is stored in the soil, and the energy with which it is held. Water will move most rapidly in coarser textured soils and a healthy soil structure promotes infiltration of water into the soil and reduces runoff and erosion. Soil texture and roughness cause significant decreases in reflectance with increasing particle and aggregate size (Baumgardner *et al.*, 1985). Bowers and Hanks (1965), working with kaolinite of different sizes, found an exponential increase in reflectance with decreasing particle size at VIS-NIR wavelengths. As particle size or aggregates become coarser, there are more shadows present and more incident flux is multiply scattered and eventually absorbed in so-called light traps. In general, one observes clayey soils to appear darker than the coarser sand particles due to the aggregated nature of clays and the higher presence of organic matter on clay soils. Ben-Dor *et al.* (1999) noted the important physical chromophores as particle size, sensor viewing angle, and solar incident angle and stated that these influences may change the shape of soil spectra, such as a baseline shift or absorption intensity, but do not alter the position of the diagnostic spectral features.

Structure is an important property of the soil that controls geometric-optical behavior, related to shading and roughness. Structureless soils tend to be the brightest, while healthy-structured soils are darker with well-defined aggregates and peds. Soil crusts influence soil surface roughness, water infiltration, retention, and overland flow. Biological soil crusts, composed of cyanobacteria, fungi, lichens, and mosses are an important surface component in arid and semiarid ecosystems and influence soil stability and local hydrologic patterns both directly and indirectly. They have profound influences on soil spectra through the presence of chlorophyll containing microorganisms (Karnieli *et al.*, 1999).

The physical crust that forms on soil surfaces during rain events also alters soil hydrology by reducing infiltration and increasing runoff. The high energy content of falling raindrops disintegrates soil aggregates and rearranges soil particles and clays within the structural crust of the soil surface. Goldshleger *et al.* (2004) found that clays may either be washed out or be enriched within the soil crust zone dependent on soil texture and mineralogy. They noted that the process of soil structural crusting resulted in distinct spectral reflectance differences. Ben-Dor *et al.* (2004) demonstrated the use of airborne, hyperspectral reflectance measurements of crusted and noncrusted soil surfaces for mapping infiltration rates of loess soils in Israel. Saline crusts vary in structure from smooth to rough, and in color, from white to dark, causing large variations in reflectance spectra (Escadafal *et al.*, 1989). Salt mineralogy has been found to produce distinctive

macromorphological features, such as puffy crusts with the abundance of sodium sulfates, and smoother salt crusts with the presence of chlorides (Eghbalm *et al.*, 1989). Overall, salty crusts are smoother than nonsaline surfaces and have an overall higher reflectance.

Soil surfaces are not Lambertian surfaces and scatter incident radiation anisotropically, and reflectance will vary with direction of illumination and viewing. A fundamental and intrinsic property governing the reflectance behavior of a surface is described by the Bidirectional Reflectance Distribution Function (BRDF), which specifies the behavior of surface reflectance and scattering as a function of view and illumination angles for a given wavelength (λ). The equation describing this function is:

$$\text{BRDF} = L\frac{(\theta_s, \phi_s, \theta_v, \phi_v, \lambda)}{E(\lambda)} \tag{4}$$

with units of sr^{-1}. L is surface leaving radiance in $Wm^{-2}\,sr^{-1}$ and E is the irradiance incident on the surface in Wm^{-2}. θ_s and ϕ_s refer to the solar zenith angle and solar azimuth, respectively, while θ_v and ϕ_v are the sensor view zenith and view azimuth angles, respectively. Often, however, it is defined simply as the bidirectional reflectance factor (BRF $= \pi$BRDF) at a multitude of view zenith and azimuthal angles for a given sun position (Walthall *et al.*, 1985). The BRDF is a physical property of the surface that may be used to derive geometric descriptors of a surface, such as size, shape, and orientation of surface "roughness" elements (Irons *et al.*, 1992). BRDF models are also useful in correcting for sun-soil surface-sensor geometry effects on spectral reflectance (Liang and Strahler, 1994).

Raina *et al.* (1993) were able to incorporate surface terrain and textural characteristics in mapping erosion and salinity classes from Landsat TM imagery. Sensors such as Systeme Probatoire pour l'Observation de la Terre (SPOT) and ASTER greatly improve surface terrain characterization by providing both fine spatial resolution (10-m panchromatic band and 20-m multispectral bands) and stereo-capabilities with pointable sensors, allowing improved mapping of drainage patterns, floodplains, relief, landscape stability, and soil erosion potential, and other structural features.

In summary, the overall complexity of soil spectra prevents a straightforward assessment of reflectance properties by physical models. The spectral response of soils is a product of the interactions between chemical and physical chromophores, and the presence of one chemical constituent, such as organic matter, can mask the presence of other constituents (iron, clays) in the soil matrix. Furthermore, the spectral influence of an absorbing constituent varies with soil physical properties, such as particle size distribution, and the presence of certain chemical constituents, such as salts, can alter a soil's physical properties. This makes it very difficult to model complex mixtures of mineral and organic chromophores with simple linear mixture models. Despite these challenges, soil spectra do carry significant information about many soil properties and for the most part, high spectral resolution data are needed over the spectrally active regions of all chromophores to derive soil properties.

MIXED SOIL AND VEGETATION SPECTRA

A significant problem in extracting soil information from remote sensing imagery is the presence of nonphotosynthetically active vegetation (NPV), litter, and vegetation in pixels. Various methods are used to extract the variability of the soil signal from the vegetation and NPV spectra, including spectral mixture analysis (SMA) and linear unmixing techniques (Smith *et al.*, 1990). The basis of a linear mixture model is that the measured spectral response of a pixel is equal to the weighted sum of multiple reflecting spectral features,

$$d_{ik} = \sum_{j=1}^{n} r_{ij}c_{jk} + \varepsilon \tag{5}$$

where d_{ik} is the measured spectral response of spectral mixture k in waveband i, n is the number of independent reflecting components in the mixture, r_{ij} is the response of component j in waveband i, c_{jk} is the relative contribution of component j in spectral mixture k, and ε is the residual error.

Roberts *et al.* (1993) showed how fine spectral resolution AVIRIS (224 bands) can be used to unmix the soil spectral signal from green vegetation and NPV. Asner and Lobell (2000) developed a SWIR-based, tied endmember approach to the separation of green vegetation, NPV, and soil (see Figure 5). Some shortcomings of linear mixing models are that knowledge of all important endmembers may be required and that significant nonlinear mixing may be present within pixels. Palacios-Orueta *et al.* (1999) utilized a more advanced, hierarchical foreground and background analysis (HFBA), to extract soil information from AVIRIS imagery. The technique employs subsets of foreground and background spectra to emphasize the presence of the spectra of interest and then uses singular value decomposition to extract this signal while simultaneously minimizing the background or undesired spectral variation (Pinzón *et al.*, 1998).

Richardson and Wiegand (1977) and Kauth and Thomas (1976) formulated the "soil-line" concept as a way to separate soil-induced optical variations from those of vegetation. This provided a vegetation measure relative to the wetting and drying behavior of underlying soils and enabled the assessment of surface soil moisture conditions in vegetated

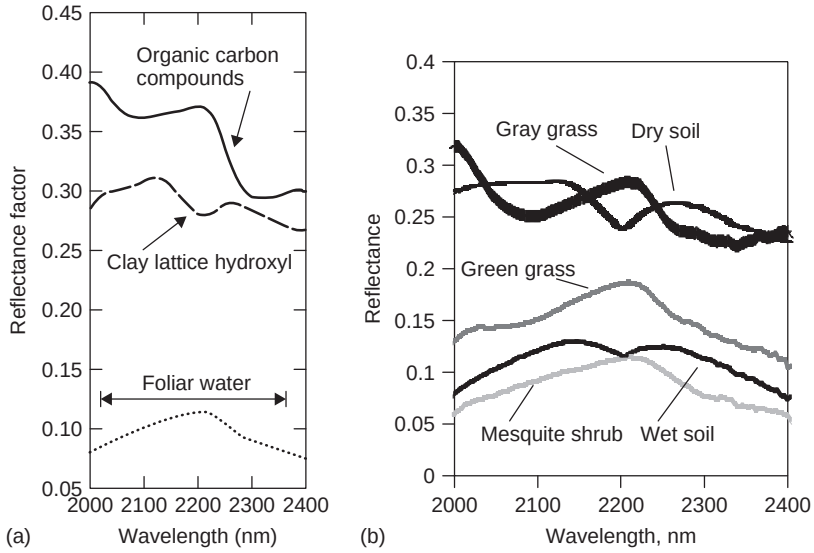

Figure 5 (a) Typical spectra of litter (solid), soil (dashed), and green vegetation (dotted) in the SWIR region (2000–2400 nm) (Reprinted from Asner and Lobell, 2000. ©2000, with permission from Elsevier); (b) Example SWIR spectra from Walnut Gulch Experimental Watershed, Arizona

pixels. When wet, drying, and dry soil spectra are plotted in two-band reflectance space, a "soil-line" is formed with a slope that represents the proportional change in reflectance in each band with soil wetting and drying (Galvao and Vitorello, 1998). In Figure 6, two soil-line derivations are presented, an 'NIR-red' soil line, which is used in the formulation of many vegetation indices, and an "NIR-SWIR" soil line, based on two bands that are increasingly being used to extract land surface moisture information from soil and vegetated surfaces. Overall, soil variations formed soil lines encompassing the dry and wet soil spectral behavior for a range of different soils. The NIR-SWIR soil line has a much lower slope (0.517) than the NIR-red soil line (1.192) due to the greater sensitivity of the SWIR region to soil wetting. The SWIR soil line also shows a greater dispersion of points among the different soils (Figure 6). NIR-red soil-line slopes have been shown to vary greatly over different soil types, ranging from 1.0 to 1.4, with organic-rich peat soils having slopes as high as 3 (Huete *et al.*, 1984; Baret *et al.*, 1993).

In Figure 7, the NIR-SWIR soil line is plotted along with vegetation spectra, using 865 nm and 1640 nm wavelengths. The soil line has a slope that is less than one (0.643), owing to the higher sensitivity of the SWIR band to moisture compared with the NIR band. Although, the soil and litter points are very dispersed, there is a good overall separation between variations attributed to vegetated pixels from those due to soil moisture variations (Figure 7). Variations associated with different vegetation amounts vary along an axis, orthogonal to the soil line, allowing information of soil and vegetation to be extracted that could otherwise not be obtained from any

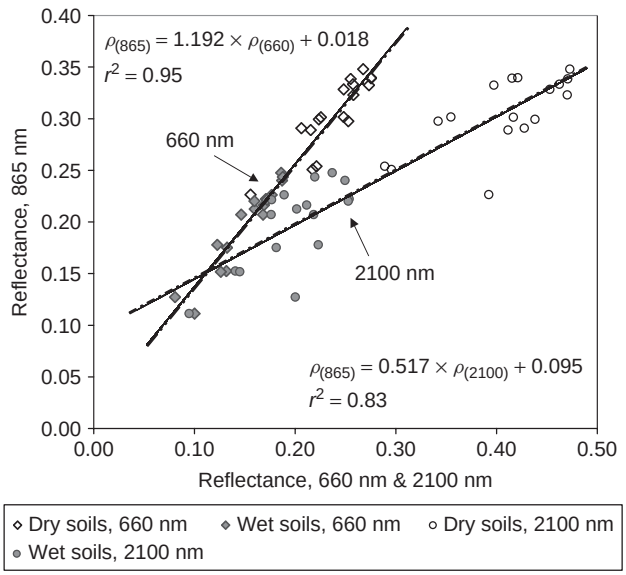

Figure 6 The NIR-Red and NIR-SWIR (2100 nm) ''soil lines'' for the Argentina and US soils from Nacuñan, Chancani, Jornada, and Walnut Gulch

one band by itself. Both increasing vegetation amounts and soil moisture cause the SWIR reflectance to decrease, but in the case of vegetation, NIR reflectance simultaneously increases while in the case of soil moisture, NIR reflectance decreases. Sparsely vegetated points, however, fell within the cloud of soil spectra and could not be resolved from soil. In these cases, the formulation of fine resolution, specific soil lines would improve upon the separation of vegetation and soil moisture reflectance variations.

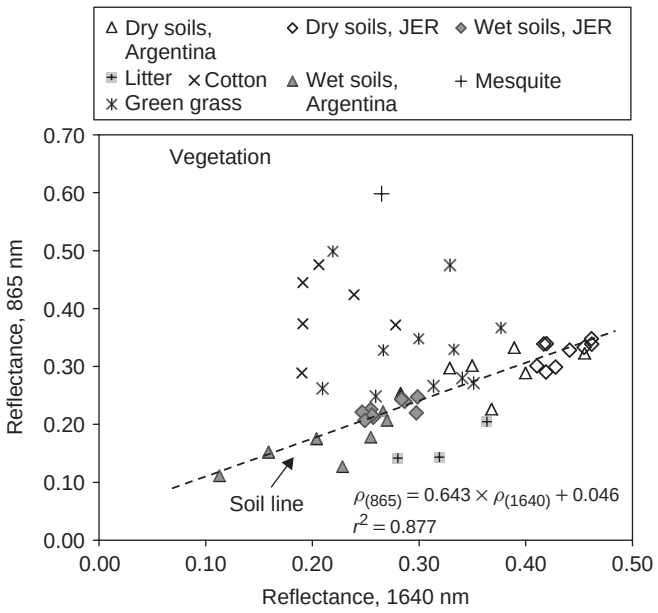

Figure 7 Soil and vegetation spectra plotted in NIR and SWIR (1640 nm) space

Although the presence of vegetation interferes with the reflectance of soil features, one can use vegetation spectra as indirect indicators of soil properties. Wiegand *et al.* (1994) found a high correlation between spectral vegetation index values and soil electrical conductivity, enabling the separation of saline-alkaline soils from nonaffected soils. Zhang *et al.* (1997) used vegetation spectra of halophytic salt-tolerant vegetation (e.g. Cynodon dactilon) as indicators of saline-alkaline affected areas and soil salinity. Ustin (1999) studied the vegetation spectral variations found over Quebec soils with heavy metals and Kooistra *et al.* (2004) utilized hyperspectral reflectance measurements of plant communities as indicators of toxic metal (Ni, Cd, Cu, Zn, and Pb) contamination in Dutch river floodplain soils in the Netherlands. Other studies have focused on the relationships between vegetation indices, rainfall, and soil moisture (Nicholson and Farrar, 1994). They noted significant differences in NDVI-rainfall relationships for various soil types in semiarid Botswana, Sahel, and found a linear relationship between NDVI and rainfall in environments where annual rainfall did not exceed 500 mm year^{-1}, or 50–100 mm per month. Above these limits, a saturation response occurs and NDVI increases with rainfall much more slowly. They further found rain-use efficiency (NDVI/rainfall) to be more a function of the underlying soil than of the vegetation formation.

SOIL-VEGETATION-MOISTURE OPTICS

Knowledge of the water status of a vegetation canopy can provide valuable information on soil moisture condition, vegetation stress, and drought status. Laboratory studies and canopy radiant transfer model simulations have shown that changes in leaf water content have a large effect on reflectances in portions of the NIR and SWIR spectral regions. Important liquid water absorptions are found at 1640 and 2100 nm, with a weaker absorption feature at 1240 nm, which result in negative relationships between reflectances at these wavelengths and leaf water content (Hunt *et al.*, 1989; Gao, 1996). Several studies have shown increases in leaf reflectance associated with plant stress across the SWIR region (Gausman and Allen, 1973; Tucker, 1980), providing useful information to infer soil moisture status in the plant root zone.

The SWIR reflectance values alone, however, are not suitable for retrieving vegetation water content as variations in leaf internal structure and leaf dry matter content as well as canopy geometry, shadowing, and soil surface moisture also influence SWIR reflectance (Cohen, 1991; Ceccato *et al.*, 2001). The assessment of vegetation water content or equivalent water thickness (EWT, g-H_2O/cm^2-leaf area) is significantly improved by the combination of NIR and SWIR bands (Ceccato *et al.*, 2002). For example, the Moisture Stress Index (MSI), calculated as the simple ratio between SWIR (1600 nm) and NIR (820 nm) spectral bands, has been successfully used to derive leaf scale functions of water content (Hunt *et al.*, 1989),

$$\mathrm{MSI} = \frac{\rho_{\mathrm{SWIR}}}{\rho_{\mathrm{NIR}}} \tag{6}$$

Hardisky *et al.* (1983) developed the Normalized Difference Infrared Index (NDII), contrasting the NIR with SWIR (~1650 nm) wavelengths,

$$\mathrm{NDII} = \frac{[\rho_{\mathrm{NIR}} - \rho_{\mathrm{SWIR}}]}{[\rho_{\mathrm{NIR}} + \rho_{\mathrm{SWIR}}]} \tag{7}$$

and found this index to be strongly correlated with canopy water content. Several variants of this index are now used in a wide range of studies using high spectral resolution as well as broadband reflectances. Xiao *et al.* (2004) used the normalized difference between the NIR and SWIR (1580–1750 nm) bands as measures of land surface moisture status with SPOT-4 VEGETATION (VGT) sensor data and named this the Land Surface Water Index (LSWI). Fensholt and Sandholt (2003) formulated the Shortwave Infrared Water Stress Index (SIWSI) from daily MODIS NIR and SWIR (1628–1652 nm) band sensor data,

$$\mathrm{SIWSI} = \frac{[\rho_{\mathrm{SWIR}} - \rho_{\mathrm{NIR}}]}{[\rho_{\mathrm{SWIR}} + \rho_{\mathrm{NIR}}]} \tag{8}$$

They reported high correlations between the SIWSI and soil moisture in the root zone in a Sahel vegetation study

in Senegal. Ceccato *et al.* (2002) proposed a Global Vegetation Moisture Index (GVMI) to retrieve EWT ($g\,m^{-2}$) from SPOT-VGT sensor data at the canopy level,

$$\mathrm{GVMI} = \frac{[(\rho_{\mathrm{NIR}}* + 0.1) - (\rho_{\mathrm{SWIR}} + 0.02)]}{[(\rho_{\mathrm{NIR}}* + 0.1) + (\rho_{\mathrm{SWIR}} + 0.02)]} \quad (9)$$

where $\rho*$ is the reflectance value of a rectified NIR band using apparent, top-of-atmosphere (TOA) reflectances as input.

Whereas the SWIR region responds to both vegetation water content and soil surface moisture, the weaker 1240-nm water-absorbing region has been shown to respond to canopy moisture status only and to be insensitive to surface soil moisture. The Normalized Difference Water Index (NDWI) uses two reflectance bands in the high NIR reflectance plateau of vegetation canopies, at 860 and 1240 nm wavelengths (Gao, 1996),

$$\mathrm{NDWI} = \frac{[\rho_{860\,\mathrm{nm}} - \rho_{1240\,\mathrm{nm}}]}{[\rho_{860\,\mathrm{nm}} + \rho_{1240\,\mathrm{nm}}]} \quad (10)$$

with the weaker, liquid water absorption feature enhanced by the high NIR scattering in the leaf. This formulation was applied to MODIS bands 5 (1230–1250 nm) and 2 (841–876 nm) and was found to be a strong indicator of canopy water content during the growing season in the Sahel (Fensholt and Sandholt, 2003). However, it was found that in dry years the vegetation cover was too dry to provide information on canopy water content, suggesting that a minimum, threshold vegetation amount must be present for the water indices to work. The water band index (WBI $= \rho_{900\,\mathrm{nm}}/\rho_{970\,\mathrm{nm}}$) is also an NIR-based indicator of canopy water content (Peñuelas *et al.*, 1997).
