89: On the Worldwide Riverine Transport of Sediment – Associated Contaminants to the Ocean

PETER W SWARZENSKI[1] AND PAMELA L CAMPBELL[2]

[1] *United States Geological Survey, St Petersburg, FL, US*
[2] *ETI, St Petersburg, FL, US*

The continuous and persistent weathering of the continents and the ensuing transport of both eroded and anthropogenic products by rivers account for almost all the dissolved solutes, particulates, and sediment-associated contaminants delivered to the ocean. Transported within this riverine load are essential nutrients (e.g. P, N, C), (oxy)hydroxides of Fe/Mn that act as highly efficient riverine scavengers, an ever-changing suite of man-made organic and inorganic constituents, as well as a wide variety of natural solutes (e.g. Si, Ca, Mg, Sr). The environmental behavior of these river-borne constituents is controlled by dynamic phase partitioning between operationally defined dissolved, colloidal, and particulate pools control. As most trace elements are bound onto river particulates, their fate is defined foremost by the nonconservative nature of such solids as they move along the particle-size continuum or are exchanged and remobilized in river bed and floodplain sediments. This paper describes the global riverine transport of sediment-associated contaminants to the ocean.

INTRODUCTION

One of the original scientific programs on worldwide river quality was initiated in the mid-1950s by the Association for Scientific Hydrology (Durum *et al.*, 1960). Livingston (1963) effectively mined these data compilations and created the first truly global-scale treatise on river chemistry. Subsequent to this work, large-scale geochemical research efforts were soon initiated for the first time on some major, "undisturbed" river systems, for example, the Amazon (Gibbs, 1973; Stallard, 1980), the Zaire-Congo (Eisma, 1978), and the Mekong rivers (Carbonnel and Meybeck, 1975) (Figure 1). These early investigations also spurred the creation and implementation of comprehensive river monitoring networks (i.e. US Geological Survey's NASQAN: Hooper *et al.*, 2001), as well as other multiyear river research programs (i.e. SCOPE-CARBON: Degens and Kempe, 1982). The worldwide freshwater quality monitoring network – GEMS-WATER – launched in the late 1970s by UNEP, WHO, UNESCO, and WMO established a global-scale database on the quality of rivers. From such reports, a reliable assessment of an entire continent's river water quality could be compiled and utilized for the first time. To validate such very large datasets, up-to-date internal guidelines on collection and analytical methods are not only essential, but also directly define such a program's success. For example, there has been an almost systematic decrease in "average" riverine trace-metal concentrations over the past 2 to 3 decades, as collection and analytical methods continually become refined (Horowitz *et al.*, 2001). It has been increasingly accepted that a comprehensive evaluation of river quality must also include a study of particulates and colloids as many trace elements, radionuclides, and organic compounds are strongly bound to such solid phases; hence their fate is tied directly to the nonconservative nature of these particulates (Trefry *et al.*, 1986) in river systems.

A river's combined load of suspended particulate matter and dissolved salts represents the single most important input to the world's ocean. This riverine load is the product of persistent chemical and physical weathering of the continents, as well as more recent anthropogenic

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

additions in the form of organic and inorganic constituents. Natural weathering processes are modulated by complex geographic, climatic, geologic, and biologic forces, yet reliable long-term riverine datasets are beginning to provide at least a reliable first-order estimate of present and future trends in this fluvial input (White and Blum, 1995; *see* **Chapter 80, Erosion and Sediment Transport by Water on Hillslopes, Volume 2**). Being able to accurately predict future river trends and contaminant discharge estimates to the ocean is critical to form a reliable assessment of anthropogenic imprints on such riverine discharge cycles. This chapter summarizes the worldwide transport of riverine particulates, dissolved solids, and sediment-associated contaminants on a continent-to-continent basis. With the notable exception of just a few relatively unpolluted river systems (e.g. Amazon, Yukon), today's river loads are typically heavily impacted by man and require careful monitoring and management.

Dissolved Loads

Water discharge from a river system can be simply expressed as an integration of net precipitation, evapotranspiration, and bidirectional groundwater exchange within a watershed (Schlosser *et al.*, 2002; Vörösmarty and Fekete, 2002). The world's 10 largest rivers (Table 1) account for close to 40% of the total fluvial water discharge entering the ocean (Figure 2). For example, the Amazon River alone contributes close to 20% of the world's freshwater

Table 1 Average discharge of the top 10 major river systems to the oceans (after Meade, 1996)

Arrow width is an approximation of relative discharge. Note that discharge numbers refer to average annual inputs. Arrows do not necessarily indicate the direction of flow. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

discharge, a value more than the combined total of the next seven largest rivers (Milliman and Meade, 1983; Meade, 1996). Material flux estimates derived from such tremendous discharge values are therefore inherently large and globally significant. Tropical regions with high rainfall, such as southern Asia, Oceania, and northern South America, contribute well over 60% of the global riverine freshwater discharge (Milliman *et al.*, 1999; Dai and Trenberth, 2002). The African continent, in contrast, discharges very little river water to the sea, with the notable exception of the Zaire–Congo and Niger Rivers.

While the geochemical composition of the ocean can be considered globally quite homogenous, continental surface waters are, however, a very unique expression of the particular terrain they traverse (Table 2). This riverine signature is defined by a combination of weathering processes, aeolian, and anthropogenic inputs, as well as the internal cycling of organic matter, and may include: (i) the prevalence of easily weathered minerals (e.g. calcite, gypsum, halite), (ii) short- and long-term climate oscillations (i.e. temperature and rainfall), (iii) the proximity to oceanic aerosols at the land-sea interface, and (iv) terrestrial primary productivity as a source of carbon and other nutrients. Global river water quality is, as a consequence, intrinsically complex and heterogeneous (Gibbs, 1977; White and Blum, 1995). In smaller watersheds (i.e. $<10\,km^2$), the concentrations of dissolved materials generally span 2–3 orders of magnitude, as opposed to 1–2 in larger watersheds (Shiller and Boyle, 1987). However, most of this variability can be found in just a few constituents, for example, sodium, chloride, sulfate, and total suspended matter (Meybeck and Helmer, 1989), which are also most affected by anthropogenic activities such as pollution (Berner and Berner, 1996).

Particulate Loads

Slightly less than half (~40%) of the global particulate load (Table 3) is carried by highly turbid rivers (total

Africa	15.34	35	530
Australia	2.20	28	62

suspended matter concentrations exceed 1500 $mg\,L^{-1}$), yet these rivers represent only 2% of the world's freshwater discharge (Meybeck, 1982). These very turbid rivers (i.e. Huanghe, Orange, Indus) are located principally in arid and semiarid regions. Rivers that drain mountainous regions (i.e. Mackenzie, Irrawaddy, Mekong, Ganges-Brahmaputra, Changjiang) carry an additional ~40% of the particulate load to the sea. The slow-flowing lowland rivers (i.e. Amazon, Zambezi, Paraná, Zaire-Congo) carry the remaining 20% of riverine particulates to the ocean, but constitute more than 50% of the global riverine water discharge (Meade, 1996).

Much has been written on the intricate relation among continental erosion, sediment yield, climate, and topography (White and Blum, 1995). For example, in the late 1950s, Langebein and Schumm (1958) established a positive correlation between sediment yield in many smaller watersheds and effective rainfall. However, as can be expected, such a simple relation between these two parameters cannot be maintained on a worldwide basis. Global erosion rates and sediment yields clearly depend on many interwoven factors such as, total precipitation, the seasonality of this rainfall, temperature, vegetative cover, topography, and the nature of surficial sediments and underlying bedrock (*see* **Chapter 86, Measuring Sediment Loads, Yields, and Source Tracing, Volume 2**). These watershed characteristics often control the riverine transport of solutes and sediment-associated contaminants (Shiller and Boyle, 1987; Chabaux *et al.*, 2003). In their comprehensive review, Milliman and Meade (1983) report that as drainage basin areas increase by an order of magnitude, sediment yield typically decreases sevenfold. This global negative correlation between drainage basin size and sediment yield reflects the inability of smaller, higher energy drainage basins to store sediments in their lower reaches as they discharge to the ocean (Meade *et al.*, 1985). As a consequence, it recently has been shown that the input from these smaller mountainous streams and rivers to the sea may have a much greater influence on the worldwide delivery of riverine particulates to the ocean than previously thought (Milliman and Meade, 1983; Milliman *et al.*, 1999; Holmes *et al.*, 2002; Syvitski, 2002).

In many watersheds, erosion rates have been substantially impacted since settlement by man. Further, the recent surge in global dam and reservoir construction (Figure 3), has effectively reduced the sediment load of many large river systems (GESAMP, 1993). In contrast, conversion of native grasslands and forests to croplands can increase

soil erosion as well as sediment loads. Sediment yields reported in Table 3 are inherently different than terrestrial erosion rates in that sediment is eroded typically at a rate much greater than what can be carried away by rivers. This difference is due at least in part to a river's capacity to store sediment downstream, either within the thalweg during low flow conditions, or as prograding deltaic sediments at the land–sea margin (Meade *et al.*, 1985). As a consequence, larger watersheds generally produce much smaller and less variable sediment yields (Milliman and Meade, 1983; White and Blum, 1995; Canfield, 1997). While riverine sediment yield is a reasonable estimate of the off-continent flux of sediment, only a small component is transported out of an estuarine system and off the continental shelf into the open ocean. Thus, estimates of worldwide riverine sediment discharge represent a source of sediments to the coastal, rather than the pelagic ocean (Milliman and Meade, 1983). The many well-known physicochemical reactions (i.e. surface complexation, dissolution, flocculation, ion exchange, sorption, (co)-precipitation, electron transfer, and biological uptake) that occur in an estuary ultimately regulate oceanic constituent distributions in what Turekian (1977) eloquently termed the "*great particle conspiracy*" (Figure 4).

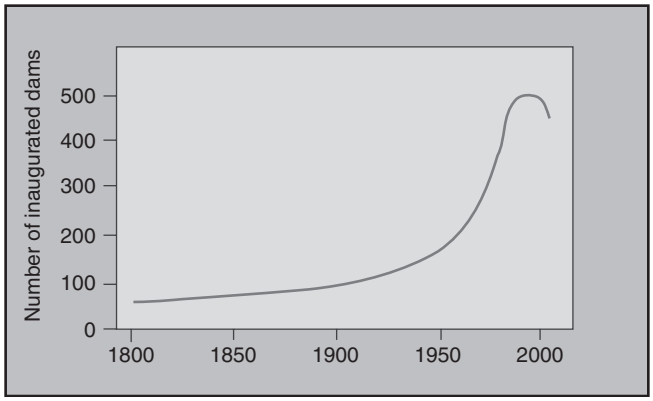

Figure 3 Global dam construction (modified from GESAMP, 1993). In terms of a ratio of the number of dams inaugurated relative to a continents population, North America leads the world (22.5 dams per million people), while Africa has the fewest new dams per population (1.4 dams per million people). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

The mineralogy of riverine particulate matter is largely a function of grain size. Clays constitute most particles that are less than about 6 μm, whereas coarser particles consist dominantly of quartz, feldspar, and carbonate fragments. The most prevalent clay minerals in riverine particulates are illite, smectite, chlorite, and kaolinite, and are present in major world rivers on the order of 45–60%,

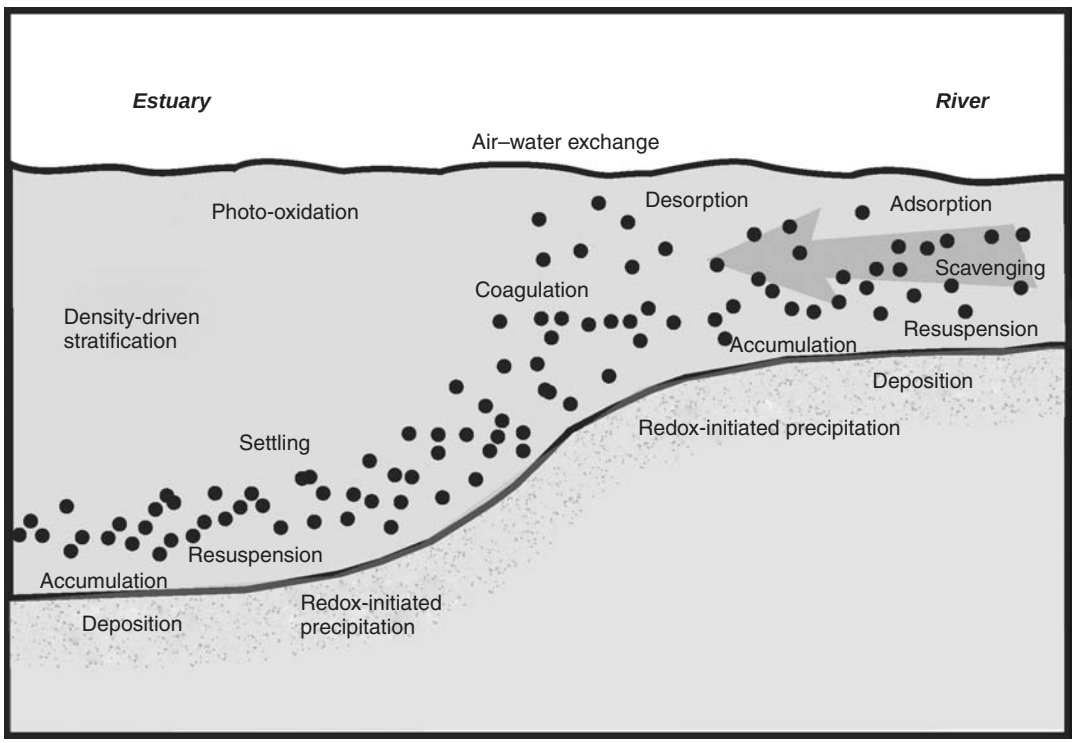

Figure 4 Idealized cartoon depicting some of the physical and biogeochemical processes/reactions that may affect trace elements during riverine transport and estuarine mixing. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

0–50%, 30–40%, and 0–100% respectively (Irion, 1991). Regardless of latitude (i.e. Yukon versus Amazon), rivers that drain young mountain ranges typically are rich in illite and chlorite (Gibbs, 1977). In contrast, temperate river systems such as the Mississippi River, as well as volcanic-borne rivers of Oceania (i.e. Fly River), are usually rich in smectite minerals.

River-borne sediments can conceptually be classified according to their origin, that is, lithogenic, authigenic, cosmogenic, and biogenic (Goldberg, 1954). However, it is usually difficult to chemically isolate such fractions. A more practical classification scheme divides sediments into their respective chemical components or phases: carbonates, clays, silicates, metal oxides/hydroxides, sulfides, phosphates, and organic matter (Jenne, 1977; Gibbs, 1973; Gibbs, 1977; Poulton and Raiswell, 2000). Most sediments are a complex combination of these various phases and may consist of multiple layers or components. These chemically distinct sediment components yield important information about the processes that control element partitioning between the dissolved and particulate phases (Förstner *et al.*, 1989).

ROLE OF PARTICULATES IN THE TRANSPORT OF RIVERINE CONTAMINANTS

It has been widely recognized that the reactive surface sites of riverine particulates, including colloids, are the major sequestering agent of dissolved trace elements and organic compounds in the aquatic environment (Goldberg, 1954; Turekian, 1977; Goldberg *et al.*, 1988; Zhang and Liu, 2002). Mechanisms involved in this dynamic dissolved-colloid-particulate partitioning (Figure 5) are complex and still not well understood. Particulate material, *per se*, consists of various phases that result from natural chemical alteration (e.g. adsorption, flocculation, complexation, or redox reactions) of weathered parent material during riverine transport (Martin and Meybeck, 1979; *see* **Chapter 83, Suspended Sediment Transport – Flocculation and Particle Characteristics, Volume 2**). Both macro- and microorganisms also may be important in waters that have low concentrations of inorganic suspended material, due to the active and/or passive incorporation of dissolved elements into soft tissues, tests, and fecal material (Dzombak and Morel, 1990). Fine-grained particles and colloids generally occur as aggregates of intermeshed or layered Fe/Mn oxides as well as organic and carbonate surface coatings (Jenne, 1977; Singh and Subranmanian, 1984; Hsi and Langmuir, 1985; Stumm, 1992). These reactive surface sites may then act as sources or sinks for dissolved elements in the aquatic environment, depending both on the chemical reactivity (i.e. lability) and on the residence time of a particular system (i.e. kinetics) (Stumm and Morgan, 1981; Sulzberger *et al.*, 1989).

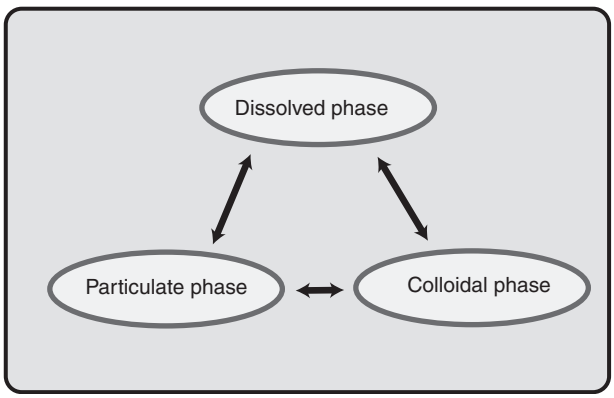

Figure 5 Phase partitioning between operationally defined dissolved (<0.45 μm), colloidal (0.45–0.001 μm), and particulate (>0.45 μm) pools. It is generally recognized that each of these pools exists within a dynamic and highly nonconservative particle size continuum (from (Swarzenski *et al.,* 1995) with permission from Elsevier). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

The affinity of reactive elements for particle surface sites controls their behavior and fate in rivers. It is useful to look at the reversible phase associations of elements to infer processes of removal for a wide variety of compounds. The most important geochemical components are the iron and manganese (oxy) hydroxides, organic coatings, and particles, carbonates, sulfides, phosphates, and detrital clays and silicates (Stumm and Morgan, 1981). The influence of these mineral components is variable and usually related to physicochemical conditions, such as, pH, Eh, conductivity, alkalinity, and temperature. River-influenced coastal areas such as estuaries are well-known sinks for many terrestrially derived elements (Sholkovitz, 1976; Swarzenski *et al.*, 2003), and many reactive pollutants tend to accumulate in these environments (Förstner and Wittman, 1979; Skei and Paus, 1979; Benoit *et al.*, 1994). Widely fluctuating chemical conditions (i.e. conductivity, pH, dissolved oxygen) and biological blooms can cause a remobilization or repartitioning of these phase-species associations (Sholkovitz *et al.*, 1994). In sediments, one phase commonly does not have a large binding capacity, and a variety of phases may exist simultaneously, depending on season and flow conditions (Sharp *et al.*, 1982). The following text describes the role of various mineral components in riverine constituent transport.

Fe and Mn Oxides

In rivers, the (oxy)hydroxides of iron and manganese are among the most important particulate components in that they typically control metal ion sorption kinetics and thus metal behavior (cf. Singh and Subranmanian, 1984). These

oxides have been described as the major carrier for many reactive elements in river water (Gibbs, 1973; 1977; Benoit *et al.*, 1994). The amorphous nature of Fe and Mn oxides present in natural waters promotes active surface sorption and complexation of various ions.

Iron and Mn oxides are typically present as coatings on clay particles (Davis and Kent, 1990; Dzombak and Morel, 1990). Because of the extremely insoluble nature of the trivalent iron oxides and fast oxidization–precipitation kinetics, an amorphous iron oxide exists as the thermodynamically favorable phase (Zinder *et al.*, 1986). As a group, manganese oxides usually are even more amorphous in character than iron oxides (Balistrieri and Murray, 1986). This amorphous nature is most likely due to the formation of nonstoichiometric Mn oxides with variable oxidation states (+2, +3, +4) and also greater isomorphic substitution as a result of slower precipitation kinetics (Jenne, 1977). The surface area of these poorly defined iron and manganese oxides can be very large (up to $600\,m^2\,g^{-1}$; Dzombak and Morel, 1990), and thus are a tremendous source of potential sorption sites. The great abundance of reactive surface sites enables these oxides to be highly efficient scavengers for radionuclides and trace elements (Singh and Subranmanian, 1984) during riverine transport.

Two general types of scavenging mechanisms may occur at the oxide surface: specific (chemical) and nonspecific (physical) adsorption (Davis and Kent, 1990; Stumm, 1992). Briefly, nonspecific adsorption describes the process by which the sorbed ion retains its solvation shell and forms an outer-sphere complex with surface functional groups such as oxides (Davis and Kent, 1990; Dzombak and Morel, 1990). Adsorption of these weakly bound ions is more dependent on the electrostatic attraction between a charged oxide surface and an oppositely charged ion. Conversely, specific adsorption describes the coordinative displacement of H^+ ions bound to the surface oxygen by cations; hence, this process is dominated by covalent bonding rather than electrostatic attraction. This latter mechanism of strongly bound metal ion adsorption will yield inner-sphere complexes at the oxide surface (Waite *et al.*, 1994). Either sorption mechanism will yield a cation-oxide complex that can behave very differently across chemical gradients in natural waters (Mayer *et al.*, 1984). For example, one would expect an outer- rather than an inner-sphere cation-oxide complex to be susceptible to ionic strength variations. An observed linear decrease in uranium K_d's (distribution coefficients) across a salinity gradient on the Amazon River shelf led Swarzenski *et al.* (1995) to conclude that U was most likely associated in a weakly bound, reactive outer-sphere cation-oxide complex. Once a cation is adsorbed to an oxide surface, which is usually a very rapid process, incorporation into the oxide lattice may occur either through molecular diffusion or precipitation. Some cations can be physically trapped in this manner into the lattice framework where they remain relatively immobile (e.g. ^{137}Cs, ^{7}Be).

Dissolution of Fe and Mn oxides can readily occur in response to a pH change, a decrease in the redox potential (Eh), or an increase in the concentration of complexing agents (Moore *et al.*, 1979). The aqueous manganese cycle, from the dissolved ion through its removal to sediments, is illustrated in Figure 6. This sequence, which in many ways is analogous to the redox chemistry of Fe, is very important in the recycling of redox-sensitive and particle-reactive elements (Broecker and Peng, 1982) across redox boundaries. Balistrieri and Murray (1986) indicate that the cycling of manganese from the dissolved to particulate state may be responsible for large-scale removal of reactive elements in the ocean. Indeed, Fe/Mn hydrous oxides are closely tied to the behavior of trace metals, rare earth elements, and radionuclides in many rivers (Gibbs, 1977; Plater *et al.*, 1992; Sholkovitz *et al.*, 1994), estuaries (Sholkovitz, 1993; Swarzenski *et al.*, 1995), anoxic basins (Swarzenski *et al.*, 1999), and interstitial waters (Burdige, 1993).

As a class, the manganese oxides appear to be more efficient scavengers of select dissolved elements than iron oxides (Balistrieri and Murray, 1986; Sholkovitz *et al.*, 1994; Swarzenski *et al.*, 1999). The sorptive properties of these oxides are related to their unique structural and colloidal characteristics, high surface charge, and cation adsorption capacity over a narrow pH range (Means *et al.*, 1978a, b). For example, Carpenter *et al.* (1984) found ~92% of ^{210}Pb associated with the manganese oxide phase, and less than 4% with the organic phase.

Organic and Inorganic Carbon

Dissolved and particulate riverine carbon may be both organic and inorganic in nature. The various forms of riverine carbon may have different sources, characteristics, and aqueous residence times (Table 4). Through various phase-partitioning processes, carbon is responsible for the transport and delivery of CO_2, as well as other carbon-associated contaminants and nutrients to the world's ocean (Meybeck, 1982; 1993).

In rivers that exhibit a natural pH range, dissolved inorganic carbon (DIC) is found mainly as the bicarbonate ion, HCO_3^-. Riverine DIC originates entirely from atmospheric and soil CO_2 in noncarbonate environments (i.e. metamorphic, volcanic, plutonic, most sandstone, and shale), while ~50% of riverine DIC in carbonate environments results from the weathering of bedrock (Esser and Kohlmaier, 1991). Riverine (particulate inorganic carbon) PIC is derived from the mechanical erosion of sedimentary rock, which results in the transfer of carbonate material from their source to the oceans.

Riverine organic carbon exists within a continuous size spectrum that extends in size from monomers and colloids to large macroparticles and aggregates. Two major pools of

Table 4 Various forms of riverine carbon and their natural sources (adapted from Meybeck, 1993)

Phase components			Natural origin
total carbon	dissolved carbon	DIC	carbonate mineral weathering atmospheric and soil CO_2
		DOC	soil and plant leaching
	particulate carbon	POC	soil erosion sedimentary rocks autochthonous sources
		PIC	autochthonous sources sedimentary rocks

DIC = dissolved inorganic carbon; DOC = dissolved organic carbon; POC = particulate organic carbon; PIC = particulate inorganic carbon.

organic carbon can be separated simply by an operational definition; organic carbon retained, for example, on a 0.4–0.7 μm filter is labeled (*particulate organic carbon*), *POC* and the carbon transferred through the filter membrane is termed (*dissolved organic carbon*). *DOC* In their review of world riverine carbon fluxes to the sea, Ittekot and Laane (1991) thus confirm that the transport of carbon in rivers, expressed as a ratio of DOC/POC, is inversely related to the concentration of suspended particulate matter (Figure 7).

The dominant components of organic carbon in natural water are operationally defined fulvic and humic acids, which together constitute humic substances (~50%), and hydrophilic acids (~30%). Simple compounds such as carbohydrates and carboxylic acids comprise the remaining 20% (Thurman, 1985). The relative abundance of these operationally defined organic components can shift dramatically from one river to the next. For example, humic substances in highly organic rivers such as the Suwannee River can exceed 90% of the entire organic carbon content. The predominant functional groups of humic substances are carboxylic acids and phenols, yet many other groups (e.g. N, S) may also strongly affect metal scavenging, depending on the particular environmental setting.

DOC concentrations in rivers range from more than $20\,\mathrm{mg\,L^{-1}}$ in some polluted or tropical rivers to less than $1\,\mathrm{mg\,L^{-1}}$ in alpine streams (Thurman, 1985). In pristine rivers, DOC is derived mainly from soil leaching with the absolute amount of exported DOC linked to the river-basin drainage patterns. For example, Moore (1989) compared two stream basins in Westland, New Zealand, and determined that the poorly drained Larry River exported $78.1\,\mathrm{g\,C\,m^{-2}\,yr^{-1}}$ (a global maximum), while the well-drained Maimai basin exported only $6.8\,\mathrm{g\,C\,m^{-2}\,yr^{-1}}$.

In addition to the strong influence riverine DOC has on the global carbon cycle, riverine organic carbon also can affect nutrient and contaminant availability as well as constituent transport (Meybeck, 1993; Onstad *et al.*, 2000). Disaggregation/aggregation reactions involving the solid

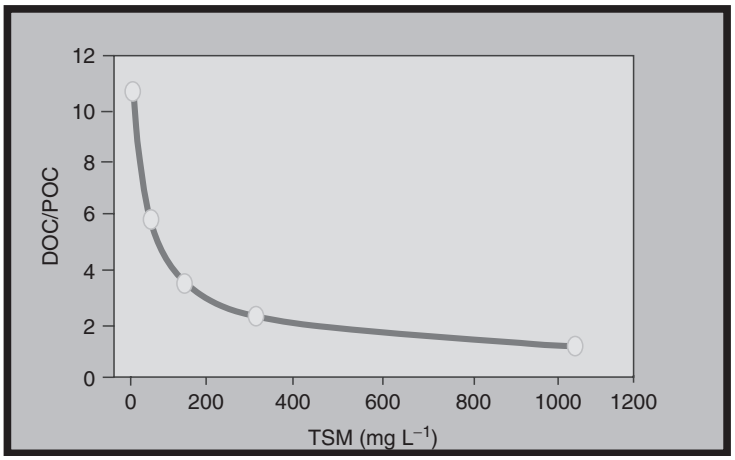

Figure 7 Relation between the ratio of dissolved and particulate organic carbon and total suspended matter from different world rivers (after Ittekot and Laane, 1991). This ratio changes with increasing concentrations of total suspended sediments. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

phase may facilitate a redistribution of contaminants into the water column that can lead to a concomitant increase in potential toxicity. Certain components of DOC (i.e. humic and fulvic acids) have cation binding and ion-charge properties that partition trace elements from the solid to the dissolved phase.

Organic carbon has a net negative surface charge that enables it to interact readily with cations, resulting in complex associations by ion exchange, adsorption, and chelation (Duinker, 1980). Organic carbon is able to modify the solubility, redox potential, and precipitation behavior of many cations, organometallic complexes, and organic contaminants (Thurman, 1985). Such transformations due to the presence of organic carbon may cause an increased solubility and mobilization in such elements as Cu, As, Pb, Hg, Cd, Co, Ag, Ni, Sn, Al, U, and Th (Santschi *et al.*, 1988) and possibly the transuranics (Olsen *et al.*, 1982). Actual mechanisms are still largely unknown, but as a class, organic material is believed to control cation adsorption onto marine particulate matter (Balistrieri and Murray, 1986). Clay minerals also strongly adsorb humic material that can then interact with metal oxides and hydroxides and greatly affect surface adsorption characteristics.

Cation adsorption onto organic matter is not well understood because of the inherent physical and chemical complexity of these organic macromolecules. Most likely, as with Fe/Mn hydrous oxides, surface functional groups of organic carbon can form either inner- or outer-sphere complexes. These sorption reactions (specific and nonspecific) commonly involve a transfer of protons, and are therefore extremely pH sensitive. A lowering in pH can frequently initiate the reduction and subsequent dissolution of Fe/Mn oxides. The nonreductive dissolution of Fe(III) or Mn(IV) can be further enhanced if the H^+ bonds to the oxygen on the oxide surface, thereby weakening the critical Fe- or Mn oxygen bond (Waite, 1990). A similar mechanism of nonreductive dissolution can be invoked for organic matter in which ligands complex Fe on the oxide surface and form soluble Fe-ligand complexes (Stone and Morgan, 1984).

Decomposition of organics within the sediment column may lead to changes in the distribution of sediment-associated contaminants, possibly altering them into more readily available or mobile phases. Flow, currents, and biological conditions also can alter the phase association of trace elements. For example, Presley *et al.* (1980) found that low flow conditions in the Mississippi River initiated an increase in particulate organic matter that could cause a change in particulate-trace element interactions. Complexing agents, such as EDTA, and natural organics also are known to promote the formation of strong complexes with certain radionuclides and can reduce the binding capacity of the particulates for the radionuclides (Means *et al.*, 1978b). In their review, Förstner and Wittman (1979) indicate that sedimentary organics play a vital role in the remobilization of trace and transuranium elements. Laboratory experiments have shown Cu, Co, Mn, Ni, and Zn can all be solubilized from carbonate and sulfide phases by interaction with organic matter (Rashid and Leonard, 1973).

Carbonates, Sulfides, and Refractory Minerals

While hydrous Fe/Mn oxides and organics are certainly the most important particulate components in terms of regulating contaminant behavior in rivers, the role of carbonates, sulfides, and refractory minerals may become significant in certain river systems. For example, under anaerobic conditions, specific bacteria are able to utilize sulfate as their terminal electron acceptor, and derive energy from the reduction of sulfate to sulfide. In the presence of sulfide, ferrous iron is rapidly removed as FeS and, due to

the fine size of the particles, adsorbs onto larger sediment grains (Berner, 1971; Burdige, 1993). This FeS coating gives anoxic sediments their characteristic black color.

Reactive trace elements may also be removed from river water by forming insoluble sulfide compounds (e.g. FeS, PbS, ZnS). This removal process, whether it be a pure sulfide precipitation, solid sulfide formation, adsorption onto FeS, or a combination of these, is often not well-known (Oakley *et al.*, 1981). Coprecipitation with iron sulfides appears to be a sink for trace elements in anoxic settings (Swarzenski *et al.*, 1999); however, direct evidence is sparse (Presley *et al.*, 1980; Förstner and Wittman, 1979). Reduction of Fe/Mn oxides in the sediment column may release substantial quantities of adsorbed trace elements that may quickly adsorb onto FeS and pyrite (Shannon and White, 1991).

The sulfide component also may be an important source of elements to the water column. Oxygen can be introduced into anoxic sediments through various physical or biological processes. This oxygenation may then cause the oxidation of sulfide minerals, and result in the subsequent release of any associated trace elements. This process may be important, especially in intermittently anoxic river sediments, where seasonal remobilization and mixing can produce ephemeral oxidizing conditions within surficial sediments.

Carbonate minerals also are potential scavengers of trace elements, and are present in varying degrees in most rivers and estuaries. Carbonate precipitation in estuarine and coastal sediments may be important in areas of high sedimentation, which limits the diffusional reequilibration of pore water to the overlying waters (Jenne, 1977). Coprecipitation of zinc and cadmium with the carbonate fraction was prevalent in Rhine River sediments (Förstner *et al.*, 1989). Under anoxic conditions, manganese carbonate precipitation may control interstitial water manganese concentrations (Förstner and Wittman, 1979).

The detrital or refractory component is a dominant phase for many elements during riverine transport. Gibbs (1973; 1977) looked at Amazon and Yukon River sediments and found the predominant components of Cu, Cr, and Co were in the crystalline lattices of detrital minerals. This phase is considered to be geochemically almost nonreactive, and unavailable for further desorption/adsorption reactions under normal conditions. Trace elements associated with this phase are assumed to be present in the weathered material, and should therefore have concentrations close to crustal abundances. The primary importance of detrital mineral phases, such as clays and silicates, is to provide adsorption sites for reactive phases or nucleation centers for flocculation and precipitation reactions (Duinker, 1980).

Chemical Extractions

Analytical techniques utilizing selective chemical extractants have been widely used to understand and describe the nature of trace element associations in sediments (cf. Gad and LeRiche, 1966; Chao, 1972; Malo, 1977; Guy *et al.*, 1978; Tessier *et al.*, 1979; Chester *et al.*, 1988). These techniques permit for a gross quantification of operationally defined sediment phases and the trace elements associated with them (Tessier *et al.*, 1979; Luoma and Bryan, 1981). Studies dealing with trace element remobilization (Skei and Paus, 1979; Presley *et al.*, 1980), potential bioavailability (Luoma and Jenne, 1976; Luoma and Davis, 1983), fate of anthropogenic riverine inputs (Slavek *et al.*, 1982; Van Valin and Morse, 1982; Raoux *et al.*, 1999), and transport and removal mechanisms of trace elements (Gibbs, 1973; 1977; Oakley *et al.*, 1981; Poulton and Raiswell, 2000) have all used selective extraction schemes. Figures 8 and 9 illustrate the partitioning of Fe, Mn and Zn, and Ni, respectively, into three operationally defined sediment phases in four large rivers (Poulton and Raiswell, 2000). In this extraction scheme, the dithionite-soluble fraction targets oxide surfaces while the HCl-soluble fraction isolates both sheet silicates as well as some carbonates. In general, multiple extraction methods should, however, be applied with much caution and may easily be subject to misinterpretation.

Radionuclide Associations with Particulate Components

Most chemical extraction studies have been developed for a suite of trace elements, including Cu, Pb, Zn, Cd, Co, and Ni. The application of such extraction schemes to radionuclides also provides a useful tool to assess the environmental fate and behavior of such elements that are potentially toxic and recalcitrant (Harmon and Ivanovich, 1993).

The role of different sediment components for radionuclides in riverine sediments and suspended particles still needs to be better understood (Chabaux *et al.*, 2003; Swarzenski *et al.*, 2004). In a recent study of uranium series disequilibrium within river sediments, Plater *et al.* (1992) reported that over 70% of all sediment-bound U exists in a chemically inert residual component. In an investigation of the behavior of uranium on the Amazon shelf, McKee *et al.* (1987) utilized a two-step $NH_2OH^{\bullet}$ HCl-Na citrate and HF-$HClO_4$ leach to separate U into a reactive ferric oxyhydroxide and a residual component. Their data suggest vastly different partitioning of U within these two fractions. At a distal offshore station (relative to the river mouth), ~80% of the uranium was bound onto an operationally defined residual component, while at a proximal station, 60% of the uranium was bound to Fe-oxyhydroxides. Results like those of McKee *et al.* (1987) and Means *et al.* (1978b) demonstrate that differing environmental conditions; that is, organic rich, reducing sediments, high biological activity, may impose differing phase associations. The ability of certain radionuclides

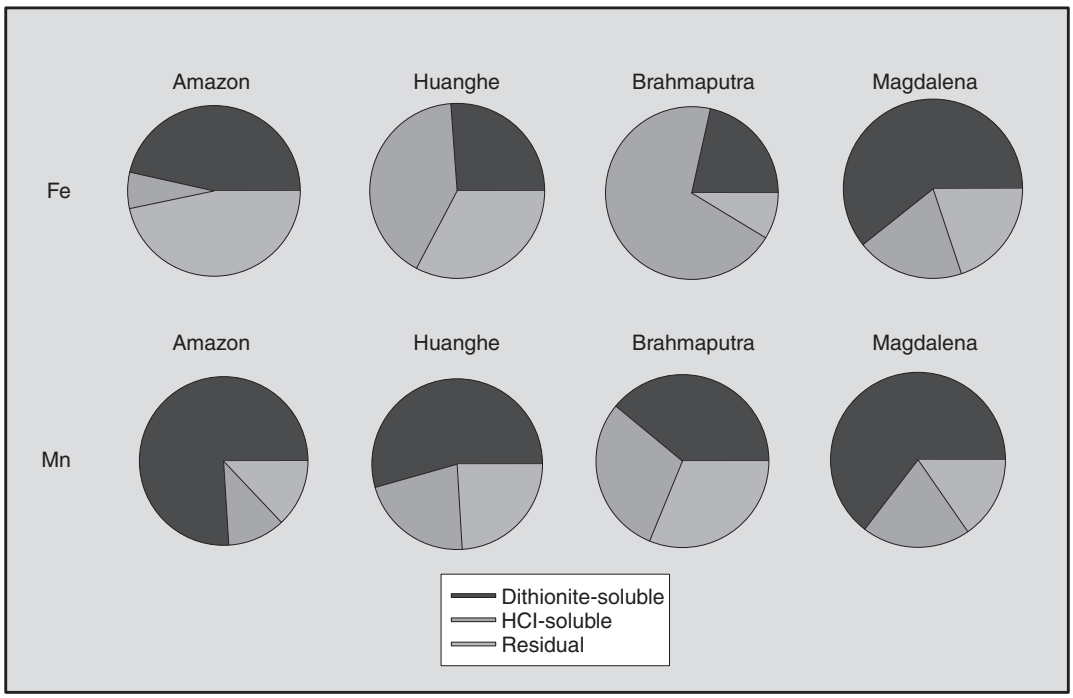

Figure 8 Fe (wt%) and Mn (ppm) partitioning into three operationally defined mineral components for the Amazon, Huanghe, Brahmaputra, and Magdalena rivers (data from Poulton and Raiswell, 2000). A dithionite extraction is expected to target elements associated with Fe hydroxide surfaces; HCl extraction will remove both sheet Si minerals as well as hydrolysable organic matter. Figure 9 Zn (ppm) and Ni (ppm) partitioning into three operationally defined mineral components for the Amazon, Huanghe, Brahmaputra, and Magdalena rivers (data from Poulton and Raiswell, 2000). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

to associate with different phases in varying environments may lead to problems in the use of radioactive elements for geochronological studies, chemical tracers, or any description of the geochemistry of the element (e.g. Benoit *et al.*, 1994). Geochemical processes, such as, particulate removal, diffusion, and biological activity, all affect the equilibrium of the natural radioactive decay series elements. A thorough treatise on riverine transport of select U-Th series isotopes is presented in Chabaux *et al.* (2003).

Riverine Flux of Nitrogen and Phosphorus

Alterations to the riverine flux of nitrogen and phosphorus have not been confined exclusively to the twentieth century (Meybeck, 1982). However, over the last 3–4 decades there has been a tremendous interest in more comprehensively understanding the local and regional transport processes of N and P at the land–sea margins (Nixon *et al.*, 1996). The impact of enhanced N and P inputs can trigger microbial and planktonic water column blooms that affect suspended matter concentrations and light availability necessary for photosynthesis. Prolonged blooms may alter local benthic and water column communities and can eventually lead to ecosystem-wide degradation (McIsaac *et al.*, 2001). For example, in the Gulf of Mexico adjacent to the Mississippi River, low oxygen concentrations (i.e. hypoxia) in a stratified water column occur frequently during summer months.

In nonimpacted river catchments, the physicochemical weathering of soils and biological uptake/regeneration, contribute to the mobilization and subsequent transport of N and P in river systems (Alexander *et al.*, 2000). Altered river catchments (i.e. deforestation, increased land drainage, impoundments, industry and agriculture) greatly increase the natural terrestrial flux of N and P to the sea. Except along active upwelling coastlines, rivers usually are considered the major estuarine contributor of N and P for both impacted and pristine watersheds, and this flux is a function of a river's sediment and water discharge budget. There are typically numerous N and P species in a river that may reside either in a dissolved (nitrate, nitrite, ammonium, organic N, organic P and inorganic P) or particle-bound (organic N, organic P and inorganic P) pool. In general, particulate species tend to dominate the overall riverine load of P more so than N, although in heavily impacted river systems, enhanced concentrations of nitrate and dissolved inorganic P species may also be observed (Downing *et al.*, 1993). It has been estimated that recent anthropogenic perturbations have increased global riverine P fluxes by as much as a factor of 3; riverine N fluxes have similarly increased across North America (3x) and Europe (6x) (Howarth *et al.*, 2002). Table 5 shows estimates ($Mt\,yr^{-1}$) for the global riverine flux of N and P into the ocean (after Tappin, 2002).

Table 5 $^{-}$Estimates ($Mt\,yr^{-1}$) for the global riverine flux of N and P (after Tappin, 2002)

Nitrogen		Phosphorus	
		DOP	0.6
DON	10	PIP	12
DIN	10–20	POP	8
PN	21	TDP	2
TDN	7	TPP	20
Total N	48–58	Total P	22.6

DON = dissolved organic N; DIN = dissolved inorganic N, PN = particulate N, TDN = total dissolved N; DOP = dissolved organic P, PIP = particulate inorganic P, POP = particulate organic P, TDP = total dissolved P and TPP = total particulate P.

CONTINENTAL DISCHARGES

It has been widely shown (cf. Trefry *et al.*, 1986; Swarzenski *et al.*, 1995; Horowitz *et al.*, 2001) that the vast majority (up to 90%) of trace elements carried downstream in a river are associated with particulates and colloids. The fate of inorganic and organic constituents during riverine transport, regardless of continent, is thus directly tied to the nonconservative fate of these solids. For example, riverine particles and colloids undergo constant aggregation/disaggregation reactions, they also can be seasonally stored in the lower reaches of slow-flowing rivers, and can be subsequently remobilized from riverbed and riverbank sediments during high discharge (Walling *et al.*, 2003). Table 6 summarizes sediment-associated trace-metal concentrations from some major world rivers.

Europe

Despite being relatively diminutive in size, the rivers of Europe are historically well documented and often well researched. For example, much more has been written on the Rhine or Danube Rivers than the comparatively sized rivers of Asia or the Americas. Well over 100 European rivers empty into varied coastal receiving basins located in the Barents, White, Norwegian, North, Baltic, Mediterranean, Black, Caspian, and Adriatic Seas, as well as the Atlantic Ocean. Combined, these European rivers contribute approximately 7.4% ($2800\,km^3\,yr^{-1}$) to the world's total freshwater discharge of $37\,700\,km^3\,yr^{-1}$ (Milliman, 2001), yet only about 2% of the total annual sediment discharge. Although none of the European rivers rank among the top 10 rivers of the world as calculated using drainage basin, water discharge, or length, only the Rhone, Po, and Danube Rivers have annual sediment loads that exceed 10 million tons (Milliman and Meade, 1983).

European rivers, although geographically confined to a small continent, exhibit a nearly global representation of rivers that can range from arctic to subtropical, low to high discharge, low to high suspended and dissolved loads, and low to high degree of human impact (Cotté-Krief *et al.*, 2000). Today, the rivers of Europe are among the most industrialized and populated, yet some of these rivers (e.g. the Po and Ebro Rivers of Greece) have undoubtedly been impacted by human activities as far back as 2,500–3,000 years ago. More recently, many rivers of Europe have been affected by urbanization, deforestation, agriculture, dam construction, mining, and industry (GESAMP, 1993; Milliman, 2001).

Africa

Several large rivers drain the African continent and rank very high among the world's largest rivers in terms of their respective drainage basins and discharge characteristics (Milliman and Meade, 1983). In terms of combined annual sediment discharge, African rivers contribute about 4% of the total worldwide estimate of $13\,526 \times 10^6\, t\, yr^{-1}$. Similar to other continents, the drainage basins of large rivers within Africa may be divided into coastal (peripheral) and inland systems. The upper Niger River, Lake Chad, and the Okavango Delta are examples of inland drainage basins. Prominent examples of coastal drainage systems include the Zaire–Congo, lower Niger, Orange, Senegal, Gambia, Volta, and Saloum, which all flow into the Atlantic Ocean. The Zambesi and Limpopo flow into the southern Indian Ocean and the Nile discharges into the Mediterranean Sea.

Africa is a well-weathered continent where the topography has been largely reduced by mechanical and chemical denudation, and the soil profiles are commonly lateritic, and consequently rich in Fe–Mn–Al hydroxides (Martin, 1988). As a result, dissolved and particulate loads are generally much lower than in other large rivers of the world (Milliman and Meade, 1983; Dupré *et al.*, 1996). Most African rivers are seasonal in discharge, yet this cyclicity has been modified by the construction of numerous dams and reservoirs (Frater, 1987). Such alterations to the natural flow of a river affect both the suspended sediment and the total dissolved solids load of a river. The Nile represents an excellent example of a river that has been almost entirely modified within the last 30–40 years by the construction of the Aswan Dam, irrigation, and extensive industry (GESAMP, 1993). The Niger, Zambesi, and Orange are further examples of African rivers that have, to varying degrees, been harnessed by man's activities. The particulate loads discharged by African rivers into the surrounding oceans are quite low. In fact, many large African rivers first empty into inland swamps or lakes before making their way to the coast, and these lakes can efficiently lower and store dissolved and particulate materials of a river (Milliman and Meade, 1983).

Asia

The largest Asian rivers can be grouped into those that drain the Himalayas (i.e. Ganges, Brahmaputra, Indus, Irrawaddy) and those that drain mainland China (i.e. Huanghe, Changjiang). Combined, these rivers contribute almost 50% of the total annual sediment discharged to the ocean (Zhang, 1995). Most of this discharge is the result of a short and energetic rainy season (monsoon-driven) and extreme topographic relief within the drainage basins (Sarin *et al.*, 2002; Meade, 1996). While the Himalayan rivers exhibit pronounced local temporal and spatial deviations (Ramesh *et al.*, 2002), collectively, their chemistry closely reflects the world average river water composition

as reported by Meybeck (1982). In contrast to the industrial rivers of Europe and North America, trace element concentrations associated with suspended particles from the two largest Chinese rivers, today, remain quite similar to background soil levels within the respective watersheds (Zhang, 1995). In the Huanghe River, 90% of the sediment load is derived from easily weathered loess deposits (Poulton and Raiswell, 2000). Although many of the Asian rivers carry a large sediment load (e.g. Ganges-Brahmaputra), as much as half of the annual sediment flux can be sequestered in their low-lying floodplains and thus, not directly delivered to the ocean. This has important implications for the off-continent riverine transport of sediment-associated contaminants (Sarin *et al.*, 2002; Zhang and Liu, 2002).

Oceania

The importance of rivers and streams draining the high-standing islands in the East Indies in global river–ocean mass-balance estimates has recently become clear. Although these islands only account for roughly 2% of the world's landmass, they contribute as much as 30% of the global sediment entering the sea (Milliman and Meade, 1983; Milliman and Syvitski, 1992; Milliman *et al.*, 1999). This disproportionately large riverine sediment load delivered from small watersheds is the result of steep topographic relief, heavy precipitation, and relatively young bedrock that is easily weathered. Together, Asia and Oceania contribute up to 75% of the riverine sediments discharged into the ocean (Milliman and Syvitski, 1992), therefore dominating the oceanic particulate flux. While many of these rivers are still relatively pristine (e.g. Purari River of Papua New Guinea), there are some notable exceptions where large mining operations, and dense urban centers introduce a wide range of inorganic and organic contaminants. From a study on riverine fluxes from several high-standing islands of Oceania, Carey *et al.* (2002) suggest that the sediment-associated trace-element concentrations approximate upper-continental crustal values. This confirms that the riverine particulates of Oceania are generally less weathered during transport than those carried by large river systems, such as the Amazon.

South America

Well over two-third's of the South American continent is drained by only six large rivers that collectively contribute about $8000\,km^3\,yr^{-1}$ of fresh water to the Atlantic Ocean. One single river, the Amazon, is responsible for almost 60% of this discharge estimate. About 13% of the world suspended-sediment budget is derived from just three South American rivers: the Amazon, the Orinoco and the Paraná. Although the South American continent extends over almost 70 degrees of latitude, almost 80% lies within the humid tropics. Of the world's major river systems, the Amazon River has few rivals. It is the second longest river in the world after the Nile, and its drainage basin ($6.3 \times 10^6\,km^2$) produces the world's largest freshwater ($6300 \times 10^9\,m^3\,yr^{-1}$) and sediment ($1{,}000-1{,}300 \times 10^6\,t\,yr^{-1}$) discharge (Meade, 1996). As in some of the large Asian rivers, large quantities of fine-grained sediment are stored and resuspended seasonally in the lower Amazon (Meade *et al.*, 1985), effectively modulating the annual discharge of sediment-bound riverine constituents. Nonetheless, the Amazon represents a tremendous source of dissolved, colloidal, and particulate riverine constituents to the Atlantic Ocean (Swarzenski *et al.*, 1995).

North America

Although the discharge and sediment loads of the major North America rivers have been reasonably well-quantified since the 1950s, the large rivers of Alaska and Canada that discharge into the Arctic Ocean have only just recently been studied in a rigorous manner (Dai and Trenberth, 2002; Holmes *et al.*, 2002; Syvitski, 2002; Álvarez *et al.*, 2003). In general, the rivers of North America that drain either the eastern or western seaboard have small sediment loads. Many of these rivers are either dammed (e.g. Columbia), or they flow first through a network of lakes and reservoirs that efficiently trap sediments (i.e. St. Lawrence). Rivers that discharge into the Gulf of Mexico carry the greatest sediment load. Of these, the Mississippi is by far the largest, both in terms of water and sediment discharge, although Meade (1995) has shown a roughly 50% decrease in this sediment load from 1700 to 1985 because of changing agricultural practices and dam construction. With the exception of Li and Sr, the majority (~70 to 90%) of trace metals are transported downstream in association with suspended sediments (Trefry *et al.*, 1986; Horowitz *et al.*, 2001). Telltale signs of upriver mining and industry as well as the distinct climatic control on watershed weathering can be clearly seen in the particulate loads of select North American rivers (Shiller, 1993; White and Blum, 1995; Canfield, 1997; Horowitz *et al.*, 2001).

Future Trends in River Research

One of the most difficult tasks for river scientists and managers alike is to more accurately relate recent anthropogenic influences in watersheds to the coastal delivery of sediments and sediment-associated contaminants. From detailed studies, rivers are now well known to effectively store their sediment load across many different timescales that can range from daily events to 1000- yr climatic cycles. Such storage and remobilization within a river also may integrate geologic and geochemical signatures that can further obscure

the relation between upland soil erosion and river-sediment transport. By developing better watershed erosion estimates and riverine particulate budgets that include storage and remobilization terms, river-discharge estimates and predictive models can be produced that are both reliable and informative for sediment-associated contaminant inventories and off-continent flux estimates.

90: Lake Sediments as Records of Past Catchment Response

JOHN DEARING

Department of Geography, University of Liverpool, Liverpool, UK

The sediments that accumulate at the beds of lakes are natural archives of information about catchment processes that extend back far further than instrument records. This article reviews the kinds of questions that long records can address, and summarises the technical and analytical approaches taken. Records of river discharge, sediment delivery, and soil erosion obtained in this way over decades and centuries are increasingly used to understand the behaviour of fluvial systems, especially the combined effects of human activity and climate. Case-studies now available for different parts of the world can be used to provide the temporal perspective to the current levels of fluvial and erosional processes in human-dominated landscapes, and together show the strong dependence of sediment delivery on catchment size.

LAKE SEDIMENTS AS SUITES OF ERODED SOIL

"Lake sediments as suites of eroded soil" was a phrase coined by John Mackereth, a British scientist working at the Freshwater Biological Association in the English Lake District, in the 1960s. He was the first scientist to articulate the potential for lake sediments to provide a unique source of information about past hydrological and sediment responses in the surrounding catchment. His 1966 paper describes the physical and geochemical properties of 6-m-long cores sampled from different lakes in the Lake District and a number of arguments for catchment-specific responses in weathering processes and soil erosion through the Holocene (Mackereth 1966). The ensuing 35 years has seen a steady rise in the number of studies engaged in reconstructing hydrological responses to climate and human activities, and today there are few zones of the world where lake sediments have not contributed to our understanding of the rate, causes and trajectory of soil erosion, flooding, or mass movements.

Drainage basins are complex cascading systems where responses in the fluvial and sediment systems to human actions or meteorological events may reverberate over large distances with significant time lags. The effect of these responses has the potential to alter agroecosystem sustainability, flood regimes, hazard risk, and even to feedback into global climates through the modification of oceanic biogeochemical cycles. The impact on global water budgets and sediment flux through future human activities, especially adaptive activities responding to rising population numbers and climate change, now demands information about response characteristics of hydro-geomorphic systems across a wide range of spatial and temporal scales. In particular, unraveling the interacting roles of climate and human impact on sediment flux may require information about process-response mechanisms that take place over long timescales (cf. Oldfield and Dearing, 2003). The following describes the scientific questions that lake sediment studies can address before reviewing lake sediment studies of past catchment responses.

SCIENTIFIC QUESTIONS

Measuring flows of water and sediment with instruments is the conventional method for monitoring hydro-geomorphic processes over time. Large numbers of gauging station records exist for river discharge but not normally for longer than a few decades. One recent review of global rivers (Walling and Fang, 2003) shows that suspended sediment records normally extend back only as far as the 1950s. Historical reconstructions that combine land use records, field monitoring, and modeling provide detailed insights

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

into catchment dynamics (e.g. Trimble, 1999), but are rare and restricted to small basins. Unfortunately, short-term monitoring records, however detailed, often represent an obstacle to the assessment of impacts of climate and human activities on hydro-geomorphic processes that operate over longer timescales. Long-term perspectives gained from using lake sediments to reconstruct hydrological processes offer the opportunity to address a number of important questions for catchments worldwide:

Are processes at the present time responding to natural climate variability or have they been modified by human activities? This is especially important to answer as we move into a period of global warming and, in many parts of the world, increased pressure on landscapes for farming and urbanization.

How large has the impact of human activities been on processes compared with the preimpact natural levels? If we want to identify catchment management or soil conservation strategies, it helps to know how far the system has moved from its "natural" state.

How has the coupling of subsystems within a catchment changed through time? The degree and extent to which subsystems in major drainage basins are coupled is often only poorly known. Major issues about the effects of land use on downstream locations, such as where sediment in reservoirs originates, or what is the contribution of surface soil to a river's total suspended load, are important questions to answer.

How are all these long-term changes a function of the size of the catchment and its subsystems? Impact–response relationships in catchments are partly a function of catchment size, with sediment storage modulating the record of sediment transport through a fluvial system: we need to have more information on what these relationships are.

How do we test predictive models that simulate future changes over decades and centuries? Reconstructed hydrological records open up the possibility of testing and validating simulation models over longer periods than the last 50–70 years provided by monitored records.

METHODS AND TECHNIQUES

The strength of lake sediment studies lies in the accumulation of particles that are derived from the surrounding catchment, allowing the coupled lake-catchment system to be used as a fundamental unit of study (Oldfield, 1977). Careful examination of the visual, microscopic, or measured sediment properties allows past environmental processes and conditions to be reconstructed, an indirect method that uses the sediment components as environmental indicators or *proxies* of past conditions. Lakes and reservoirs cover $\sim 3.1 \times 10^6\,km^2$ or 2.3% of the land surface and drain ~20% of the land surface. Freshwater bodies vary enormously in their size and form, from recently created small ponds and farm dams less than 1 ha in area and a couple of meters deep, to the 30 million year old Lake Baikal, in Siberia, which at over 1600 m deep contains the world's largest volume of freshwater. The large variations in lake and catchment size have led to the development of many different sampling and analytical procedures, covered by several reviews (Dearing, 1986; Lowe and Walker, 1997; Roberts, 1998; Smol, 2002). Crucial to lake sediment reconstructions of hydrological processes are sediment chronology and analytical measurements used as proxy data.

Chronology

Typically, around 5–15 m of mud has accumulated at the bottom of lakes during the Holocene, the geological period covering the past 11 000 years. In some lakes, the mud is deposited with a seasonal cycle that gives rise to visible layers known as *laminations* which afford a means of dating through counting the seasonal layers from the present to find the sediment age for any particular depth. But in the majority of sedimentary archives, dating relies on analytical procedures such as ^{14}C dating of organic remains (~40 000–300 year BP), optically stimulated luminescence dating of quartz or feldspar grains (~1 000 000–100 year BP) and ^{210}Pb dating that gives sediment ages over the past 100–150 years. Other dating techniques utilize pollution markers like the radioactive fall-out of ^{137}Cs and ^{241}Am from the Chernobyl accident (1986) and early bomb tests (1963), or other markers in the sediment that have a known and often local date, such as pollen linked to the introduction of an exotic plant species or tephra layers from known volcanic eruptions. Dating is the most important aspect of lake sediment studies but also the most problematic (Lowe and Walker, 1997; Roberts, 1998). Old carbon, hardwater effects, insufficient bleaching, postdepositional mobility of ^{137}Cs are all potential problems that need to be excluded or avoided by careful site and sample selection.

Proxy Measurements

The reconstruction of past environments is never perfect, but the ingenuity of paleoecologists has led to a surprisingly large number of environmental states and processes that may be successfully reconstructed (Lowe and Walker, 1997). Several hydrological processes may be reconstructed (Table 1), and climate, vegetation, and soils may also be inferred through a combination of paleoenvironmental analyses. Sediment accumulation rates in dated cores, particularly annually laminated sediments, can provide an estimate of sediment load to the lake bed, though sediment focusing may mean that basinwide accumulations derived from multiple cores are needed for greatest accuracy. Particle-size, and some magnetic properties dependent on particle-size, can be used as a proxy for flood intensity, especially in sediment cores sampled from zones of the lake bed influenced by inflowing rivers and streams. Most

Table 1 Examples of hydrological processes recorded in lake sediment

Response	Proxy evidence
Flood events	Stratigraphy, particle-size, magnetic susceptibility
Water balance	
Salinity	Diatoms
Lake levels	Stratigraphy
Sediment flux	
Accumulation rates	^{14}C, ^{210}Pb, ^{137}Cs, laminations, biostratigraphy
Sediment properties/sources	
Minerogenic particulates	LOI, geochemistry, particle-size, mineral magnetics
Organic particulates	LOI, organic chemistry, isotopes
Nutrient flux	
Phosphorus	Diatoms, geochemistry
pH	Diatoms

measurements used for reconstructing hydro-geomorphic processes require some degree of calibration with known or monitored changes. In some studies, the proxy in modern sediments is calibrated against modern conditions or monitored records to produce a statistical *transfer function* that may then be applied to earlier sediments; in others the sediment property is matched to material in the catchment to give a fingerprint of a particular type, zone, or horizon of soil, and substrate.

LAKE SEDIMENT RECORDS OF CATCHMENT PROCESSES

Holocene Trends

Small lakes draining small-medium catchments ($<10^3$ km^2) provide the largest number of reconstructed hydrological records. These records give information about long-term trends (10^2–10^3 year) and short-term responses (10^0 year) in the sediment flux record, changes in sediment source and often information about river discharge and links between forcings and responses. Long proxy records of sediment flux (measured as sediment load to the lake) found in previously glaciated parts of Central and Northern Europe and North America (Dearing, 1994) tend to show high pre-Holocene rates declining to minimum values during the early to mid-Holocene, suggesting a shift from high energy-high sediment supply to low energy-low sediment supply conditions (Figure 1a and b). In contrast, mid-to-late-Holocene trends appear to differ according to the level of human activity in the drainage basin. In North America, the rise in sediment flux is much later than in Europe and corresponds to the introduction of European agricultural methods within the past 350 years. Older mid-Holocene peaks in lake sediment accumulation in North America are rare and may actually represent artifacts of uncalibrated radiocarbon dating (Webb and Webb, 1988). In Central and Northwest Europe, later peaks in sediment load often register Bronze Age, Iron Age, Medieval, and Modern phases of farming, and these are comparable to the history of pollen evidence (% nonarboreal pollen – NAP) for open land (Figure 1b) and erosion forcings deduced from geomorphology, archaeology, and environmental history (Figure 1c). Edwards and Whittington's (2000) review of 50, largely upland, sites in Britain and Ireland shows that there is pollen evidence for anthropogenic impact at virtually all sites where accelerated sedimentation occurs. The start of accelerated accumulation varies from site to site with dates clustered around 5295–4970, 4530–4235, and 2980–2810 BP. At lowland sites too, for example, at Llangorse Lake, in South Wales, sediment accumulation rates rise ~4–13-fold following major deforestation phases after ~5000 BP and ~4-fold after the mid-nineteenth century (Jones *et al.*, 1985). At Blelham Tarn, in the English Lake District, the recent rises in sedimentation rate (~10-fold since the 1950–1960s) are positively correlated with high levels of grazing in the catchment (van der Post *et al.*, 1997). Erosion records in Central America show the initial impact of maize cultivation by indigenous agriculturalists ~4–5000 BP at both lowland (Goman and Byrne, 1998) and high altitude (Bradbury, 2000) locations in Mexico, followed by a second phase of erosion (between 2600 and 1600 BP) in the lowlands linked to drier conditions (Goman and Byrne, 1998). The study by O'Hara *et al.* (1993) at Lake Pátzcuaro in the Michoacán Highlands identified erosion early as 3640–2500 BP well before the intense erosion of the Preclassic/early Classic periods where erosion rates were double those under preimpact conditions. In contrast to the lowlands, catchment stability was related to reduced agriculture brought on by drought conditions. Accelerated erosion in the later Postclassic period (850–350 BP), predating European contact, increased average rates to 5–6 times the preimpact level. At some sites, both response and recovery trends are observed in the erosion record, as in the history of Mayan agriculture in Guatemala (Deevey *et al.*, 1979; Curtis *et al.*, 1998). Records from Southeast Asia are rare, but evidence from two small lake-catchments in subtropical Yunnan, China, show sedimentation rates 13–15 times above the predisturbance levels (Whitmore *et al.*, 1994). In New Zealand, lake sediment studies (Page and Trustrum, 1997; Eden and Page, 1998) show mean accumulation rates increasing by ~5-fold under European pasture compared with rates under Polynesian occupation. Polynesian deforestation led to a landscape dominated by bracken fern/Coriara vegetation, but mean accumulation rates were less than twice those under pre-Polynesian indigenous forest. The studies illustrate the complex interactions between

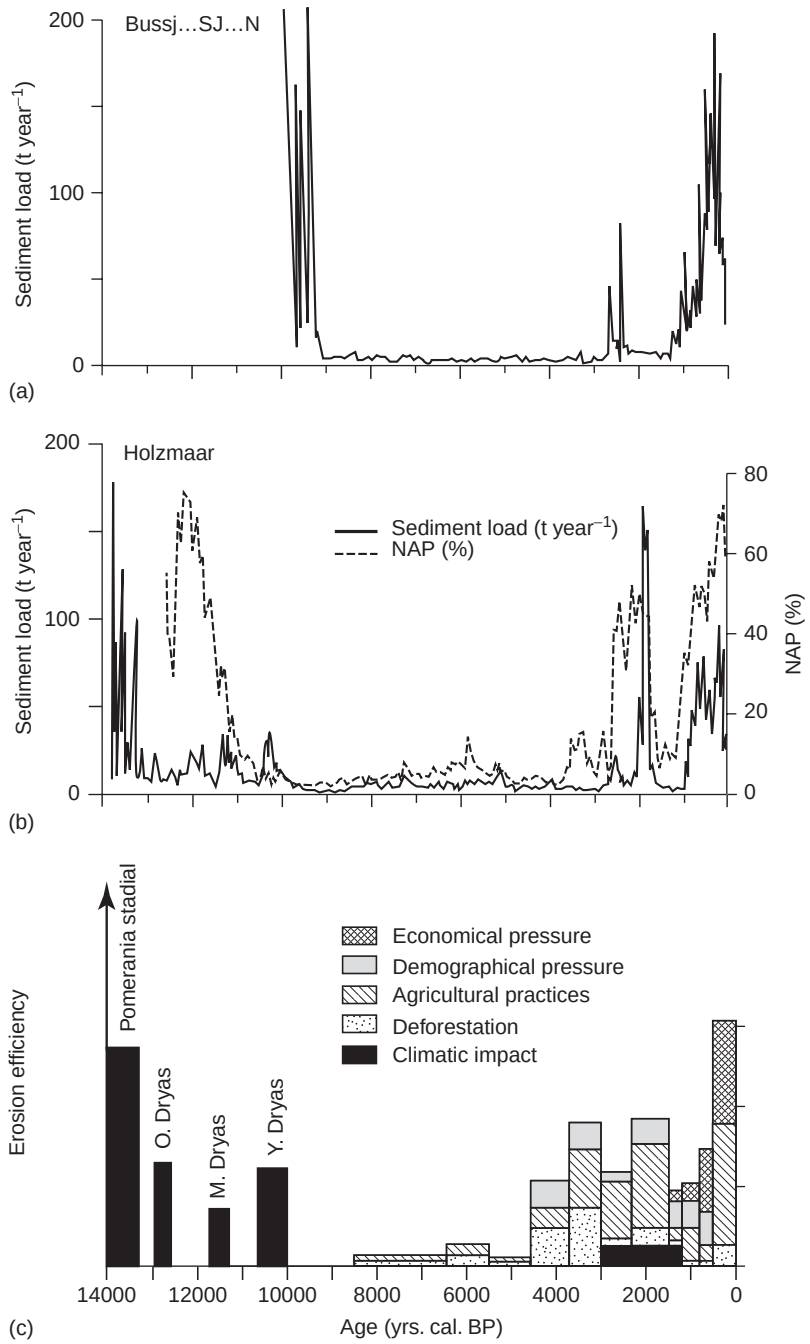

Figure 1 Holocene sediment flux in Northwest Europe: (a) Bussjössjön, southern Sweden (Reproduced from Dearing *et al.*, 1990, by permission of John Wiley & Sons Ltd); (b) Holzmaar, Germany, showing also nonarboreal pollen proxy for open land (Reprinted from Zolitschka 1998, © 1998, with permission from Elsevier); (c) history of erosion forcings deduced from geomorphological investigations and environmental history (Reproduced from Van Vliet–Lanoë *et al.*, 1992, by permission of Oxbow Press, Oxford)

land use, earthquakes, and high-magnitude storm events that trigger land slides.

Recent Records

Detailed records of recent sediment accumulation rates period exist for many sites, usually based on a ^{210}Pb chronology covering the last 100 years, often show strong correlations between sediment accumulation and land use (Figure 2). At Frain's Lake, Michigan, (Davis, 1976) the sedimentation record shows how the levels rise ~30-fold following deforestation and stabilize at a far lower level

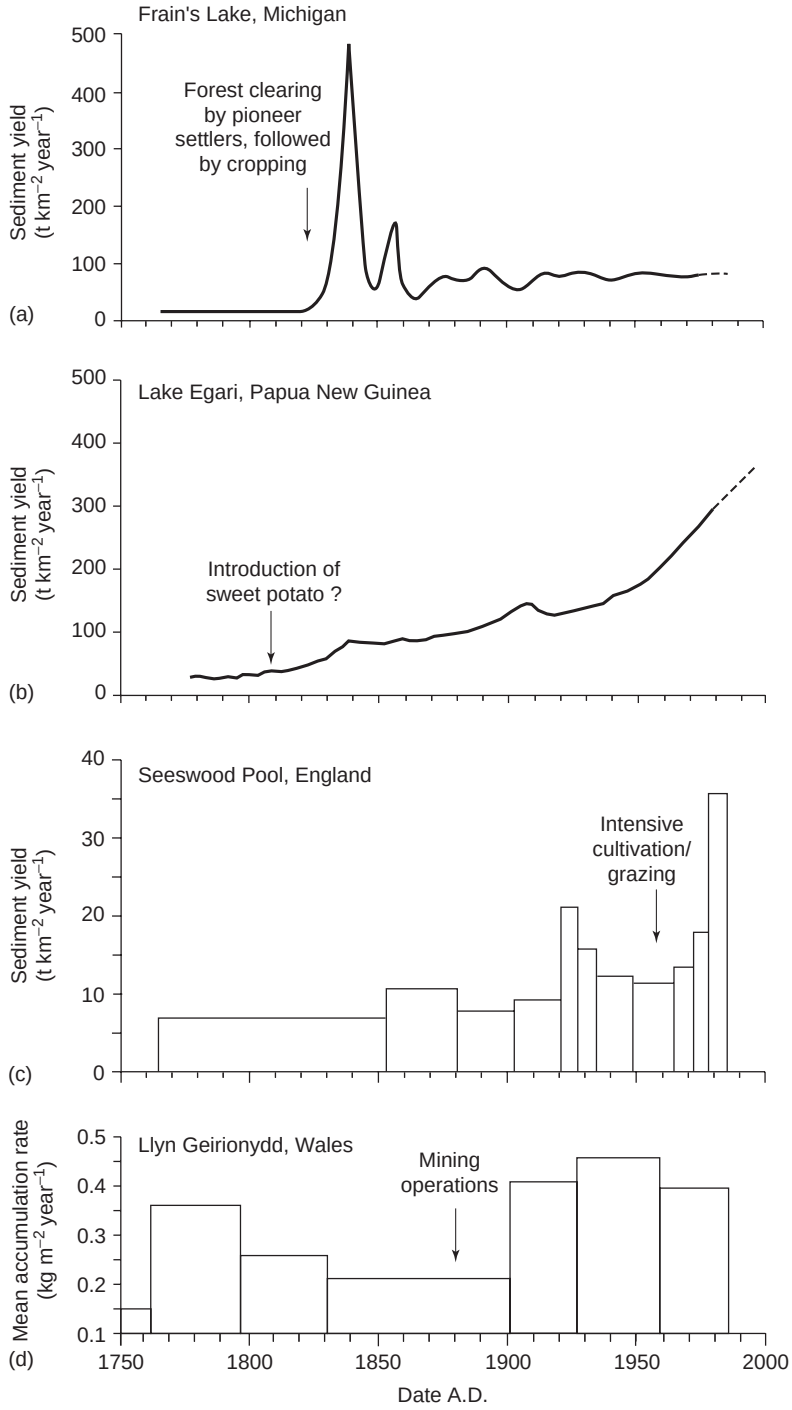

Figure 2 Recent responses to human impact in small catchments: (a) Frain's Lake, Michigan (Reproduced from Davis, 1976, by permission of Cambridge Unviersity Press); (b) Lake Egari, Papua New Guinea (Reproduced by permission of Oldfield *et al.*, 1985); (c) Seeswood Pool, England (Reproduced from Dearing and Foster, 1987, by permission of John Wiley & Sons Ltd); (d) Llyn Geirionydd, Wales (Reproduced from Dearing, 1992, by permission of John wiley & Sons Ltd)

than recorded for the initial clearance phase, but still higher than preclearance levels (Figure 2a). In the Papua New Guinean Highlands, Oldfield *et al.* (1985) show that sediment flux continues to rise into the late twentieth century following clearance and the introduction of sweet potato in the nineteenth century (Figure 2b). This suggests that sediment supply continues to increase at the present time and long-term agricultural sustainability may

be difficult to achieve. Changes in agricultural methods in lowland England since 1950 towards more intensive cultivation, and especially more intense cattle grazing, appear to have been the main cause of higher rates of sediment accumulation at Seeswood Pool (Figure 2c) (Dearing and Foster, 1987). In South America, Cisternas *et al.* (2001) argue that 15-fold rises in sediment accumulation rates in a lake in Central Chile, since the 1800s, are associated not only with losses of forest but also with replacement of the native forest by pine plantations. The erosional impacts of land-use change other than deforestation and farming are also clearly recorded, as seen in Wales (Figure 2d) where there is a long history of mining and quarrying (Dearing *et al.*, 1981; Dearing, 1992). In upland Scotland and Ireland, initiation of peat erosion is recorded in sediments between A.D. 1500 and 1700 and was caused either by climate change during the Little Ice Age or by an increase in the intensity of burning (Stevenson *et al.*, 1990). In the Canadian prairies, sedimentation rates reached a maximum in the 1950–1960s (De Boer, 1997) and lake sediment records seem to confirm the effectiveness of recent soil conservation schemes in reducing erosion rates.

Large Catchments and Sediment Storage

There are far fewer lakes, and consequently lake sediment records, representing large catchments (10^3–10^6 km^2). At the lower end of this range, the sediment records are familiar. The stepped rise of sediment flux in Europe, broadly paralleling human activities, is seen in the Upper Doubs River (Bichet *et al.*, 1999) in the French Jura. In North and South America, the impact of European agricultural methods in large catchments is also clear. There is, however, a tendency for records from lakes draining large catchments to exhibit lower levels of sediment flux variability. Colman *et al.* (2000) show that sedimentation rates in southern Lake Michigan have risen by 2–11-fold in the period 1840-modern compared with mid-Holocene levels, which compares with the ~30-fold increase in the smaller Frain's Lake in Michigan. In the tropics and subtropics there are few case studies to draw upon, but increases in recent sedimentation rates in the large subtropical Lake Erhai, Yunnan, China, are only 1.3 times the predisturbance values (Whitmore *et al.*, 1994), despite a mountainous catchment and well-documented deforestation and irrigated farming practices extending back at least 2000 years (Elvin *et al.*, 2002). Lakes with smaller catchments in Yunnan show records with much higher variability. Change in sediment flux is most suppressed in the largest drainage basins. At Lake Baikal, Siberia, fed by the River Selenga, rises in accumulation rate over the last 100 years are only ~2-fold and comparisons with older ^{14}C dated sequences suggest that the mean modern accumulation rates are very close to long-term averages (Appleby *et al.*, 1998), even though the main period of industrial activity and population expansion has been in the last 75 years (Flower, 1998). Estimates for the Black Sea basin suggest modern rates are lower or equal to the mean Quaternary rate. Estimates of sediment yield for the drainage basin of the Caspian Sea suggest modern rates match the long-term Quaternary average in the south basin but are higher by up to 38-fold in the north basin. Modern rates for the Aral Sea basin are also higher than long-term averages by up to 200-fold, but the sedimentation rate data from both the Aral and north Caspian Sea are strongly affected by water level changes and a significant aeolian dust input (Einsele and Hinderer, 1997).

At the global scale, "modern" monitored sediment loads are normally positively related to drainage basin area, while area-specific sediment yields are inversely related (e.g. Milliman and Syvitski, 1992). Similarly, lake sediment accumulation rates have also been found to correlate positively with catchment : lake area ratio (Blais *et al.*, 1998), while area-specific sediment yields derived from lake sediment records are inversely related to the catchment: lake area ratio (Dearing and Foster, 1993). Barlow and Thompson (2000) show that 66% of the variance in mean sediment flux estimates derived from UK lakes and reservoirs can be explained by the log of catchment area. What these sediment trends with drainage basin area do not describe, however, is the influence of spatial scale on the variability of sediment fluxes through time at any given location. An analysis of the minimum and maximum sediment accumulation rates in lakes representing 7 orders of magnitude of catchment sizes (10^{-1} to 10^6 km^2) shows that catchment size seems to be a major control on the variability of sediment delivery over long timescales (Figure 3), with the largest ratios of impact/preimpact rates found in small catchments. Despite long histories of climate and human impact, the variability of fluvial sediment transport in catchments $>10^4$ km^2 may be very low as a result of large storage on floodplains insensitive to hydrological changes (Dearing and Jones, 2003).

Calibration of Lake Records

There are some studies that attempt explicitly to use the lake sediment record as an extension to monitored records of contemporary hydro-geomorphic processes. Studies in two catchments in Midland England (Merevale Lake and Seeswood Pool: Figure 2c) showed that lake sediment-derived estimates of sediment flux are not only comparable with those derived from stream monitoring (Foster *et al.*, 1985; Dearing and Foster, 1987), but could be used as the basis for reconstructing past sediment budgets (Foster *et al.*, 1990). Direct calibration of sediment properties to meteorological or hydrological data is becoming more common where high temporal resolution in sediment properties exists (e.g. Cooper and O'Sullivan, 1998; Wohlfarth

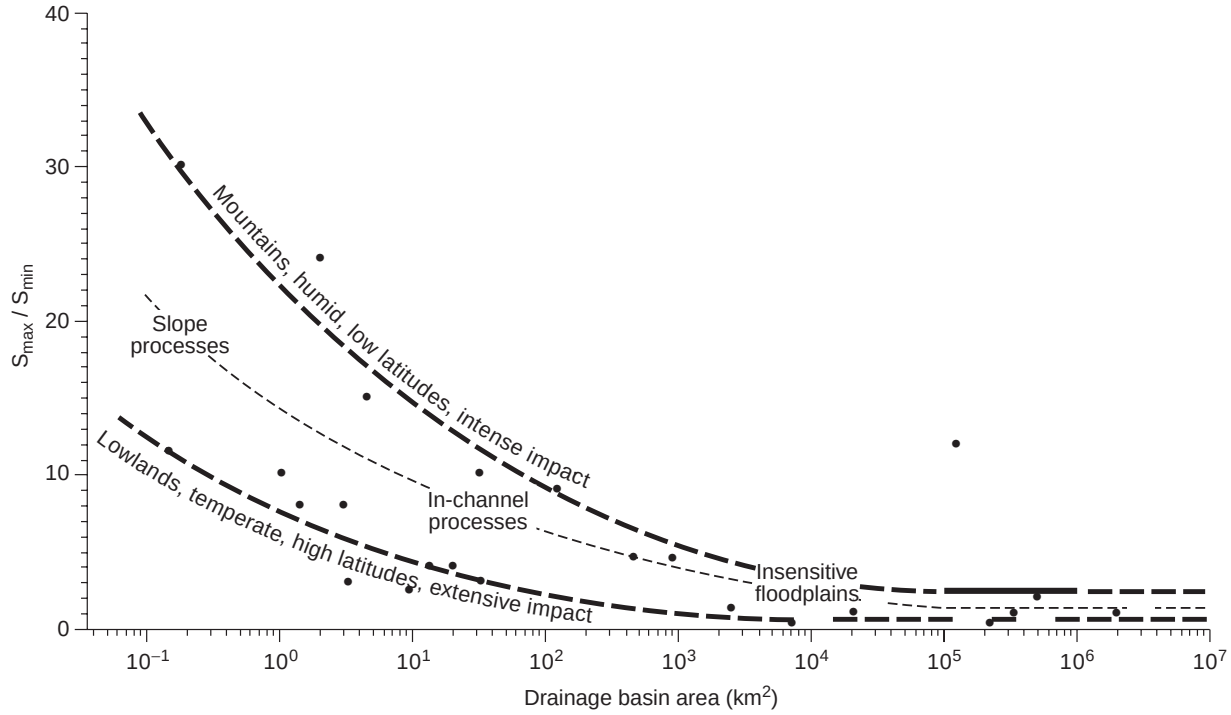

Figure 3 The relative magnitude of change between minimum, baseline, or preimpact sediment flux and maximum sediment flux (dimensionless ratio S_{max}/S_{min}) plotted against drainage basin size (km^2) from published case studies of late-Holocene sediment accumulation rates. Also shown are apparent controls on upper and lower limits, and the likely trend of increasing decoupling between slope and channel, and increasing sediment storage, as basin area of basin increases. Horizontal line (10^5–10^6 km^2) shows maximum range of estimated long-term sediment yields for large Asian rivers. The data suggest that although sediment flux at a site, and at a point in time, is controlled by the local combination of climate, land use, topography, elevation, and tectonic factors, the range of long-term variability is constrained by catchment area. The available data suggest that the upper limit of the distribution is associated with mountainous landscapes, humid climate (especially in low latitudes), and intense human impact. The lower limit is associated with lowlands, temperate climate, and extensive human impacts (Reprinted from Dearing and Jones, 2003, © 2003, with permission from Elsevier)

et al., 1998; Zolitschka, 1998; Foster *et al.* 2003). Dearing and Flower (1982) demonstrated that variations in the magnetic susceptibility of material in Lough Neagh sediment traps closely followed variations in the preceding monthly precipitation. They argued that high susceptibility was linked to the transport of relatively large particles of primary titanomagnetite in flood events, thus providing a process link between hydrological processes and the lake sediment susceptibility record. Thus Holocene lake sediment records of magnetic susceptibility that increase towards the present (Figure 4), probably reflect an increasing frequency and/or magnitude of flooding caused by climate or human-induced changes in runoff and increased sediment supply; an interpretation which is strongly supported by correlations with pollen evidence for open landscapes. If the same hydrodynamic explanation is applied to records with long-term trends in magnetic susceptibility decreasing to the present, the implications are that sediment availability and the efficiency of fluvial processes in many high latitude and upland sites have declined during the Holocene and may have been insensitive to climate change.

Changes in sediment source over time may indicate the spatial location of catchment disturbance. The Holocene record of sediment load at Bussjössjön (Figure 1) in southern Sweden (Dearing *et al.*, 1990), broadly similar to the Holzmaar record, is complemented by magnetic-based tracing of sediment sources (Dearing, 1999, 2000). The results suggest that sediment has been derived largely from channel sources, despite modern process monitoring that measures high rates of surface soil movement on surrounding arable fields. Similarly, in their study of sediment delivery in the Southern Tablelands of Southeast Australia, Wasson *et al.* (1998) use historical surveys and reservoir sedimentation rates in the Jerrabomberra Creek catchment to show that initial disturbance in the late nineteenth century, largely through sheep grazing, increased sediment yields 900-fold, which then reduced to 6-fold after the 1940s. Monitoring and tracer studies in the same landscape (e.g. Olley *et al.*, 1993) showed that channel incision and gullying were the

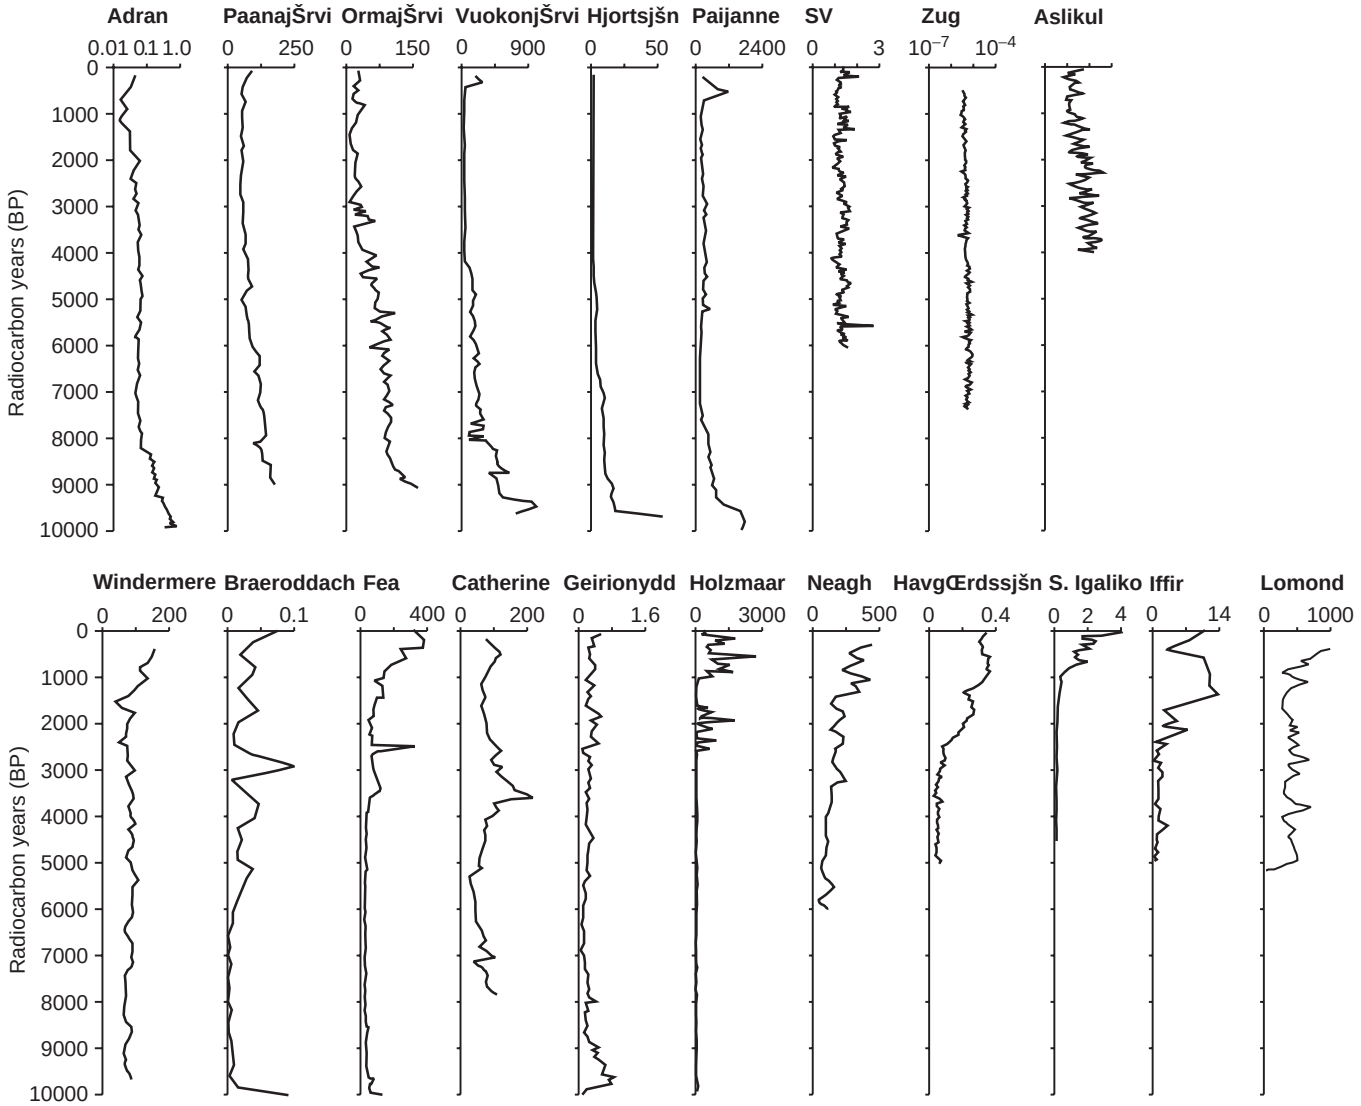

Figure 4 Holocene lake sediment records of magnetic susceptibility, used to infer river discharge. (a) Decreasing or stationary trends; (b) increasing trends from mid-to-late Holocene to the present. Sediment dating variously derived from radiocarbon, paleomagnetic secular variation and late-glacial/Holocene boundaries, with approximate timescale of 0–10 000 BP (Reproduced from Dearing, 1999, by permission of Cambridge University Press)

dominant processes of both sediment production and downstream sediment delivery.

Unraveling Natural Variability and Human Impact

In a few studies, high resolution and multiproxy analyses of sediment cores provide the means to unravel the interactions between climate and human impact. For example, the laminated sediment record from Holzmaar, Germany, (Zolitschka, 1998) shows major rises in minerogenic sediment flux dated to the periods of the Iron Age, the Roman Empire, the High Middle Ages and the seventeenth to eighteenth centuries (Figure 1b). The record from lake Bussjössjön, southern Sweden, (Dearing *et al.*, 1990), similar except for the lack of a sedimentation spike ~2000 BP attests to the fact there was no Roman occupation (Figure 1a). The overall similarity in these records, except where human impact differs, strongly indicates the overriding importance of land use. Estimated sediment yields at Holzmaar rose from $\sim 1.5\,\mathrm{t\,km^{-2}\ year^{-1}}$ before major human impact to a maximum of $49\,\mathrm{t\,km^{-2}\ year^{-1}}$ in the seventeenth and eighteenth centuries, an overall maximum increase of 33-fold over prehuman impact values. A mathematical analysis of the accumulation rate data for the period 3000–9000 cal. BP, prior to major human impact, suggests that it may be a time period across Central and Northwest Europe when the hydro-geomorphic system was in

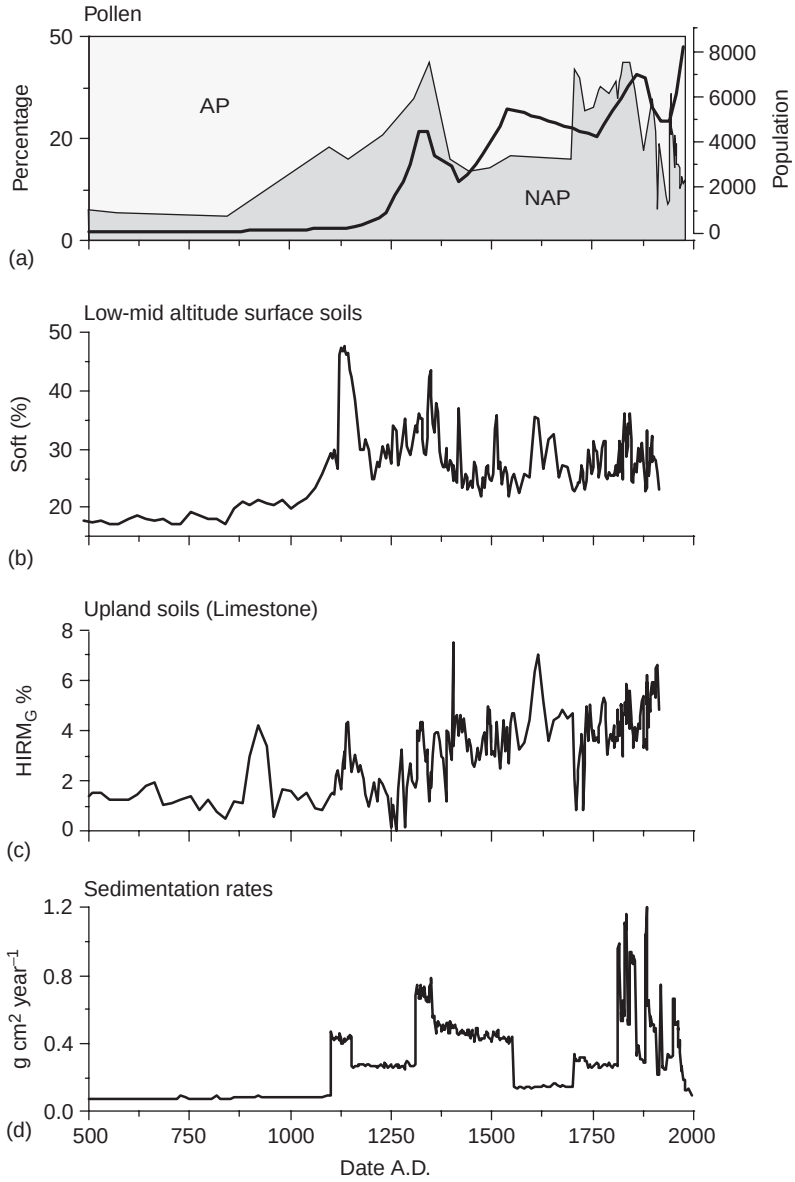

Figure 5 Erosion and land use history (~A.D. 500–2000) of the Petit Lac d' Annecy catchment, Haute Savoie, France, based on lake sediment analyses of sediment flux and sources, and historical documents: (a) arboreal (AP) and nonarboreal (NAP) pollen curves (shaded) as measures of forest cover and land openness, with human population (solid line); (b) soft magnetic remanence proxy for lowland soil; (c) high magnetic remanence proxy for upland soil; (d) sediment accumulation rate as proxy for sediment flux (Reproduced from Dearing *et al.*, 2001, With kind permission of Springer Science & Business Media)

a state of self-organized criticality where the impact of external forcings on sediment flux from the catchment was subordinate to the internal organization of processes (Dearing and Zolitschka, 1999).

At another site in Europe, Lac d'Annecy, France, the Late-Holocene record of sediment flux (Figure 5d) is also similar to Holzmaar, Bussjössjön, and other records in the region, such as the Jura (Bichet *et al.*, 1999), but with a strong erosional pulse triggered by deforestation (% nonarboreal pollen – NAP) and population expansion (Figure 5a) into high valleys during the monastic period in the tenth to thirteenth centuries. Here, sediment-source tracing allows disaggregation of the total sediment flux into specific sediment sources that provides a basis for reconstructing the degree of slope-channel coupling. Interestingly, the early deforestation phase caused not only a rise in low-mid-altitude soil erosion (Figure 5b), but also apparently triggered long-term instability in the high valleys, as shown by the continued upward trend in the signature for upland soil (Figure 5c). The Petit Lac d'Annecy catchment

has excellent land use records, particularly for population, forest clearance, and agricultural land use (Crook *et al.*, 2002), giving the opportunity to define the timescales over which different types of interaction between climate and land use occur. Recent studies have therefore used land use records in combination with a calibrated magnetic proxy for flooding to model the responses to meteorological events and land use (Foster *et al.*, 2003). Climate fluctuations at Annecy have controlled fluxes of total suspended sediment fluxes on short timescales 10^0-10^2 year, whereas phases of land use change have driven the major shifts in the sediment system over timescales of 10^2-10^3 year. It is the intermediate timescale of several decades to a few centuries that has seen the strongest interactions between a fluctuating climate and subtle shifts in land use. Importantly, this timescale dominates global projections and, at least for this subalpine landscape, may be the period in which sediment responses are the most complex to understand and model. The use of climate model outputs as drivers for modeling future sediment responses requires downscaling to spatial scales of the "human landscape" represented by small-medium drainage basins. In this sense, 200-year long reservoir sediment records in Midland England have already been successfully used (Wilby *et al.*, 1997) to model the impact of climatic change on sediment yields under different land uses, using a weather pattern–based approach.

SUMMARY

- Holocene proxy records of sediment yield point to the dominant role of human activities in controlling erosion rates, rather than climate directly. The impact of early agriculturalists before 2000 BP is clear in records from Europe, South America, New Zealand, and China. Later rates of sediment yield are normally higher, especially where European agricultural techniques were introduced within the past 400 years. In many catchments, the current levels of sediment loss are at least 10 times greater than the preimpact state. Sediment source data are less widely available, but where they exist tend to show that sediment is often derived from nonsurface sources. This suggests that catchment disturbance has, in general, caused rates of runoff and stream channel erosion to rise faster than delivery rates of surface soil.
- Analysis of the variability of sediment flux records suggests that the magnitude of changes in sediment transport following catchment disturbance increases as catchment size becomes smaller. This means that surface soil erosion is less marked in lake records of large catchments simply because of greater storage, and not necessarily because of less erosion at the field scale. This also implies that rates of change in sediment accumulation on floodplains increase with basin size. Thus, floodplain and lake sediment records within the same drainage basin may provide contrasting records of fluvial responses. Lake sediments, dominated by the fines in the system, are more likely to preserve the temporal shifts in sediment supply often linked to land use change and more efficient slope-channel coupling. In contrast, alluvial stratigraphies may be more sensitive to fluvial competence, driven by meteorological events, both to entrain and transport coarser particles and to rework existing sediments within the channel and valley floor.
- In terms of global transport of sediment to the coast, long-term perspectives suggest that disturbance of small catchments that feed directly to the coast will deliver relatively more sediment than from large catchments where there is significant sediment storage on floodplains and in large reservoirs. Future climate shifts or widespread land-use changes may result in only minor or even undetectable relative changes in the sediment flux at the outlets of large basins and in near-shore zones. This has implications for the stability of coastlines and the transfer of inorganic and organic sediment to the continental shelf.
- In the future, we may expect that lake sediment records will help form the basis for classifying the sensitivity of modern fluvial and sediment systems to future impacts. For example, systems that have evolved into complex self-organized states under low levels of disturbance may be relatively more susceptible to dramatic shifts in climate and land use than systems already conditioned by long histories of human impact. Recent mathematical and cellular automaton models of long-term erosion (Coulthard *et al.*, 2000; Tucker and Slingerland, 1997) also suggest that sediment delivery over timescales of 10^1-10^2 years is essentially a highly nonlinear product of land-cover change and high-magnitude rainfall events. There are now the exciting prospects of using lake records to test these models, thereby providing a framework of study across a very wide range of spatial (10^0-10^6 m^2) and temporal (10^0-10^3 year) scales.

Water Quality and Biogeochemistry

91: Water Quality

MICHEL MEYBECK[1], NORMAN E PETERS[2] AND DEBORAH V CHAPMAN[3]

[1]Sisyphe/CNRS, University of Paris, Paris, France

Water quality is the term used to describe the chemical, physical, and biological characteristics of water. Furthermore, the physical, chemical, and biological characteristics of a water body, "its water quality", determine the suitability of that water for a particular value, for example, potability, ecosystem status, agriculture, industry, recreation. Water-quality issues have become a rapidly evolving component of the environmental sciences primarily due to the increasing demand on water resources and amenity value and the intricate linkage between water-quality use and ecosystem health. Water quality varies markedly in time and space. Episodic temporal water-quality variations can occur in minutes whereas, periodic variations can occur on short timescales from diurnal, associated with variations in light and temperature, to seasonal and longer associated with climatic variations. Spatial variations also vary markedly from millimeters and centimeters in soil profiles to very large-scale variations (>1000 km), for example, associated with water residence times, lithology, landscape position, land use, and bioclimatic zone. In the absence of the effects of human activities, water quality is primarily controlled by climate (precipitation and temperature) and geology (lithology, geomorphology, soil). The water quality of a given volume of water is derived from the sum of effects of mixing and interactions from all upstream sources including atmospheric deposition (precipitation and dry deposition), soil water (matrix and macropore), groundwater, springs, wetlands, irrigation ditches and canals, streams, ponds, lakes, reservoirs, rivers, and estuaries. In most parts of the world, human activities have now caused multiple and complex changes in background water quality.

INTRODUCTION

Water quality is a rapidly evolving environmental science discipline that began more than 150 years ago with a few basic physical (e.g. temperature), chemical (e.g. ammonia, dissolved oxygen), and microbiological (e.g. fecal coliform) variables. Now, water quality integrates dozens of analyses, *in situ* or in the laboratory, on water, particulates, and aquatic organisms and has evolved towards a global understanding of the aquatic environment including the description of habitat and biotic communities. Water-quality studies are conducted by all types of hydroscientists and on all types of continental waters including precipitation, soil water (matrix and macropore), groundwater, springs, wetlands, irrigation ditches and canals, streams, ponds, lakes, reservoirs, rivers, and estuaries. The currently rapid evolution of the water-quality discipline is attributed to the intricate relation among humans and the ecosystem or environmental needs and wants for water (short and long-term), the associated water-quality requirements for the prescribed use and the availability of water with an appropriate quality, and the decreasing availability of water having acceptable water quality.

Water-quality research and development has been driven for many years by the need for (i) scientific understanding of the aquatic environment, (ii) qualification of water for human uses, and (iii) management of land, water, and biological resources. More recently, a fourth objective also has driven water-quality research and development: the fluxes of dissolved and particulate material, through rivers and groundwater, including organic and inorganic components to lakes and reservoirs (Vollenweider, 1968)

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

and from the land to the oceans as part of the Earth System functioning (Livingstone, 1963; Garrels *et al.*, 1973; Berner and Berner, 1987; Vörösmarty and Meybeck, 2004), and is responsible for the degradation of the highly productive and recreationally attractive estuarine and coastal zone (Rabalais and Turner, 2001).

Water quality varies in time and space and its assessment largely depends on the state of scientific knowledge, the financial and technical means available to support the assessment, and the level of "water-literacy" of the community/society. Despite natural linkages between water quality and the lithosphere, water-quality characteristics are increasingly dependent on effects of human activities. Human activities create multiple and competing pressures on land and water resources through agriculture, urbanization, mining, industry, energy production, tourism, water supply, and transportation (water and land). These activities generally degrade water quality while being very demanding for specific water-quality criteria.

This article focuses primarily on surface water chemistry, and river chemistry in particular. Characteristics of water quality are presented in the first section ("Introduction"). General origins, pathways, and controls of water-quality variables are presented in the Section "Water-quality characteristics" and the lithological controls on river chemistry are presented in the Section "Natural river water quality: origins, pathways, and controls of river chemistry". The spatial and temporal distributions of water quality in river basins are the foci for Sections "Spatial variability of major ion concentrations in streams and rivers" and "Temporal variations of river water quality" respectively. Finally, the Section on "Riverine fluxes" focuses on riverine fluxes.

For additional information about water quality, read the articles on monitoring (**Chapter 92, Water Quality Monitoring, Volume 3**), acidification (**Chapter 95, Acidic Deposition: Sources and Effects, Volume 3**), effects of human activities on water quality (**Chapter 93, Effects of Human Activities on Water Quality, Volume 3**), point and nonpoint sources of pollution (**Chapter 94, Point and NonPoint Source Pollution, Volume 3**), nutrient cycling (**Chapter 96, Nutrient Cycling, Volume 3**), urbanization (**Chapter 97, Urban Water Quality, Volume 3**), pathogens (**Chapter 98, Pathogens, Volume 3**), trace elements, salinization (**Chapter 185, Integrated Land and Water Resources Management, Volume 5**), and modeling (**Chapter 100, Water Quality Modeling, Volume 3**). WATER-QUALITY CHARACTERISTICS

Water quality incorporates information primarily from three scientific disciplines (physics, chemistry, and biology) to provide a holistic characterization of a freshwater body.

Physical and Chemical Aspects of Water Quality

The physical component consists of physical measurements that describe the aquatic habitat and its time and space variability. Some physical characteristics that effect biota and chemistry include, but are not limited to, the distribution and characteristics (scattering) of light in a water body, usually below the air-water interface; the color of the water; the water temperature ($T°$) and its distribution temporally and spatially in the water body; specific conductance (K_{SC}), the ability of the water to transmit an electrical current at 25 °C that is primarily determined by the total concentration of charged solutes dissolved in the water; the amount and distribution of particle sizes of suspended material and bed material; the density of the water; the hydrologic characteristics including water discharge and the circulation or hydrodynamics; the slope of the water surface, the spatial interrelation of water flow, and characteristics of the bed material, biota, and geomorphology.

The chemical data comprises analyses of water either filtered or raw (unfiltered), particulates, biota tissues or whole organisms; for organic and inorganic components, elemental isotope content, metals, and radionuclides. For solids, the chemical contents are usually expressed as mass per mass (e.g. $g\,kg^{-1}$, $\mu g\,g^{-1}$), and for "dissolved" (i.e. conventionally after filtration on 0.45 μm, which may still include part of the colloidal fraction) or suspended components, the contents typically are reported as mass per unit volume of water (e.g. $mg\,l^{-1}$ or ppm, $\mu g\,l^{-1}$ or ppb), or for solutes, as moles of solute per unit volume of water ($mol\,l^{-1}$, $\mu mol\,l^{-1}$) or equivalents of charge per unit volume of water ($eq\,l^{-1}$, $meq\,l^{-1}$, $\mu eq\,l^{-1}$). Most natural freshwaters, in the absence of human impacts, have a relatively narrow range of few characteristics that either

reflect the chemistry, such as specific conductance (K_{SC}), or control the chemistry, such as the acid–base status as measured by pH (minus the logarithm of the hydrogen ion concentration) and alkalinity (capacity of water to neutralize acid), and the oxidation and reduction conditions or redox as typically measured by ion pairs and the dissolved oxygen (DO) concentration. In addition, biogeochemical cycles are affected by the affinity of the elements and compounds to adsorb or bind to each other and to other compounds and solids, and by their ability to dissolve in water.

For natural or background conditions, the chemical composition of waters and waterborne particulates is characterized by dozens of elements and compounds including:

Major dissolved ions: cations: Ca^{2+}, Mg^{2+}, Na^{+}, and K^{+}; anions: Cl^{-}, SO_4^{2-}, HCO_3^{-}, and CO_3^{2-}; generally reported in $mg\,l^{-1}$ in ion or elementary form (e.g. mg NO_3^{-} l^{-1} or mg NO_3-N l^{-1})

Minor dissolved elements: Fe, Al, Mn, Ba, and Sr, reported in $\mu g\,l^{-1}$;

Trace dissolved elements: As, B, Cd, Cr, Cu, Hg, Pb, Se, Sn, Sb, Zn, and many others that generally are reported as $\mu g\,l^{-1}$ or $ng\,l^{-1}$;

Natural organic compounds: amino-acids, lipids, humic and fulvic acids, and natural hydrocarbons, generally in trace amounts and dissolved organic carbon (DOC in $mg\,l^{-1}$);

Synthetic organic compounds: several hundreds of man-made products (*xenobiotics*), generally toxic, must be controlled particularly for drinking waters including herbicides, pesticides, solvents, plasticizers, fire retardants, hydrocarbons, and polyaromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs). Some of them are very Persistant Organic Pollutants (POPs) and can be transported in aerosols over long distance, or attached to suspended matter.

Nutrients: used by aquatic plants, including nitrogen (N) species (NO_3^{-}; NO_2^{-}; NH_4^{+}); dissolved and particulate organic N (DON and PON); Kjeldahl N (N_K); total N (TN); phosphorus (P) species orthophosphates (PO_4^{3-}); dissolved organic P (DOP); particulate P (PP); total P (TP), and dissolved silica (H_4SiO_4, generally reported as SiO_2).

Miscellaneous: total dissolved solids (TDS); sum of cations $\sum^{+}$ and anions $\sum^{-}$ (expressed in $meq\,l^{-1}$; they should be equal in balanced analyses); suspended solids (SS), typically expressed as total suspended solids concentration (TSS), and deposited sediments in lakes, reservoirs, floodplain, and sometimes river beds. SS are often considered as a key media for the monitoring of nutrients (N, P), particulate organic carbon (POC; carbon linked to carbonate minerals or PIC both expressed in % of particulate matter), minor and trace particulate elements (Al, Fe, Mn, Si, As, Cd, Cu, Hg, Pb, Sb, Zn) and these are commonly analyzed and reported as content per dry weight ($\mu g\,g^{-1}$, $ng\,g^{-1}$); chlorophyll A and total pigments ($\mu g\,l^{-1}$) as a measure of active and total phytoplankton biomass.

Biological and Microbiological Aspects of Water Quality

All aquatic organisms, whether bacteria, invertebrates, vertebrates, vascular plants, or planktonic algae, have preferred environmental conditions in which they thrive. Many, however, can also be found within certain tolerance limits of these conditions. The basic parameters to which biota are sensitive are physical (e.g. light, $T°$, DO, turbulence, sediment grain size) and chemical (e.g. acidity, nutrients, toxic chemicals). Aquatic organisms need a source of energy – for photosynthetic organisms this means adequate light and nutrients and for others it means a source of suitable food, ranging from organic detritus to plant material to other invertebrates or vertebrates. Thus, directly, or indirectly through the food chain, aquatic organisms are dependent on the physical and chemical aspects of water quality.

In turn, the presence of aquatic organisms influences water quality – photosynthesis by planktonic algae and macrophytes can increase oxygen concentrations to levels of supersaturation at times of high light intensity, and the respiratory action of bacteria decomposing dead and dying plankton or macrophytes can use up the oxygen in the water thus resulting in a daily O_2 cycle whose intensity is a measure of the aquatic production. A living plankton is a component of the total suspended matter, and decaying plants and plankton contribute organic matter particles to both suspended and deposited sediments with a ratio algal organic carbon/total pigments between 30 and $40\,g\,g^{-1}$ for plankton. During photosynthesis (or production P), phytoplankton uptakes dissolve inorganic nitrogen, NO_3^{-} and NH_4^{+}, and phosphorus (PO_4^{3-}) according to the Redfield molar ratio C_{106}:N_{16}:P_1. As organisms decay, they also release nutrients back into solution and the seasonal cycles of phytoplankton species and/or macrophytes can greatly influence the seasonal fluctuations in lake nutrient concentrations. Under less productive conditions, the oligotrophic state, diatom algae are generally dominant particularly in spring blooms of the temperate and cold regions. In addition to N and P nutrients, these algae also use dissolved silica. As a result of seasonal algal uptakes marked cycles of H_4SiO_4, NO_3^{-}, NH_4^{+}, and PO_4^{3-} are observed in lakes and reservoirs and in some highly productive (eutrophic) rivers. The bacterial decomposition (or respiration, R) of the organic matter produced in the aquatic system leads to oxygen depletion. When the P/R ratio <1 there is a net O_2 depletion, as in lake bottom waters in the absence of vertical mixing, or in turbid macrotidal estuaries. This depletion may also be caused by the decomposition of organic wastes, for example, from urban sewage, thus resulting in an oxygen sag-curve downstream of untreated and partially treated effluents. Thus the traditional perception of water quality

cannot be separated from the aquatic organisms present in the water body and this has led, in recent decades, to a more holistic approach to the study of water quality to include some, or all, biological components of aquatic systems.

The interaction between suitable habitats, that is, environmental conditions, and suitable food supplies leads to communities of organisms that typically thrive together in natural water bodies. These communities include bacteria using dissolved organic carbon, primary producers (plants and plankton), herbivorous invertebrates, detritivores, fish, and even mammals (the tropic pyramid). Any impact on one of these groups can cause effects on the dependent groups, for example, through loss of food supply, alteration of environmental conditions (physical or chemical), and altered predator–prey relationships. Ultimately, the natural balance of the whole aquatic system may be altered, and with it the physical, chemical, and biological water quality.

Aquatic organisms are more and more used to describe the water quality in its wider definition (Chapman, 1996). Certain individuals or combinations of organisms can be associated with narrow ranges of water quality, particularly the extremes of clean and polluted water. Thus, the organisms themselves provide a monitoring tool, whereby their presence or absence can be indicative of certain classes of water quality (*see* **Chapter 92, Water Quality Monitoring, Volume 3**). Some of those aquatic organisms are chosen for their limited mobility (e.g. benthos); they integrate at one given station the effects of human influences on their environment (chemical and physical) over the period of their lifetime that can vary from months to decades. Other organisms have a great mobility, such as fish, or may even travel along an entire aquatic system from headwaters to ocean, and are chosen for their overall integration of both physical and chemical degradation (e.g. salmon). Some aquatic organisms also accumulate toxic compounds and can serve as indicators of contamination through biomagnification of the signal. Organisms also demonstrate physiological or morphological effects caused by the presence of anthropogenic emissions (*see* **Chapter 92, Water Quality Monitoring, Volume 3** and MHSPE (1995, vol 32)).

Historical interest in water quality has been largely based on potential human health impacts and, even today, the presence of pathogenic organisms in water, including some bacteria, enteric viruses, and parasites, is a major concern. In many developing parts of the world, it is the only aspect of water quality to which resources are directed for monitoring and management. *Escherichia coli* (E. coli, a primary indicator of fecal contamination) and fecal coliforms are usually found in low concentrations (10^0 to 10^3 counts per 100 ml) in the absence of human impacts, and therefore, are the most common indicators of fecal contamination. Fecal pathogens can cause a wide variety of intestinal diseases, many of which result in diarrhea; the World Health Organization (WHO) considers them as the most important water-quality issue globally, particularly in the developing world. Once added to water by disposal of human excreta, particularly domestic sewage, coliforms decay very rapidly at ambient temperature (by one to two orders of magnitude within 24 h). In highly contaminated water, total coliform may exceed 10^5 or 10^6 coli $100\,ml^{-1}$. WHO recommends that water containing any *E. coli* should not be used for drinking (WHO, 2004). Also, a monthly geometric mean for *E. coli* of <130 coli $100\,ml^{-1}$ is recommended for contact recreation, such as swimming and boating.

More recent human health concerns relate to the presence of naturally occurring planktonic organisms known as *cyanobacteria* or blue–green algae. These organisms thrive in highly eutrophic water bodies with limited water circulation, such as ditches, shallow lakes, and ponds and the surface layers of stratified lakes in the summer months. Some species produce toxins and release them into the water as the cells decay during the end-of-season collapse of the population. The toxins are hard to detect, but the presence of the species themselves can be used to signal caution that the water may not be of "good quality" for human as for domestic animals (Chorus and Bartram, 1999).

Water-quality issues can be assessed by specific variables (Table 1). Depending on the availability of human and financial resources, their monitoring can focus on first order variables or include also the second order variables. Simple to complex combinations of water-quality variables referred to as a *water-quality index*, are used to indicate the status of a freshwater body with respect to some particular problem or issue. For example, pH and alkalinity, a measure of the capacity of a water body to neutralize acid, are used to indicate the susceptibility of a water body to acidification, and various nutrient species and chlorophyll A concentrations are used to determine the tropic status of a water body. Sodium and calcium are combined in a Sodium Adsorption Ratio, which is used in irrigation to assess the risk of salinization Hem (1989).

NATURAL RIVER WATER QUALITY: ORIGINS, PATHWAYS, AND CONTROLS OF RIVER CHEMISTRY

The natural origins and pathways of riverine materials are multiple and vary from headwaters to estuaries and are controlled by many physical, chemical, and biochemical processes (Figure 1 left part). The fate of river-borne material eventually depends on the chemical composition of the dissolved or particulate phases, the source of the component, the hydrologic pathways, the transformation of the component or other interactions or reactions with materials

Table 1 Major water quality issues. Physical and chemical monitoring variables, their relevance to aquatic biota (0 to +++ scale), the origin of pressures, and limitations of uses (**bold**: very important)

Issues	1st priority variables	2nd priority variables	Aquatic Biota	Origins of stresses	Use limitations
Thermal pollution	Temperature[a]		++	**D, F, G_1, G_2**, Z	G, I
Salinization	Electrical conductivity[a]	Major ions	++	**B_3**, D, **K, X**, Z	A, **B_3**, C, D, I
Acidification	pH[a], Alkalinity	Major ions; DOC	++	**D, E, K, G_2**	C, **D, I**
Oxygen balance	Dissolved oxygen[a]	BOD, COD; DOC, POC	+++	**B_2, J, D**	**C**, D_2, H, **I**
Chemical contamination					**A**, B, **C**, D_2, H, **I**
NH_4^+	NH_4^+		+	**B_2, J**	
NO_3^-	NO_3^-			**B_1, J**	
Metals	Cd, Cu, Hg, Pb, Zn; Al	As, Cr, Ni, Se, Sb...	++	**D**, E, J, **K**	
POPs	total PCBs; total PAH	Individual compounds	+	**D, J**	
Pesticides	total pesticides	Individual compounds	+	**B**, J	
Endocrine disrupters		Individual compounds	?	**B_2, D, J**	
Microbial contamination	Total coli; *E. coli*	Streptococci...		**B_2, J**	**A, B, C**, D_2, **H**, I
Eutrophication	Total P and N; chloro A	C, N, P, Si species, algal counts	++	**B, B_2**, D, I, **J**, W	C, E, G, **H, I**
Water-related diseases	Specific surveys (parasites, insects larvae...)			**B_2, J**, X, Y, W, Z	**A, C**, D_2, **H**
Habitat destruction	Specific surveys		+++	B,**E, F, G_3, J**, X	
Radionuclide contamination	Total α, β, γ activity	Individual radionuclides		D, **G**, J	**A, B, C**, D, **H, I**

[a]possible *in situ* and continuous measurement
Human activities: A = traditional agriculture and rural settlement, B = Intensive agriculture (B_1 = fertilized crops, B_2 = cattle feedlots, B_3 = irrigated agriculture), C = Drinking water, D = Industries (D_1 = nuclear industries), D_2 = food industries, E = Transportation (ground, air, fluvial), F = Damming, G = Energy production (G_1 = nuclear power plant, G_2 = coal and fuel power plant, G_3 = hydropower), H = Recreation, I = Fisheries, J = Urbanization, K = Mining.
Global change: W = Biodiversity alteration, X = Hydrological balance, Y = Sea level rise, Z = Global warming.

during transport, the residence time and interaction of the various hydrological pathways resulting in mixing, and biogeochemical processes. Atmospheric deposition (Figure 1, #4) is an important source of Na^+, Cl^-, and SO_4^{2-}, originating from ocean aerosols (Figure 1, #1), with the highest deposition occurring closest to the source, and somewhat important sources of Ca^{2+}, Mg^{2+}, and SO_4^{2-}. Dust originates from Aeolian erosion (Figure 1, #3) and volcanism and terrestrial vegetation (Figure 1, #2). Decaying terrestrial and aquatic vegetation (Figure 1, #2), which previously fixed atmospheric CO_2 and N_2, are the main source of C and N species in surface waters. Soil leaching provides DOC and DON. Soil mechanical erosion delivers POC, PON, PP, and SS. Mineral weathering provides major ions and silica (Figure 1, #10) through different water pathways including groundwater inputs (Figure 1, #11); the highest streamwater concentrations are associated with the highest groundwater proportion in surface waters during the dry season. Saline deep aquifers and hydrothermal water can yield high concentrations of SO_4^{2-}, Cl^-, and K^+ in some volcanic and/or tectonically active regions, as in the East African Rift or in New Zealand (Figure 1, #12). Erosion or resuspension of particulates resulting from stream and riverbed incision also may be important.

The fate of SS in aquatic systems is characterized by a succession of deposition and remobilization within a river channel dependent on variations in the velocity of streamflow and through different filters that characterize the river system. The filters include hillslopes and wetlands located in headwaters (Figure 1, #5), lakes (Figure 1, #6), alluvial plains and related wetlands (Figure 1, #9), and estuaries. Each filter retains particulate matter and associated chemicals (PIC, POC, P, PN, PP, and POPs), except during major floods when some of these materials may be remobilized. The in-stream/channel retention (erosion and deposition) of SS varies markedly between high and low flows and is highly variable during individual hydrological events. However, riverbed storage generally is not permanent on medium timescales (2–10 years), unless cementation occurs in the channel sediment (e.g. the Huang He river channel in China).

Several chemical and biochemical processes occurring in terrestrial vegetation, soils, and waterscape filters, such as wetlands, lakes, and reservoirs control

major ions, nutrients, organic carbon, and particulates (Table 2). For a more detailed discussion of nutrient cycling in freshwater, *see* **Chapter 96, Nutrient Cycling, Volume 3**.

Evaporation concentrate solutes in surface waters (Figure 1, #7) and ultimately in dry and semiarid regions (e.g. Central Asia, Altiplan, Great Basin, and Lake Eyre Basin) causes the water to become saturated with respect to various minerals that precipitate typically in the order of calcite, magnesium calcite, gypsum, and anhydrite. The precipitated minerals occur in soils, floodplains, and depressions where water ponds after floods (Figure 1, #8).

In impacted basins, new sources and pathways of materials occur leading to accelerated fluxes and/or increased retention (e.g. in impoundments). Physical changes due to climate change and land use change are also important for water quality. These impacts are schematically described in Figure 1 (right part) and in Table 2, and fully developed in **Chapter 95, Acidic Deposition: Sources and Effects, Volume 3**, **Chapter 93, Effects of Human Activities on Water Quality, Volume 3** and **Chapter 94, Point and NonPoint Source Pollution, Volume 3**.

SPATIAL VARIABILITY OF MAJOR ION CONCENTRATIONS IN STREAMS AND RIVERS

Global Scale Variability of Water Chemistry

At the global scale under natural conditions, major ion concentrations of streams are regulated by chemical weathering for more than 90% of river basin area and for more than 90% of river water flow followed by atmospheric deposition and evaporation (Gibbs, 1970). In some highly dilute waters and for some constituents, the storage and cycling of elements by vegetation may be another important control on streamwater chemistry (Meybeck, 2003).

Table 2 Principal sources, sinks, and controls of main chemical descriptors of rivers under natural conditions. For an explanation of the numbers in column 1, see Figure 2

Figure 2 Schematic	Processes	SS	POC	H_4SiO_4	Ca^{2+} Mg^{2+}	Na^+	K^+	Cl^-	SO_4^{2-}	HCO_3^- (DIC)	TN	PO_4^{3-}	DOC	O_2

+++: essential process; ++ important in some occasions; + may occur. SS: suspended solids; POC and DOC: particulate and dissolved organic carbon.

Chemical weathering is controlled by soil mineralogy, rainfall amount, and partitioning into groundwater recharge and surface runoff, temperature, and terrestrial vegetation (Drever, 2003). The relative abundance of minerals in the soil and surficial rocks and their sensitivity to weathering are major factors controlling the composition of a basin's surface water.

Surface water can be further classified into nearly a dozen of principal chemical types on the basis of major ion concentrations (Meybeck, 2003). These include a few classes that are dominated by atmospheric deposition and evaporation/precipitation (Table 3).

Atmospheric deposition may affect river water quality. In the first 100 km of coastlines where rainfall is an important contributor to surface water, the ocean inputs of Na^+, Cl^-, Mg^{2+}, K^+, and SO_4^{2-} may be important and may even dominate relative to the contribution of chemical weathering. These constituents are present not only in rainfall, but in oceanic aerosols that accumulate on vegetation and land surfaces and are washed off by the rainfall. For the coastal ribbon the primary source of Na^+, Cl^-, Mg^{2+} is almost always atmospheric deposition, particularly if the ionic content in local rock types is negligible or low and, consequently, the concentration ratios among these constituents are similar to that of seawater (Table 3(b), The Cusson River).

Except in evaporitic sedimentary rocks, chlorine is generally very rare at the Earth's surface. Chloride ion (Cl^-), the dominant form of chlorine in surface water, is generally attributed to ocean-derived atmospheric deposition in the absence of human activity. In turn, the related ions can be determined on the basis of ionic ratios of the solute to Cl^-, as occurs in seawater (e.g. $Na^+/Cl^- = 0.88\,eq\,eq^{-1}$). However, Cl^- is concentrated and contributed by many human activities and natural levels of Cl^- are often exceeded by anthropogenic inputs, as for Na^+, K^+, and SO_4^{2-}.

(a) analyses corrected for rain inputs assuming Cl^- to be of oceanic fallout origin. (b) uncorrected analyses from various climatic zones and lithology: (1) pure quartz sand, Brasil; (2) basalt (La Réunion); (3) arkose sand with important oceanic fallout (Landes, France); (4) with limestone outcrops Congo basin; (5) outlet of Lake Edward, hydrothermal inputs (Uganda); (6) evaporated endorheic river (Morocco); (7) pyritic shales (Montana); (8) hydrothermal stream (New. Zealand); (9) draining salt deposits (N.W.T., Canada); and (10) Central Asia.

In basins where chemical weathering is very low (see Rio Negro tributaries, Table 3(b)), terrestrial vegetation is a major store and regulates the release of elements derived from atmospheric deposition, including Ca^{2+}, K^+, SO_4^{2-}, NO_3^-, NH_4^+, and Cl^-.

Examples of average chemical concentrations of streams draining monolithologic basins are given in Table 3(a) for 15 rock types from a set of 200 small temperate and relatively undisturbed basins in France. A second set of analyses is from heterogeneous lithologic basins (Table 3(b)). Differences in the solute concentrations among these rivers are primarily due to the bedrock composition except for H_4SiO_4, which also increases with average annual temperature for a given rock type. Note that except for H_4SiO_4, the solute concentrations for the wet tropics such (e.g. Rivière de l'Est, basalt, La Réunion or Lufira, limestone, Congo basin) are very similar to those in the temperate regions for the same rock type. For the Cusson River in the coastal French Landes (quartz and feldspar sand deposits), more than 80% of major ions are derived from the atmospheric deposition of ocean aerosols, and consequently, the Na^+ to Cl^- ratio ($0.87\,eq\,eq^{-1}$) is approximately that of seawater (0.88). If the atmospheric deposition of marine-derived constituents (i.e. all Na^+, all Cl^-, most Mg^{2+}, and most SO_4^{2-}) were subtracted from the Cusson River analyses, the cation sum would decrease from $1463\,\mu eq\,l^{-1}$ to $250–300\,\mu eq\,l^{-1}$.

Waters draining basins containing evaporite minerals, particularly halite (NaCl), are difficult to differentiate from waters subjected to high evaporation in arid and semiarid regions. Both can be extremely mineralized. For example, where rainfall greatly exceeds potential evaporation, the Salt River in northern Canada ($\Sigma^+ = 312\,meq\,l^{-1}$) (Table 3(b), #9) and where evaporation exceeds rainfall by

about 10 times (runoff $q = 14\,\mathrm{mm\,y^{-1}}$), the Saoura River (South Morocco, $\Sigma^+ = 26.1\,\mathrm{meq\,l^{-1}}$, Table 3(b), #6) and the Tedzhen, a river in Central Asia ($\Sigma^+ = 13.2\,\mathrm{meq\,l^{-1}}$, Table 3(b), #10).

The hydrothermal and/or deep-water discharge to surface water can effect surface water solute concentrations in some volcanic regions (e.g. Iceland, New Zealand, Japan, Kamchatka), active mountain building regions (e.g. Himalayas, Caucasus), and in rift zones (e.g. Semliki River of East Africa, Table 3(b), #5). H_4SiO_4 concentrations also can be very high (e.g. the Tokaanu in New Zealand, Table 3(b), #8).

Spatial Distribution of Water Chemistry within River Basins

The statistical analysis of mean chemistry at stations that are implicitly assumed to be independent from each other is a first step in many spatial analyses. Mapping of water chemistry is common for groundwater, but is more difficult for surface water within river basins because: (i) river water quality integrates the water quality of contributing waters upstream, that is, from the entire drainage basin, (ii) differences in the drainage area of each station reflects, to some extent, the residence time of water in the basin that, in turn, a effects weathering-derived solute concentrations, and (iii) the upstream–downstream interdependency of nested stations.

For river basins with many water-quality monitoring stations, concentration distributions can be represented and compared using a probability scale. *Very common* concentrations are represented by concentrations between C_{25} and C_{75} percentiles, *common* concentrations between $C_{10}-C_{25}$ and $C_{75}-C_{90}$, *uncommon* concentrations C_1-C_{10} and $C_{90}-C_{99}$, and *rare* concentrations between $C_{0.1}-C_1$ and $C_{99}-C_{99.9}$ (Meybeck, 1996). These qualifications apply to any basin scale and are useful for comparing results among regions. Examples of within-basin spatial distributions are shown in Figure 2 for SO_4^{2-} and pH for some regions in relatively undisturbed basins, from the very dilute central Amazon waters to the mineralized Mackenzie River basin.

Longitudinal and Transversal Profiles of River Chemistry

Most mapping is realized on major stream orders through longitudinal profiles by simple interpolation between stations, particularly on the river main stem, such as for the Mississippi River (Meade, 1995). In river basins that are heterogeneous with respect to climate or lithology, water

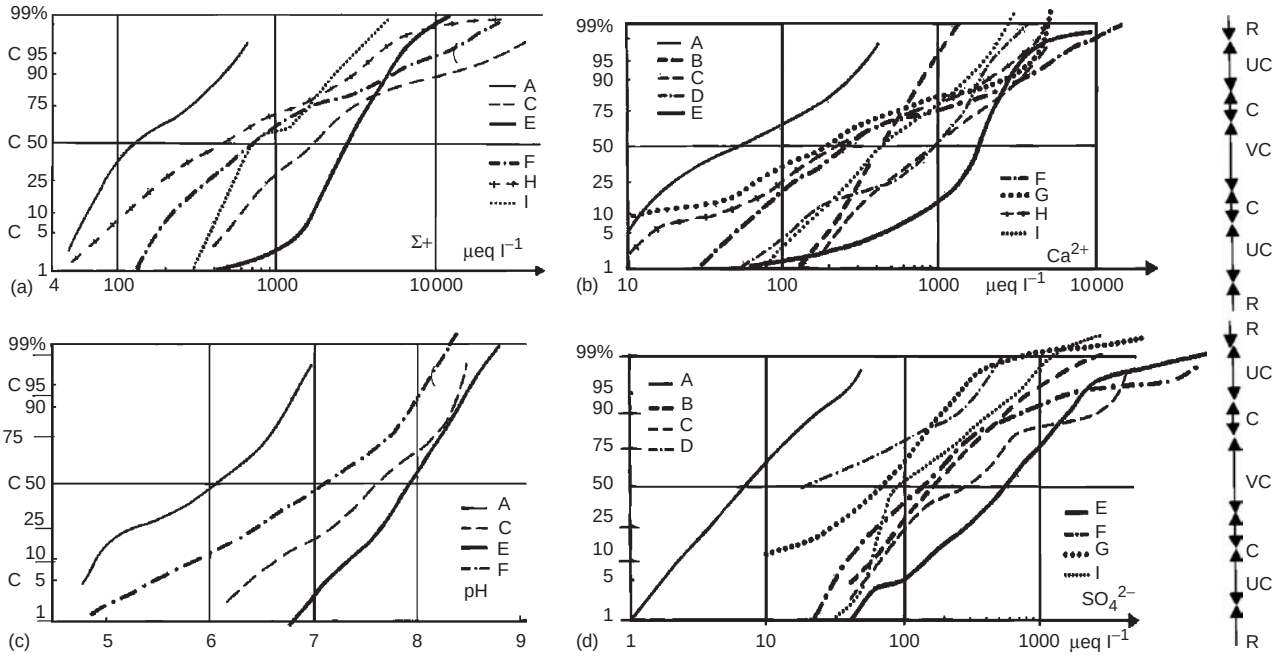

Figure 2 Cumulative distribution of ion chemistry in rivers from selected relatively undisturbed regions. (a) cation sum Σ^+ (μeq L^{-1}); (b) Ca^{2+} (μeq L^{-1}); (c) pH; (d) SO_4^{2-} (μeqL^{-1}). A: central and lower Amazon ($n = 40$); B: Japan ($n = 225$); C: Andean tributaries of Amazon ($n = 42$); D: Thailand ($n = 31$); E Mackenzie river basin ($n = 100$); F monolithologic French streams ($n = 250$); G ''temperate'' stream model; H: Monolithologic miscellaneous streams ($n = 75$); I: major world rivers ($n = 60$). For distributions of K^+, Na^+, HCO_3^-, and SiO_2: see Meybeck (1994). For more detailed information about the individual data series, see Meybeck, 2003 and Meybeck and Ragu, 1996 and references therein. VC = ''Very common'' concentrations: between 25% and 75% of distributions; C = ''common'': 10 to 25% and 75 to 90%; UC = ''uncommon'': 1 to 10% and 90% to 99%; R = ''rare'': 0.1 to 1% and 99% to 99.9%

quality can vary longitudinally, and, occasionally, across the river section as a result of poor mixing of tributary flow into the river.

For example, the TDS of the Arkansas River, a major tributary of the Mississippi River varies longitudinally (Stoner, 1984). The river headwaters in Colorado are somewhat mineralized with an average TDS of 273 mg l^{-1}. Downstream in Kansas, TDS increases to 3670 mg l^{-1}, then decreases to 880–1100 mg l^{-1} in Oklahoma and increases again to 3000 mg l^{-1} in Arkansas. During low flow at some stations, TDS and Cl^- may exceed 35 000 and 250 mg l^{-1} (the drinking water limit) respectively. The cause of the salinity variations is mostly natural due to drainage of underlying Permian salt deposits, common in this basin but rarely found at the global scale, but evaporation in reservoirs also may be important.

Under certain conditions, river water quality varies laterally across the river section, such as downstream of confluences where the water quality of each stream differs markedly. Two examples have been particularly well described: (i) in Brazil, the confluence of the Rio Negro "Black water" (organic rich, extremely dilute; Table 3(b), #1) with the Rio Solimoes "White waters" (sediment rich, dilute) that forms the Amazon River downstream of Manaus; (ii) in Canada, the triple confluence of the Upper St Lawrence River (i.e. the Lake Ontario outlet) that is depleted in DOC and is medium dilute, the Ottawa River that is organic rich and dilute, and streams draining the southern Laurentian Mountains, that have high SS and are medium dilute (Centre Saint Laurent, 1996). In each case, complete mixing does not occur until hundreds of kilometers downstream of the confluence despite very high-stream velocity (>1 m s^{-1}).

In basins impacted by human activities, the spatial distribution of water quality is generally more variable and is often affected by stepwise degradation of the aquatic habitat, downstream of point discharges of pollutants, downstream of nonpoint or diffuse sources of pollutants atmospheric deposition, and mobilization of the agrochemicals applied to fields, or as a result of water engineering (e.g. dams, diversions, irrigation returns).

TEMPORAL VARIATIONS OF RIVER WATER QUALITY

Temporal variations in river systems are specific for each water-quality variable and provide important information on the origins, pathways, and controls of that variable, particularly when evaluated with respect to changes in climate, hydrology, and land use or human activities in the basin. The variations range from sub-daily to secular. Although some patterns are associated with major changes either due to climate or human activities, frequently periodic patterns occur within each year associated with seasonality for which the cycles are called "*regimes*", and daily, called *diurnal* (24 h) and *nychtemeral* cycles; *nychtemeral* cycles are more specifically linked to the alternating light conditions from day and night that controls aquatic primary production. In most rivers, important water-quality variations are observed during floods due to the mixing of surface runoff, subsurface runoff, and groundwater discharge – for streams – and/or, for the large and heterogeneous basins, due to the mixing of major tributaries. In impacted basins during high water stages, point sources of contaminants are diluted, whereas soil erosion (e.g. TP) and leaching (e.g. NO_3^-) may result in higher concentrations. Initial steps in analyzing streamwater concentration variations include assessing the concentration relation with discharge and evaluating concentrations patterns during individual floods.

Long-term (>10 years), fixed-interval (weekly to bimonthly) monitoring provides information for assessing seasonal variations of river water quality. Several types of seasonal chemical regimes have been described from these data including (i) the influence of seasonal river flow regime; (ii) seasonal biogeochemical cycles; and (iii) seasonal anthropogenic affects from various types of human activities, such as reservoir operation, agriculture, forestry, mining, industry, and tourism (Table 1). At least 10 years of water-quality indicators are needed to detect trends from interannual variations by appropriate statistical tests (Peters, 1996 and Hooper and Kelly, 2001). The trends of riverine concentrations are generally linked to the magnitude of human activities and related implementation of waste management and pollution abatements.

Concentrations Variations with River Discharge

Constituent concentrations (C_i) typically vary with water discharge (Q). The use of specific discharge $\bar{q}$ (l s^{-1} km^{-2}) also allows for the easy comparisons of stations with very different basin size; normalizing q to long-term average q and concentrations C to median values C_{50} aids the comparison of different chemical variables from trace elements to major constituents (Figure 3). Most major ions and dissolved silica concentrations are higher in groundwater than in soil water or surface water due to a longer residence time of the groundwater that provides more time for concentrations to increase as a result of weathering. For streams where the source of these constituents is primarily groundwater, concentrations moderately decrease (partial dilution) with increasing discharge (Figure 3, #A). Near-perfect dilution (i.e. a quasi-constant flux) (Figure 3, #B) occurs downstream of point sources, such as saline springs and wastewater outfalls (e.g. NH_4^+, PO_4^{3-}). Clockwise hysteresis (concentrations increase more rapidly with increasing discharge on the rising limb of a storm hydrograph than decrease during recession) often occurs for DOC concentrations (Figure 3, #C1) because of rapid leaching or flushing and subsequent depletion of the DOC from the

upper soil layers during stormflow. SS concentrations in lowland basins typically show the same pattern because of the scouring of previously deposited channel sediment (Figure 3, #C_2). In contrast, in mountainous regions on a double logarithmic scale, the SS concentration is often linearly related to discharge (Figure 3, #D). Most particulate nutrients, pollutants, and metals, follow patterns of C_2 or D. POC, expressed in percent of SS, typically decreases with increasing SS in most rivers, but the concentrations as $mg\,l^{-1}$ increase moderately (Figure 3, #E) with regards to the SS pattern.

A few other patterns occur including: (i) apparent plateau at high flows (Figure 3, #F) resulting from seasonal nutrient uptake at lake outlets or stream denitrification of NO_3^- at summer low flows, a common pattern in some western European rivers; (ii) a dilution/resuspension pattern (Figure 3, #G) occurs for TP concentrations downstream of urban wastewater outfalls; the dilution of urban sewage PO_4^{3-} is followed by a resuspension of P-rich sediment, an example of the inverted behavior for two chemical species that are often analyzed together in unfiltered samples; (iii) a dilution/hysteresis pattern (Figure 3, #H), either clockwise or counterclockwise occurs in heterogeneous basins because of the different timing of tributary discharges to a river; they are often associated with variable concentrations because of basin heterogeneity, some combination of processes, or processes yet to be identified; (iv) near constant concentrations (Figure 3, #I) can be observed in groundwater dominated streams and are also observed for Cl^- when derived primarily from atmospheric deposition; and (v) temporally, sometimes seasonally, variable rare patterns with maximum or minimum concentrations lagging climatic or hydrologic causes of variation.

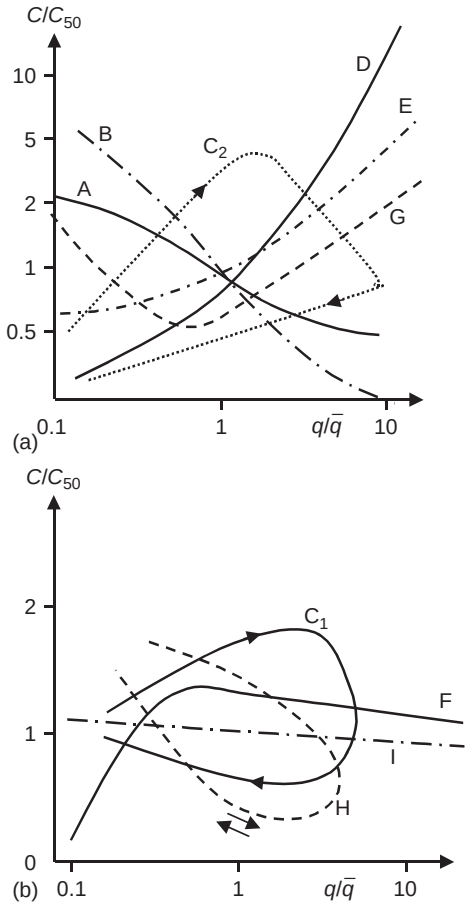

Figure 3 Concentration patterns (C. normalized to median concentrations, C_{50}) with respect to specific discharges ($\bar{q}$, normalized to the annual average q). A, B: dilution; C_2, D, E: soil erosion and leaching; F, G: complex variations; C_1, C_2, H: hysteresis cycles; and I: constant

Common and Rare Events

Water quality can change rapidly under natural conditions. Some variations are systematic and may occur each year. For example, during snow melt in the northeastern United States and in Scandinavia, acid anions (NO_3^-, SO_4^{2-}) and H^+ ion increase in streamwater resulting in episodic stream acidification, which has adverse affects on biota, such as macroinvertebrates and fish (*see* **Chapter 95, Acidic Deposition: Sources and Effects, Volume 3**). Other natural accidental events, including extreme droughts, hurricanes, landslides, forest fires, and volcanic eruptions can result in major changes in water quality, with concentration variations at least one order of magnitude higher than under normal conditions. These events typically are rare on the human timescale (>100 year return period), and are generally not captured during routine surveys. The duration of rare events may be short, but their impact on water quality may be enormous and last for (forest fires)hundreds of years. After the mount St Helen eruption (Oregon, USA), the local river TSS concentrations and yields increased by two orders of magnitude and the sediment discharged by the Columbia River increased from 10 to 40 $Mt\,y^{-1}$ in the years after the eruption, although most of the sediment (140 Mt) remained in the Cowlitz River, a Columbia River tributary (Meade and Parker, 1985).

Water-quality Trends and Interannual Variations

Year-to-year or interannual variations of water quality are caused by climatic and related hydrological variations (e.g. water discharge for rivers) and by changes of human activities in river basins. During wet years, material derived from point sources are diluted more than during dry years, and major ions, NH_4^+ or PO_4^{3-} concentrations are generally lower (Figure 3, dilution patterns #A, B, H). In contrast, average concentrations of particulate-bound components (Figure 3, patterns #C_1, C_2, D, E, and G) are much higher than during dry years. Particulate-bound components include POPs and total (unfiltered water) metal

concentrations, POC, and TP. Interannual variations of eutrophication indicators such as total pigment, chlorophyll A, and daily cycles of pH and DO are caused by insulation and water temperature variations.

RIVERINE FLUXES

The mass output (or flux) from a given upstream basin is used to evaluate material balances (outputs minus inputs), and more recently, to assess the status of degradation or improvement of stream reaches to assist land and water resources managers. For example, water-quality standards in the United States have targeted the total maximum daily load (TMDL) of contaminants for stream reaches (US EPA, 2004).

A mass flux (F, mass per time) combines concentration (C, mass per volume) of a solute, solid, or compound with discharge or streamflow (Q, volume per time). The mass flux is commonly determined for major ions, suspended matter (SPM), toxic substances, nutrients, carbon species, and organic matter, and several commonly used synthetic organic compounds, such as PAHs, PCBs, herbicides, and pesticides. The flux typically is determined at stream-gauging stations at which streamflow is continuously monitored because the computation requires discharge, and sometimes the use of specific sampling instrumentation and at higher frequencies than available from synoptic or routine manual sampling. Theoretically, F should be derived from the continuous measurements between t_1 and t_2 of both Q and C of the targeted dissolved or particulate constituent (i):

$$F_i(t) = \int_{t_1}^{t_2} C_i(t)\, Q(t)\, \mathrm{d}t \qquad (1)$$

Because C_i is rarely continuously measured or estimated (e.g. through a relation with a surrogate variable that is continuously measured like electrical conductivity), it is necessary to rely on a set of discrete water-quality (chemistry) analyses obtained from n fixed samples taken at time t_j coupled with continuous Q data, sometimes only with discrete Q_j measured during the water-quality sampling. Different approaches to flux calculation can be used and many of them incorporate concentration–discharge relationships (Phillips *et al.*, 1999).

CONCLUSION

During the last 150 years, measurement of water quality has evolved from few physical and chemical determinations to the analysis of the concentrations of hundreds of chemical compounds conducted in many types of media from dissolved to various particulate phases and to the consideration of aquatic biota and habitat. Also, while water quality is still considered a "subjective standard for human usage" for drinking water and multiple other uses, such as agriculture and industry, it is increasingly complemented by *aquatic environmental quality* that aims to be an "objective attribute for classification" (Boon and Howell, 1997).

Under natural conditions, water quality can vary markedly in time and space with most chemical descriptors varying by more than 1–2 orders of magnitude. In addition, human activities can markedly affect spatial and temporal variations of water quality, that is, chemical concentrations, the nature of the habitat, and modification of the aquatic communities. Metrics of water quality and reference scales also are evolving rapidly reflecting human and water relations at a given location and time for a given culture, even if some water-quality criteria (e.g. drinking water) are now universally used.

The continuous developments of our scientific and technical knowledge on water quality and of new issues and the growing linkage between water quality and social sciences (e.g. predictive models of carbon and nutrients for the twenty-first century combining Global Change and local pressures scenarios) have transformed water-quality studies into an autonomous multidisciplinary hydroscience.

Water quality monitoring is the process of gathering data that describes the physical, chemical, and biological condition of a water body. This chapter presents an overview of the processes involved in water quality monitoring and illustrates some of the approaches used with examples of existing monitoring programs. Over the last century, improved understanding of water quality, combined with advances in measurement and monitoring technology have increased the possibility of measuring hundreds of different variables in surface and groundwaters. However, efficient use of resources for monitoring depends on careful selection of objectives for the water quality monitoring program and on targeting variables and monitoring methods that address those objectives. Recent appreciation of the close link between the physical and chemical condition of a water body and its biological component has led to the incorporation of biological approaches in many large-scale programs to assess surface water quality. Today, monitoring programs take many forms, from measurement of a few specific variables to establish trends or effectiveness of remediation measures, to sophisticated evaluation of toxic impacts of wastewaters, to relatively simple determination of the state of the aquatic environment using citizen participation. Confidence in all data gathered and its resultant usefulness for management and policy development is essential; this can only be achieved by a careful program of quality assurance that extends from sample collection in the field, to analysis in the laboratory, to data handling and manipulation.

INTRODUCTION

Effective management of rivers, lakes, and groundwaters must be based on an understanding of their physical, chemical, and biological characteristics, that is, the water quality. This understanding can only be achieved through the collection and interpretation of appropriate information. The raw data that provides this information is obtained through the process of monitoring or data gathering. Monitoring is an activity that can take many forms, as illustrated in this chapter, but essentially it consists of the systematic collection of data over temporal or spatial scales. Human impacts on water quality and quantity (*see* **Chapter 93, Effects of Human Activities on Water Quality, Volume 3** and also **Chapter 187, Land Use Impacts on Water Resources – Science, Social and Political Factors, Volume 5** and **Chapter 188, Land Use and Water Quality, Volume 5** for examples of specific impacts) have resulted in more complex management problems and an associated demand for relevant information that will help support management decisions. In addition, policy makers increasingly have to consider regional and even global scales in policy design. This expansion in the need for information is posing challenges for those responsible for monitoring, both in terms of meeting diverse needs within a limited resource base and in designing cost-effective methods and approaches that provide data that will be useful and meaningful.

The term "monitoring" is used loosely to include all activities that involve the gathering of data by making measurements, whether in the field situation or during a process such as water treatment. In practice, many monitoring programs are set up to fulfill a particular goal aimed either at determining whether water is fit for a specific use or whether water quality has deteriorated

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

because of human activities. Examples of more precise monitoring goals are:

- Operational monitoring (also known as *surveillance*) – checking compliance with set criteria such as maximum allowable concentrations, water quality standards or discharge consents
- Surveys – limited duration data gathering exercises to determine the status of the water body at that given time (for example, in response to an accidental pollution incident)
- Background monitoring – collection of baseline data to indicate reference, background or unperturbed conditions for comparison with other sites, or for comparison with the same sites when studying trends or recovery/remediation effects (often used to determine impacts of future or remote activities)
- Trend monitoring – long-term data gathering specifically aimed at showing environmental change over time
- Flux monitoring – gathering of data at defined boundaries to determine the flux of specific materials from one environment, or water body, to another

The diversity of reasons for monitoring and of methods used is too great to discuss in detail in this chapter – thus it presents a guide to the principal activities involved, together with an overview of the approaches taken to monitoring water quality in different geographical regions and with different objectives. Some selected examples of water quality monitoring programs from around the world are also included. Examples have been chosen to illustrate some practical approaches that are in more widespread use and from well-established programs that have been in operation for at least a number of years.

To ensure that monitoring activities result in useful and credible information, it is necessary to choose appropriate methods at all stages of the monitoring process – from field to laboratory, and even to data interpretation, storage, and handling – and to apply rigorous quality checks to all these stages. Reliable and accurate water quality data are the foundation of the information that is needed for aquatic resource management in conjunction with the appropriate hydrological information. The raw data, in themselves, may be of little value unless some process of interpretation and presentation is applied to make them accessible and understandable to the users, namely, water resource managers, policy makers, and the public. This interpretation can take the form of a simple graph showing fluctuations over time to a complete assessment of the environmental situation. Thus, water quality monitoring should not be seen as an activity on its own, but as part of the overall water quality assessment process. This process begins with the setting of objectives, continues through the data gathering exercise and concludes with interpretation and assessment.

HISTORICAL DEVELOPMENT OF WATER QUALITY MONITORING

The concept and understanding of water quality has been developing gradually over more than one hundred years and is likely to continue to evolve because of (i) increasing demand for water qualified by the type of use, (ii) increasing human demands on continental water resources, (iii) improving knowledge and perceptions about the aquatic environment, and (iv) developing technology, from field measurements and sampling, and laboratory analyses to data management, analysis, and communications.

In the 1850s, the first water quality analyses (e.g. Seine and Thames rivers) were based on a few physical and chemical variables, such as T°, pH, DO, K_{SC}, Cl, NH_4^+, and NO_3^-. The longest record of water quality for these variables exceeds 100 years for the Rhine River. Just before World War I, the first systematic geochemical studies of rivers were conducted on United States' and Canadian rivers, and routinely included the concentrations of major ions: Ca^{2+}, Mg^{2+}, Na^+, K^+, (usually measured as Na^+ plus K^+), Cl^-, SO_4^{2-}, NO_3^-, H_4SiO_4, and HCO_3^-, and sometimes other variables including NH_4^+, PO_4^{3-}, iron (as Fe_2O_3), aluminum (as Al_2O_3), and salinity. Although some sewage contamination studies were conducted as early as 1900, the first routine surveys of microbiological contamination indicators, including total fecal coliform counts, were conducted during the 1930s at public water supply intakes of major cities. Around the same time, the first routine measurements of riverine suspended particulate matter (SPM) were conducted to determine baseline fluxes prior to damming (e.g. USA, former USSR, China).

During the 1950s and 1960s, atmospheric nuclear bomb testing created a need for artificial radionuclide and plutonium surveys. These surveys generally were independent of other types of water quality monitoring and typically were not accessible to scientists or to the general public. Meanwhile, eutrophication issues and the development of automated nutrient analyses accelerated the measurements of N species and other nutrients including PO_4^{3-}, total P, and H_4SiO_4. Since the middle of the 1970s, organic carbon analyzers have enabled the analyses of total, dissolved, and particulate organic carbon concentrations (TOC, DOC, and POC, respectively), which have been gradually replacing biochemical oxygen demand (BOD) and chemical oxygen demand (COD) measurements. Investigations of chemical components of water quality also have benefited greatly, since the 1970s, from technological advances in instrumentation and analytical techniques such as atomic absorption, ion chromatography, inductively coupled plasma spectrometry, gas chromatography, and mass spectrometry. Analytical improvements have been mostly driven by the growing demand for analyses of a growing list of contaminants such as polychlorinated biphenyls (PCBs), industrial products similar to the DDT insecticide, polyaromatic hydrocarbons

(PAHs), phthalate plasticizers and other persistent organic pollutants (POPs). POPs are highly toxic and accumulate in soils, sediments, and biological tissues because they have a high affinity for particulate matter, are highly soluble in fat tissues, and have a low solubility in water. Most of these compounds are not natural and typically occur at very low concentrations in the environment. The first routine surveys of sediment quality were also conducted in the 1970s. The combination of chemical (e.g. C, N, P, metals, POPs) and biological analyses (e.g. pigments, diatom assemblages) of sediment cores permitted the reconstruction of past water quality issues (e.g. salinization, eutrophication, oxygenation, acidification) over decades and more, opening another rapidly growing-scientific field in water quality, namely, the study of sediment archives.

Since the 1960s, water quality monitoring has also included biota, especially benthic species, photosynthetic pigment concentrations (as an indicator of primary productivity or algal biomass), algal species counts, and chemical analyses of contaminants in biota (e.g. freshwater mussels) or in specific tissues of the biota (e.g. fish muscle) (see following text).

The total number of variables that should be considered in a comprehensive water quality monitoring program, if all regulations and water quality approaches were strictly followed, would now exceed 500. Because of financial constraints, and because human activities which affect water quality vary spatially and temporally, most monitoring programs rarely include more than 100 variables for individual samples, even at the most well-equipped monitoring laboratories. In less developed countries, where water quality monitoring exists, the number of variables rarely exceeds 20, including major ions, some nutrients, total suspended solids (TSS), pH, T°, and conductivity. The choice of variables, and the laboratory-based analytical methods associated with those variables, is often governed by the resources (financial, technical, and human) available for the monitoring program. Where resources are not limited, the analytical techniques should be selected for which standardized methods and appropriate quality assurance programs (see following text) exist, bearing in mind any specified or anticipated detection limits. Electronic information sources, such as the National Environmental Methods Index (NEMI) (NWQMC, 2004a), can assist with such selection.

Efforts to obtain useful information with limited expenditure and/or resources have driven the development of water quality indicators (physical, chemical, and biological – see following text). An indicator is a measured variable, or combination of variables, that can be related to particular environmental conditions and is representative of those specific conditions, for example, the Secchi depth (see following text) as an indicator of eutrophication. It can also be a specific aquatic organism that is associated with a defined range of water quality variables (see following text).

MONITORING PROGRAM DESIGN

The setting of objectives should be the first activity in the steps required to design and implement a water quality monitoring program (Figure 1). Water quality monitoring can be very demanding on the resources of any organization, sometimes requiring considerable personnel, and/or advanced technical facilities. Expenditure on such resources must be justifiable by the ultimate provision of useful information for management or policy needs. In order to ensure that resources are not wasted, it is important to define clearly the objectives of any monitoring program in terms of its expected outputs. The objectives should take into consideration the technical capability of the monitoring organization and should be achievable within the resources available to the operators of the program. The more focused and well-defined the objectives, the more likely it is that resources will not be wasted and that expectations will be met (e.g. NWQMC, 2004b).

Water quality objectives, the related monitoring variables, and the type of water quality surveys and studies can vary markedly for the same water body among hydrological disciplines depending on the purpose of the scientific investigation (e.g. process studies made by geochemists, biogeochemists, and some hydrologists) or requirement for compliance with water quality criteria as

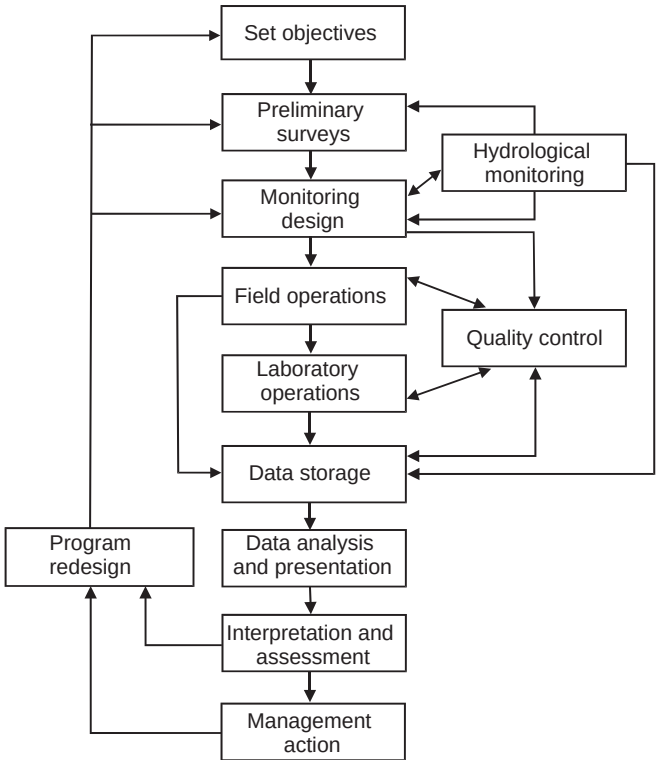

Figure 1 Stages of the water quality monitoring process

Table 1 Typical monitoring objectives and associated activities undertaken by different hydrological science disciplines

Disciplines	Objectives	Variables	Type of study, survey, or monitoring program
Environmental chemists	Detect and quantify trace amounts of any contaminants including degradation products	Trace elements, synthetic organic compounds, new compound on the market (e.g. pesticides) and/or synthesized by chemical and pharmaceutical industries	In-depth inventories; surveys of ambient backgrounds; sediment archives
Geochemists	Chemical composition with regards to natural drivers (lithology, climate...); inputs to oceans	Ca^{++}, Mg^{++}, Na^{+}, K^{+}; Cl^{-}, SO_4^{2-}, HCO_3^{-}; dissolved/colloidal/particulate trace elements; chemical speciations	Process studies (stream scale); fluxes (basin scale)
Biogeochemists	Cycles and transformations of nutrients (dissolved and particulate organic/inorganic)	Carbon, nitrogen, phosphorus, and silica species; micronutrients	Links with algal production and bacterial activities
Ecologists	Physicochemical quality; occurrence and levels of contaminants; pigment levels	pH; T° TSS; color; dissolved oxygen; total dissolved solids; nutrients; ammonia contaminants; endocrine disruptors; chlorophyll A	Overall quality; general mapping; seasonal regime extreme events; bioaccumulations; biomagnifications
Limnologists	Ecological functioning; conservation; potential for lake uses; paleo-records of water quality	Dissolved O_2; nutrients; pH; conductivity; pigments; contaminants	Process studies (fine time, space, and scales); vertical profiles; seasonal variations; sediment mapping; sediment archives
Hydrologists	River fluxes of dissolved and particulate matter; tracers of water pathways	Major ions; SPM; natural isotopic tracers (e.g. $^{13}HCO_3^{-}$, $^{14}HCO_3^{-}$, $^{2}H_2O$, $^{3}H_2O$, $^{34}SO_4^{2-}$ ...); artificial radionuclides	Flood cycles; seasonal regimes; yearly fluxes; trends; stream order; structure of water quality
Sanitary engineers	Water-borne and water-related diseases; indicators of pollution	biochemical oxygen demand and chemical oxygen demand; microbial contamination indicators (fecal and total coli, streptococci); nitrate; endocrine disruptors; radionuclides	Water quality at intakes; continuous surveillance; detection of threshold quality (accidents)
Water manager	Comparison with water use criteria; pollution sources inventories	Most of above variables with growing focus on microcontaminants such as pesticides and endocrine disruptors	Contaminant mapping and budgets; longitudinal profiles; long-term surveillance; emergency survey
Community/citizen volunteer monitor	Trends in water quality in relation to water use/human impact; protection of biodiversity	Simple field measurements of physical/chemical variables; identification and enumeration of organisms	Trends; spatial surveys; species inventories

might be evaluated by sanitary engineers or water managers (Table 1).

Well-defined objectives aid the efficient design of all stages of the monitoring program (Table 2), from the selection of measurement variables to site selection, to choice of field and laboratory methods, to data interpretation and presentation techniques (Spooner and Mallard, 2003). The simplest monitoring programs may have only one objective; an example would be to check that water abstracted from a well is fit for human consumption according to the World Health Organization (WHO) guidelines for drinking water quality (WHO, 2004). In this case there is a specific monitoring site (the point of abstraction from the well) and the variables to be measured, together with their recommended frequency, are defined by the need to check whether guidelines concentrations are met for specific variables. The output of the program is an assessment of whether, on each sampling occasion, the water in the well meets the concentrations defined in the guidelines and is considered fit to drink.

Table 2 Principal activities associated with each stage of a monitoring program

Stage of monitoring program	Principal activities
Setting objectives	Consider water uses, legislation, guidelines, standards, and so on
	Consider economic and technological constraints
	Define expected outcomes of monitoring program
	Establish data quality objectives
Preliminary survey	Survey literature and databases for existing physical, chemical, biological, or hydrological data, information on methods, and so on.
	Test field and laboratory methods if necessary
	Carry out special survey to evaluate potential sites and/or methods for long-term use
	Establish measurement quality objectives
	Evaluate technical and financial resources required
Program design	Decide spatial and temporal sampling regime
	Select monitoring media (water, sediments, biota), variables (physical, chemical, biological), field sites, sampling frequency, specific methods, and equipment
	Produce final program design, including guidelines for technical personnel, standard operating procedures, field record sheets, laboratory record sheets
Implementation	Field operations: Collect biota, sediments, and water samples for laboratory analysis, take *in situ* physicochemical measurements and carry out on-site biological and chemical analyses, record field data
	Hydrological measurements: collect information on flow, velocity, water level, and so on.
	Laboratory operations: Preparation of sample bottles and addition of pretreatment chemicals, analysis of samples, recording of results
Quality control	Checking accuracy of field and laboratory methods, for example, with sample blanks and duplicate samples
	Checking in-house analytical techniques with sample blanks and spiked samples
	Participation in interlaboratory quality assurance exercises
	Regular checking for suspect data in databases
Data manipulation	Data storage: Transferring results from field and laboratory operations into database
	Analysis of data: Application of statistical methods, for example, correlations, trend analysis
	Assimilation and presentation of data: Tables of results, data summaries, graphs

Source: Adapted from Chapman (1996).

The increasing need over the last few decades to manage and protect all aspects of water resources has led to a greater understanding of the functioning of water bodies and of their interactions with other components of the hydrological cycle. The demand for management of freshwater resources in an integrated way, such as that required under the European Union Water Framework Directive (EU, 2000) can lead to the need for monitoring programs with multiple objectives. It is particularly important that monitoring programs with multiple objectives are reviewed periodically to evaluate whether all the objectives are still valid and necessary and whether the program is achieving the objectives. There should be regular feedback from the users of the outputs of the monitoring program to the designers and operators in order to ensure that the program remains appropriate and cost-effective (see Figure 1).

Just as monitoring programs should be designed to meet specific objectives, they should also be designed specifically to suit the type of water body. This means that at least a fundamental understanding of the hydrology of the specific water body is necessary. Where this information does not already exist, it may have to be obtained through a preliminary survey. Typical hydrological information required before designing a monitoring program is summarized for the three main types of water body in Table 3. Knowledge of hydrological features is essential for selecting the appropriate sites for sampling. For example, it is important to know the direction and velocity of groundwater flow when selecting sites for boreholes with the aim of studying pollutant dispersion. In river waters, variations in contaminant concentrations are closely related to discharge and depend on whether the contaminant is in the dissolved state or is associated with particulate matter (*see* **Chapter 91, Water Quality, Volume 3**). Discharge in rivers is highly variable depending on rainfall, the size, and other physical and geological characteristics of the catchment and the resultant runoff, varying over minutes to hours to days to months to seasons, and for some climate impacts, to years or decades. Flux calculations (*see* **Chapter 86, Measuring Sediment Loads, Yields, and Source Tracing, Volume 2** and **Chapter 91, Water Quality, Volume 3**) depend on the river discharge at the time of sampling. Thus, wherever possible, it is recommended that measurements are made at frequent intervals or even continuously. In lakes and reservoirs, short residence times might influence the frequency of monitoring, whereas turbulence and mixing

Table 3 Hydrological information and key measurements required for increasing complexity of water quality monitoring programs

Level of complexity of monitoring program	Rivers	Lakes/reservoirs	Groundwaters
All programs	Map of catchment plus:	Depth at samples site(s); water residence time; thermal regime plus	Type of aquifer; direction of groundwater flow plus:
Low ▼ ▼	Water level at time of sampling	Lake level at time of sampling, depth of thermocline if present	Piezometric level
▼ ▼ ▼	Discharge at time of sampling	As above plus vertical profiles of temp. and O_2 at time of sampling	Piezometric level between sampling, aquifer map
High	Continuous measurement of discharge	As above plus rate of water inflow and patterns of water movement within lake	Full knowledge of groundwater hydrodynamics

Modified from Meybeck *et al.* (1996).

might influence the sampling station locations and depths from which the samples are collected. For an explanation of the hydrology of lakes and reservoirs, *see* **Chapter 108, Lake Ecosystems (Stratification and Seasonal Mixing Processes, Pelagic and Benthic Coupling), Volume 3** and **Chapter 109, Reservoirs, Volume 3**.

The necessity for preliminary information on chemical and ecological interactions depends on the nature of the intended water quality monitoring program. If a biological monitoring approach based on the presence or absence of certain species is to be used (see following text), it may be necessary to determine first of all whether the water body has any natural chemical characteristics that might affect the presence or absence of species to be included in the monitoring program. Similarly, a preliminary survey of the sources and nature of chemical discharges into a water body can assist in the targeted selection of chemical compounds to include in a biological or ecotoxicological monitoring program.

Many of the detailed aspects of program design, such as frequency of sample collection, number of samples, number of replicate samples, and so on, are important to the successful application of certain data analysis methods and statistical techniques. Thus it is important to consider, and even to select, the type of data analysis methods that will be applied to the results obtained before proceeding any further with the monitoring program design (Dixon and Chiswell, 1996). Finally, using all available information on the water body, including that from published sources, previous programs, or specific preliminary surveys, the monitoring program can be designed in detail. The design should consider and specify all the following activities:

- sites to be sampled, that is, location specified by grid reference,
- sample details, for example, precise depth at which each sample is to be taken,
- frequency of sampling,
- variables to be measured in the field, including hydrological variables,
- variables to be measured in samples returned to the laboratory,
- requirements for replicate sampling,
- methods for field analysis,
- methods and equipment for field sample collection and storage,
- methods for laboratory analysis of samples, including any instructions for storage of samples,
- recording procedures and storage methods for results,
- quality control procedures related to both field, laboratory, and data handling operations.

Time taken in specifying and documenting the precise details of each step of the monitoring program can be justified by the resultant confidence in the reliability of the data generated. Over the last decade, much progress has also been made in testing and standardizing aquatic monitoring methods, particularly through the International Organization for Standardization (ISO) (ISO, 2004a).

MONITORING IN THE FIELD

There are four important aspects to the field-based activities within a monitoring program:

- selection of sites at which samples should be taken,
- frequency with which samples should be taken,
- the type of samples to take,
- the methods to be used for sampling.

Selection of sampling locations depends on an understanding of the water body and the objective of the program.

It may also have to take into consideration the practicality of the method, the accessibility of the sites and intended use of the data obtained (e.g. statistical techniques, association with other grid-referenced data, anticipated links with other monitoring activities, etc.).

Programs with the objective of determining baseline or background water quality must be based on sample sites that are distanced from any human influence or, at the very least, be unaffected by the emissions for which they form the baseline or background measurements. Programs monitoring for impacts of particular emissions should include sites close to the emission and, if possible, distributed spatially over the anticipated range of effect. Sampling sites for operational monitoring programs are sometimes defined by the national or international water quality standards or guidelines against which the water quality is being monitored, or by the operational license controlling the activity. Typically, such sites are at the point of water abstraction or discharge. Water quality status monitoring requires sites to be geographically dispersed to cover the area of interest and to include all relevant water bodies, for example, nationally, regionally, or globally. For practical reasons it may be necessary to select one site to be reasonably representative of a large water body, although this assumption should be tested first with a set of synoptic samples collected over a wider area within the water body. Careful choice of such monitoring sites to avoid unusual influences, such as wastewater discharges and outfalls, is essential.

Sampling frequency must be chosen to give adequate data for interpretation of the expected changes in water quality without imposing too great a demand on resources. Long-term trends can be studied by means of infrequent sampling at regular intervals, such as once a year, provided the samples are always taken at the same time of the year to eliminate changes due to seasonal variations in water quality. Sampling to determine fluxes and loads may require high frequency sampling, continuous monitoring techniques or targeted sampling in relation to periods of high flow (see Robertson and Roerish, 1999 for a discussion of the applicability of different water quality sampling strategies). The degree of variability in physical, chemical, and biological aspects of water quality may have to be determined by a preliminary study before deciding on the most appropriate sampling frequency. Groundwaters usually show little variability over time, unless very shallow or influenced by tidal fluctuations, whereas most rivers are highly variable, depending on rainfall and runoff, which in turn is related to climate and season.

The *sampling methods* used depend on the medium to be sampled (water, sediment or biota) and the variables to be measured in the sample (e.g. USGS, 2004a). Chemical and microbiological analyses require samples to be collected without the risk of contamination by any substance or organism that will subsequently be measured in the sample. This can involve special cleaning or sterilization procedures for sampling equipment and sample storage bottles, as well as care in the way the samples are taken. For example, water samples for subsequent analysis of dissolved or particulate metal concentrations should not come into contact with metals, that is, sampling apparatus and sample bottles should be constructed of polyethylene plastic, Teflon, or glass with no metal parts.

Discrete samples of water, sediment, or biota are only representative of the point of sampling at the time that the sample was collected. Hydrological influences, such as flow in rivers and groundwaters or stratification in lakes, may require that either a number of samples are taken at different locations at the same time or that a time- or depth-integrated sample be obtained. Integrated samples can be taken either by mixing a series of discrete samples or by the use of a special sampling technique, for example, a hosepipe sampler, pumping mechanism, or isokinetic sampler (Figure 2). Time-integrated samples are produced by combining discrete water samples from the same site at regular time intervals or by continuously withdrawing water into a large container over a fixed time. This approach is only suitable where the variable being studied does not change biologically or chemically during the time interval between the first and the last sample being taken and mixed together. The precise choice of method should, where possible, be governed by the monitoring objectives and the associated measurement quality objectives.

SAMPLING DIFFERENT MONITORING MEDIA

Depending on the objectives of the monitoring program, it may be appropriate to take water samples, living organisms, sediments, or a combination of these media (see above). For certain types of biological or sediment samples, the same or similar collection methods may be used as for water samples. Specialized approaches may require their own methods and specific precautions to ensure that samples are not contaminated. Some of the more common methods are described here (Table 4, Figure 2).

Water Samples

Discrete water samples, sometimes known as *grab samples*, such as those commonly used for chemical, nutrient, and microbiological analysis, are taken by a field operator and transported to the laboratory. There are several methods available for collecting discrete samples, and the choice depends on the subsequent sample handling or on the need for depth (vertically from top to bottom of a site on the water body) and width (horizontally across the water body) integrated samples (e.g. USGS, 2004a). The simplest method involves submerging a jug or bucket –

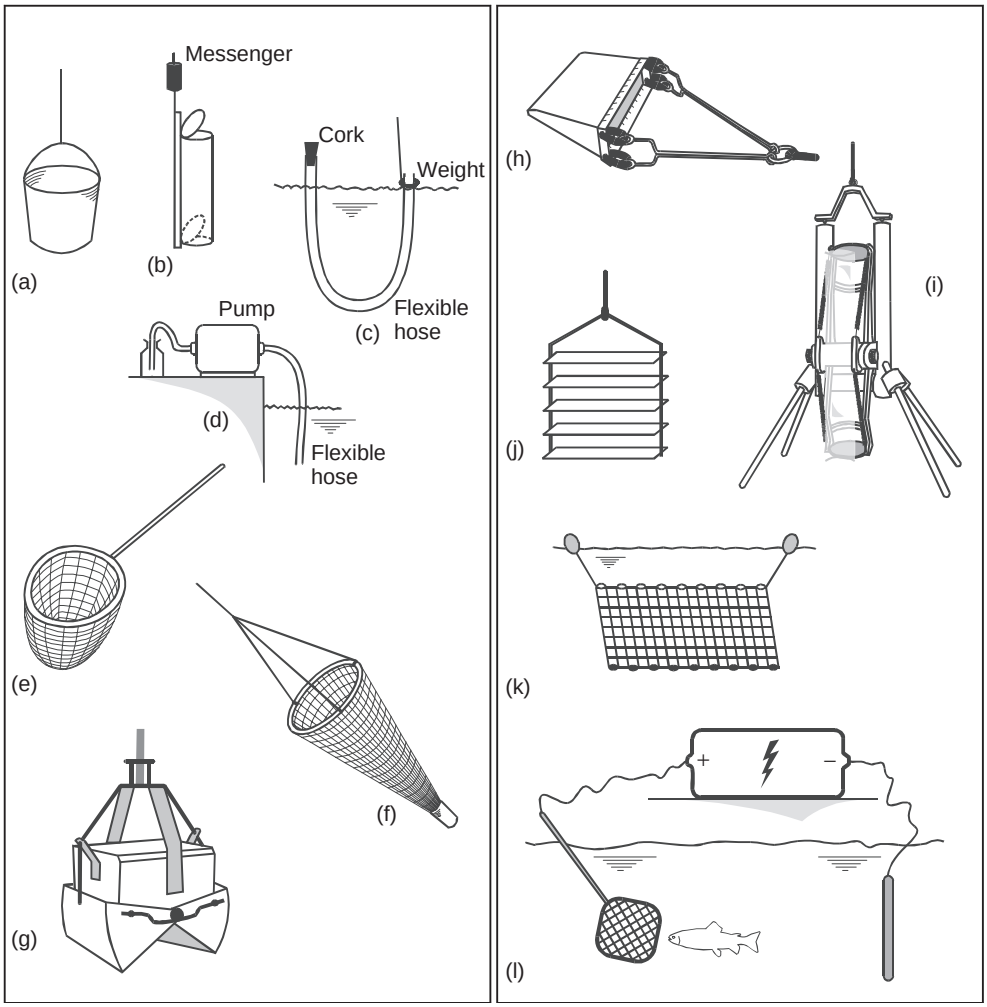

Figure 2 A selection of methods and equipment for collecting discrete or depth- and width-integrated water, sediment, and biota samples. (a) Simple bucket or beaker on a length of rope for collecting surface samples; (b) surface operated bottle sampler for grab samples at depth; (c) flexible pipe for integrating a depth sample in still waters; (d) mechanical or electrical pump for lifting volumes of water from specific depths; (e) fine mesh net on a rigid pole for collecting nonmotile organisms in shallow waters, for example, benthic invertebrates; (f) fine mesh net on a calibrated rope for collecting open water samples of organisms, for example, plankton; (g) mechanically operated grab for collected samples of deposited sediment and associated organisms in deep waters; (h) dredge-type sampler for collecting surface living organisms from shallow or deep waters; (i) remotely operated corer for collecting deposited sediments with minimal disturbance; (j) artificial substrate (e.g. flat plates suspended on a rope) for collecting attached organisms in all types of water body; (k) net or trap for collection of organisms such as fish; (l) electro-fishing equipment for near-quantitative sampling of fish

open face downwards – to the required depth and then slowly turning it upright so that it fills at the sampling depth (Figure 3). More complex methods involve remotely triggered devices, such as the Friedinger and Ruttner samplers (see Table 4, Figure 2), that open at depth to contain a vertical column of water of known volume. For certain advanced analytical measurements, or for variables occurring at very low concentrations, discrete samples are essential, combined with special pretreatment or storage conditions (e.g. addition of fixative chemicals, storage in the cold and dark). Depending on the subsequent analyses to be performed on the sample obtained (e.g. trace metals, microbiological), it may be necessary to take special precautions to avoid contamination of the water sample or the collection of an unrepresentative sample. Such precautions include facing the opening of the collection vessel into the water current, wearing sterile gloves, rinsing the sample bottle several times in the water body to be sampled and discarding the water (away from the collection point) prior to filling, avoiding sampling close to stream or lake beds so as not to disturb fine sediments, and careful cleaning of samplers between sampling trips.

Some water quality variables can be measured *in situ* with portable or fixed submersible probes on site or by

Table 4 Comparison of methods and equipment for sampling water, suspended particles, and aquatic organisms (see Figure 2)

Sampler/sampling mechanism	Figure no.	Type of sample	Most suitable habitats	Advantages	Disadvantages
Jug, bucket, beaker, or bottle	2a	Water, suspended sediment/particles inc. plankton and microorganisms	Lakes and rivers	Cheap, simple, quantitative.	Surface or subsurface samples only.
Bottle samplers (e.g. Friedinger, Van Dorn, Ruttner)	2b	Water, suspended sediment/particles inc. plankton and microorganisms	Still or slow flowing waters, groundwaters	Quantitative. Enables samples to be collected from discrete depths.	Expensive unless manufactured ''in-house''.
Hosepipe sampler	2c	Water, suspended sediment/particles inc. plankton and microorganisms	Still waters	Integrates sample from surface to depth. Quantitative. Cheap and simple to use.	Small volume of sample.
Water pump	2d	Water, suspended sediment/particles inc. plankton and microorganisms	Lakes and rivers, groundwaters	Quantitative if calibrated. Rapid collection of large volume samples. Integrated depth sampling possible.	Expensive. Requires power supply.
Isokinetic sampler		Water and suspended sediment	Flowing waters	Enables flow-related depth-integrated samples	Expensive
Collection by hand		Macrophytes, attached or clinging organisms	River and lake margins, shallow waters, stony substrates	Cheap – no equipment necessary.	Qualitative only. Specific organisms only collected.
Hand net on pole (c. 500 μm mesh)	2e	Benthic invertebrates	Shallow river beds, lake shores	Cheap, simple.	Semiquantitative. Mobile organisms may avoid net.
Plankton net	2f	Phytoplankton and/or zooplankton depending on mesh size	Open waters, mainly lakes	Cheap and simple. Large volume or integrated samples possible.	Qualitative only (unless calibrated with a flowmeter). Selective according to mesh size. Possible damage to organisms.

(*continued overleaf*)

Table 4 (*continued*)

Sampler/sampling mechanism	Figure no.	Type of sample	Most suitable habitats	Advantages	Disadvantages
Grab (e.g. Ekman, Peterson, Van Veen)	2g	Sediments, benthic invertebrates living in or on the sediment. Macrophytes and attached organisms	Sandy or silty sediments, weed zones	Quantitative sample. Minimum disturbance to sample.	Expensive. Requires winch for lowering and raising.
Dredge type (e.g. Surber sampler)	2h	Mainly surface living benthic invertebrates	Bottom sediments of lakes and rivers	Semiquantitative or qualitative analysis depending on sampler	Expensive. Mobile organisms avoid sampler. Natural spatial orientation of organisms disturbed.
Corer (e.g. Jenkins)	2j	Sediments, microorganisms and benthic invertebrates living in sediment	Fine sediments, usually in lakes	Discrete, quantitative samples	Expensive. Small quantity of sample.
Artificial substrates (e.g. glass slides plastic baskets)	2k	Epiphytic algae, attached invertebrate species, benthic invertebrates	Open waters of rivers and lakes, weed zones, bottom substrates	Semiquantitative. Cheap	May not be truly representative of natural communities. Positioning in water body important for successful use.
Poisons (e.g. rotenone)		Fish	Small ponds or river stretches	Total collection of fish species in area sampled	Destructive technique
Fish net/trap	2l	Fish	Open waters, river stretches, lakes	Cheap. Nondestructive.	Selective. Qualitative unless mark recapture techniques used.
Electro-fishing	2m	Fish	Rivers and lake shores	Semiquantitative. Nondestructive.	Selective according to current used and fish size. Expensive. Potential safety risk.

Modified from Friedrich *et al.* (1996).

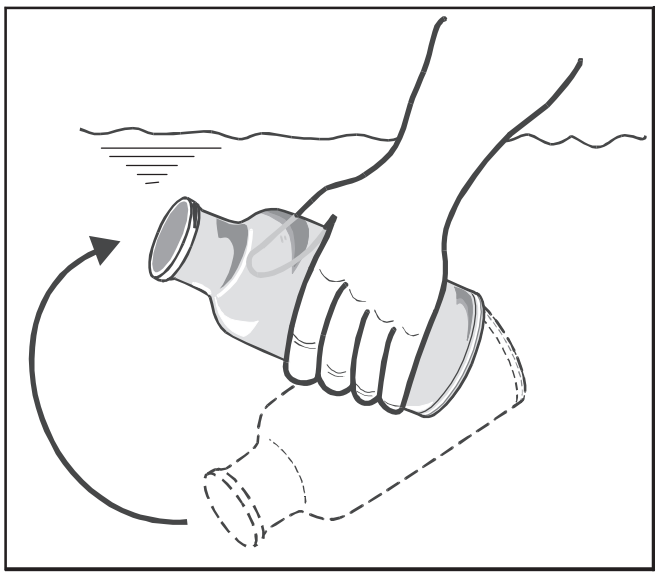

Figure 3 Taking a surface water sample by hand – the bottle is submerged with the opening facing downwards and then tilted up to allow it to fill at the required depth. The bottle should be rinsed several times in the water body before taking the sample and, if used in a river, the opening should be faced upstream. Care should be taken to avoid disturbance of sediment

diverting a flow of water through a monitoring instrument situated very close to the water body. Fixed monitoring instruments provide real-time data on changes occurring within the water body. The outputs can be either stored onto a data logging system and periodically downloaded or transmitted telemetrically to a central data gathering facility. Such systems are currently well developed for measurement of parameters such as velocity, temperature, oxygen, conductivity, pH, total organic carbon, turbidity, and fluorescence (Glasgow *et al.*, 2004). These types of measurements provide an essential early warning mechanism of changes in water quality at sites of water abstraction for municipal or industrial use. Permanent hydrometric stations provide real-time information of discharge that is essential for flood control planning and efficient operation of hydropower generation facilities in small catchments (e.g. NRC, 2004; USGS, 2004b).

Automated sample collection systems are available that divert water from the water body to a unit which fills sample bottles at preset time intervals or when remotely triggered to do so. Such sample collection mechanisms are particularly useful in remote locations where much time and effort may be spent traveling to and from the sampling site, especially if the required sampling frequency is high such as when estimates are being made of rainfall runoff or when loads are being calculated. The range of variables that can be determined in such samples is sometimes limited to those that will not be affected by the time delay between automatic collection and subsequent analysis in the laboratory, although some sampling systems enable the addition of chemical fixatives *in situ* and can refrigerate the samples until collection and analysis. Some automated sample collection systems can also be coupled to automatic analyzers capable of making a limited range of measurements within defined limits of accuracy (Glasgow *et al.*, 2004). All such remote and automated equipments do, nevertheless, require occasional maintenance and could also be subject to undesirable human interference.

Sediment

Sediments and particulate matter can be responsible for transporting and storing contaminants and nutrients in rivers and lakes. Monitoring programs involving sediment samples may be designed to determine, for example, the transport of contaminants in suspended sediment, storage of nutrients in surficial deposited sediment or the historical record of accumulation of contaminants over time. These three objectives require different approaches to the collection of the samples for analysis. The concentration of suspended sediments in rivers is closely related to discharge because of turbulent resuspension, especially during floods; thus it is essential that the discharge is known or measured at the time of sampling. Suspended sediment samples are usually collected in rivers by taking water samples using one of the methods mentioned above. The water samples can then be filtered or centrifuged to concentrate the sediment from the known volume of water sampled. In lakes, suspended sediment concentrations are determined from known volume water samples or using sediment traps. A simple sediment trap consists of a tube with a conical base ending in a collection vessel; the trap is usually suspended in the water column for a period of time ranging from hours to weeks. The tube collects all suspended material that is settling in the water column and can provide an estimate of sedimentation rates over time.

Sampling methods can affect data interpretation; for example, SPM is sampled by horizontal isokinetic samplers (to sample in such a way that the water-sediment mixture moves with no change in velocity as it leaves the ambient flow and enters the sampler intake) at several verticals in a cross-section of a river. SPM differs from TSS in a river sample because TSS samples are collected at one point on the river surface. Although, TSS may be very different from SPM for the same site at the same time, TSS are routinely used as a substitute for SPM to determine particulates fluxes because they are easier and much cheaper to obtain.

Samples of surficial deposited sediments in lakes or rivers can be collected by grabbing a volume of sediment with a scoop by hand (where the water is sufficiently shallow) or, in deeper waters, by using a remotely triggered grab sampler (Figure 2). Undisturbed samples that can be used to study the profile of grain size or chemical content with

depth in the sediment (e.g. for historical studies) can be obtained using a coring device (Elliott and Tullett, 1978) (Figure 2). A full discussion of the use of particulate material in monitoring programs is available in Thomas and Meybeck (1996).

Biological Samples

There are many ways in which biological samples are incorporated in water quality monitoring programs (Table 5) and the choice of sampling method is dictated by the biological approach being used. Most methods are either (i) passive, in which organisms are collected from their own environment for enumeration or analysis or (ii) active, in which organisms are deliberately placed into a particular environment and then removed for analysis at later intervals. Examples of some biological sampling methods are given in Table 4. Microbiological monitoring to determine whether water is of adequate quality for human consumption is the most widely performed water quality monitoring activity; it is carried out on surface and groundwaters, as well as treated water, prior to distribution to domestic users. Microbiological monitoring may also be included in monitoring programs designed to detect the impact of wastewater discharges, runoff from agricultural activity or the quality status of water resources. Samples must be collected, handled, and processed with special care to prevent contamination (see, for example, Myers and Wilde, 2003 for a detailed description of methods). Another common biological monitoring approach involves identifying and counting the invertebrates present at specific sites in a river and calculating a water quality index or pollution score (see Section on "Examples of monitoring programs"). This approach is based on the principle that certain organisms have particular environmental preferences or tolerances and can act as indicators of defined quality ranges (sometimes broadly correlated with physical and chemical quality indicators) (see following text). The index or score system usually prescribes the sampling and analysis method – the most common method of collecting samples is with a net, which provides a semiquantitative sample. Some of the more widely accepted methods have now been standardized by the ISO and by relevant national authorities. Planktonic organisms, suspended in the water column, can also be sampled by filtration, centrifugation, or sedimentation of a known volume of water sample collected by one of the water sampling methods described above and in Table 4. Particular groups of organisms can be collected by encouraging them to adhere to, or live on or in artificial substrates, such as glass or plastic plates with flat surfaces or baskets of stones (see Figure 2) (Chapman and Jackson, 1996).

Some groups of relatively immobile aquatic organisms provide useful media for studying the long-term pollution or recovery of water bodies with contaminants such as heavy metals or organic chemicals. These substances can be difficult to measure at low concentrations in the water, but are accumulated within the tissues of the organisms at concentrations higher than that found in the water itself. The higher concentrations can often be analyzed with less sophisticated equipment and thus enable detection in situations that might otherwise have been limited by available analytical equipment. Some organisms, such as those that feed on fine organic particles, can assimilate both dissolved and particulate contaminants, while others may specifically reflect the presence of substances dissolved in the water, or of accumulation in the aquatic food chain. When designing a monitoring program aimed at studying concentrations of contaminants in organisms it is important that the natural or background concentrations of the contaminant of interest, *in the specific tissues of the monitored organism*, should be known or determined in advance of the sampling program. An alternative approach is to use active monitoring, where organisms from a single batch or reference site, and with known background concentrations of the contaminant of interest, are placed in the water body to be monitored. Subsamples are then taken at time intervals for analysis.

EXAMPLES OF MONITORING PROGRAMS

The complexity of a monitoring program can range from regular measurements of one or two variables at a single site over a long time period to many physical, chemical, and biological variables at numerous sites and at varying time intervals, depending on the objectives. Every monitoring program should be designed to answer specific questions, that is, to generate data that can be used for research, management, or policy development. For this reason, there are many examples of different types of monitoring programs (Table 1) at local, national, regional, and even global scales (see Dixon and Chiswell, 1996 for a review of monitoring program design). Table 6 presents a selection of current examples of monitoring programs from around the world. More common approaches to water quality monitoring are highlighted in this section by reference to some specific examples.

Programs Based on Physical and Chemical Measurements

Some physical measurements can be very simple and inexpensive to perform, requiring relatively little training or expertise, and for these reasons they are incorporated in most monitoring programs (irrespective of whether they will yield useful information or not!). Methods range from the simple turbidity or transparency tube (e.g. Kent State University, 2004a) and Secchi disc (see following text) to handheld digital meters and *in situ* continuous monitoring

Table 5 Uses of biological methods for different types of water quality monitoring programs and their relative advantages and disadvantages

	Ecological methods		Microbiological methods	Physiological and biochemical methods	Bioassays and toxicity tests	Chemical analysis of biota	Histological and morphological methods
	Indicator species[a]	Community studies[b]					
Principal organisms used	Invertebrates, plants, and algae	Invertebrates	Bacteria and viruses	Invertebrates, algae, fish	Invertebrates, fish	Fish, shellfish, plants	Fish, invertebrates
Types of monitoring	Water quality status, impact surveys, trend monitoring	Impact surveys, trend monitoring	Operational surveillance, impact surveys	Early warning monitoring, impact surveys	Operational surveillance, early warning monitoring, impact surveys	Impact surveys, trend monitoring	Impact surveys, early warning monitoring
Types of pollution or other human impacts detected	Organic matter pollution, nutrient enrichment, acidification	Organic matter pollution, toxic wastes, nutrient enrichment	Human and animal fecal waste, organic matter pollution	Organic matter pollution, nutrient enrichment, toxic wastes	Toxic wastes, pesticide pollution, organic matter pollution	Toxic wastes, pesticide pollution, human health risks (toxic contaminants)	Toxic wastes, organic matter pollution, pesticide pollution
Advantages	Simple to perform. Relatively cheap. No special equipment needed. Trained biologist/ecologist may be necessary	Simple to perform. Relatively cheap. No special equipment needed. Minimal biological expertise required	Can indicate risk to human health. Simple to perform. Relatively cheap. Very little special equipment required	Usually very sensitive. Commercial kits available for some methods. Cheap and expensive options. Some methods allow continuous monitoring	Usually simple to perform. Minimal equipment requirements. Fast results. Relatively cheap. Some continuous monitoring possible	Can indicate risk to human health. Requires less advanced equipment than for the chemical analysis of water samples	Some methods very sensitive. Simple and complex methods available. Cheap or expensive options
Disadvantages	Some methods only applicable within limited geographical area. Knowledge of taxonomy required. Results can be influenced by natural changes in aquatic environment	Relevance to aquatic systems not always tested. Results can be influenced by natural changes in aquatic environment	Organisms can be easily transported in water and thus it may be difficult to relate positive results to a specific pollution source	Specialized knowledge and techniques required for some methods	Laboratory-based tests not always indicative of field conditions	Analytical equipment and well trained personnel necessary. Generally expensive	Specialized knowledge required. Some special equipment needed for certain methods

instruments measuring, for example, temperature, oxygen, conductivity (as an indicator of total dissolved solids) or pH.

An indication of the trophic state of lakes, reservoirs, and ponds can be obtained from the measurement of transparency. Transparency is the ability of light to pass through the water column and is affected by particulate and dissolved material present in the water. It can be measured optically with a light meter or approximated by using a Secchi Disc (a flat round disc painted in black and white quarter segments). The depth at which the quartered disc disappears and reappears from sight when lowered and then raised in its horizontal position, is known as the *Secchi depth*. In eutrophic lakes, phytoplankton densities in the upper water layers can be very high, leading to reduced Secchi depth. Thus, measurements of Secchi depth provide a simple, inexpensive indicator of spatial or temporal variations in phytoplankton population density (and other suspended material) in lakes when biological expertise to identify characteristic species associated with nutrient enrichment is lacking. This simple technique is being used for a long-term monitoring program aimed at examining spatial differences and trends in the transparency of lakes throughout North America. Monitoring is performed on a designated day each year by volunteers and the results are submitted to a central database via the Internet. The program known as the *Great North American Secchi Dip-In* is coordinated by Kent State University, with the sponsorship of the United States Environmental Protection Agency (US EPA) and the North American Lake Management Society and commenced in 1994. Data are now available on more than 5900 water bodies (Kent State University, 2004b)

Carefully selected chemical measurements can often be used to indicate the impact of certain human activities on water quality. Typical examples are phosphorus, which is usually associated with sewage and domestic wastewater discharges, and nitrates, which are frequently associated with agricultural activities such as the use of inorganic fertilizers. Regular measurements of total phosphorus in Lake Geneva from the 1950s to the present time indicate the improvement in water quality resulting from efforts to control phosphorus in wastewater discharges (Figure 4). Monitoring water quality to determine the presence of, and/or recovery from, wastewater discharges can be based either on one or more selected chemicals that are known to occur in the effluent, such as a specific organic compound, or a general indicator measurement such as total organic carbon that can be automated and monitored continuously. For most regular monitoring activities, water samples are taken to the laboratory for analysis, but portable instruments exist for selected chemical measurements, such as nitrates. Although these instruments often have a narrow range of measurement and limited precision, they can be useful for emergency water quality monitoring, for obtaining a rough indication of a likely problem requiring more detailed investigation or for occasions where large distances need to be covered between sites without recourse to an analytical laboratory.

In some countries where technical resources are limited, water quality monitoring in river stretches affected by numerous industrial effluents or multiple sources of pollution is based on easily performed physical and chemical, and sometimes simple biological, measurements. The results from each site are compiled into a water quality index (usually based on a numerical score, e.g. 1–100) that provides a simple indication to policy makers of whether conditions are improving or getting worse. The Oregon Water Quality Index is just one of many examples – it is based on eight water quality variables (temperature, dissolved oxygen, BOD, pH, ammonia + nitrate nitrogen,

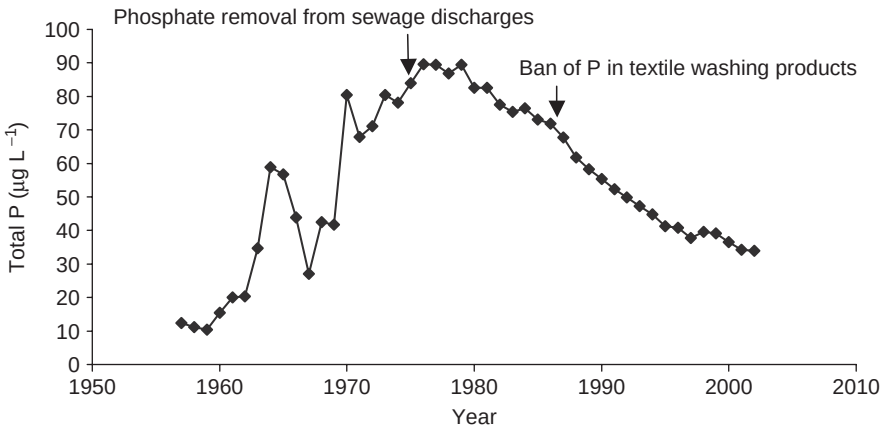

Figure 4 Decreasing concentrations of mean total phosphorus in Lake Geneva, reflecting improvements in water quality because of controls applied to wastewater discharges between 1973 and 2000 (Data from Commission Internationale pour la Protection des Eaux du Léman contre la pollution (CIPEL)). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

total phosphorus, total solids, and fecal coliforms) and has been in use since the 1970s, although it has been updated recently to reflect recent understanding of water quality (Cude, 2001).

Biological Monitoring of Water Quality

Any change in water quality (whether natural or human-induced) usually affects, to some degree, the aquatic biota associated with the water body. Such effects, ranging from the death of sensitive species, to changes in the aquatic community structure, to metabolic changes or reproductive disorders and the accumulation of toxic substances in cells and tissues, have been exploited in many ways as a means of monitoring water quality or the "health" of a water body. Biological monitoring and assessment is now widely accepted as an effective means of determining the response of an aquatic system to human interference and different methods and approaches are being routinely included in many state, national, and regional assessments of water quality. In addition to water quality criteria based on physical and chemical measurements, biological quality criteria are now being built into regulatory standards to monitor point and nonpoint sources of pollutants into surface waters (Davis and Simon, 1995).

Even a quick visual or qualitative assessment of the biota present in a water body can give a rough evaluation of water quality or trophic status, especially if carried out by an experienced aquatic biologist. Such approaches range from simply identifying the common macrophytes present (if any), to lifting stones and examining them for specific invertebrate species, to taking semiquantitative benthic invertebrate samples with a net on a long pole. Such basic monitoring approaches can be developed into numerical indices that rank water quality, such as the many diversity, biotic, or similarity indices that are based on mathematical theory (Washington, 1984). One such example is the use of indicator species of macrophytes to assess the trophic status of rivers in the United Kingdom that are subject to wastewater discharges from sewage treatment works (Dawson *et al.*, 2000).

Benthic invertebrates are particularly suitable for monitoring water quality impaired by the presence of biodegradable organic matter because many species are sensitive to depletion of dissolved oxygen and they are relatively immobile. There are numerous examples of monitoring programs based on the presence or absence of sensitive benthic species, known as *indicator species*, and each has been (or should be) tailored to meet national or regional objectives. In general, the method is applicable to a wider geographical area when the score is based on the family level of identification as in the Biological Monitoring Working Party Score (BMWP) (ISO-BMWP, 1979).

Indictor species can even be used for rapid, on-site bioassessment of the effects of biodegradable organic wastes in rivers. Typically, benthic invertebrates are collected in shallow stretches of the rivers by kicking up the substrate and collecting dislodged invertebrates in a net on a long pole (Figure 2). The relative abundance of easily identifiable indicator species is noted whilst still in the field. The presence or absence of certain species, together with their relative abundance, enables the sample to be assigned an index. In Ireland, the sample is assigned a Q value ranging from Q1 to Q5 – the higher the Q value, the better the species community diversity and the better the water quality. Where additional observations are made, such as dissolved oxygen measurements, the presence of silt, and so on, the Q value can be assigned more accurately to correspond with four major water quality classes (McGarrigle *et al.*, 2002):

Class A Unpolluted (Q5, Q4–5, Q4); Class B Slightly polluted (Q3–4); Class C Moderately polluted (Q3, Q2–3); Class D Seriously polluted (Q2, Q1–2, Q1). This approach forms the basis of the Irish national river water quality monitoring program where designated sites are sampled at the same time of the summer each year. The results provide the data for the annual reports of water quality that identify trends in impacts from agriculture and other sources of biodegradable organic waste, such as sewage discharges, and the food processing and dairy industries (McGarrigle *et al.*, 2002; Clabby *et al.*, 2003; EPA, 2004). The simple classification enables policy makers and the public to see whether river water quality is improving or not (Figure 5). The cost-effectiveness of such approaches makes them particularly attractive for use in developing countries, but it is essential that the method is validated in the region of interest before being put into widespread use (e.g. Henne *et al.*, 2002).

Recent developments in the use of biological monitoring include the setting of biological criteria for water bodies (equivalent to water quality criteria based on physical and chemical standards) based on a variety of numerical indices (e.g. diversity indices (Washington, 1984)), indicator species, fish stock assessments, and so on. An example of the development of such indices has been presented by Yoder and Rankin (1995). The approach has been endorsed by the USEPA (US EPA, 1999a; Hall *et al.*, 2000) as a means of describing reference conditions of aquatic communities inhabiting water bodies that have been designated for specific uses. Their use can aid the detection of impacts on water bodies, indicate whether a water body is meeting the quality criteria for its designated uses and indicate whether additional monitoring is necessary (Simon, 2000). The success of these criteria is based on the widely accepted premise that biological data are a better predictor of environmental impacts than chemical or toxicological data, especially when other information on the nature of the impact is lacking (Simon, 2000).

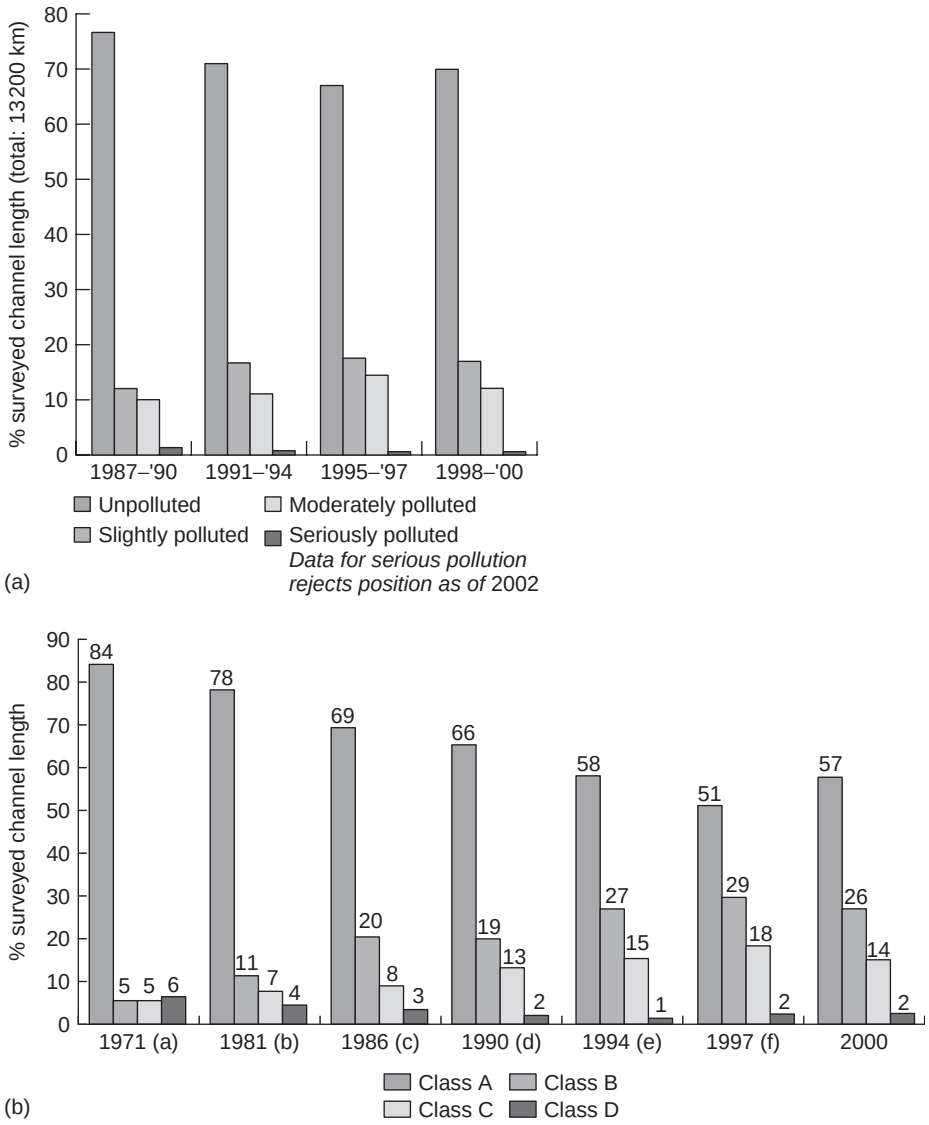

Figure 5 Changes in river water quality in Ireland as indicated by a biological assessment procedure. From McGarrigle *et al.*, 2002 (with permission from the Environmental Protection Agency) (**`http://www.epa.ie/NewsCentre/ReportsPublications/IrelandsEnvironment2004/`**). Monitoring Toxic Pollution

Deliberate or accidental discharges of toxic compounds into water bodies upset the natural water quality, present a risk to the aquatic ecosystem, and may pose a threat to human health if the water is to be extracted for municipal use. Monitoring designed to establish the spatial and temporal extent of the discharge may take the form of a limited duration survey if the discharge is short-lived, but could also involve routine evaluation of the water quality if the discharge is continuous or long-term (as in some industrial discharges). Measuring chemical compounds can be expensive and require technically advanced equipment. Thus, when the discharge has known toxic potential, or when a combination of compounds could lead to toxic impacts, it can be simpler (and sometimes cheaper) to use a routine bioassay technique. Many toxicity and bioassay methods have been standardized (see ISO, 2004a) and some, such as the *Salmonella* mutagenicity assay (Ames test), have been incorporated into local or regional water quality monitoring programs, for example, São Paulo State, Brazil (Umbuzeiro *et al.*, 2001). Changes in the activity of fish in response to adverse environmental conditions, that is, a change in water quality, have been incorporated into biological early warning systems that monitor water quality upstream of water intake points on highly industrialized rivers. The river water is diverted

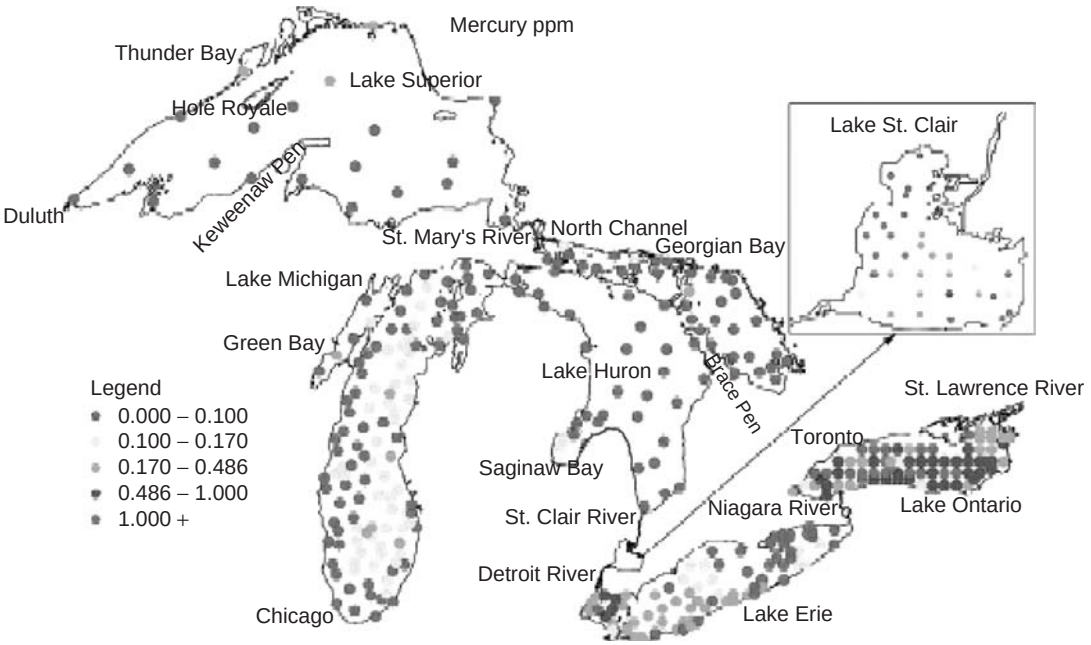

Figure 6 Total mercury concentrations in surficial sediments of the Great lakes (1997–2000). Spatial and temporal trends in surface water and sediment contamination in the Laurentian Great Lakes. *Environmental Pollution*, **129**, 131–144. (Reprinted from Marvin *et al.*, 2004. © 2004, with permission from Elsevier). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

through tanks containing live fish and detectors register the levels of their activity.

Potentially toxic contaminants released to the environment from various human activities are transported with atmospheric deposition, runoff or direct discharge to surface water bodies. Persistent substances can accumulate in sediments to concentrations above those in the water itself and which can be more easily detected. Deposited sediments can also be used to illustrate historical changes in the concentration of persistent compounds or metals in the environment (e.g. Van Metre *et al.*, 1998). Sediments have been used in the long-term and spatial monitoring of contaminants such as mercury in the Great lakes of North America and Canada (Figure 6) (Marvin *et al.*, 2004)

Community and Citizen Monitoring Programs

The growing demand for information about water quality from policy makers and the public is stretching the resources of many government agencies and local authorities, and they can no longer keep up with the demand for monitoring data. One approach to meeting the demand for information while minimizing costs, is to involve local people or other interested citizens in monitoring activities. Such volunteer programs, that range from simple activities such as the Great North American Secchi Dip-In (see above) to detailed lake and stream monitoring (e.g. US EPA Office of Water; Canadian Community Monitoring Network) are proving to be extremely valuable for generating water quality information and even for getting local people involved in the management of their water resources. Training programs and instruction manuals for citizens are available from many State agencies (e.g. US EPA, 1997, 2004; CCMN, 2004).

DATA HANDLING AND REPORTING

Data handling and reporting are the final steps of the water quality assessment process (see Figure 1). In the past, there was a tendency to archive data sets generated from monitoring activities with very little scrutiny or interpretation of the data. As a result, the data generated were not transformed into useful information and rarely served the purpose of management or policy generation or refinement (Ward *et al.*, 1986). Data collection is the principal objective of all monitoring activity and in order to make the monitoring effort worthwhile, the data generated must be assessed or synthesized to provide meaningful information for management, policy guidance, or public use. Advances in computer-based data storage and handling facilities have not only made it easier to share data and to analyze it and present it in many different ways, but they have also created a stronger need to ensure the quality, compatibility, and comparability of data made freely available, especially through the Internet. Developments in online accessibility to databases, combined with a need for public accountability, has led to many international, national, or state agencies

providing access to raw and/or synthesized data through the Internet (e.g. EEA, 2004; USGS 2004e). All data made available for public use must be reliable (see above regarding quality of data).

Modern monitoring techniques often result in data that is stored directly onto the electronic media from field or analytical equipment, using personal digital assistants (PDAs), field computers, data loggers, telemetric transfer mechanisms or cabled links. In addition, the widespread availability of inexpensive, handheld Global Positioning System (GPS) units has led to greater use of Geographic Information Systems (GIS) in data storage and presentation. Nevertheless, some information such as that recorded in the field by a field operator may have to be entered into a database manually and it is therefore essential that quality assurance procedures are applied as rigorously to data storage and handling activities as to any other step in the complete monitoring process (see following text). Links should be maintained between all relevant data that could have a bearing on the interpretation of any particular data set so that misinterpretation is avoided. For example, it is important that discharge data are available in association with water quality data for rivers; this might necessitate combining data from a hydrometric database with that from a different water quality database.

QUALITY ASSURANCE AND CONTROL

The data generated from a monitoring program must be of high quality, reliable, credible and, as far as possible, compatible with data generated from similar monitoring programs. This should be achieved through a rigorous process of quality assurance applied at all stages of the monitoring process, from sample collection in the field to data storage. It has been suggested by Meybeck *et al.* (1996) that approximately 10–20% of the total financial, technical, and personnel resources available in any monitoring program should be devoted to quality assurance procedures. For data compatibility with other monitoring programs, it is useful to adopt standardized methods, such as those published by the International Organization for Standardization (ISO) (ISO, 2004a), the German Industrial Standards (DIN – Deutsche Industrie-Normen), US EPA or other national standards where available. If accreditation and validation by a third party is not appropriate (perhaps because of the expense involved) quality assurance can be implemented by reference to international standards such as ISO 9000 or ISO 14000 (ISO, 2004b).

Whereas quality control may be very familiar to those working in an analytical laboratory, it is much less so to workers engaged in field work or nonchemical monitoring methods. Quality control for field sampling and measurements can be achieved by thorough training and the provision of detailed written operation procedures or manuals. Such procedures should also specify the appropriate storage and handling for the analysis that is to follow, ensuring that no deterioration or changes in composition can take place that might influence the eventual analytical results. Field note books or record sheets should always be used to record all necessary information in the field, such as the time, date, and location of sample collection, depth, method used, measurements taken, deviations from standard procedures, and so on. These notebooks can help variations from expected analytical results to be checked for possible explanations, such as unforeseen environmental influences, deviation from standard methodology or sampling site, and so on. From the point of sampling, all samples should be logged with a unique identification code that accompanies the sample through its handling and analysis in the laboratory to the final output and storage of results. In this way it is possible to trace the history of each sample including, for example, whether the sample was split for different analyses, diluted, concentrated, and so on. All equipment, whether field or laboratory, should be properly maintained and periodically calibrated (where appropriate) in accordance with the manufacturers' recommendations. Records of these activities should also be kept.

Analytical Quality Control

Analytical quality control is well established in many laboratories involved in water quality monitoring programs and demonstrates that the laboratory is producing data of adequate precision, accuracy, and sensitivity. It is based on a system of traceability and feedback; for this purpose a laboratory logbook should be maintained for all analytical procedures to which samples are submitted. There are two main aspects to analytical quality control: internal quality control and external quality control. The former involves the choice of method appropriate to the objectives of the monitoring program, and the validation of the method. Validation includes determining (i) the linearity of the calibration, (ii) the limit of detection, (iii) within-day or day to day precision, and (iv) the accuracy of the method. Typical methods for checking validity include:

- the inclusion of a blank sample, for example, distilled water, in a batch of analyses,
- duplicate analyses carried out on the same sample, and
- the use of certified reference materials.

The use of reference materials in routine analysis and the production of Shewhart charts enable a continuous check to be kept on the precision and accuracy of the technique (Briggs, 1996). Where problems are encountered, they should be addressed.

External quality control is particularly important where different laboratories contribute results to a single monitoring program and for which comparability between the

data generated by the participating laboratories is important (e.g. USGS, 2004c). External quality control also provides a method by which a laboratory can have its own accuracy checked independently (e.g. USGS, 2004d). Samples with known and unknown concentrations of the relevant variables are distributed to participating laboratories from a single reference laboratory. Each laboratory analyses the samples and reports its results to the reference laboratory. The deviation of each laboratory from the target value of each individual analysis is reported to the participating laboratory together with comments on whether the accuracy of the results submitted is satisfactory or not (Briggs, 1996; USGS, 2003). If the results show poor accuracy, measures should be taken by the laboratory to improve performance and the level of confidence associated with the results from that laboratory should be associated with any data made available for comparison with results from other laboratories. Laboratories providing data to national or regional databases may be required to take part in national accreditation programs (e.g. NWQMC, 2004b,c). As a general rule about 10% of all analyses should include external quality assurance samples.

Data Checking and Validation

The full process of quality control in a monitoring program should extend to the handling and storage of the data. Results should be scrutinized as soon as they are generated and before they are stored in a database or entered into reports. Inexplicable results should either be omitted from reports or flagged and, where possible, a degree of confidence assigned. The sudden or unexpected occurrence of unusually high or low values should automatically initiate checks on all stages of the sample handling and processing from collection in the field to final analysis in the laboratory. Events that could have resulted in unusual results, such as flood conditions in a river, change in the method of sampling, different analytical procedure, and so on, should have been recorded in field and laboratory notebooks. Where no explanation can be found, equipment and reagents should be checked and instruments should be recalibrated. Errors can be introduced in the manual copying of instrumental outputs or readings and their transcription from one notebook to another or onto a computer through keyboard entry. Many modern instruments will connect directly to the computer and transfer data electronically, thus reducing the risk of transcription errors. Databases for storing monitoring data can be arranged to highlight results that do not fall within expected ranges and this acts as another check on their validity.

CONCLUSIONS

Monitoring programs to define water quality occur at local, national, regional, and even global scales. These programs take many forms depending on the specific program objectives, varying from highly specific measurements associated with regulatory compliance to broad, multidisciplinary programs aimed at defining environmental quality status. The methods and approaches that are currently in widespread use vary from simple physical measurements to determination of trace concentrations of complex organic chemicals, from identifying the presence or absence of key indicator organisms to measuring physiological and biochemical processes in organisms, and from annual sampling events to determine long-term trends to intensive or continuous discharge-linked measurements to determine fluxes. Modern requirements to make monitoring data and their interpretation available to diverse users, including policy makers, other monitoring programs and often the general public, has placed an even greater emphasis on the need for quality assurance of monitoring data. Quality assurance techniques need to be applied to all of the steps involved in the gathering of monitoring data – from field sample collection, to laboratory analysis, to data handling and storage. This overview has highlighted some of the diverse approaches currently taken to monitoring water quality and the key steps involved in the monitoring processes.

93: Effects of Human Activities on Water Quality

NORMAN E PETERS[1], MICHEL MEYBECK[2] AND DEBORAH V CHAPMAN[3]

[1]U.S. Geological Survey, Georgia Water Science Center, Atlanta, GA, US
[2]Sisyphe/CNRS, University of Paris, Paris, France

Water quality comprises the physical, chemical, and biological characteristics of a water body. The water body acquires these characteristics from a suite of complex interactions among the water, atmosphere, soils, and lithology. Human activities affect both water quality and quantity. Human activities change land use and land cover, which changes the water balance and usually changes the relative importance of processes that control water quality. Furthermore, most human activities generate waste ranging from gases to concentrated radioactive wastes. Although each issue can be subdivided into a myriad of individual processes or activities, the primary water-quality issues affected by human activities include organic material, trace elements (heavy metals), acidic atmospheric deposition and runoff, salinization, nutrients (primarily nitrogen and phosphorus), pathogenic agents including bacterial pathogens, enteric viruses, and protozoans, suspended sediment, oil and grease, synthetic organic compounds, thermal pollution, exotic and invasive species, pesticides and herbicides, and radioactivity. In addition to the various issues, each human activity has a potential cyclical and cascading effect on water quality and quantity along hydrologic pathways. The degradation of water quality in one part of a watershed can have negative effects on users downstream; the timescale of effects is determined by the residence time of that substance along various hydrological pathways. An extremely important factor is that substances added to the atmosphere, land, and water generally have relatively long timescales for removal or cleanup. The nature of the substance, including its affinity for adhering to soil and its ability to be transformed, affect the mobility and the timescale for the removal of the substance and its effects on water quality, for example, biota.

INTRODUCTION

Human activities alter the natural characteristics of air, land, and water, which subsequently affect water quality. Prior to and immediately after World War II, the main water contamination problems in developed countries were fecal and organic pollution from untreated human waste and the by-products of early industries, particularly in urban areas. Through improved waste treatment and disposal during the past few decades, developed countries have addressed this problem resulting in water-quality improvements. Most of this has been accomplished through pollution laws and pollution-control technologies, particularly with respect to point sources such as factories and sewage treatment plants. Prior to wastes being treated, the management philosophy was essentially that *dilution is the solution to pollution*, which still persists in many areas of the world.

Human activities can affect water quality directly and indirectly. Direct effects are those that change water quality through the addition of some chemical constituent, physical characteristic, or biological component. The discharge of wastewater to a stream directly affects the stream chemistry, the application and leaching of fertilizer affects groundwater chemistry that can affect surface water by groundwater discharge, and the combustion of fossil-fuel, including coal, oil, and wood plus forest fires (biomass burning), affects air quality. The air quality affects precipitation, chemistry, and the water quality of the receiving water bodies. Increasing the temperature of a stream or lake by discharging heated water from the cooling tower of a power plant is an example of a direct change in physical characteristic.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Biological systems are directly affected by exotic and invasive species, for example, the introduction of nonindigenous aquatic species (animals or plants), such as zebra, mussels, or Brazilian waterweed, to streams and lakes. Indirect effects include alteration of the landscape (construction, mining, and farming), which affects hydrological pathways that change the rates at which water interacts with the environment and flushes out materials from that landscape.

An extreme example is the landscape alteration accompanying urbanization where pavement and building construction produce impervious surfaces that cause rainfall or snowmelt to rapidly runoff through concrete drains and pavement-lined stream channels. The runoff washes off chemicals and biota, such as bacteria and feces, which accumulated prior to the hydrologic event. In the natural state or prior to making the surfaces impervious, more of the rainfall or snowmelt infiltrates the soil and replenishes soil moisture, which had been transported to the atmosphere by evapotranspiration through grasses, shrubs and trees, and recharges groundwater. The groundwater travels along a much longer hydrological pathway to the stream than that occurs when water runs off an impervious surface.

Water-quality degradation is one of the most persistent, and in most cases, visible signs of human effects on the natural environment. As we continue to learn more about the complex interactions among the physical, chemical, and biological components of aquatic ecosystems, and as we have begun to clean up some of the oldest and worst contaminant problems, we find that our efforts are often offset by a misunderstanding or an incomplete knowledge of the processes and a myriad of new contaminants that have unknown effects on aquatic ecosystems and may degrade our potable water. Many of the dominant natural factors and the primary human activities affecting water quality are shown in Figure 1. The primary water-quality issues, their causes and effects, are listed in Table 1. The World Resources Institute (WRI)

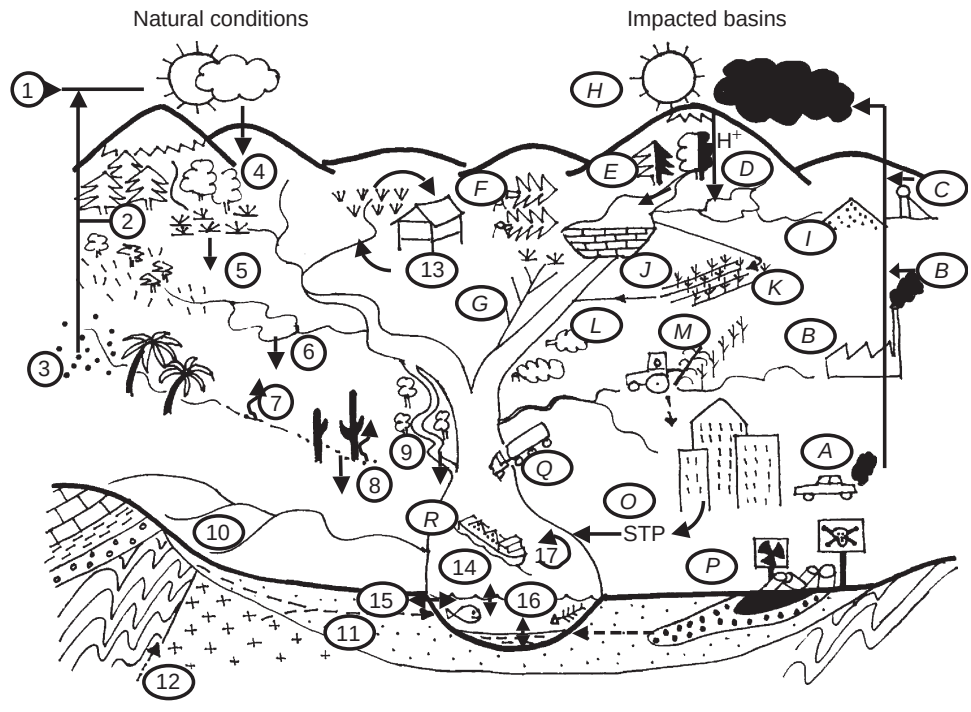

Figure 1 Sources, pathways, and main processes regulating water quality in natural conditions and impacted basins. Atmospheric fallout (4) originating from oceanic inputs (1), vegetation emissions (2) and eolian erosion (3); retention and transformation in wetlands (5) and lakes (6); evaporation leading to salinization (7) and precipitation in soils and endorheic basins (8); retention and exchange with floodplain (9); chemical weathering and mechanical erosion of various rock types (10); direct inputs of groundwater (11); hypothermal inputs (12); closed N, P cycles in traditional agriculture (13); exchange between surface waters and atmosphere (14), groundwater (15) and sediments (16); internal cycling of carbon and nutrients in aquatic food webs (17). Contaminated and/or acidified atmospheric deposition (D) due to urban and traffic, (A), industrial sources and mining/smelting sources (C); forest die back (E) and forest cutting (F); wetland draining (G); climate change (H); mining (I) and industrial (B) wastewaters; river fragmentation through damming (J); enhanced evaporation after irrigation (K); use of fertilizers and pesticides in agriculture (K, M); river course channelization and floodplain isolation (L); release of treated and untreated urban sewage (O); leak of dangerous chemicals from waste dumps (P); accidental spills (Q) and chronic leaks (R); enhanced eutrophication (17)

Table 1 Common contaminants and their sources and effects on water quality

Contaminant	Primary source(s)	Source/contaminant examples	Some primary effects
Organic material	Domestic sewage, industrial wastewater, and agricultural activities	Urban outfalls of untreated or treated sewage, pulp and paper plant discharges, farmyard and feedlot runoff	Decomposition of the organic material uses oxygen from the water, which stresses or in the extreme kills aquatic biota
Trace elements (heavy metals)	Industry and mining	Improper disposal or leakage of silver salts from film processing, atmospheric deposition of fly ash from fossil-fuel combustion, leakage, or flooding of tallings ponds,	Persist in vegetation, sediments, and wetlands, and accumulate in biota. Toxic to humans and aquatic organisms.
Acidic atmospheric deposition and runoff	Fossil-fuel combustion and mining runoff	Automobiles and power plants, and coal mine areas	Acidification of streams and lakes, which stresses or is toxic to aquatic organisms, and mobilizes metals
Salinization	Leaching and precipitation of salts from soils by irrigation, movement of saltwater from over pumping groundwater in coastal areas or reduced streamflow from overuse of freshwater upstream	Groundwater pumping in coastal areas, crop or horticulture irrigation in arid or semiarid areas	Salt accumulation poisons the soils so that plants will not grow, intrusion of saltwater into freshwater causes the freshwater to become nonpotable
Nutrients (N and P)	Runoff from farm land, septic tank leakage and sewage disposal, atmospheric deposition of N	Runoff of inorganic fertilizer or manure from cropland and animal feedlots, sewage effluent discharges to streams, migration of nutrients in septic tank leachate through groundwater to streams or lakes	Nutrients stimulate growth of aquatic plants causing eutrophication (algal blooms), change in species composition, decrease in water transparency, the excess plant material decomposes causing oxygen depletion, and so on. High nitrate concentrations in drinking water can cause methemoglobinemia (blue baby syndrome)
Pathogenic agents including bacterial pathogens, enteric viruses, protozoans	Sewage and urban stormwater mobilizing human and animal feces	Bacteria – *E. coli, Salmonella, Shigella* Viruses – Hepatitis A, Rotavirus Protozoa – *Giardia, Cryptosporidium*	Infectious diseases are spread through contaminated drinking water leading to diarrhea and intestinal diseases and parasites and in the extreme causing mortality

(*continued overleaf*)

Table 1 (*continued*)

Contaminant	Primary source(s)	Source/contaminant examples	Some primary effects
Suspended sediment (+ and −)	Soil erosion, land clearing for construction or agriculture in watersheds, damming	Erosion and transport from cultivated crop land, housing construction, runoff from impervious areas causing high streamflow and bank collapse, sediment starved rivers due to damming, reservoir sedimentation	Sediment entrainment affects habitat of aquatic organisms, sediment deposition fills lakes and fouls water intakes and filters, sediment-bound contaminants can affect human and aquatic ecosystem health, removal of sediment in reservoirs increases anoxia and generates greenhouse gases and also starves rivers of sediment for maintaining habitat and fertilizing floodplains
Oil and grease	Stormwater runoff, leakage from fuel storage and distribution facilities, industrial and urban waste	Leakage from barges or tankers, physical clogging of drains causes sewage to overflow	Affects respiratory system of aquatic organisms; affects feathers, preventing birds from flying; sewage overflow can be toxic to humans and aquatic organisms when ingested
Synthetic organic compounds	Untreated and treated sewage, septic tank leachate, urban storm runoff, runoff from animal pastures and feedlots	Prescription and nonprescription drugs (including antibiotics, antibacterial compounds), caffeine and derivatives, plasticizers, fire retardants, solvents, plant, and animal steroids, PAH, Fuels, and so on.	Some pharmaceuticals are known to disrupt the endocrine cycle of humans and aquatic organisms, affecting reproduction; effects vary by compound
Thermal pollution	Power generation, industrial cooling	Discharge of heated water in power plant and industrial (e.g. brewing) cooling towers to streams or lakes	Affects metabolic rates of biota and can change species composition of aquatic organisms. Affects oxygen levels and decomposition rates of organic material.
Exotic and invasive species	Transportation of water and other earth resources	Discharge of ballast water from ships, use of invested crops or other resources	Change in food webs and associated biological communities. Changes in biogeochemical cycling
Pesticides and herbicides	Agricultural use, urban use	Seasonal applications to cropland and runoff during the spring, runoff from suburban and urban areas, herbicide use along highways, domestic sewage	Toxic to aquatic biota
Radioactivity	Nuclear industry, military	Atmospheric fallout from bomb testing, leaks from nuclear power plants, migration, or leaks from waste facilities	Carcinogenic to humans and biota (terrestrial and aquatic)

provides a wide range of summary information regarding human activities on a global scale, and several of their maps have been included in this article to highlight the geographical distribution of various characteristics (WRI, 2004). Many of the topics in Table 1 will be discussed later and also topics of other articles of the encyclopedia of hydrological sciences, for example, acidification, **Chapter 95, Acidic Deposition: Sources and Effects, Volume 3**; point and nonpoint source pollution, **Chapter 94, Point and NonPoint Source Pollution, Volume 3**; nutrient cycling, **Chapter 96, Nutrient Cycling, Volume 3**; urban water quality, **Chapter 97, Urban Water Quality, Volume 3**; pathogens, **Chapter 98, Pathogens, Volume 3**; and salinization, **Chapter 99, Salinization, Volume 3**. The relative global impacts of these issues on specific water bodies (streams, lakes, reservoirs, and groundwater) are listed in Table 2. Also, water quality can affect human health, which is beyond the scope of this article (For more details of water-quality effects on human health, see Barzilay *et al.*, 1999).

When considering the impact of direct and indirect human effects on water quality, it is important to note that the effects are cyclical and cascading along hydrologic pathways in a watershed context. Hydrologic pathways are routes along which water moves from the time it is received as precipitation (e.g. rain and snow) until it is delivered to the most downstream point in a watershed, and the drainage area is defined by the downstream point to which flow converges. The degradation of water quality in upstream parts of a watershed can have negative effects on downstream users, and because there is generally a continuum of human activities and users throughout a watershed, the degradation effects cascade through the watershed. Cyclical effects include the artificial movement of water upstream, such as groundwater abstraction for irrigated agriculture. Each pathway has a residence time associated with transport and mixing. Consequently, everyone lives downstream of the effects of some human activity, and in the extreme, contaminants can originate outside a watershed and be deposited into it from the atmosphere. Also, substances added to the atmosphere, land, and water generally have relatively long timescales for removal or cleanup.

LANDSCAPE ALTERATION

Humans have altered the landscape in most areas of the world to satisfy basic needs in providing water, food, shelter, fuel for cooking and heating, and related services. Humans have also surpassed needs and have been currently very aggressive in providing for wants, which appear to be limited only by technology and imagination. The most intense landscape alteration has occurred in lowlands in fertile floodplains, where agricultural production is the highest, typically in small or localized areas for human settlement and mining.

As human population has become more concentrated or dense, the demand for resources to supply needs and wants has increased and so has the production efficiency. Whereas hunting and gathering were the main methods of food supply to many relatively sparse indigenous populations historically, higher population densities can only be supported by farming, which includes alteration of the landscape for crop production and pasturing for livestock. In addition, building construction requires basic earth resources ranging from grasses and wood to soils and rock.

Table 2 The relative water-quality issues of different water bodies, estimated at the global scale. The issues and related effects vary widely at the regional and local scales and the degradation generally reflects the economic development and land use. For a more complete discussion about the sources and effects of each issue, see Chapter 1 of Chapman (1996)

	Water body		
Issue	Rivers	Lakes/reservoirs	Groundwater

na, not applicable

[a]mostly in small shallow water bodies.
[b]other than resulting from aquatic primary production.
[c]algae and macrophytes.
[d]from landfills and mine tailings.
[e]water diversion, damming, overpumping, and so on.

Farming, lumbering, and mining supply these resources. Transportation has expanded from simple road building for the movement of humans and animals to trains, automobiles, and airplanes having a much higher demand for a complex array of earth resources including manufacturing materials and fuel (e.g. petroleum products). Mining provides geologic materials, which are altered by various processes to forms that can be used for manufacturing. In some cases, the geologic materials are used directly for construction such as sand and gravel, or a specific element or compound is extracted from the ore deposit leaving most of the geologic material behind as waste. Also, water supply and the use of water for navigation, manufacturing, and power generation requires alteration of river channels and the building of dams.

Deforestation

Deforestation, or the removal of a forest, typically occurs in humid climates, such as tropical or temperate zones, where rainfall is abundant and vegetation can easily grow (Figure 2). The impact of deforestation can have both indirect and direct effects on water quality.

The density of leaves and needles that can be maintained on a plant is a function of environmental conditions, mainly the amount of available nutrients, water, and solar radiation (sun energy), and the relative number of competing plants in the area. The leaves and needles, as well as branches and whole plants, which die and fall on the ground, are broken down by chemical reactions and insects, and in the process, release nutrients to the soil. This biogeochemical cycle also yields carbon dioxide, which when combined with water produces a mildly acidic solution, carbonic acid. The carbonic acid in soil waters and groundwater attacks rocks and minerals, breaking them down into more fundamental and smaller particles and releasing solutes.

Figure 2 Clearcut logging in New Zealand. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Typically, larger plants (trees compared to shrubs or grasses) transpire more water per unit area. Consequently, deforestation (tree or forest removal) has a large effect on water partitioning by decreasing transpiration and decreasing the permeability of the surface soils caused by an extensive root structure, and subsequently, increasing the runoff and water yield. The trees also reduce the erosion impact of rain drops by changing the pathway of the rain through the canopy along branches and down stems as stemflow and through the leaves/needles and branches either to shrubs or soil and litter as throughfall. The trees lower groundwater levels, and after deforestation, groundwater levels rise and waterlogging occurs, particularly, in and around lowland areas.

Another effect of deforestation is changing the thermal regime of the landscape and rivers. Forests provide shade, which is critical for the development of a particular aquatic biota. For example, fish, such as trout, are sensitive to increasing water temperatures and related decreases in dissolved oxygen concentrations resulting from tree removal from riparian zones.

The direct water-quality effect is a rapid turnover of nutrients and increased erosion. Erosion mobilizes both mineral soil and organic material, which can affect aquatic food webs by destroying the habitat and changing the balance of nutrients in the streams. The deforestation of riparian areas also reduces the food supply for macroinvertebrates and fish, thus affecting the biological quality. Higher water tables within the basin can also have a large effect on soil characteristics and stream chemistry, particularly in areas where the groundwater chemistry is enriched in salts because of weathering. For example, the removal of forests in eastern Australia, such as in the Murray–Darling basin, caused the water tables to rise to the surface of the soils. The highly saline groundwater contaminated the soils and the streams.

Deforestation has been extensive during the past 8000 years (Figure 3). Tropical forests, such as the Amazon basin, are currently being rapidly logged, burnt, or otherwise degraded, losing from 11 000 to 19 000 km^2 annually during the 1990s (Houghton *et al.*, 2000). For more detailed information about land use and land-cover effects on runoff from deforestation, see **Chapter 119, Land Use and Landcover Effects on Runoff Processes: Forest Harvesting and Road Construction, Volume 3**.

Agriculture

Food production is determined by the soil fertility, which was historically augmented with the application of organic matter and manure (Figure 4), but is now being increasingly augmented by a myriad of inorganic fertilizers to increase plant growth rates, and chemicals for the control

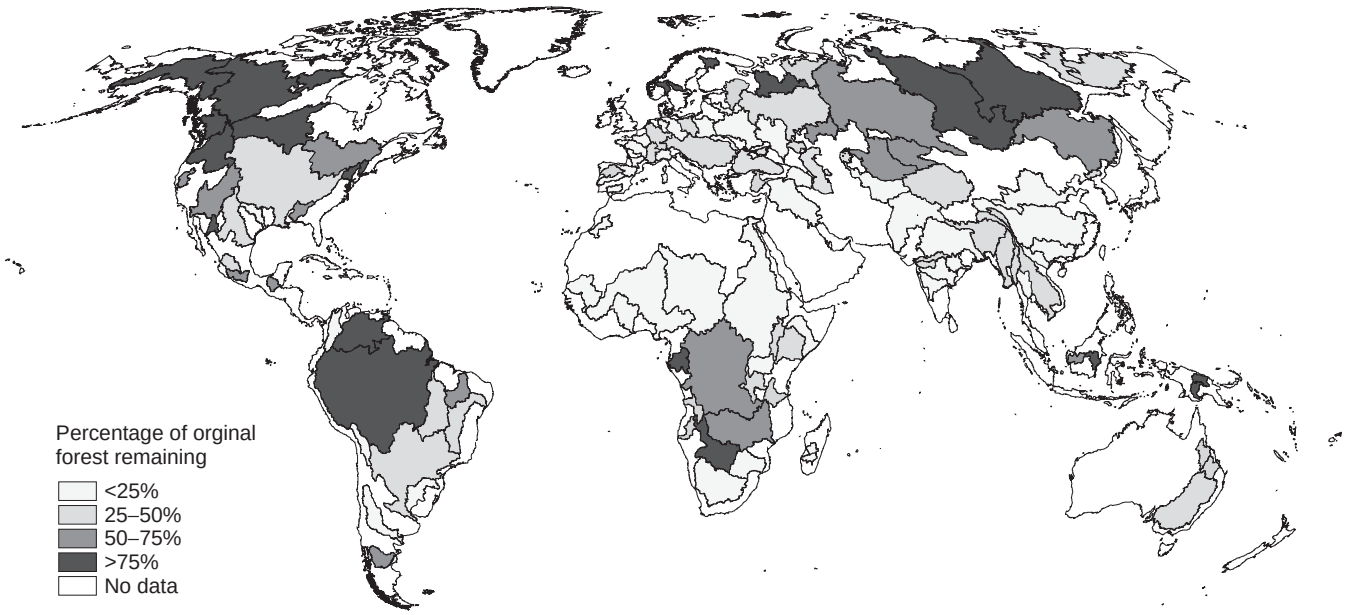

Figure 3 Remaining original forest cover by basin (Taken from **http://earthtrends.wri.org**/ ©2003 WRI by permission of World Resources Institute; Billington *et al.*, 1996; WRI *et al.*, 2003). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

of weeds (herbicides) and insects (insecticides or pesticides) (Figure 5). Lowland areas, including floodplains and riparian zones, in general are the areas targeted for agricultural production. In many cases, the high water table of lowland areas requires drainage and in the extreme, wetland removal. The act of tilling the land and planting crops or maintaining pastures originally altered the natural vegetation, and consequently, caused a change in water partitioning. Plants use soil water and groundwater. The soil water and groundwater is typically drawn through the roots and then transpired as water vapor through the leaves or needles by the process called *evapotranspiration*, which is driven by sunlight and photosynthesis. The water transported through the plant also carries nutrients and releases carbon dioxide to the atmosphere. In the process, the plants develop roots, which change the porosity and infiltration rate of the soil, and these roots extract nutrients from the soil, some of which are products of the chemical breakdown of rocks and minerals or chemical weathering.

Figure 6 Cattle grazing with direct access to a stream in a pasture near Hamilton, New Zealand. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Raising stock likewise has some major effects on water quality. Direct impacts result from overgrazing and allowing livestock direct access to surface water (Figure 6). The treatment and the disposal of animal wastes and the increasing use of pharmaceuticals in animal production alters the chemical composition of receiving waters. Direct water-quality impacts also result from poor storage and treatment of manure slurry from concentrated animal production and feedlots. For more detailed information about land use and land-cover effects on runoff from agriculture, see **Chapter 118, Land Use and Land Cover Effects on Runoff Processes: Agricultural Effects, Volume 3**.

The removal of native vegetation for farming increases the erosion potential of the land, and the transport of sediment is largely determined by the intensity and the duration of major hydrological events, which provides the energy for suspending or otherwise mobilizing solids. Technology and developments in agricultural management practices have changed markedly and these affect the potential mobility of contaminants. The development of larger farm vehicles and machinery require larger fields, which reduce the number of hedgerows and encourage the entrainment of sediment and other contaminants. Ploughing a field along the contours rather than up and down the slope reduces erosion, but the timing of the ploughing is critical with respect to major hydrological events. Likewise, the timing and the rate of application of manure or inorganic fertilizers and other agrochemicals as detailed below has a major effect on groundwater and surface water quality.

Agrochemicals

The demand for food has increased proportionally with the increase in human population. Technology has made some large contributions to food production efficiency, but not without negative effects on water quality. The major agrochemicals affecting water quality are fertilizers, pesticides, and herbicides. Global population increased from 2.5 billion people in 1950 to more than 6 billion people in 2004. The related food production increases and the resulting effects on water quality have been spatially disproportional because of the geographic distribution of the population and hydroclimatic conditions in the high population areas.

Historically, some of the modern-day farming practices such as application of manure and liming, and crop rotations with legumes were used. Ancient civilizations, such as the Egyptians (~3000 B.C.), recognized the importance of flood deposits in maintaining soil productivity. The Chinese have used organic manures to fertilize crops for the past 3000 years. The Greeks recorded the use of city sewage on vegetable crops and olive groves and a canal system for delivering the sewage to fields about 5000 years ago. Furthermore, the Greeks recorded the effects of green manure crops, particularly legumes, on crops. Both the Greeks and the Romans recorded the use of marl and plant ashes for soil enrichment and the acidity of lowland soils was adjusted using ashes or lime. Mineral fertilizers were not entirely unknown in past civilizations, as the Greeks and Romans fertilized plants with saltpeter, potassium nitrate. However, the extensive use of inorganic fertilizers did not begin until the twentieth century.

Two main factors contributed to the accelerated use of inorganic fertilizers beginning in the early 1900s. The first factor was the rapid commercialization and progressively cheaper synthetic production of ammonium, called *the Haber–Bosch process*. The second factor was the discovery of a couple of large sedimentary rock deposits of hydroxyapatite, a calcium phosphate mineral, which when treated with sulfuric acid yielded a highly soluble form called *superphospate*. The accelerated use of inorganic fertilizers began following World War II in most developing countries, for example, in Europe and North America, and a couple of decades later in many developing countries (Figure 7). Crop production (t ha^{-1}) followed, but was disproportionate to the increased use of inorganic fertilizers, increasing only by a factor of 3 from 1950 to 2000, while inorganic nitrogen fertilizer application increased by a factor of 23 and phosphorus application increased by a factor of 8.

The timing of the agrochemical application; the rate at which it is applied; the chemical, physical, and hydrologic characteristics of the watershed; and the hydrologic conditions at the time of application affect the rate at which the chemical can leach into groundwater and/or runoff into surface water. Needless to say, the more agrochemical added, the higher the probability that leaching and runoff of the agrochemical will occur. The continued use and the

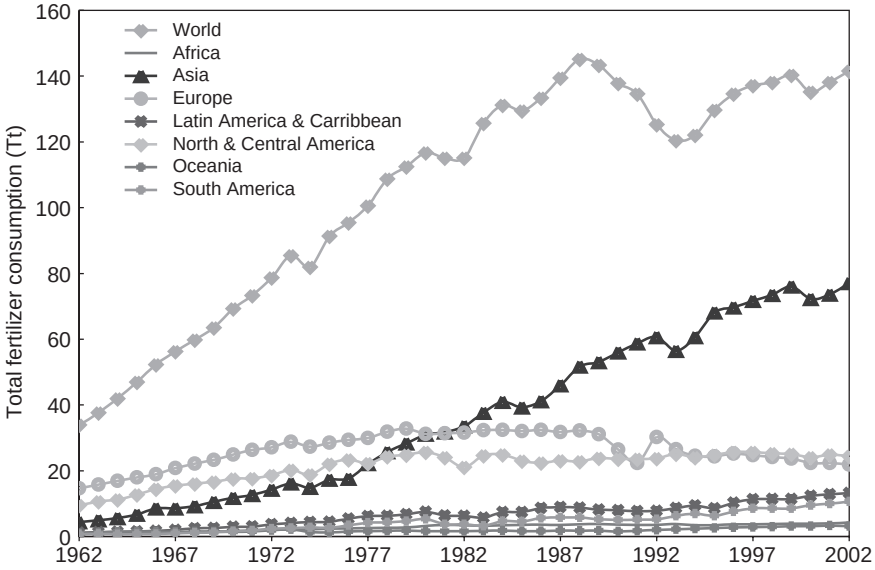

Figure 7 Annual fertilizer consumption of the World from 1962 to 2002 (FAOSTAT data, 2005). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

high application rates of fertilizer have resulted in a high probability of nitrate contamination of shallow groundwater (Burkart and Stoner, 2001). Furthermore, direct runoff and discharge of contaminated groundwater in agricultural areas having high fertilizer application rates increases the eutrophic status of receiving waters. Inorganic and organic nutrient concentrations increase, causing aquatic plant growth to increase. In the extreme, the occurrence of algal blooms has become more frequent and increased plant growth can result in hypoxia (oxygen depletion) because of plant decay. The high use of inorganic nitrogen fertilizers in the midwestern United States and subsequent transport in the Mississippi River system is considered responsible for the persistence of hypoxia in an increasingly larger area of the Gulf of Mexico (Burkart and James, 1999). Hypoxia is detrimental to the survival of bottom dwelling organisms, such as shellfish and bottom feeding fish.

In general, surface water phosphorous concentrations have decreased significantly downstream of urban areas since the 1980s, primarily because of the improvements in wastewater treatment and the decreasing use of phosphorous detergents, which affects urban wastewater (point source) and not agricultural runoff (diffuse or nonpoint source). However, phosphorous concentrations are still much higher than the background and remain a problem in most regions of the developed countries, for example, Europe and North America. The number of sewage treatment plants has also increased, which has reduced the amount of ammonium, which is toxic to fish. However, the sewage treatment process converts ammonium to nitrate, which is released into waterways and affects the nutrient balance. Dissolved nitrate in drinking water can also harm human health. For a more detailed discussion about nutrient cycling, see **Chapter 94, Point and NonPoint Source Pollution, Volume 3**.

Pesticides and herbicides are also leached or mobilized with fine sediment and have different water-quality effects than the more mobile inorganic fertilizers. Many of the first pesticides and herbicides were extremely toxic and persistent in the environment. For example, lindane, DDT, and dioxin, which were applied several decades ago, are still measurable today. The symbiotic and cumulative environmental effects of these compounds, even at low concentrations, are still not known.

Irrigated Lands

In contrast to the effects of deforestation for establishing agriculture in humid areas, establishing agriculture in semiarid and arid zones requires large additions of water to sustain the vegetation (Figure 8). Diverted surface water or abstracted groundwater is used for irrigation in semiarid and arid zones and each affects water quality. As discussed in the section on deforestation, a large percentage of available water is transpired to the atmosphere by vegetation. The low supply and high demand on water in arid and semiarid areas accentuate water-quality degradation issues; the poorer the quality the less water is available from an already depleted resource. Poorly designed and implemented irrigation schemes can cause waterlogging, salinization, and alkalization of soils.

Salinization results from concentrating solutes to excess in soils and surface water by relatively increasing the

Figure 8 Irrigation (Courtesy of T.R. Maret, US Geological Survey). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

loss of water due to evaporation and evapotranspiration with respect to supply. The result is that water added by irrigation is evaporated at a relatively high rate, leaving behind brine, which ultimately creates a soluble residue in the soil upon complete evaporation. The residue poisons the soil and prevents vegetation from growing even if sufficient water was available. The solution to potential salinization for fertile agricultural areas is to routinely flush the soil, which dissolves the salts and transports them in drainage water to nearby streams and lakes. Naturally, unless flushing continues throughout the entire system, the salts will continue to accumulate in a downstream water body. In some circumstances, the salinization is seasonal and a combination of snowmelt or seasonally high rainfall may result in an effective flushing of the salt from an entire watershed. For a more complete discussion about salinization processes and effects on water quality, see **Chapter 99, Salinization, Volume 3**.

Mining

Archaeological discoveries have shown that mining, the process of extracting useful rocks and minerals from the surface of the Earth, was conducted by humans as early as 40 000 years ago from a mine shaft in Switzerland (Gregory, 2001). The mining of metals, such as gold, silver, copper, and lead date to approximately 4000 B.C. and quarried stone was used for pyramid construction in Egypt in 2600 B.C. (Gregory, 2001). The disaggregation of the lithosphere varies by the mining technique, which is determined by the type of rock or mineral being mined. Some common mining practices include, (i) open pit (or strip) mining, in which the soil and rock (overburden) above a seam of coal, mineral, or rock is removed and the exposed material is extracted (Figure 9); (ii) hydraulic mining, in which a

Figure 9 Open pit or strip mine for building stone near Pirenopólis, Brazil. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

powerful jet of water is used to dislodge minerals present in unconsolidated ground or coal from a seam; (iii) placer mining, in which the mineral is separated by dredging and washing and typically occurs in alluvial deposits below or adjacent to streams; (iv) hardrock mining, in which picks and shovels, rock drills, and explosives create shafts and tunnels following the ore body or vein; and (v) solution mining, in which the mineral is dissolved and mobilized using a solvent, typically hot water. In each case, the earth materials are disturbed, affecting hydrologic pathways and exposing new mineral surfaces to the air or water. Each of these can change the natural characteristics of weathering and release contaminants. The valuable rock or mineral is surrounded by gangue (uneconomic material) that needs to be separated in a concentrating process and the processed gangue, called *tailings*, is typically discarded in piles and ponds. Sulfide minerals are commonly found in the rocks adjacent to coal deposits, and when they are exposed to the air and water, they oxidize and hydrolyze producing sulfuric acid. The sulfuric acid can acidify streams and lakes producing a pH in the range from 2 to 3 that is sufficiently acidic to mobilize metals, which are deleterious to aquatic biota. Also, the breaching of tailings ponds during flood conditions poses a major environmental threat by releasing high concentrations of contaminants and sediment to streams and lakes.

Urbanization

Land-use change affects freshwater quality (Falkenmark *et al.*, 1999). The geographic distribution of cities, roads, mining, agricultural land, and natural areas within a watershed influences infiltration properties, transpiration rates, and runoff patterns, affecting water quantity and quality.

Figure 10 Imperviousness produced by a mixture of houses, commercial buildings, parking lots, sidewalks, and roads in a residential area of Auckland, New Zealand. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Increasing imperviousness of an area increases the volume and discharge (flow rate) of runoff of receiving streams and impacts the water quality and biodiversity of freshwater systems. Urbanized areas have more impervious areas than nonurbanized areas and also have more (or at least concentrated) sewage and industrial pollution (Figure 10).

Construction, such as is prevalent for highways and buildings, generally results in the alteration of the landscape and the movement of earth materials, which may generate high sediment concentrations and loads in rivers. Construction alters the partitioning of water as discussed previously when forests are cleared, but roofs, parking lots, and roads stop water from infiltrating the soil and convey the runoff into ditches, drainage channels, and retention basins. The net result of the increased imperviousness is a rapid washoff of contaminants that accumulate on the surfaces and an increased velocity and volume of runoff, which increases bank erosion along the waterway. Materials are excavated and relocated, altering the existing hydraulic characteristics.

The potential deleterious human activity effects on water quality are amongst the highest for urban areas. Also, the most highly urbanized watersheds generally are in coastal areas (Figure 11). Of the 6.2 billion people in the world in 2002, approximately 47% live in urban areas, which are also the areas undergoing the most rapid change in population (WRI, 1996). It is projected that 75% of the global human population will live in urban areas by 2030 and that three of four urban dwellers will live in a megacity, that is, having a population of more than 10 million people (WRI, 1996). For more detailed information about land use and land-cover effects on runoff from urbanization and suburban development, see **Chapter 117, Land Use and Land Cover Effects on**

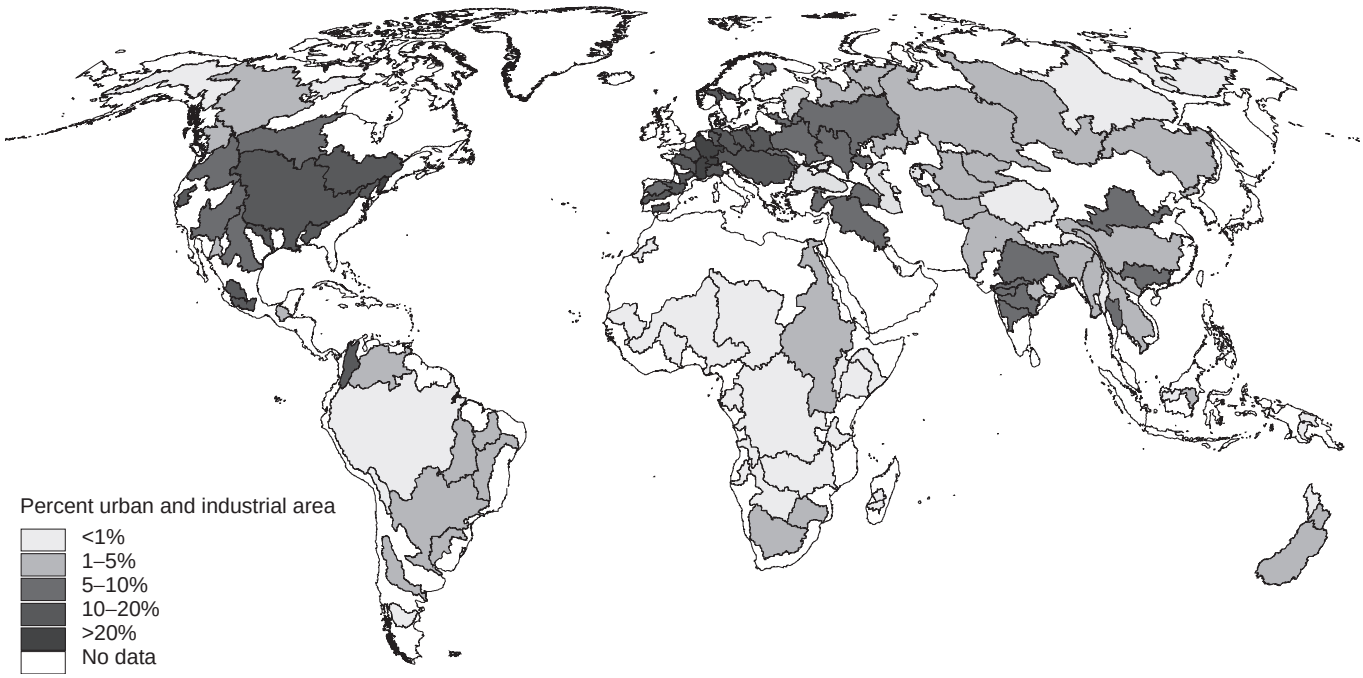

Figure 11 Global distribution of urban and industrial areas by basin (Taken from **http://earthtrends.wri.org**/ ©2003 WRI by permission of World Resources Institute; NOAA, 1998; WRI *et al.*, 2003). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Runoff Processes: Urban and Suburban Development, Volume 3.

Dams and River Channel Alteration

Dams have been built for thousands of years. They have been built to manage floods, to provide drinking water and water for industry and farming, and to provide electricity. In addition, the natural channels of many major rivers have been managed (channelized) primarily by dredging to maintain deep water for ship, boat, and barge traffic, and by altering the bank material to reduce erosion, which generally has been effective for low to moderate flows, but not during major floods. During 2000, approximately 50% of the world's rivers had at least one large dam, and the flow in more than 37% of the major river basins has been altered (WRI, 2004; Figure 12). About 50% of the world's large dams were built primarily to provide irrigation, which accounts for about 40% of irrigated farmlands worldwide. During 2000, large dams generated about 20% of electricity; 33% of countries rely on hydropower to supply more than 50% of their electricity.

Dams and their management change the natural flow of rivers, affecting the timing and the amount of supply of water and sediment downstream. Under natural conditions, the ecology of riparian zones, naturally very fertile areas, was determined by flood flows and associated deposition of sediment during overbank discharges. Major damage due to flooding has decreased considerably in most major river basins of the world. Dams have served the public well by controlling river flow for the protection of life and property. Downstream water supply from dams, particularly large dams, typically is derived from reservoir bottom water, which has distinctly different thermal and chemical characteristics from the background river affecting nutrient cycling. Consequently, these characteristics have a deleterious effect on natural aquatic biological communities downstream and the terrestrial biota, which are linked to the aquatic biota through food chains. Dams cause a change in biological communities and a reduction in biodiversity. Furthermore, dams influence carbon cycling. Reservoirs are sites for carbon burial, that is, in the sediments, and the anoxic conditions in the sediments and bottom waters of the reservoir produce methane from decomposing biomass. Emissions of methane and carbon dioxide from tropical reservoirs have been shown to be of similar order of magnitude as fossil-fuel greenhouse gas emissions. For more detailed information about floodplain sedimentation and reservoir sedimentation, see **Chapter 84, Floodplain Sedimentation – Methods, Patterns, and Processes: A Review with Examples from the Lower Rhine, the Netherlands, Volume 2** and **Chapter 88, Reservoir Sedimentation, Volume 2**, respectively.

OTHER DIRECT EFFECTS ON WATER QUALITY

Water pollution spans a wide range of chemical, physical, and microbial factors, but over the years, the balance of major pollutants has shifted markedly in most industrialized countries. Unfortunately, a new suite of contaminants from intensive agriculture and development activities in watersheds has kept the cleanup from being complete. In general, national water cleanup programs have been effective in reducing point sources of contamination and controlling the dumping of wastes from pipes. However, cleanup programs have *not* been effective in reducing "nonpoint" pollutants such as nutrients, sediments, and toxic compounds that come in runoff from agriculture, urban and suburban stormwater, mining, and oil and gas operations. In developing countries, sewage is still being discharged directly to rivers, streams, and coastal waters without any waste treatment (WRI, 1996). In developing countries, the more traditional pollution problems, such as sewage, in combination with new contaminants, such as pesticides and insecticides, heavily degrade water quality, particularly near urban industrial centers and intensive agricultural areas.

Surface-water bodies, such as streams, lakes, and reservoirs, are extremely susceptible to direct discharges of liquid and solid waste. Very dilute waters, typically in headwater areas, are susceptible to impacts from atmospheric deposition (acid rain). However, surface-water bodies are not the only ones that suffer from pollution. Groundwater, which is a critical source of drinking water and irrigation water for people in semiarid and arid regions, is also affected. The major causes of groundwater pollution are leaching of pollutants from agriculture, industry, and untreated sewage, and saltwater intrusion caused by over pumping.

Once the pollutants enter an aquifer, the environmental damage can be severe and long lasting, partly because of the long time needed to flush pollutants from the aquifer (Table 3). Because groundwater is primarily used for drinking water, pollution from untreated sewage, intensive agriculture, solid waste disposal, and industry can cause serious human health problems. People in rural areas primarily rely on shallow groundwater supply for drinking water, and shallow groundwater is more susceptible than deeper groundwater to contamination because of improper human waste disposal and agrichemical application. Although information to assess the status of groundwater resources is largely lacking globally, groundwater contamination from fertilizers, pesticides, industrial effluents, sewage, and hydrocarbons is occurring in many parts of the world.

As noted for surface water, nitrate pollution is one of the most serious threats to groundwater. In general, the risk of agrochemical pollution of groundwater supplies is directly related to the amount of agrochemicals applied to the land, the characteristics of the individual chemical, and the permeability of the soil. Furthermore, although untreated wastewater (point source) was a primary source of nitrate in surface waters 40 years ago, the increased use of inorganic fertilizers in agriculture, coupled with improved urban and suburban wastewater treatment, has resulted in a shift to diffuse or nonpoint sources, and especially agriculture, as the most important source of nitrate in surface waters and groundwater (Table 4). The trends of nitrate concentrations in shallow groundwater are similar to that of fertilizers used (Figure 7). For example, 50% of groundwater samples in a heavily fertilized region of northern China contain nitrate levels above the safe limit for drinking water ($10\,mg\,l^{-1}$). In the United States, where groundwater supplies drinking water for more than 50% of the population, high nitrate concentrations are widespread in shallow groundwater aquifers in agricultural areas and groundwater nitrate pollution in Europe is similarly widespread (Burkart and Stoner, 2001).

Although the map in Figure 3 is of the areal extent of deforestation, it largely represents the distribution of watersheds containing intensive agriculture. Watersheds with intensive agricultural development are likely to experience water-quality degradation from pesticide and nutrient runoff and increased sediment loads. The intensive agricultural land is concentrated in Europe, India, eastern China, southeastern Asia, and the midwestern United States, with smaller concentrations in Argentina, Australia, and Central America. Africa is striking in its lack of intensively cropped land, with the exception of small patches along the Mediterranean coast and in South Africa.

Surface-water quality has improved in most developed countries since about 1985, but nitrate and pesticide contamination remain persistent problems. Data on water quality in other regions of the world are sparse, but water quality appears to be degraded in almost all regions with intensive agriculture and rapid urbanization. Unfortunately, little information is available to evaluate the extent to which chemical contamination has impaired the health of freshwater ecosystems. However, incidents of algal blooms and eutrophication (the enrichment of water by nutrients, especially compounds of nitrogen and phosphorus, which will accelerate the growth of algae and higher forms of plant life) are widespread in freshwater systems all over the world – an indicator that these systems are affected by water pollution (Figure 13). In addition, the massive loss of wetlands at a global level has greatly impaired the capacity of freshwater systems to filter and purify water. Groundwater quality suffers from many of the same pollution problems as surface waters and faces the additional challenge of being very difficult to restore once the underlying aquifer is contaminated because the residence times are much longer and variable than for surface

Table 3 Relations among water-quality issues, causes, controlling factors, and spatial and temporal scales of degradation and recovery (Peters and Meybeck, 2000)

waters and the hydrological pathways are generally not known.

Waste Generation, Treatment, and Disposal – Air, Land, and Water

Wastes are generated from most human activities and their disposal depends on the form and the treatment, which is often a function of the population density. In rural areas, sewage treatment may not be a viable option and solid and liquid wastes are disposed of on the land or through septic systems. In urban areas, wastewater systems are sewered. Sewage can be classified into three types: domestic sewage carries used water from houses and apartments and is called *sanitary sewage*; industrial sewage is used water from manufacturing or chemical processes; and storm sewage, or storm water, is runoff from precipitation that is collected in a system of pipes or open channels. Sewage directly affects water quality. Sanitary sewage contains a variety of dissolved and suspended impurities, including organic material and disease-causing microbes. Industrial sewage typically contains specific and identifiable chemical compounds. Storm sewage carries dissolved and suspended materials, which are washed from the land surface. In addition to the solid and liquid wastes, contaminants can be dispersed to the atmosphere either because of combustion or the exposure of waste to the atmosphere and the volatility of the individual compound. For example, biomass burning, which occurs on a large scale in the Amazon basin, not only affects the composition of the atmosphere (Crutzen and Andreae, 1990), but the large emissions (gases, aerosols, and particles) also affect climate (Levine *et al.*, 1995).

Human, agricultural, commercial, manufacturing, and industrial wastes occur in solid, liquid, and gaseous forms and each can affect water quality. The characteristics of the waste and the method used for disposal will have varying effects on contaminant transport and transformation, and consequently, on the effect that a given contaminant in the waste will have on water quality. For example, the combustion of fossil fuels (coal and oil) produces gaseous and aerosols that have resulted in major human and environmental health problems through the exposure to heavy metals on particles, for example, fly ash, and the downwind transport and transformation of sulfur dioxide and nitrous oxides resulting in an acidic atmospheric deposition. The high nitrogen content in pollution can fertilize terrestrial vegetations such as the forests in the Sierra Nevada, California downwind of Los Angeles. In contrast, high pollutant emissions and atmospheric deposition have been attributed to forest decline and dieback in some areas, such as the "Black Triangle" consisting of southwestern Poland, eastern Germany, and northern Czech Republic (Figure 14). The high smog levels in cities, which have deleterious effects on the human respiratory system, also results from the emissions of noxious gaseous, which when washed out of the atmosphere in precipitation, can deplete nutrients from the soils and degrade the quality of surface and groundwater. Historical changes in waste disposal or treatment practices have largely resulted from scientific evidence of cause and effect relations. These changes also have affected the transformation and transport of contaminants.

For acid rain, although smog effects on human health were suspected as early as the late 1800s, the deleterious effects on lakes and rivers were only realized when fisheries and other aquatic biota were affected, and the scientific investigations suggested a causal linkage among pH, alkalinity (the capacity of a water to neutralize acidity), and fish decline or deformation. The particles emitted

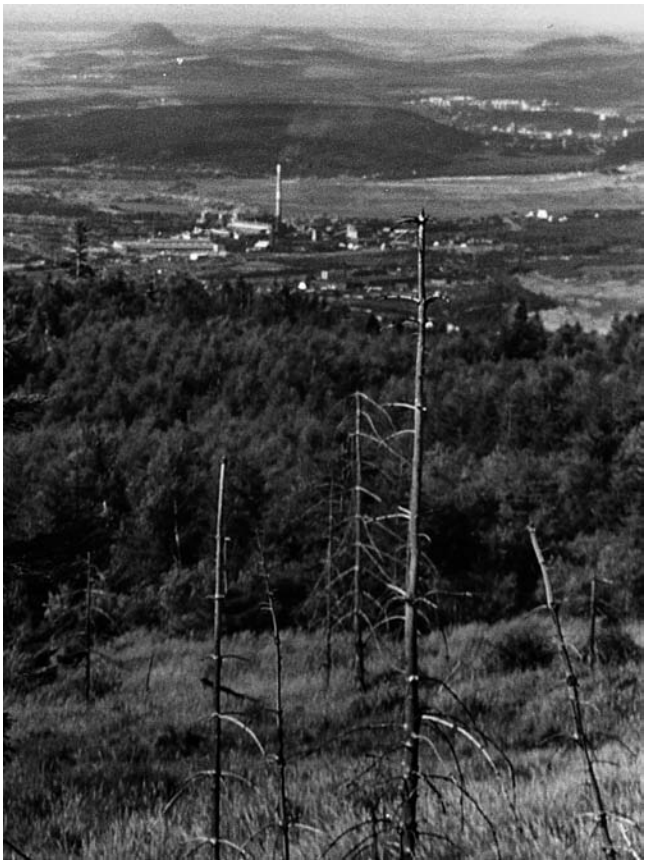

Figure 14 Dead trees in the foreground and power plant with plume in the background, Krusne Hóry, Czech Republic. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

during the combustion of a fossil fuel, particularly coal, are extremely basic, and when combined with rainfall that contains sulfuric and nitric acid produced from the gases emitted by the fossil-fuel combustion, neutralize the acid rain. However, it was first recognized that the particles needed to be removed because of human health concerns related to the heavy metal content. Scrubbers were installed on the smoke stacks of power-generation stations to remove the particulates, and that resulted in concentrated gaseous emissions, which produced very acidic rainfall near the stack. The next solution was to build taller smoke stacks to put the emissions higher into the atmosphere where they could be diluted and transported further downwind. This improved the air and the precipitation quality near the smoke stack, but transported the contaminants to the land and water farther downwind of the stack, evolving from a local to a regional problem. The land and water eventually showed signs of stress from accumulated loadings. Finally, additional technological solutions were applied to remove the acid-producing gases from the stacks, and in the case of coal, to wash or otherwise remove the acid-gas–producing compounds from the coal before combustion. For a more comprehensive discussion about freshwater acidification, see **Chapter 95, Acidic Deposition: Sources and Effects, Volume 3**.

Miscellaneous

There is a growing awareness that increased water used by humans does not only reduce the amount of water available for industrial and agricultural development, but has a deleterious effect on aquatic ecosystems and their dependent species. Human activities have severely affected the condition of freshwater ecosystems, to a point where many freshwater species are facing rapid population declines or extinction. The introduction of exotic or invasive species, such as the zebra mussel, water hyacinth, and hydrilla in the United States, also is stressing ecosystems, because many of these species have no predators to keep their reproduction and growth in check. Consequently, the invasive or exotic species out-compete the indigenous biota and have caused major changes in biological communities and related food webs (Mooney and Hobbs, 2000).

In addition, biota and humans, in particular, are susceptible to various pathogenic agents in freshwater, including enteric viruses, protozoa, bacteria, and parasites. From 1% to 25% of a given warm-blooded animal group is *infected* and given survival times of a few days to several years. The potential for contamination of surface water by a pathogenic agent is high depending on the safeguards and wastewater and solid waste treatment processes used (Geldreich, 1999). Receiving waters of urban centers and highly concentrated animal operations are particularly susceptible to pathogens.

94: Point and NonPoint Source Pollution

KEITH LOAGUE[1] AND DENNIS L CORWIN[2]

[1]Department of Geological and Environmental Sciences, Stanford University, Stanford, CA, US
[2]USDA-ARS, George E. Brown, Jr. Salinity Laboratory, Riverside, CA, US

The information age has ushered in a global awareness of complex environmental problems that do not respect political or physical boundaries: climatic change, ozone layer depletion, deforestation, desertification, and pollution from point and nonpoint sources. Among these global environmental problems, point and nonpoint source pollution represent a perfect example of a complex multidisciplinary problem that exists over multiple scales with tremendous spatial and temporal complexity. A point source of pollution discharges to the environment from an identifiable location, whereas a nonpoint source of pollution enters the environment from a widespread area. The ability to accurately assess present and future point and nonpoint source pollution impacts on ecosystems ranging from local to global scales provides a powerful tool for environmental stewardship and guiding future human activities.

INTRODUCTION

The objective of this chapter is to introduce the subject of point and nonpoint source pollution, the entirety of which could easily fill several volumes. The point and nonpoint source problems are defined and important related legislation is identified in the following two subsections. Monitoring and modeling (with consideration for uncertainty) are discussed, relative to characterizing the impacts from point and nonpoint source pollution, in the section on assessment. Excerpts from three case studies are presented in the example section; two of the case studies are for nonpoint source pollution, the third case study is for point source pollution. It should be pointed out that the chapter is focused, with the exception of one of the case studies, on the United States.

Point versus Nonpoint Source Pollution

Point source pollutants, in contrast to nonpoint source pollutants, are associated, as the name suggests, with a point location such as toxic-waste spill site (see Figure 1). As such, point source pollutants are, compared to nonpoint source pollutants, characteristically (i) easier to control, (ii) more readily identifiable and measurable, and (iii) generally more toxic. Nonpoint sources of pollution (see Figure 1) are the consequence of agricultural activities (e.g. irrigation and drainage, applications of pesticides and fertilizers, runoff and erosion); urban and industrial runoff; erosion associated with construction; mining and forest harvesting activities; pesticide and fertilizer applications for parks, lawns, roadways, and golf courses; road salt runoff; atmospheric deposition; livestock waste; and hydrologic modification (e.g. dams, diversions, channelization, over pumping of groundwater, siltation). Point sources include hazardous spills, underground storage tanks, storage piles of chemicals, mine-waste ponds, deep-well waste disposal, industrial or municipal waste outfalls, runoff, and leachate from municipal and hazardous waste dumpsites, and septic tanks. Compared to point source pollution, nonpoint source pollution is more difficult, related to monitoring and enforcement of mitigating controls, due to the heterogeneity of soil and water systems at large scales. Characteristically, nonpoint source pollutants (i) are difficult or impossible to trace to a source, (ii) enter the environment over an extensive area and sporadic timeframe, (iii) are related (at least in part) to certain uncontrollable meteorological events and existing geographic/geomorphologic conditions, (iv) have the potential for maintaining a relatively long active presence on the global ecosystem, and (v) may result in long-term, chronic (and endocrine) effects on human health and soil-aquatic degradation.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

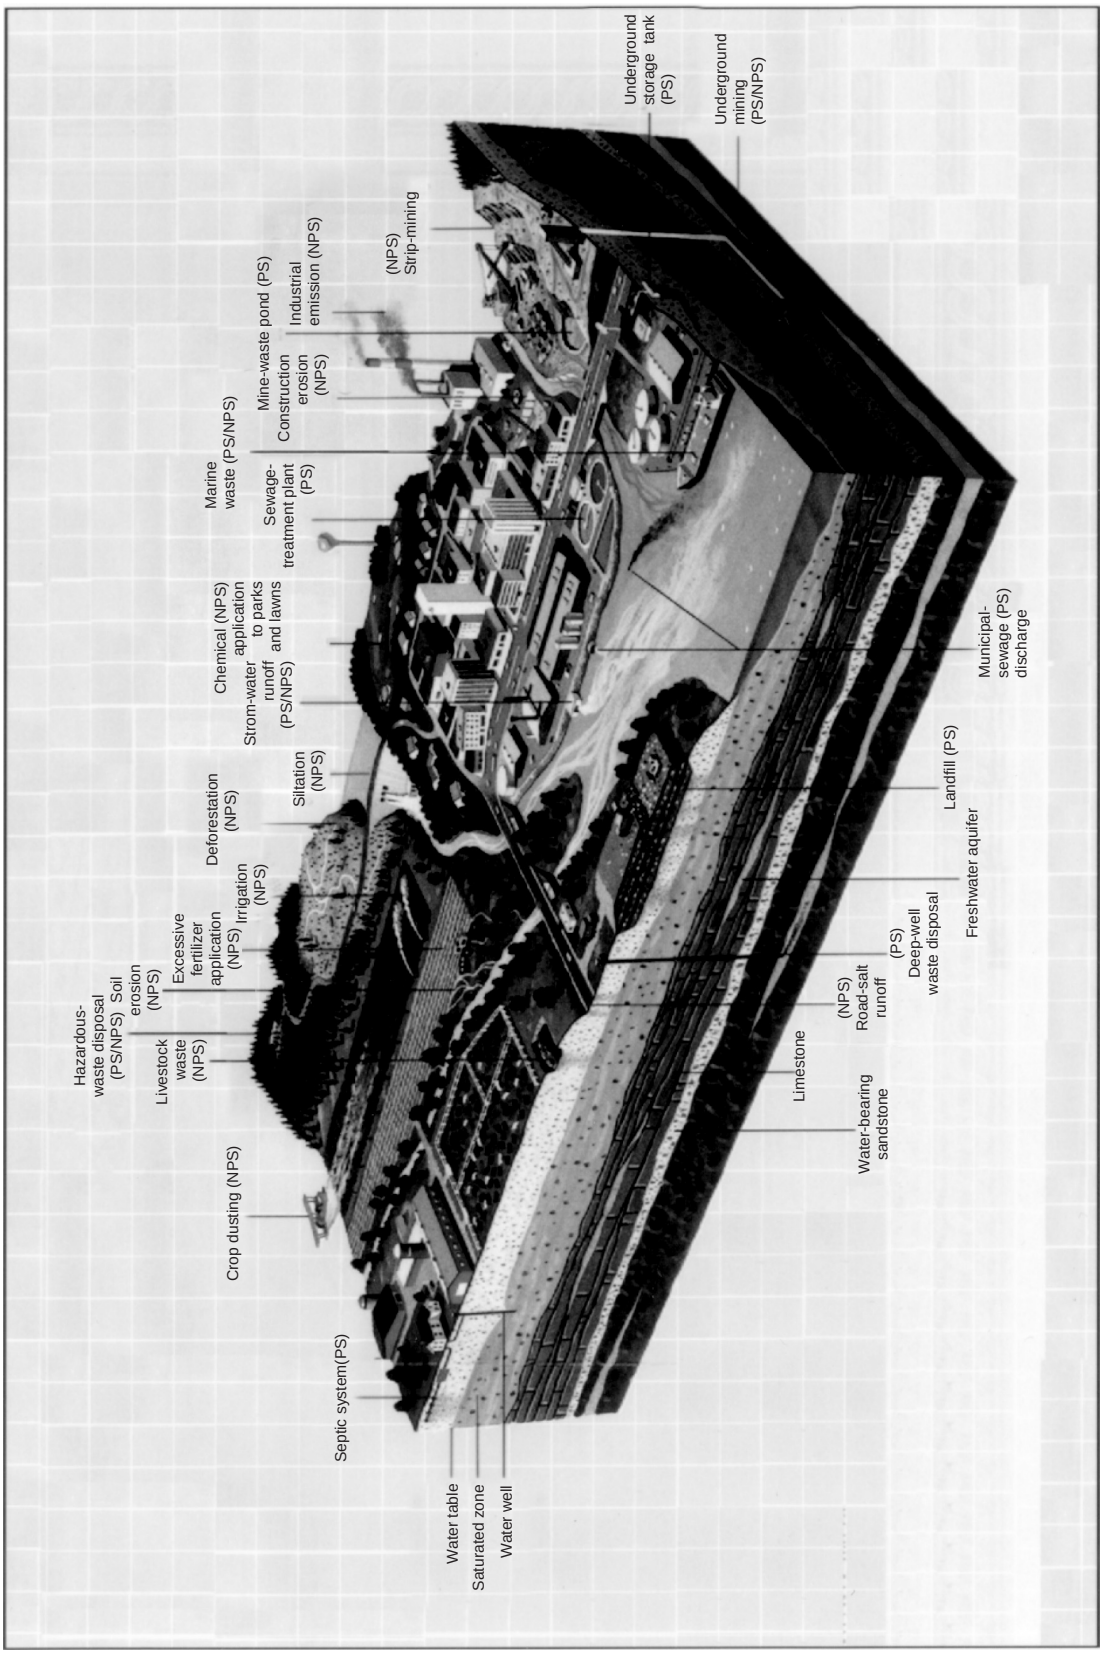

Figure 1 Examples of point and nonpoint source pollution (Reproduced from Corwin *et al.* (1999) by permission of American Geophysical Union. Adapted from a map published by National Geographic Society, 1993). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Nonpoint source pollution was generally not recognized until the mid-1960s. Initially, nonpoint source pollution was associated entirely with pollution from storm water and runoff. Subsequently, nonpoint source pollution has expanded to encompass all forms of diffuse pollutants. Nonpoint pollutants are defined as "contaminants of [air, and] surface and subsurface soil and water resources that are diffuse in nature and cannot be traced to a point location" (Corwin and Wagenet, 1996). It is important to note the statutory definitions of point and nonpoint source pollution (see Novotny and Olem, 1994). In essence, point sources of pollution "were originally defined as pollutants that enter the transport routes at discrete identifiable locations and that can usually be measured", while nonpoint source pollution was "everything else". Table 1 provides a list of statutory point and nonpoint sources of pollution compiled by Novotny and Olem (1994).

There can be a fine line between point and nonpoint source pollution. The distinction depends entirely upon the scale of interest. One person's point source pollution can easily be another person's nonpoint source pollution. For example, a single quarter-section (65 ha), in a watershed of hundreds of thousands of hectares, might be considered a point source of nitrogen fertilizer, and, yet, within the area of interest, the fertilizer could be viewed as a nonpoint source because of the broadcasting of millions of granules of the active ingredient. The scale of reference ultimately determines whether a pollutant is viewed as coming from a point or nonpoint source.

Historically, point source pollutants have received the greatest attention, both publicly and scientifically, because of the conspicuous severity of their impacts at a localized point (e.g. Love Canal (Mercer *et al.*, 1983) and Woburn (Harr, 1995)). However, over recent years, public, political, and scientific attention has shifted more and more toward pollutants that are widespread. This shift reflects an awareness of the scope and potential impact of the nonpoint source pollution problem (see Corwin and Loague, 1996; Corwin *et al.*, 1999).

Table 1 Statutory point and nonpoint sources of pollution (after Novotny and Olem, 1994)

Statutory Point Sources
• Municipal and industrial wastewater effluents
• Runoff and leachate from solid waste disposal sites
• Runoff and infiltrated water from concentrated animal feeding operations
• Runoff from industrial sites not connected to storm sewers
• Storm sewer outfalls in urban centers with populations of more than 100 000
• Combined sewer overflows
• Leachate from solid waste disposal sites
• Runoff and drainage water from active mines, both surface and underground, and from oil fields
• Other sources, such as discharges from vessels, damaged storage tanks, and storage piles of chemicals
• Runoff from construction sites that are larger than 2 ha
Statutory Nonpoint Sources
• Return flow from irrigated agriculture
• Other agricultural and silvicultural runoff and infiltration from sources other than confined concentrated animal operations
• Unconfined pastures of animals and runoff from range land
• Urban runoff from sewered communities with a population of less than 100 000 not causing a significant water quality problem
• Urban runoff from unsewered areas
• Runoff from small and/or scattered (less than 2 ha) construction sites
• Septic tank surfacing in areas of failing septic tank systems and leaching of septic tanks effluents
• Wet and dry atmospheric deposition over a water surface (including acid rainfall)
• Flow from abandoned mines (surface and underground), including inactive roads, tailing, and spoil piles
• Activities on land than generate wastes and contaminants, such as:
• Deforestation and logging
• Wetland drainage and conversion
• Channeling of streams, building of levees, dams causeways, and flow-diversion facilities on navigable waters
• Construction and development of land
• Interurban transportation
• Military training, maneuvers, and exercises
• Mass outdoor recreation

A Bit of the Legal History, for the United States

Up until the 1800s, the rural environment remained largely pristine in contrast to the filth of the urban areas as exemplified by historic centers such as ancient Rome, and, in the Middle Ages, London and Paris. By the mid-1800s, the sewage and runoff of the urban areas that polluted the surface waters became associated with waterborne disease. The concern for public health led to the first awareness of the repercussions of the environmental degradation and the close association of humankind's well being to environmental quality, thereby heralding the first environmental activist period. By the twentieth century, sewage systems and sewage treatment plants came into being.

Public interest in the environment through the first half of the twentieth century was almost negligible primarily because the epidemics associated with the Middle Ages had been controlled or eliminated, and because the use of chemical insecticides and fertilizers did not occur to an appreciable extent until the late 1950s. Once human-made chemicals, such as DDT (1,1,1-trichloro-2,2-bis-(4-chloropheny)-ethane)), were introduced in the mid-1950s

and the dumping of outflows from post-World War II factories continued unabated, pollution of soil and water resources rapidly increased. The book *Silent Spring* by Rachel Carson in 1962, which revealed the spread and potential danger of toxic human-made chemicals to the unwitting public, is heralded as initiating the second environmental activist period.

Freeze (2000) astutely points out that environmental policy and perspective over the last half century have been driven by the prevailing socio-politico-economic climate. The environmental pendulum, as Freeze refers to it, has swung from underkill to overkill and from concern that breeds action to disillusionment that breeds reaction. Table 2 provides a timetable of some of the significant environmental and statutory events that have shaped the last six decades and an overview of the pendulum swing from the environmental perspective to a retrospective from the New Right.

The positive result of the environmental activism of the 1960s and the 1970s was the formation of the Environmental Protection Agency (EPA) in 1970 and the Clean Water Act (CWA) of 1972 (Public Law 92–500). It should be pointed out, however, that the CWA called for "zero discharge" into surface waters, which, in actuality, shifted the onus of pollution from surface water to soil and groundwater. Prior to the CWA, the Refuse Act of 1899 and the Water Pollution Control Act of 1948 (Public Law 80–845) were used to control water pollution from industrial sources, but these archaic statutes were generally ineffective in controlling pollution.

The CWA was intended to be a comprehensive water quality program. For example, under the CWA, each State was to establish water quality standards based upon a total maximum daily load (TMDL), which is the amount of a pollutant that a body of water can handle from all sources. Once a TMDL is established, it is used as a basis for putting limits on the amount of that pollutant that can be discharged into the system. In reality, most of the emphasis of the CWA was placed on controlling point source rather than nonpoint source pollution (Novotny and Olem, 1994). The CWA established three crucial tasks (Novotny and Olem, 1994): (i) the regulation of point source discharge, (ii) the regulation of oil spills and other hazardous substances, and (iii) financial assistance for wastewater treatment plant construction. The most significant contribution of the CWA was the formulation of a means of enforcement through the National Pollution Discharge Elimination System (NPDES). This system has served as the basic mechanism for enforcing the implementation of pollution abatement of point sources and some nonpoint sources legally classified as point sources (Novotny and Olem, 1994).

The Water Quality Act (Clean Water Act) of 1987 (Public Law 100–24) provided three sections (Section 319, 402, and 404) that are significant to the control of nonpoint source pollution. Of these, Section 319 most directly applies to nonpoint pollution, requiring each State to prepare a State Nonpoint Source Assessment Report, and provides the incentive of matching Federal funds to encourage States to develop and implement management programs.

Table 2 Timetable of environmental and statutory events (after Freeze, 2000)

Decade	Environmental perspective	Environmental events	US Federal response	Prevalent environmental concepts	Influential books	New right retrospective
1940s	Chemical Revolution				*A Sand County Almanac* Leopold (1949)	Chemical Revolution
1950s	Age of Carelessness			Throwaway society		Age of Economic Prosperity
1960s	Age of Awakening		EPA (established, 1970)	Conservation, wilderness protection	*Silent Spring* Carson (1962)	Age of Social Upheaval
1970s	Age of Awareness and Action	Earth Day Love Canal	CWA, SDWA, TSCA, RCRA, PP list, NOR	Limits to growth	*The Closing Circle* Commoner (1971)	Age of Overreaction
1980s	Age of Disillusion	Three mi Island	CERCLA, HSWA, SARA	Soft energy paths		Age of Vindication
1990s	Age of Reaction	Earth Summit	PPA in Rio	Sustainable yield	*Earth in the Balance* Gore (1992)	Age of Reason

CERCLA = Comprehensive Environmental Response, Compensation, and Liability Act; CWA = Clean Water Act; EPA = Environmental Protection Agency; HSWA = Hazardous and Solid Waste Amendments (to RCRA); NOR = National Organics Reconnaissance; PPA = Pollution Prevention Act; PP list = Priority Pollutant List; RCRA = Resource Conservation and Recovery Act; SARA = Superfund Amendments Reauthorization Act; SDWA = Safe Drinking Water Act; TSCA = Toxic Substances Control Act.

Section 319 establishes a regulatory link between nonpoint source pollution and groundwater quality; specifically requiring States to develop best management practices (BMPs) that consider the impact of management on both surface water and groundwater quality. Examples of BMPs include grassy waterways, buffer strips, reduced application rates for pesticides and fertilizers, and the proper storage and disposal of animal wastes.

Besides the CWA, there are a plethora of Federal statutory laws concerning the environment, floodplain management, the US Department of Agriculture, and mining that affect point and nonpoint source pollution and water quality (e.g. National Environmental Policy Act; Federal Environmental Pesticide Control Act; Rare and Endangered Species Act; Safe Drinking Water Act; Federal Insecticide, Fungicide, and Rodenticide Act; Toxic Substance Control Act; The Wild and Scenic River Act; Coastal Zone Management Act; Flood Control Act (and amendments); National Flood Insurance Programs; Flood Disaster Protection Act; Rural Development Act; The Food Security Act; Surface Mining Control and Reclamation Act; Federal Land Policy and Management Act). Novotny and Olem (1994) provide an excellent discussion of the laws, regulations, and policies related to point and nonpoint sources of pollution. Table 3 shows the relative importance of pollutants with respect to their source. Domenico and Schwartz (1990) provide a list of the EPA priority pollutants.

ASSESSMENT OF POINT AND NONPOINT SOURCE POLLUTION

Assessment involves the determination of change of some constituent over time and space. This change can be measured in either real time or simulated with a model. Real-time measurements reflect the activities of the past, whereas simulations can provide useful glimpses into the future. Both means of assessment are valuable. Related to real-time measurement and monitoring, the distribution and trends of pesticides in the atmosphere (Majewski and Capel, 1995), groundwater (Barbash and Resek, 1996), surface water (Larson *et al.*, 1997), and fluvial sediments and aquatic biota (Nowell *et al.*, 1999) have been carefully assessed. For more than 10 years, the US Geological Survey's (USGS) *National Water Quality Assessment* (NAWQA) program (see **`http://water.usgs.gov/nawqa`**) has played a key role in the assessment of nonpoint source contamination from various pollutants to both surface water and groundwater, with studies in more than 50 major river basins and aquifers (Gilliom, 2001). An example of the importance of real-time measurement is the field

Table 3 Relative importance of pollutant concentration in soil-water systems (after Peirce *et al.,* 1998)

Nonpoint source	Suspended solids and sediment	BOD	Nutrients	Toxic metals	Trace elements	Pesticides	Pathogens	Salinity/ TDS
Urban storm runoff	M	L-M	L	H	M	L	H	M
Construction	H	N	L	N-L	N-L	N	N	N
Highway de-icing	N	N	N	N	N	N	N	H
Instream hydrologic modification	H	N	N	N-H	N-H	N	N	N-H
Noncoal mining	H	N	N	M-H	M-H	N	N	M-H
Agriculture								
• Nonirrigated crop production	H	M	H	N-L	N-L	H	N-L	N
• Irrigated crop production	L	L-M	H	N-L	H	M-H	N	H
• Pasture and range	L-M	L-M	H	N	H-L	N	N-L	N-L
• Animal production	M	H	M	N-L	N-L	N-L	L-H	N-L
Forestry

N = Negligible; L = Low; M = Moderate; H = High; TDS = Total Dissolved Solids.

characterization of the April 1977 accidental spill of approximately 1900 L of the pesticide EDB (ethylene dibromide) within approximately 20 m of a well that provided drinking water to the village of Kunia on the Hawaiian island of Oahu. The point source area around this spill would eventually become a *Superfund* site.

Modeling

A distinct advantage of simulation is that it can be used to alter the occurrence or future impact of detrimental conditions. Obviously, simulation cannot replace *real* data. It should also be pointed out that field observations and simulation are not mutually exclusive entities. Simulation requires considerable information to establish (i) the problem of interest (e.g. climatic data, land-cover characteristics, spatial distributions of near-surface soil-hydraulic properties) and (ii) test (in some cases) the model's performance (e.g. spatial and temporal distribution of chemical concentrations). The use of mathematical models for assessing point and nonpoint sources of pollution, especially after ground truth comparisons, fills in information gaps, identifies critical areas and chemicals for future monitoring, and provides the *what if* capability needed for both regulation and remediation.

By definition, a mathematical model integrates existing knowledge into a framework of rules, equations, and relationships for the purpose of quantifying how a system behaves. As long as a model is applied over the range of conditions from which it was developed, it serves as a useful tool for prognostication. When sufficient information exists to characterize point and nonpoint pollution at a given time, a model can be calibrated (e.g. adjusting model parameter values within a reasonable range so that simulated concentrations closely match observed concentrations) and subsequently employed to make predictions (Loague and Green, 1991). When sufficient information does not exist, a model can still be used in a *what if* mode to address questions related to potential impacts (Abrams and Loague, 2000). Models can range in complexity from the simplest empirical equation to complex sets of partial-differential equations that are only solvable with numerical approximation techniques.

Addiscott and Wagenet (1985) present a categorization for models on the basis of a conceptual approach, distinguishing between deterministic and stochastic, and mechanistic and functional. The key distinction between deterministic and stochastic models is, according to Addiscott and Wagenet (1985), that deterministic models "presume that a system or process operates such that the occurrence of a given set of events leads to a uniquely definable outcome" while stochastic models "presuppose the outcome to be uncertain". Stochastic models consider the statistical credibility of both input conditions and model predictions, whereas deterministic models ignore any uncertainties in their formulation. The second level of model distinction is between mechanistic and functional models. As described by Addiscott and Wagenet (1985), "mechanistic is taken [here] to imply that the model incorporates the most fundamental mechanisms of the process, as presently understood", whereas the term functional is used for "models that incorporate simplified treatments of solute and water flow and make no claim to fundamentality, but do, thereby, require less input data and computer expertise for use".

Three categories of, for example, deterministic models are: (i) regression models, (ii) overlay and/or index models, and (iii) transient-state solute transport models. Regression models generally use multiple linear regression techniques to relate various causative factors. Overlay and/or index models, which can be property or process based, compute an index of pollutant mobility. Transient-state, process-based models are capable of simulating the movement of a pollutant in a dynamic flow system. Transient-state, process-based models describe some or all of the processes involved in, for example, solute transport (e.g. advection, dispersion, diffusion, and retardation). Corwin *et al.* (1997) summarize several geographical information system (GIS) based nonpoint source pollution modeling efforts.

Uncertainty

There can be considerable uncertainty in modeling point and nonpoint source pollution. So, why model? In general, there are two idealized uses for simulation. The first is the prediction (or forecasting) of future events based upon a calibrated and validated model. The second use is the development of concepts for the design of future experiments to improve the understanding of processes. There are three sources of error inherent to modeling: (i) model error, (ii) input error, and (iii) parameter error. Model error results in the inability of a model to simulate the given process, even with the correct input and parameter estimates. Input error is the result of errors in the source terms (e.g. soil-water recharge, chemical application rates). Input error can arise from measurement, juxtaposition, and/or synchronization errors. Parameter error has two possible connotations. For models requiring calibration, parameter error usually is the result of model parameters that are highly interdependent and nonunique. For models with physically based parameters, parameter error results from an inability to represent aerial distributions on the basis of a limited number of point measurements. The aggregation of model error, input error, and parameter error is the total (or simulation) error. For multiple-process and comprehensive model simulation, error is complicated further by the propagation of error between model components.

In general, the methods for characterizing uncertainty can be grouped into three categories (Loague and Corwin, 1996): (i) first-order analysis, (ii) sensitivity analysis, and

(iii) Monte Carlo analysis. First-order analysis is a simple technique for quantifying the propagation of uncertainty from input parameter to the model output. The first-order approximation of functionally related variables is obtained by truncating a Taylor-series expansion (about the mean) for the function after the first two terms. Sensitivity analysis is used to measure the impact that changing one factor has on another. The sensitivity of a model's output to a given input parameter is the partial derivative of the dependent variable with respect to the parameter. Monte Carlo analysis is a stochastic technique of characterizing the uncertainty in complex hydrologic response model simulations. The Monte Carlo method considers each model input parameter to be a random variable with a probability density function (PDF). Monte Carlo simulations are based upon a large number of realizations, from every input parameter distribution, created through sampling the different PDFs with a random number generator. A separate hydrologic response simulation is made for each parameter realization. The number of possible simulations, based upon all the combinations of parameter realizations, is infinite; therefore, a finite number of cases (e.g. several hundred) are usually investigated. Estimates of the average simulated hydrologic response, and the associated uncertainty, are made from the combined outputs of the simulations (i.e. the total ensemble of the different realizations). Loague and Corwin (1996) provide examples of first-order uncertainty analysis, sensitivity analysis, and Monte Carlo simulation.

THREE EXAMPLES

There are thousands of documented cases of point and nonpoint source pollution, far too many to list here. Three examples (from the first author's work) that combine field observations and modeling are briefly discussed in this section. The second example (II) is a local-scale legacy assessment of *point source* pollution from three Manufactured Gas Plants. The first (I) and third (III) examples are both for *nonpoint source* pollution. Example I is a regional-scale legacy assessment associated with agrochemical use in California's Central Valley. Example III is a regional-scale assessment focused on the future management of forested areas on the Canary Island of Tenerife. Assessments of the type shown in Examples I, II, and III can be useful for regulatory decisions and remediation efforts. It is worth pointing out that both examples I and II were undertaken related to major civil actions.

Example I: Nonpoint Source Pollution, the Fresno Case Study

Between the late 1950s and the time of its statewide cancellation in August of 1977, there was widespread use of DBCP (1,2-dibromo-3-chloropropane) throughout the San Joaquin Valley in California. More than two decades after its cancellation, DBCP-contaminated groundwater persisted as a problem in the San Joaquin Valley. The objective of the Fresno Case study (Loague *et al.*, 1998a,b) was to address, from a simulation perspective supported by field observations, if *label recommended* NPS applications were likely to be the principal source of the DBCP groundwater contamination in Fresno County.

The San Joaquin Valley, at the southern end of California's Central Valley, extends in a southeasterly direction for approximately 400 km from just south of Sacramento. East-central Fresno County, situated between the San Joaquin River to the north and the Kings River to the south, is the largest agricultural county in the valley. The spatial distribution of DBCP use in the study area, between 1960 and 1977 (see Figure 2a), was estimated using land-cover maps for different years.

The numerical model used for the 1D simulations (Loague *et al.*, 1998a) of dissolved phase DBCP concentration profiles in the unsaturated zone was PRZM-2 (Mullins *et al.*, 1993). The potential fate and transport of DBCP between the surface and the water table for multiple NPS applications, related to different and changing land use between 1960 and 1977, was quantitatively estimated for 1172 elements for a 35-year period. The aggregate of the DBCP concentrations loaded to the water table for each grid element make up the annual loading files for the 3D saturated transient transport simulations. The numerical models used for the 3D simulations (Loague *et al.*, 1998b) of saturated subsurface fluid flow and DBCP transport are MODFLOW (McDonald and Harbaugh, 1988) and MT3D (Zheng, 1992), respectively. Recharge to the water table for the saturated simulations was estimated as the residual (precipitation plus irrigation minus evapotranspiration) in the PRZM-2 water-balance simulations. The area focused upon for the saturated simulations was represented by a 3D finite-difference grid made up of 76 440 elements (i.e. 2184 1 km^2 surface elements with 35 layers).

The 13-step approach used by Loague *et al.* (1998a,b) to simulate the impact of multiple DBCP applications under changing land use and groundwater pumping/recharge in the Fresno study area are summarized in Table 4. Figure 2(b) shows a 1999 snapshot of the simulated DBCP loading water table from the Fresno Case study. The simulation results from the Fresno Case study lead to the following general comments (Loague *et al.*, 1998a,b):

- The areas most likely to facilitate DBCP leaching through the entire unsaturated soil profile were targeted.
- The first appearance of DBCP above the detectable limit at the water table was simulated as most likely occurring between 1961 and 1965.
- The estimated DBCP concentrations reaching the saturated subsurface exceed the maximum contaminant level (MCL) at several locations at different times. The

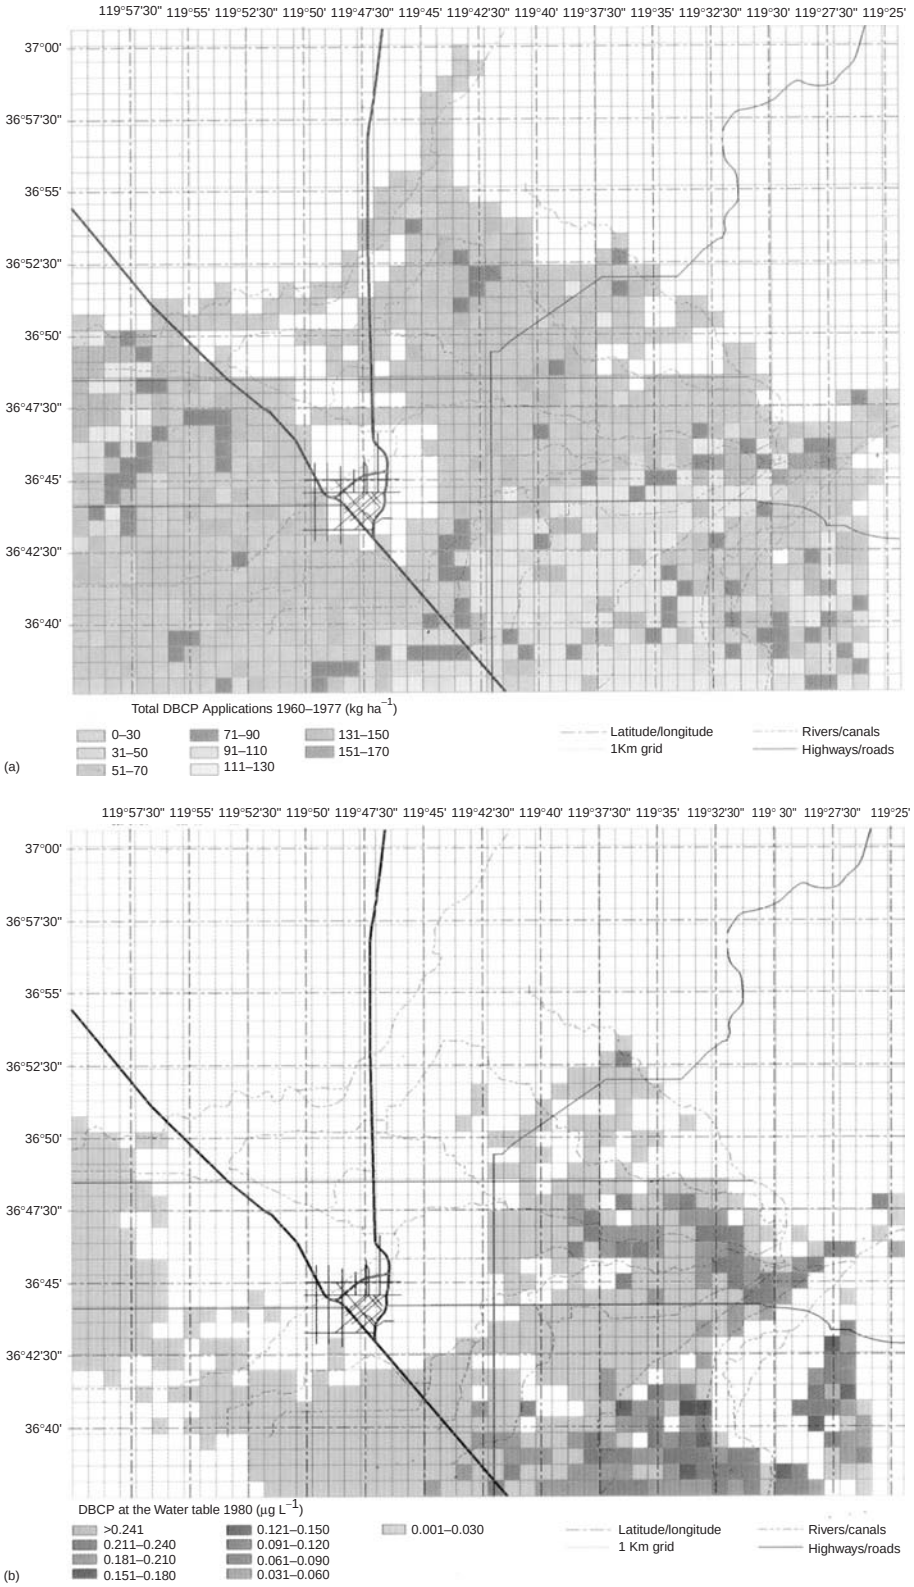

Figure 2 Components of the Fresno Case study example (i.e. Example I) of nonpoint source pollution (After Loague *et al.*, (1998a) © 1998, with permission from Elsevier). (a) Aggregate of the estimated DBCP applications. (b) Simulated 1990 DBCP loading at the water table (Note, this snapshot is taken from a continuous simulation animation). Table 4 Steps used in the Fresno Case study (after Loague *et al.*, 1998a,b)

1. Approximate the climatic history (1950–1994).
2. Approximate the distribution of soils.
3. Approximate the land-cover history (1958–1994).
4. Approximate the average irrigation history (1960–1994).
5. Approximate the water table depth history (1960–1994).
6. Simulate (with PRZM-2) transient unsaturated fluid flow and DBCP transport (1960–1994).
7. Abstract the DBCP concentration at the water table for each element (1960–1994).
8. Approximate the geology.
9. Approximate the distribution of saturated hydraulic conductivity.
10. Approximate the recharge history (1960–1994).
11. Approximate the pumping history (1960–1994).
12. Simulate (with MODFLOW) groundwater flow (1960–1994).
13. Simulate (with MT3D) saturated transient DBCP transport (1960–1994).

Table 5 Steps used in the simulations of three former manufacture gas plants (after Abrams and Loague, 2000)

1. Approximate the climatic history (MGP inception* – 2000).
2. Approximate the soil properties for each site.
3. Approximate the operational history of each MGP.
4. Simulate (with LEACHM) unsaturated fluid flow and dissolved naphthalene transport for subsurface sources (MGP inception – 2000).
5. Abstract the dissolved naphthalene concentration at the water table for each source (MGP inception – 2000).
6. Approximate the geology.
7. Approximate the distribution of saturated hydraulic conductivity of each site.
8. Simulate (with MODFLOW) groundwater flow for each site (MGP inception – 2000).
9. Simulate (with MT3D) saturated dissolved naphthalene transport for each site (MGP inception – 2000).

first appearance above the MCL was between 1965 and 1970 (note, by 1990, the concentrations are below the MCL).

- Relative to the size of the study area, the extent and duration of the estimated DBCP contamination was small.
- DBCP concentrations are a function of the spatial and temporal variations in (i) the application rates, (ii) the application frequency, (iii) the unsaturated profile thickness, (iv) the soil-hydraulic properties, and (v) the near-surface sorption.
- The DBCP plume evolves (grows and retracts) with time owing to the loading rates at the water table.

Example II: Point Source Pollution, Three Manufactured Gas Plants

From the early 1800s to about 1950, manufactured gas plants (MGPs) were operated in the United States to produce gas from coal or oil. By the time they began to close down, when the distribution of natural gas became more economical, approximately 2000 MGPs had been constructed throughout the USA. The contamination legacy resulting from the production of manufactured gas poses a significant and ongoing groundwater quality problem. The disposal of by-products from the manufacturing process at MGPs contributed to the contamination of MGP sites. Although coal tar was perhaps the most abundant manufacturing by-product, it was not always considered waste as it was sold for multiple uses (e.g. dyes, explosives, pesticides, pharmaceutical preparations, pipe coatings, plastics, road tar, roofing pitch, and wood preservatives). Because of its commercial value, coal tar was usually stored in holding tanks. After a MGP was decommissioned, the coal tar was often left in the holding tanks. Fifty years later, many of these holding tanks remained as *point sources* of contamination.

The purpose of the study reported by Abrams and Loague (2000) was to address, in a *what if* (forensic) mode, using all available data, if contamination emanating from the holding tanks at three former MGP sites (located in Indiana), could cause undesirable impacts to groundwater quality. The nine-step approach used by Abrams and Loague (2000) to simulate the subsurface transport of dissolved naphthalene, under variable precipitation for ~150 years, is summarized in Table 5. The numerical model used for the 1D unsaturated naphthalene transport simulations in this study was a slightly modified version of LEACHM (Hutson and Wagenet, 1992). The characterization, through simulation, of the temporally variable naphthalene loading histories at the water table was used for the input to subsequent 3D simulations of saturated subsurface fluid flow with MODFLOW (McDonald and Harbaugh, 1988) and solute transport with MT3D (Zheng, 1992).

The simulation results reported by Abrams and Loague (2000) indicate that accidental releases of dissolved naphthalene, from the holding tanks at the three former MGP sites, most likely resulted in severe, negative groundwater quality impacts. Figure 3 illustrates, for one of the three sites, components of effort reported by Abrams and Loague (2000). The assumptions made by Abrams and Loague (2000) in conducting these simulations had little impact on the overall conclusion that leaks from the holding tanks can reasonably be expected to lead to groundwater contamination. The sensitivity analyses performed by Abrams and Loague (2000) support this conclusion. It is interesting to note that the approaches used in Examples I (see Table 4)

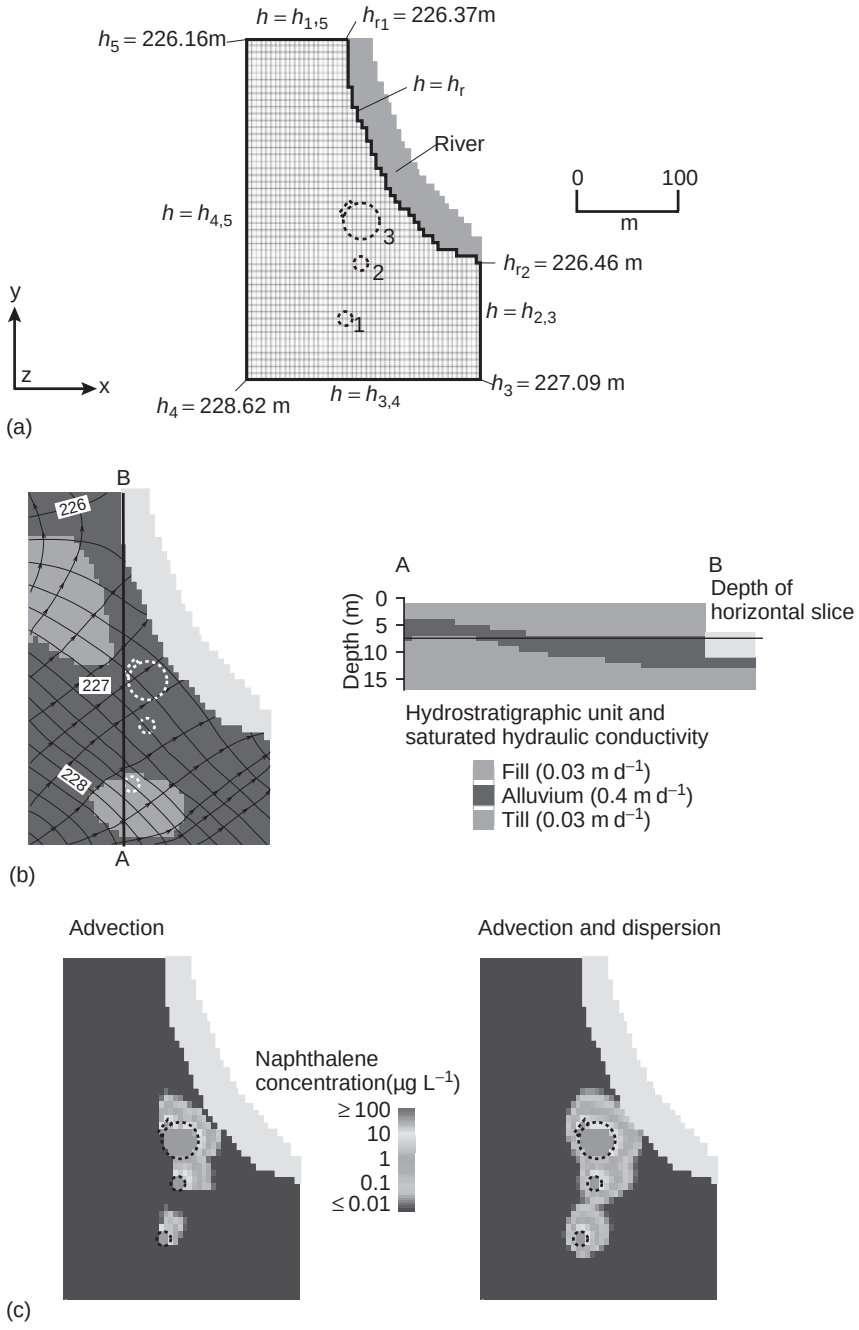

Figure 3 Components of the manufactured gas plant example (i.e. Example II) of point source pollution (Reproduced from Abrams and Loague (2000), by permission of Springer). (a) Site map showing finite-difference grid and boundary-value problem. and II (see Table 5) are very similar. The major differences between the nonpoint and point source pollution examples are the scale of the two problems and the characterization of the sources (i.e. dispersed and well defined).

Example III: Nonpoint Source Pollution, the Forested Areas of Tenerife

It is widely known that the use of pesticides in modern agriculture can result in groundwater contamination.

The impact of pesticide use in forestry has received considerably less attention. Pesticide use in forest management falls into two main categories. The first category consists of applying herbicides, soil insecticides, and fumigants for site preparation before reforestation, using herbicides to control undesired vegetation during initial tree growth, and applying insecticides and fungicides to prevent and control sporadic outbreaks of pests. The second category of pesticide use in forest management is the application of herbicides to clear firebreaks and road edges. Pesticide applications in forest management began during the late 1950s and early 1960s, with chlorinated insecticides, such as DDT. In many cases, organochlorines are still manufactured today for use in less developed countries.

The focus of the study reported by Diaz–Diaz and League (2001) was to estimate the potential for groundwater contamination on the Canary Island of Tenerife resulting from the use of pesticides for forest management purposes. In Tenerife, there are currently no guidelines for the use of pesticides in forested areas despite the ongoing use of some chemicals. Diaz–Diaz and League (2001) used an index-based model to rank the leaching potential of 50 pesticides that are or could be used for forest management in Tenerife forests. Once the pesticides having the greatest leaching potential were identified, regional-scale groundwater vulnerability assessments with consideration for uncertainty were generated using soil, climatic, and chemical information in a GIS framework for all of the pine forest areas.

On the basis of the leaching potential ranking, Diaz–Diaz and League (2001) suggest that, for the pine forest areas of Tenerife (see Figure 4a), the potential leachers are picloram (potassium salt of 4-amino-3,5,6-trichloro-2-pyridinecarboxylic acid), tebuthiuron (*N*-(5-(1,1-dimethyl)-1,3,4-thiadiazol-2-yl)-*N*,*N*′-dimethylurea), carbofuran (2,3-dihydro-2,2-dimethyl-7-benzofuranyl-*n*-methylcarbamate), triclopyr (triethylamine salt of 3,5,6-trichloro-2-pyridinyloxyacetic acid), and hexazinone (3-cyclohexyl-6-(dimethylamino)-1-methyl-1,3,5-triazine-2,4-(1*H*,3*H*)-dione). Following the identification of the five potential leachers, Diaz–Diaz and League (2001) prepared regional-scale groundwater vulnerability assessments in a GIS-driven format, for the pine forest areas of Tenerife. Two *hot spots* were identified on the northern side of the study area, their locations corresponding to soils classified as Inceptisols and high recharge rates. The uncertainties in the leaching assessments, related to the uncertainties in the soil, recharge, and pesticide data, were shown to be significant. Figure 4(b) illustrates the distribution of soils and recharge across the pine forest areas of Tenerife. Figure 4(c) shows the regional-scale groundwater vulnerability assessments, and their uncertainty, for picloram and carbofuran.

EPILOGUE AND FOOD FOR THOUGHT

This article only provides an introduction to the huge subject of point and nonpoint source pollution. The value of real-time measurements for assessing point and nonpoint sources of pollution and the heroic contributions of the NAWQA program are stressed. The use (and types) of

mathematical models as well as the characterization of uncertainties associated with modeling point and nonpoint source problems are covered, illustrated by three examples.

There has been no effort in the allotted space here to address the exposure/human-health outcome question as it relates to point and nonpoint source pollution. Unquestionably, point and nonpoint sources of pollution pose a potentially serious long-term health threat. The EPA, CDC (Center for Disease Control and Prevention), NIH (National Institutes for Health), and the USGS (and their counterparts in Canada and Europe) have each focused considerable energy on developing the linkages between environmental indicators (contaminants), exposure routes, and human-health outcomes. Nevertheless, there is a feeling amongst some scientists and policymakers that the perceived severity of the threats resulting from point and nonpoint source pollution, relative to human health, must be better documented. This view is clearly expressed in Al Freeze's (2000) book *The Environmental Pendulum*. Anyone interested in this controversy should investigate further.

The reader interested in point and nonpoint source pollution may also want to read the following chapters: **Chapter 3, Hydrologic Concepts of Variability and Scale, Volume 1**; **Chapter 10, Concepts of Hydrologic Modeling, Volume 1**; **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2**; **Chapter 69, Solute Transport in Soil at the Core and Field Scale, Volume 2**; **Chapter 78, Models of Water Flow and Solute Transport in the Unsaturated Zone, Volume 2**; **Chapter 79, Assessing Uncertainty Propagation Through Physically based Models of Soil Water Flow and Solute Transport, Volume 2**; **Chapter 91, Water Quality, Volume 3**; **Chapter 100, Water Quality Modeling, Volume 3**; **Chapter 122, Rainfall-runoff Modeling: Introduction, Volume 3**; **Chapter 131, Model Calibration and Uncertainty Estimation, Volume 3**; **Chapter 152, Modeling Solute Transport Phenomena, Volume 4**; **Chapter 153, Groundwater Pollution and Remediation, Volume 4** and **Chapter 150, Unsaturated Zone Flow Processes, Volume 4**.

95: Acidic Deposition: Sources and Effects

CHARLES T DRISCOLL[1], KATHY FALLON-LAMBERT[2], AND LIMIN CHEN[1]

[1]Civil and Environmental Engineering Department, Syracuse University, Syracuse, NY, US
[2]Ecologic: Analysis and Communications, Quechee, VT, US

Acidic deposition delivers acids and acidifying compounds to the Earth's surface, which are then transported through soil, vegetation, and surface waters and, in turn, set off a cascade of adverse ecological effects. Acidic deposition has altered forest soil by accelerating the leaching of available base cations, enhancing the accumulation of sulfur and nitrogen, and increasing the concentration of dissolved inorganic aluminum in soil waters. Soils that are compromised by acidic deposition are less able to neutralize additional amounts of acidic deposition, and provide poorer growing conditions for plants. Acidic deposition has impaired the surface water quality by lowering pH, decreasing acid-neutralizing capacity (ANC), and increasing concentrations of dissolved inorganic aluminum. These changes have reduced the species diversity and abundance of aquatic life. Regulatory controls initiated in Europe and North America over the last three decades have decreased emissions of sulfur dioxide and to a lesser extent nitrogen oxides. Emission reductions have resulted in widespread decreases in concentrations of sulfate in surface waters, with some waters showing an increase in ANC. Given the loss of acid-neutralizing base cations and the accumulation of sulfur and nitrogen in soil, many ecosystems have become more sensitive to additional acidic deposition and recovery will likely be delayed. Long-term research shows that deeper emissions cuts will lead to greater and faster recovery from acidic deposition in impacted regions.

ACIDIC DEPOSITION

Acidic atmospheric deposition, popularly referred to as *acid rain*, is the transfer of strong acids and acid-forming substances from the atmosphere to the Earth's surface. Acidic deposition is comprised of sulfuric and nitric acids, and ammonium derived from atmospheric emissions of sulfur dioxide, nitrogen oxides, and ammonia, respectively. These compounds are emitted by the burning of fossil fuels and by agricultural activities. Once such compounds enter an ecosystem, they can acidify soil and surface waters and bring about a series of ecological changes. The term acidic deposition encompasses all forms in which these compounds are deposited to the Earth, including gases, particles, rain, snow, clouds, and fog (see Box 1; *see* **Chapter 28, Clouds and Precipitation, Volume 1**; **Chapter 30, Topographic Effects on Precipitation, Volume 1**). Acidic deposition was first reported in the United Kingdom in the latter half of the nineteenth century (Gorham, 1989). Ecological effects were first documented in Scandinavia in the 1960s with the link between acidic deposition, surface water acidification, and loss of fisheries (Gorham, 1989). Atmospheric deposition of sulfate, nitrate, and ammonium are elevated in eastern North America, Europe, and large portions of Asia (Rodhe *et al.*, 1995).

Electric utilities account for the greatest proportion of anthropogenic sulfur dioxide emissions in Europe and North America. For example in the United States in 2002, the major sources of sulfur dioxide emissions were electric utilities (67%), industrial combustion (15%), and industrial processes (9%; EPA 2004). Transportation sources – including cars, trucks, and non-road vehicles (i.e. construction equipment) – accounted for more than 50% of anthropogenic nitrogen oxide emissions in the United States. Other major sources of nitrogen oxides include electric utilities (22%) and industrial combustion (14%). Ammonia emission are derived largely from livestock waste and fertilized soil (83% of total ammonia; Driscoll *et al.*, 2003). Motor vehicles and industrial processes also contribute to ammonia emissions.

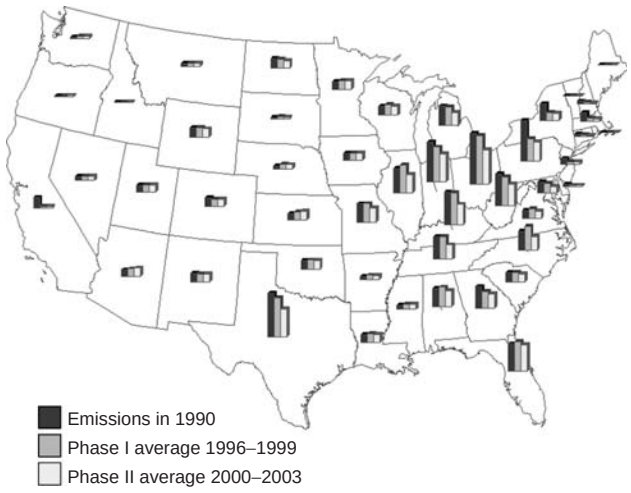
Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Box 1 How is acidic deposition monitored?

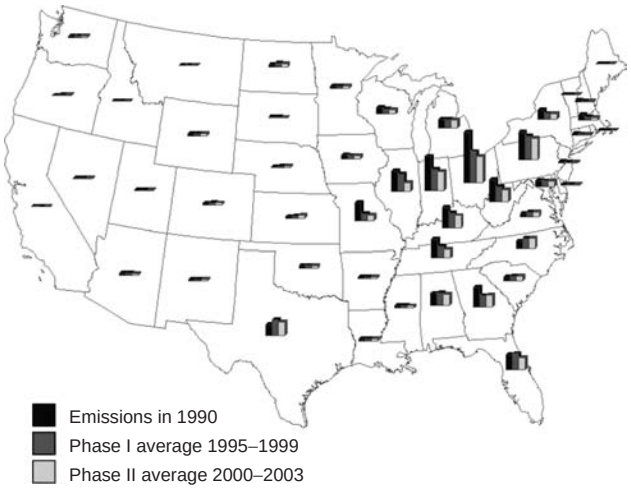
Acidic deposition occurs in three forms: wet deposition, which falls as rain, snow, sleet, and hail; dry deposition, which includes particles, gases, and vapor; and cloud or fog deposition which occurs at high altitudes and coastal areas. In the United States, wet deposition has been monitored at more than 200 sites, by both independent researchers and the interagency National Atmospheric Deposition Program/National Trends Network (**http://nadp.sws.uiuc.edu/**). Dry deposition is monitored at 70 sites in the United States by the U.S. Environmental Protection Agency Clean Air Status and Trends Network (**http://www.epa.gov/castnet/**), and at 13 other sites by the National Oceanic and Atmospheric Administration AIRMON-dry Network. Cloud and fog deposition has been monitored for limited periods at selected high-elevation sites, largely by independent researchers. Dry and cloud deposition patterns are extremely variable over space and time, making it difficult to characterize patterns. Therefore, even though cloud and dry deposition comprise a significant proportion of total deposition, this report primarily presents general patterns and trends of wet deposition. Some researchers also measure bulk deposition, in which deposition is collected in an open collector. Bulk deposition is greater than wet deposition because it includes some dry deposition.

An airshed or source area is an area where "significant portions of emissions result in deposition of air pollutants to a region" (**www.epa.gov**). In North America, emissions of sulfur dioxide are highest in the midwestern United States (hereafter the Midwest), with seven states in the Ohio River Valley accounting for 51% of the total sulfur dioxide emissions in the United States in 2002 (Figure 1a). Five of these states are also amongst the highest emitters of nitrogen oxides (Figure 1b). Moreover, the Midwest is a significant source of atmospheric ammonia. In addition to regional pollution sources, local emissions of sulfur dioxide and nitrogen oxides from electric utilities and motor vehicles have significant impacts on local air quality. Analysis of continental air currents shows that a multistate region, including the Midwest comprise the source area for sulfur dioxide, nitrogen oxide, and ammonium emissions that are transported downwind to acid-sensitive areas of eastern North America (Butler *et al.*, 2001d).

There have been significant efforts to reduce emissions of acidic and acidifying substances in North America and Europe over the past three decades. Although regulatory controls have decreased emissions, levels remain high compared to background conditions. Importantly, emissions and deposition of base cations (i.e. elements such as calcium and magnesium that help counteract acidic deposition) have declined substantially since the early 1960s with the enactment of pollution controls to reduce fine particulate matter (Hedin *et al.*, 1994).



(a) Scale: Largest bar equals 500 000 tons of emissions in Ohio, 1990



(b) Scale: Largest bar equals 2.2 million tons of emissions in Ohio, 1990

Figure 1 State by state emissions of sulfur dioxide (a) and nitrogen oxides (b) in the United States. Values are shown for three periods: 1990, after Phase I (1995–1999), and after Phase II (2000–2003) of control of utility emissions in response to 1990 Amendments of the Clean Air Act (after US EPA, 2004). Note the bars are scales to 1990 emissions for Ohio (2 million metric tons for sulfur dioxide and 454 000 tons for nitrogen oxides). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Total sulfur dioxide emissions in the United States peaked in 1973 at approximately 29 million metric tons annually. The 1970 and 1990 Amendments of the Clean Air Act (CAAA) led to a 52% decrease in sulfur dioxide emissions nationwide, to approximately 13.9 million metric tons in 2002. The multistate source area for the eastern North America has shown substantial decreases in sulfur dioxide emissions over this period (Figure 2). The 1990 CAAA set a cap of 14 million metric tons of total annual sulfur dioxide emissions to be achieved by 2010. The cap

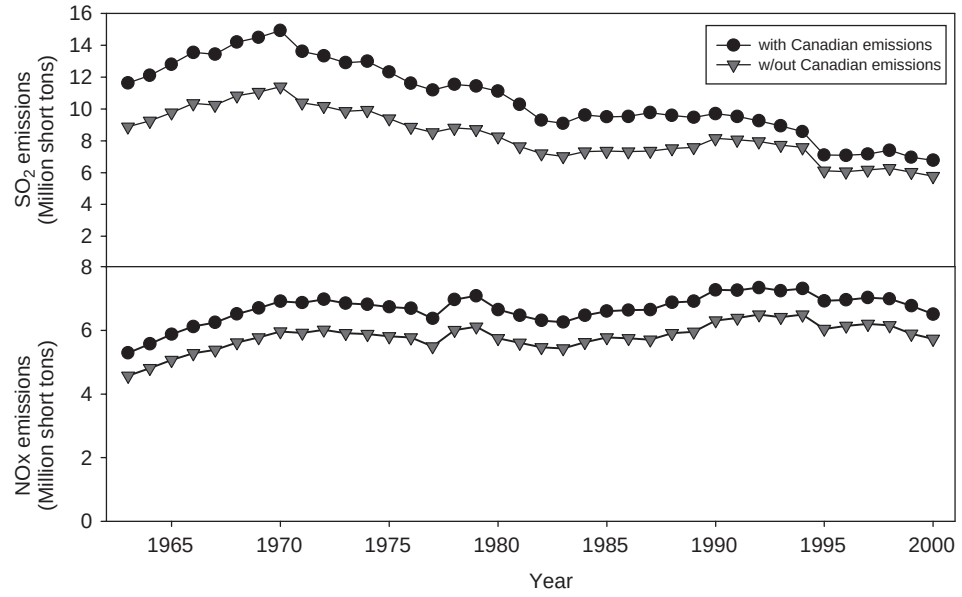


Figure 2 Annual emissions of sulfur dioxide and nitrogen oxides for the source area of the Hubbard Brook Experimental Forest. The source area was determined by 24-h back trajectory analysis. Shown are emissions from both United States and Canadian sources. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

on electric utilities is set at 8.9 million metric tons and the cap on industrial sources is 5.6 million metric tons to be reached by 2010.

Nitrogen oxide emissions in the United States have increased over the past decades, peaking at nearly 22.7 million metric tons in 1990. From 1990 to 2002, nitrogen oxide emissions have decreased by 12%. The 1990 CAAA calls for an additional reduction that will result in the emission of 1.8 million fewer tons of nitrogen oxide than the level that would have occurred without the CAAA. However, no cap on total annual emissions of nitrogen oxides was set. Nevertheless, it is expected that nitrogen emissions will decrease gradually in the future because of a variety of federal and state emission control programs. In contrast to sulfur dioxide, the multistate source area for the eastern North America has shown little change in nitrogen dioxide emissions since the early 1970s although some decrease has been evident in recent years (Figure 2).

Ammonia emissions play an important role in the acidification of soil and surface waters. Deposition of ammonium accounts for approximately 30% of the total nitrogen deposition measured in eastern North America and has not changed appreciably over the past 30 years. Trends in ammonia emissions in the United States are consistent with this pattern and have shown little change over the past 10 years.

European efforts to reduce emissions of air pollutants have been brought together in a series of protocols under the United Nations Economic Council for Europe (UN/ECE) Convention on Long Range Transboundary Air Pollution (LRTAP; Sundqvist *et al.*, 2002; Ferrier *et al.*, 2001). The first binding protocol was the 1985 Protocol on the Reduction of Sulfur Emissions that was intended to reduce sulfur dioxide emissions by at least 30% by 1993 compared to the 1980 levels. This was expanded in 1994 with the Protocol on Further Reductions of Sulfur, with the objective of decreasing sulfur dioxide emissions by 80% by 2010 from 1980 values. In 1988, the Protocol concerning Control of Emissions of Nitrogen Oxides stabilized nitrogen oxide emissions. Finally, the 1999 Protocol to Abate Acidification, Eutrophication, and Ground-level Ozone established national caps for multiple air pollutants, including sulfur dioxide, nitrogen oxides, and ammonia, with attainment expected by 2010 (Kurz *et al.*, 2001). These actions have resulted in marked reductions in emissions of sulfur dioxide (65%) and nitrogen oxides (30%) from 1990 to 2002. Ammonia emissions have remained essentially constant over the same period. Once implemented, sulfur dioxide emissions will decrease by at least 63%, nitrogen oxide emissions by 41%, and ammonia emissions by 17% relative to 1990 values.

An important framework for emission reductions and ecosystem recovery is "critical loads." Critical loads are based on the idea that emission control strategies should be effect-driven. A critical load is the total deposition of a pollutant to an ecosystem below which significant harmful ecological effects do not occur (Nilsson and Grennfelt, 1988). Following the UN/ECE Convention on LRTAP, maps of critical loads were developed for Europe (Posch *et al.*, 1995). These maps have been revised (Posch and Hettelingh, 2001) and the resulting critical loads were used

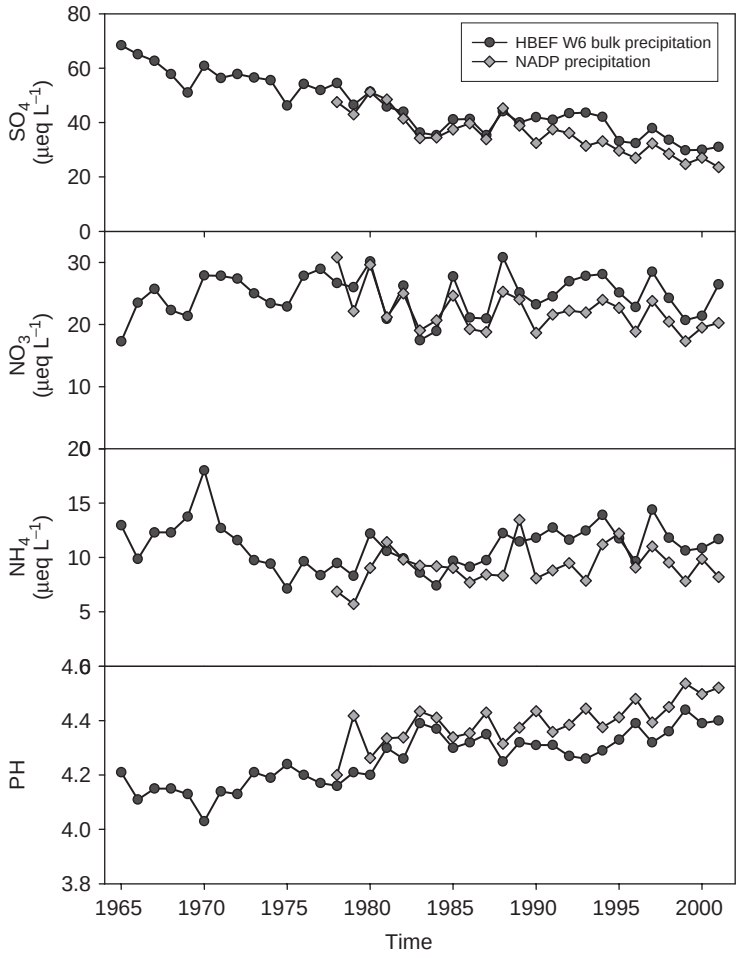

Figure 3 Annual volume-weighted sulfate, nitrate, and ammonium concentrations and pH in bulk and wet deposition at the Hubbard Brook Experimental Forest, New Hampshire, 1963–2000. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

to regulate emissions through the 1999 Protocol. Critical loads have only been applied to a limited extent in the United States.

In contrast to North America and Europe, emissions in Asia have been increasing and are expected to continue to increase in the coming decades (Galloway, 1995; Klimont *et al.*, 2001).

Trends in acidic deposition mirror emission trends in the source area. For example, over the past 30 years in eastern North America, sulfate deposition has declined, but nitrogen and ammonium deposition have remained relatively stable (Figure 3). Decreases in precipitation sulfate have coincided with increases in pH. The Hubbard Brook Experimental Forest in New Hampshire has one of the longest continuous records of precipitation chemistry (see Box 2). Long-term data from the Hubbard Brook show declining concentrations of sulfate in bulk deposition since the mid-1960s and wet deposition since the late 1970s (see Figure 3). On the basis of these long-term data, there is a strong positive correlation that exists between sulfur dioxide emissions in the source area and sulfate concentrations in precipitation at Hubbard Brook

Box 2 The Hubbard Brook Experimental Forest

The Hubbard Brook Experimental Forest is a long-term ecological research site established by the United States Department of Agriculture Forest Service in the White Mountains of New Hampshire to investigate the structure and function of forest and aquatic ecosystems, and their response to disturbance (Likens and Bormann, 1995; Groffman *et al.*, 2004). Hubbard Brook was the site where acidic deposition was first reported in North America (Likens *et al.*, 1972). Hubbard Brook receives elevated inputs of acidic deposition and the forest ecosystem is very sensitive to these inputs. There have been long-term measurements and studies of acidic deposition and its effects on forests and streams at Hubbard Brook (Likens *et al.*, 1996; Driscoll *et al.*, 2001).

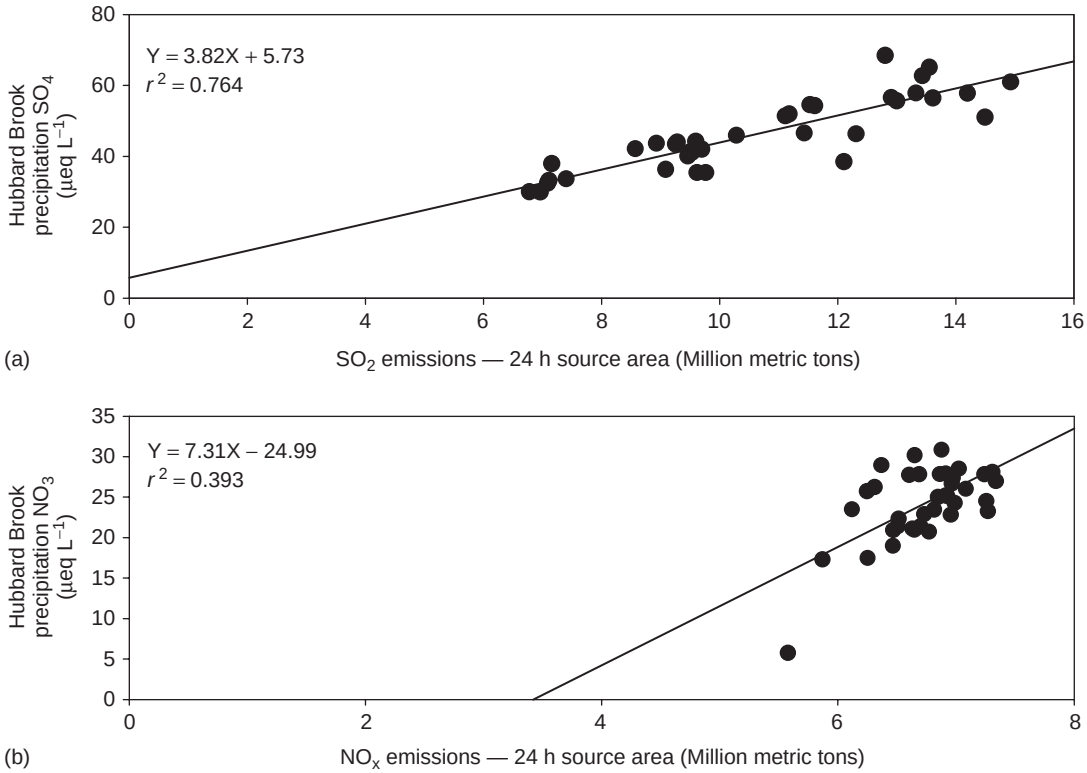

Figure 4 Relationships between sulfur dioxide and nitrogen oxide emissions for the source area of the Hubbard Brook Experimental Forest (see Figure 2) and annual volume-weighted concentrations of sulfate and nitrate in bulk deposition

(Figure 4). It is now expected that the sulfate concentration of atmospheric deposition will decrease in a direct linear response to decreases of sulfur dioxide emissions in the source area.

The relationship between sulfur dioxide emissions and wet sulfate deposition extends throughout the eastern United States. The portion of the eastern United States with high wet deposition of sulfate decreased markedly over the interval 1989–1991 to 2001–2003 (see Figure 5). These reductions in wet sulfate deposition are consistent with the emissions reductions called for in the 1990 CAAA.

In contrast to sulfate trends in wet deposition, concentrations of nitrate or ammonium at Hubbard Brook have not shown large changes since 1963 (see Figure 3). There is a relationship between nitrate concentrations in bulk deposition at Hubbard Brook and nitrogen oxide emissions in the source area (Butler *et al.*, 2003), but the relationship is much weaker than observed for sulfate (Figure 4). This weak relationship is due to the fact that nitrogen oxide emissions and nitrate in bulk deposition have not changed much since measurements were initiated in 1963. Patterns of wet deposition of nitrogen at Hubbard Brook are consistent with the picture across the entire eastern United States, which shows limited change over the last several years (see Figure 6).

EFFECTS OF ACIDIC DEPOSITION ON ECOSYSTEMS

Acidic deposition alters soils, stresses forest vegetation, acidifies lakes and streams, and harms fish and other aquatic life. These effects can alter important ecosystem services such as forest productivity and water quality (*see* **Chapter 193, Markets for Watershed Services, Volume 5**). Decades of acidic deposition have also made many ecosystems more sensitive to continuing pollution. Moreover, the same pollutants that cause acidic deposition contribute to a wide array of other important environmental issues at local, regional, and global scales (see Table 1).

Effects of Acidic Deposition on Forest Ecosystems

Until recently, understanding the effects of acidic deposition on soils was limited. However, current research has shown that acidic deposition has chemically altered forest soils with serious consequences for acid-sensitive ecosystems. Soils compromised by acidic deposition lose their ability to neutralize continuing inputs of strong acids, provide poorer growing conditions for plants, and extend the time needed for ecosystems to recover from acidic deposition. Acidic deposition has altered and continues to alter base-poor forest soils in three important ways. Acidic

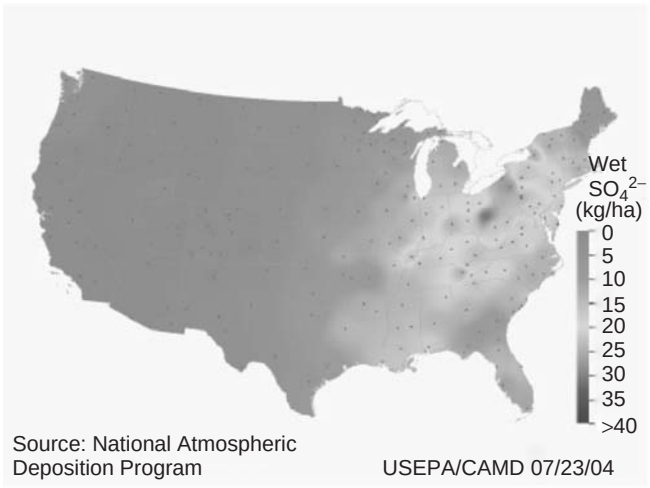

Figure 5 Annual sulfate in wet deposition in the eastern United States for 1989–1991 and 2001–2003 (data were obtained from the National Atmospheric Deposition Program). Note that there have been marked reductions in wet sulfate deposition in response to emission controls. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

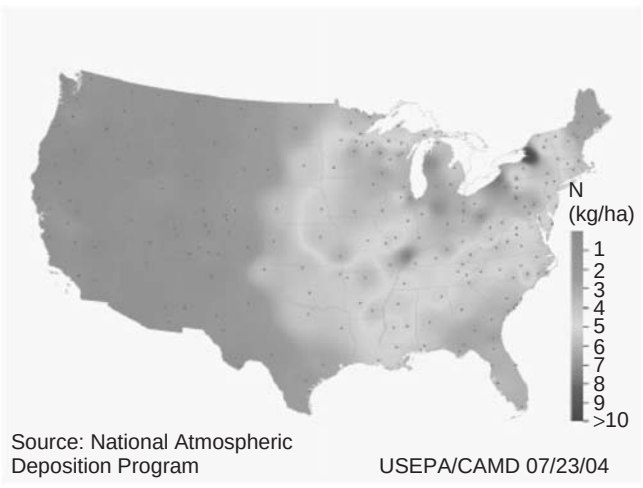

Figure 6 Annual inorganic nitrogen (ammonium plus nitrate) deposited in wet precipitation in the eastern United States for 1989–1991 and 2001–2003 (data were obtained from the National Atmospheric Deposition Program). Note that there have been limited changes in wet deposition of inorganic nitrogen. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

deposition depletes available calcium and other nutrient cations (e.g. magnesium, potassium) from soil, facilitates the mobilization of dissolved inorganic aluminum into soil water, and increases the accumulation of sulfur and nitrogen in soil.

The cycling of calcium and other nutrient cations in forest ecosystems involves the inputs and losses of these materials (Figure 7; *see* **Chapter 69, Solute Transport in Soil at the Core and Field Scale, Volume 2**). For most forest ecosystems, the supply of calcium and other nutrient cations largely occurs by weathering (i.e. the breakdown of rocks and minerals in soil). Calcium and other nutrient cations may also enter forests by atmospheric deposition, although this pathway is generally much smaller than weathering. Losses largely occur by vegetation uptake and drainage waters. An important pool of ecosystem calcium and nutrient cations is the soil-available pool, or the soil cation exchange complex. Plants are generally able to utilize this source of nutrients. Forest ecosystems that are naturally sensitive to acidic deposition are generally characterized by low rates of weathering and generally low quantities of available base cations (i.e. calcium, magnesium, sodium, potassium). Under conditions of elevated inputs of acidic deposition and subsequent transport of sulfate and nitrate in drainage waters, nutrient cations will be displaced from available pools and leached from soil (Ruess and Johnson, 1986). This condition is not problematic for areas with high weathering rates and high

Table 1 The links between sulfur dioxide and nitrogen oxide emissions, acidic deposition, and a range of environmental issues

Problem	Linkage to acid deposition	Reference
Coastal eutrophication	Atmospheric deposition adds nitrogen to coastal waters.	Paerl *et al.*, 2002
Mercury	Deposition of sulfate enhances methylation of mercury. Surface water acidification increases mercury accumulation in fish.	Branfireun *et al.*, 1999; Driscoll *et al.*, 1994
Visibility	Sulfate aerosols diminish visibility and views.	Malm *et al.*, 1994
Climate change	Sulfate, nitrate, and ammonium aerosols may offset global warming in the short-term, but nitrous oxide is a potent greenhouse gas.	Moore *et al.*, 1997 (*see* **Chapter 195, Acceleration of the Global Hydrologic Cycle, Volume 5**)

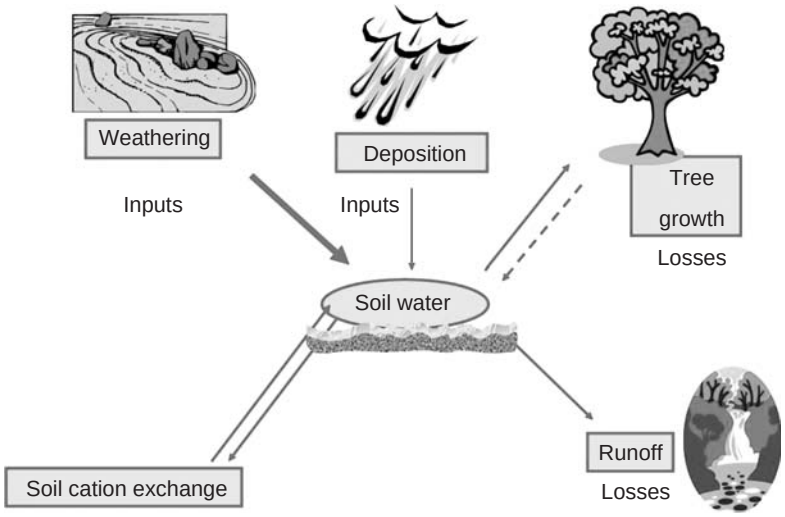

Figure 7 Conceptual diagram illustrating calcium cycle in forest watersheds. Inputs of calcium include weathering and atmospheric deposition; of these weathering is usually the greatest. Losses of calcium include tree accumulation and stream runoff. Under conditions of elevated acidic deposition stream losses increase, potentially depleting available calcium from the ecosystem, particularly from the soil exchange complex. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

pools of available nutrient cations. However, over the past century, acidic deposition has accelerated the loss of large amounts of available calcium and magnesium from the soil in acid-sensitive areas (Likens *et al.*, 1996; Kirchner and Lydersen, 1995; Huntington *et al.*, 2000). Depletion occurs when base cations are displaced from the soil by acidic deposition at a rate faster than they can be replenished by the slow breakdown of rocks or the deposition of base cations from the atmosphere. This depletion of base cations fundamentally alters soil processes, compromises the nutrition of some trees, and hinders the capacity for sensitive soils to recover from inputs of acidic deposition.

Dissolved inorganic aluminum is often released from soil to soil water, vegetation, lakes, and streams in forested regions with high acidic deposition, low stores of available calcium, high soil acidity, and limited watershed retention of atmospheric inputs of sulfate and/or nitrate (Cronan and Schofield, 1990). High concentrations of dissolved inorganic aluminum can be toxic to plants, fish, and other organisms. Concentrations of dissolved inorganic aluminum in streams and lakes in acid-sensitive regions

receiving high inputs of acidic atmosphere are often above levels considered toxic to fish and much greater than concentrations observed in forested watersheds with low inputs of acidic deposition (Driscoll *et al.*, 1988).

Acidic deposition results in the accumulation of sulfur and nitrogen in forest soils. As sulfate is released from the soil in response to decreases in emissions and atmospheric deposition of sulfur, it is transported to adjacent streams and lakes (Likens *et al.*, 2000). The recovery of surface waters in response to emission controls has therefore been delayed and will not be complete until the sulfate left by a long legacy of acidic deposition is released from the soil.

Similarly, nitrogen has accumulated in soil beyond the amount needed by the forest and appears now to be leaching into surface waters in Europe and North America (Dise and Wright, 1995; Aber *et al.*, 2003). Forests typically require more nitrogen for growth than is available in the soil. However, several recent studies suggest that in some areas, nitrogen levels are above what forests can use and retain. This condition is referred to as "nitrogen saturation" (Aber *et al.*, 1989; Aber *et al.*, 1998). Note that the levels at which atmospheric nitrogen deposition can result in elevated leaching losses of nitrate from forest watersheds appear to be higher in Europe ($9-25\,\mathrm{kg\,N\,ha^{-1}\,year^{-1}}$) than eastern North America ($7-8\,\mathrm{kg\,N\,ha^{-1}\,year^{-1}}$). The reason for this difference is not evident, but may be due to a greater fraction of atmospheric nitrogen deposition occurring as ammonium in Europe; ammonium inputs are more readily retained in watersheds than nitrate. Alternatively, this difference may be due to highly managed forests in Europe and greater nitrogen retention compared to eastern North America.

Acidic Deposition Stress to Trees

Although it is difficult to separate the effects of air pollution from other stresses, recent research shows that acidic deposition appears to have contributed to the decline of red spruce trees throughout the eastern North America and sugar maple trees in central and western Pennsylvania in the United States. Symptoms of tree decline include poor crown condition, reduced tree growth, and unusually high levels of tree mortality.

Red spruce and sugar maple are the tree species that have been most intensively researched, and therefore, they provide instructive case studies of the effects of acidic deposition on trees. Red spruce and sugar maple research has shown that acidic deposition has both direct and indirect effects on trees. In acid-impacted forests, acidic deposition harms trees directly by leaching calcium from the leaves and needles (i.e. foliage) of trees, rendering them more susceptible to winter injury. Acidic deposition can also affect trees indirectly by changing the underlying soil chemistry. In acid-sensitive soils, acidic deposition depletes available nutrient cations, such as calcium and magnesium, which are important plant nutrients that are necessary to maintain the health and vigor of trees. The depletion of nutrient cations also leads to soil acidification that increases the availability of aluminum to the trees' roots, thereby impairing the ability of trees to obtain necessary nutrients from the soil.

Red Spruce

Acidic deposition appears to be the major cause of red spruce decline at high elevations in North America. Since the 1960s, more than half of large canopy trees in the Adirondack Mountains of New York and the Green Mountains of Vermont and approximately one-quarter of large canopy trees in the White Mountains of New Hampshire have died. Significant growth declines and winter injury to red spruce have been observed throughout its range, suggesting that damage from acidic deposition is likely widespread (DeHayes *et al.*, 1999).

Recent research indicates that the decline of red spruce is linked to the leaching of calcium from cell membranes in spruce needles by acidic deposition (DeHayes *et al.*, 1999). The loss of calcium renders the needles more susceptible to freezing damage, thereby reducing the tolerance of trees to low temperatures and increasing the occurrence of winter injury and subsequent tree damage or death. In addition, elevated aluminum concentrations in the soil, resulting from soil acidification, limits the ability of red spruce to take up water and nutrients through its roots. This limitation can lead to nutrient deficiencies that can lower a tree's tolerance to environmental stress and cause decline.

Sugar Maple

The decline of sugar maples has been studied in the eastern United States since the 1950s and there is growing evidence that sugar maple decline is linked to acidic deposition. Extensive mortality among sugar maples in Pennsylvania appears to result from deficiencies of base cations, coupled with other stresses such as insect defoliation or drought. Sugar maples are most prone to die on sites where base cation concentrations in soil or foliage are lowest (Horsley *et al.*, 2000). Data from many acid-sensitive regions link the loss of soil calcium and magnesium with the leaching of these base cations by acidic deposition. Low levels of base cations can cause a nutrient imbalance and reduce a tree's stress tolerance. As such, acidic deposition is a predisposing factor in sugar maple decline. Under these conditions, the likelihood increases that stresses such as insect infestation and drought will cause the dieback of a tree's crown or kill a tree.

Finally, there may be adverse effects on other tree species. For example, one might speculate that hardwood species such as white ash and basswood, which prefer rich sites high in nutrient cations, may experience problems in areas where nutrient cations have been depleted by acidic deposition. However, additional research is needed

Box 3 What is ANC?

Acid-neutralizing capacity, or ANC, is the ability of water from a lake or stream to neutralize strong acid (Stumm and Morgan, 1996). ANC is an important measure of the impacts of acidic deposition as well as an indicator of chemical recovery from acidic deposition. Surface waters with ANC values below 0 μeq L^{-1} during base flow conditions are considered chronically acidic. Waters with ANC values ranging from 0 to 50 μeq L^{-1} are susceptible to episodic acidification. Waters with ANC values greater than 50 μeq L^{-1} are less sensitive to acidic deposition. The capacity of a watershed to prevent decreases in ANC and resist the effects of acidic deposition depends on many factors, including climate, soil conditions, surficial and bedrock geology, and land-use history.

to completely assess the response of these tree species to acidic deposition.

Effects of Acidic Deposition on Aquatic Ecosystems

Acidic deposition degrades water quality by lowering pH levels (i.e. increasing acidity), decreasing acid-neutralizing capacity (ANC; see Box 3), and increasing dissolved inorganic aluminum concentrations. While sulfate concentrations in lakes and streams have decreased over the last 20 years, they remain high compared to background conditions ($<20\,\mu eq\,L^{-1}$; Sullivan, 1991).

An important characteristic influencing the acid–base status of surface waters is the supply of naturally occurring organic solutes. These materials include naturally occurring organic acids that decrease the ANC of waters and mobilize aluminum from soil through complexation reactions. Watersheds with an abundance of wetlands typically have high concentrations of dissolved organic carbon, and associated surface waters can be naturally acidic due to organic acids. However, in contrast to watersheds that are acidified by acidic deposition, waters that are acidic due to organic acids have high concentrations of aluminum which is largely complexed with organic solutes and therefore less toxic to aquatic biota (Driscoll *et al.*, 1980, 1988).

Acidification of surface waters due to elevated inputs of acidic deposition have been reported in many acid-sensitive areas receiving elevated inputs of acidic deposition, including Great Britain, Nordic countries, northern, central, and eastern Europe (Evans *et al.*, 2001), southwestern China (Seip *et al.*, 1995), southeastern Canada (Jeffries, 1991), the northeastern United States (Driscoll, 1991) the upper Midwest (Cook and Jager, 1991), and the Appalachian mountain region of the United States (Elwood, 1991). Large portions of the high-elevation western United States are also potentially sensitive to acidic deposition (Fenn *et al.*, 2003); however, atmospheric deposition to this region is relatively low. Concern over effects of acidic deposition in the mountain regions of western United States may be overshadowed by potential effects of elevated nitrogen deposition, including eutrophication of naturally nitrogen-limited lakes.

One of the most highly impacted areas in North America is the Adirondack region of New York. A comprehensive survey of Adirondack lakes greater than 0.2 ha in surface area was conducted between 1984 and 1987 to obtain detailed information on the acid–base status of waters in this region (Kretser *et al.*, 1989). Of the 1469 lakes surveyed, 24% had summer pH values below 5.0. Also, 27% of the lakes surveyed were chronically acidic (i.e. ANC $< 0\,\mu eq\,L^{-1}$) and an additional 21% were susceptible to episodic acidification (i.e. ANC between 0 and $50\,\mu eq\,L^{-1}$; see Box 4). Note that 54% of these acid-sensitive lakes (733 lakes) are characterized by relatively low concentrations of dissolved organic carbon (i.e. $<6\,mg\,C\,L^{-1}$). The chemical composition of these lakes suggests that their acidity was largely derived from inputs of sulfate associated with acidic deposition (Driscoll *et al.*, 2003). In contrast, 46% of the lakes are characterized by high concentrations of dissolved organic carbon (i.e. $>6\,mg\,C\,L^{-1}$) and naturally occurring organic acids. These lakes are probably naturally acidic. While the contribution of naturally occurring acidity is greater in these lakes, sulfate was the dominant anion; the acidity of these lakes has been clearly enhanced by acidic deposition.

Decreases in pH and elevated concentrations of dissolved inorganic aluminum have reduced the species diversity and

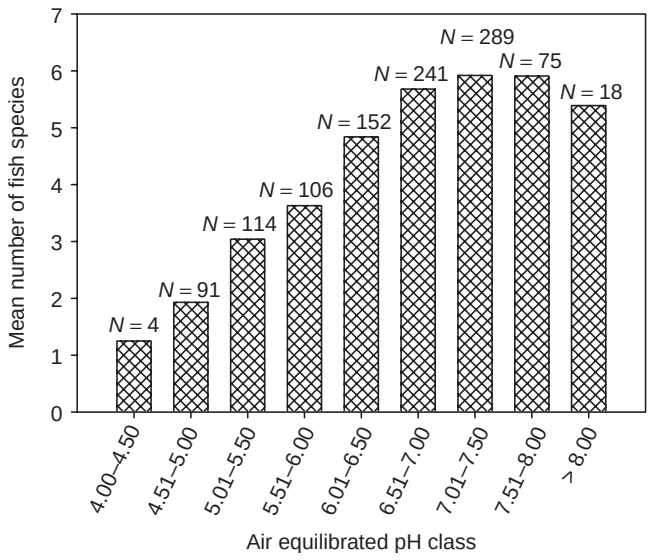

Figure 8 The mean number of fish species for pH classes from 4.0 to 8.0 in lakes in the Adirondack region of New York. *N* represents the number of lakes in each pH class (After Driscoll *et al.* 2001. © American Institute of Biological Sciences)

Table 2 Biological effects of surface water acidification (After Baker *et al.*, 1990)

pH decrease	General biological effects
6.5–6.0	Small decrease in species richness of phytoplankton, zooplankton, and benthic invertebrate communities resulting from the loss of a few highly acid-sensitive species, but no measurable change in total community abundance or production
	Some adverse effects (decreased reproductive success) may occur for highly acid-sensitive species (e.g. fathead minnow, striped bass)
6.0–5.5	Loss of sensitive species of minnow and dace, such as blacknose dace and fathead minnow; in some waters decreased reproductive success of lake trout and walleye, which are important sport fish species in some areas
	Visual accumulations of filamentous green algae in the littoral zone of many lakes, in some streams
	Distinct decrease in the species richness and change in species composition of the phytoplankton, zooplankton, and benthic invertebrate communities, although little if any change in total community biomass or production
5.5–5.0	Loss of several important sport fish species, including lake trout, walleye, rainbow trout, and smallmouth bass; as well as additional nongame species such as creek chub
	Further increase in the extent and abundance of filamentous green algae in lake littoral areas and streams
	Continued shift in the species composition and decline in species richness of the phytoplankton, periphyton, zooplankton, and benthic invertebrate communities; decrease in the total abundance and biomass of benthic invertebrates and zooplankton may occur in some waters
	Loss of several additional invertebrate species common in oligotrophic waters, including *Daphnia galeata mendotae, Diaphanosoma leuchtenbergianum*, and *Asplanchna priodonta*; all snails, most species of clams, and many species of mayflies, stoneflies, and other benthic invertebrates Inhibition of nitrification
5.0–4.5	Loss of most fish species, including most important sport fish species such as brook trout and Atlantic salmon; few fish species able to survive and reproduce below pH 4.5 (e.g. central mud minnow, yellow perch, and in some waters, largemouth bass)
	Measurable decline in the whole-system rates of decomposition of some forms of organic matter, potentially resulting in decreased rates of nutrient cycling
	Substantial decrease in the number of species of zooplankton and benthic invertebrates and further decline in the species richness of the phytoplankton and periphyton communities; measurable decrease in the total community biomass of zooplankton and benthic invertebrates in most waters
	Loss of zooplankton species such as *Tropocyclops prasinus mexicanus, Leptodora kindtii*, and *Conochilis unicornis*; and benthic invertebrate species, including all clams and many insects and crustaceans
	Reproductive failure of some acid-sensitive species of amphibians such as spotted salamanders Jefferson salamanders, and the leopard frog

abundance of aquatic life in many streams and lakes in acid-sensitive areas (Table 2). Fish have received the most attention to date, but entire food webs are often adversely affected (Baker *et al.*, 1990).

Decreases in pH and increases in dissolved inorganic aluminum concentrations have diminished the species diversity and abundance of plankton, invertebrates, and fish in acid-impacted surface waters. For example, in the Adirondacks, a significant positive relationship exists between the pH and ANC levels in lakes and the number of fish species present in those lakes (see Figure 8). The Adirondack Lakes Survey showed that 24% of lakes (i.e. 346) in this region do not support fish. These lakes had consistently lower pH and ANC and higher concentrations of dissolved inorganic aluminum than lakes that contained one or more species of fish. Experimental studies and field observations demonstrate that even acid-tolerant fish species such as brook trout have been eliminated from some waters.

Although chronically high acid levels stress aquatic life, acid episodes are particularly harmful because abrupt, large changes in water chemistry allow fish few areas of refuge (see Box 4). High concentrations of dissolved inorganic aluminum are directly toxic to fish and pulses of dissolved inorganic aluminum during acid episodes are a primary cause of fish mortality (Baker *et al.*, 1996; Van Sickle *et al.*, 1996). High acidity and dissolved inorganic aluminum levels disrupt the salt and water balance in a fish's blood, causing red blood cells to rupture and blood viscosity to increase (MacAvoy and Bulger, 1995). Studies show that the viscous blood strains the fish's heart, resulting in a lethal heart attack.

ECOSYSTEM RECOVERY

Recovery from acidic deposition involves decreases in emissions resulting from regulatory controls that in turn lead to reductions in acidic deposition and allow *chemical recovery*. The chemical recovery process is characterized by decreases in concentrations of sulfate, nitrate, and dissolved inorganic aluminum in soils and surface waters. If sufficient, these reductions will eventually lead to increased pH and ANC, as well as higher concentrations of base cations in water and on the soil exchange complex. As

Box 4 Seasonal and episodic acidification

Seasonal acidification is the periodic increase in acidity and the corresponding decrease in pH and ANC in streams and lakes. Episodic acidification is caused by the sudden pulse of acids due to spring snowmelt (*see* **Chapter 114, Snowmelt Runoff Generation, Volume 3**) and large rain events in the spring and fall. Increases in nitrate are important to the occurrence of acid episodes and tend to occur when trees are dormant, therefore using less nitrogen. Short-term increases in acid inputs to surface waters can reach levels that are lethal to fish and other aquatic organisms.

chemical conditions improve, the potential for the second phase of ecosystem recovery, biological recovery, is greatly enhanced.

An analysis of the scientific literature suggests that the following five thresholds can serve as indicators of chemical recovery. If chemical conditions in an ecosystem are above these thresholds, it is unlikely that the ecosystem has been substantially impaired by acidic deposition. Conversely, if chemical conditions are below these thresholds, there is a high likelihood that the ecosystem is vulnerable to acidic deposition (see Table 3).

The time required for chemical recovery varies widely among ecosystems, and is primarily a function of:

- the historic loading rate of sulfur and nitrogen oxides;
- the rate and magnitude of decreases in acidic deposition;
- the extent to which available base cations such as calcium have been depleted from soil;
- the extent to which sulfur and nitrogen have accumulated in the soil and the rate at which they are released as deposition declines;
- the weathering rate of the soil and underlying rock and the associated supply of base cations to the ecosystem; and
- the rate of atmospheric deposition of base cations.

Table 3 Indicators of chemical recovery from acidic deposition

Forest ecosystems
• Soil base saturation of 20% or higher (i.e. the percent of available cations in the soil that are bases)
• Calcium to aluminum molar ratio in the soil solution of 1.0 or greater
Aquatic ecosystems
• Stream and lake pH of 6.0 or higher (except where pH is lower under background conditions)
• Stream or lake ANC of 50 μeq L^{-1} or higher
• Stream or lake concentrations of dissolved inorganic aluminum less than 2 μmol L^{-1}.

As chemical conditions in soils and surface waters improve, *biological recovery* is enhanced. Biological recovery is likely to occur in stages, since not all organisms can recover at the same rate and may vary in their sensitivity to acidic deposition. The current understanding of the response of biological species to improvements in chemical conditions is incomplete, but research suggests that stream macroinvertebrates may recover relatively rapidly (i.e. within 3 years), while lake zooplankton may need a decade or more to fully reestablish. Fish populations in streams and lakes should recover in 5–10 years following the recovery of the macroinvertebrates and zooplankton that serve as food sources (Gunn and Mills, 1998). It is possible that, with improved chemical conditions and the return of other members of the aquatic food web, the stocking of streams and lakes could help accelerate the recovery of fish.

Terrestrial recovery is even more difficult to project than aquatic recovery. Given the life span of trees and the delay in the response of soil to decreases in acidic deposition, it is reasonable to suggest that decades will be required for affected trees on sensitive sites to recover once chemical conditions in the soil are restored. Overall, the timing and extent of chemical and biological recovery depend on how soon and how significantly emissions that cause acidic deposition are reduced. Moreover, human influences (i.e. land disturbance, introduction of exotic or invasive species) in addition to acidic deposition, can delay biological recovery after chemical recovery has occurred.

Long-term stream data from Hubbard Brook reveal a number of long-term trends that are consistent with trends in lakes and streams across Europe and eastern North America (Stoddard *et al.*, 1999; Evans *et al.*, 2001; Stoddard *et al.*, 2003; see Figure 9). Specifically, the concentration of sulfate in streams at Hubbard Brook declined 32% between 1963 and 2000. The pH of streams subsequently increased from 4.8 to 5.0. Although this represents an important improvement in water quality, streams at Hubbard Brook remain acidic compared to background conditions, when stream pH was estimated to be approximately 6.0. Moreover, the ANC at Hubbard Brook – a biologically important measure of a lake or stream's susceptibility to acid inputs – has remained acidic (ANC $< 0\,\mu$eq L^{-1}).

Trends in surface water chemistry in Europe (Evans *et al.*, 2001) and eastern North America (Stoddard *et al.*, 1999) indicate that recovery of aquatic ecosystems impacted by acidic deposition is occurring over a large geographic scale since the early 1980s. Some regions are showing rather marked recovery, while others exhibit low or nonexistent increases in ANC. On the basis of long-term monitoring, virtually all surface waters impacted by acidic deposition in Europe and eastern North America exhibit decreases in sulfate concentrations. This pattern is consistent with decreases in emissions of sulfur dioxide and atmospheric sulfate deposition. The exception to

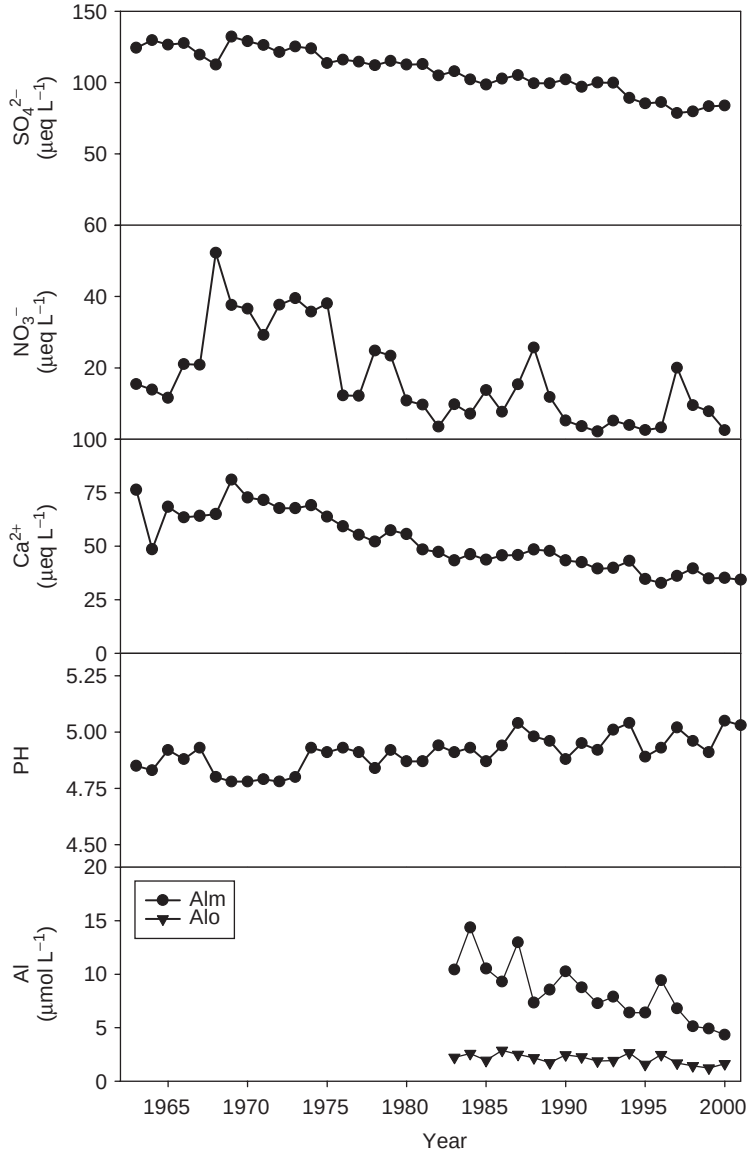

Figure 9 Annual volume-weighted stream water sulfate, nitrate, calcium concentrations, pH, and concentrations of total (Alm) and organic dissolved aluminum (Alo) at the reference watershed of the Hubbard Brook Experimental Forest from 1963 to 2000. Note that dissolved inorganic aluminum is the difference between total and organic dissolved aluminum

this pattern is streams in unglaciated Virginia. Watersheds in this region exhibit strong adsorption of atmospheric sulfate deposition by highly weathered soils. In Europe, the most marked decreases in surface water sulfate have occurred in the Czech Republic and Slovakia, regions that have experienced historically very high rates of atmospheric sulfate deposition. Almost more than half of the surface waters monitored in Europe show an increase in ANC (Evans *et al.*, 2001). The rate of ANC increase in Europe is relatively high. This pattern is in part due to the relatively high rates of sulfate decreases, but also that decreases in base cations only account for about half of the decreases in sulfate plus nitrate, allowing for relatively large rates of ANC increases. In contrast, in the United States only three regions show statistically significant increases in ANC-lakes in the Adirondacks and upper Midwest and streams in the Northern Appalachian Plateau (Stoddard *et al.*, 2003). In the United States, decreases in the sum of base cations closely correspond to decreases in sulfate plus nitrate, limiting rates of ANC increase.

Three factors have limited the recovery in chemical water quality at Hubbard Brook and other watersheds in acid-sensitive regions that have received elevated inputs of acidic deposition. First, levels of acid-neutralizing base cations in surface waters have decreased markedly because of the depletion of available base cations from the soil

and, to a lesser extent, a reduction in atmospheric inputs of base cations. Second, as forest ecosystems mature, their requirement for nitrogen decreases (Aber *et al.*, 1989; Aber *et al.*,1998). As a result, forested watersheds with limited disturbance that extracts nitrogen (e.g. tree harvesting, fire, agriculture) are expected to exhibit increasing losses of nitrate as forests develop. Finally, sulfur has accumulated in the soil under previous conditions of high atmospheric sulfur deposition and is now being released to surface water as sulfate, even though sulfate deposition has decreased.

While there is considerable information about the response of surface waters to decreases in acidic deposition under chronic conditions, much less is known about how episodic acidification responds to these changes. Laudon and Hemond (2002) reported decreases in episodic acidification following decreases in atmospheric sulfur deposition in northern Sweden. Unfortunately, comparable data sets have not been developed for other regions.

An alternative to recovery from controls on emissions of acidic or acid-forming substances is mitigation. Mitigation (or base addition or liming) involves the application of basic materials directly to surface waters or watersheds to neutralize strong acid inputs (Olem *et al.*, 1991). The most common material for mitigation is calcium carbonate (or limestone), although other materials have been effectively used. Mitigation has been practiced in Europe and North America to treat the effects of acidic deposition with some success. Direct application to lakes has been shown to neutralize acidity and allow for the survival of fish and other sensitive aquatic biota. This approach is less successful in lakes with short hydraulic residence times and to recover a reproducing fish population (Driscoll *et al.*, 1996). Alternatively, watershed treatment has been shown to be successful over the longer term by improving the base status of soil and allowing for a reproducing fish population. Note, mitigation is not an attractive alternative to source control. It might be implemented in areas that exhibit severe depletion of exchangeable nutrient cations and/or have biological species that are endangered because of acidic deposition. Acidic deposition impacts ecosystems in remote and wilderness areas that are difficult or inappropriate to treat by base addition. While no negative short-term effects of base treatment have been noted, long-term studies of the ecological response to base treatment have not been conducted.

RECOVERY OF ACID-SENSITIVE ECOSYSTEMS WITH FUTURE DECREASES IN EMISSIONS

To date, emissions targets set in the United States and Europe have been met or exceeded. There are widespread decreases in surface water concentrations of sulfate and some waters are showing increases in ANC. Nevertheless, data suggest that these targets may not be sufficient to achieve the full recovery of sensitive ecosystems. In order to evaluate the extent to which historic and future emissions reductions will facilitate ecosystem recovery from acidic deposition, it is necessary to use acidification models to project the future relationship between emissions, deposition, and chemical recovery of acid-sensitive forest watersheds (see Box 5).

Box 5 Acidification models

Scientists have developed computer models that depict the physical, chemical, and biological processes within forest watersheds. Watershed acidification models can be used as research and management tools to investigate factors responsible for the historical acidification of soil and water, as well as the ecosystem response to anticipated future changes in acidic deposition. In order to effectively predict the pH, ANC, and aluminum concentrations in streams, all major chemicals must be accurately simulated (e.g. sulfate, nitrate, calcium, magnesium). The acidification model PnET-BGC was used for this assessment because it has been rigorously tested at Hubbard Brook and other sites in the northeastern United States, and it allows the user of the model to consider the ecosystem response to multiple chemicals simultaneously. Other frequently used acidification models include Model of Acidification of Groundwater in Catchment (MAGIC) (Cosby *et al.*, 2001), and the nutrient cycling model NuCM (Lui *et al.*, 1992).

We used the model PnET-BGC (Gbondo-Tugbawa *et al.*, 2001) to compare current emissions reductions required by the 1990 CAAA with an additional 55% and 75% cut in emissions of sulfur dioxide and 20% and 30% decreases in nitrogen oxides by 2010 (Figure 10). These scenarios are based on the electric utility emission reductions embodied in bills recently introduced to the US Congress. PnET-BGC considered changes in sulfur dioxide and nitrogen oxide emissions. It was assumed that base cation and ammonium deposition and climate would remain unchanged.

According to the results of the computer model, the 1990 CAAA will have a positive effect on stream concentrations of sulfate at Hubbard Brook, but will not facilitate appreciable progress toward chemical recovery of key indicators of acidification stress, such as pH or ANC. With moderate reductions in emissions (i.e. sulfur dioxide 55%, nitrogen oxides 20%) beyond the requirements of the 1990 CAAA, measurable chemical improvements occur. However, none of the five indicators reach the threshold needed to support complete biological recovery at Hubbard Brook by 2050 (see Table 3). More aggressive reductions in emissions (i.e. sulfur dioxide 75%, nitrogen oxides 30%) beyond the 1990 CAAA hastens and promotes more significant improvements in chemical conditions. For example, under this scenario streams in watersheds similar to Hubbard Brook would change from acidic to nonacidic in roughly

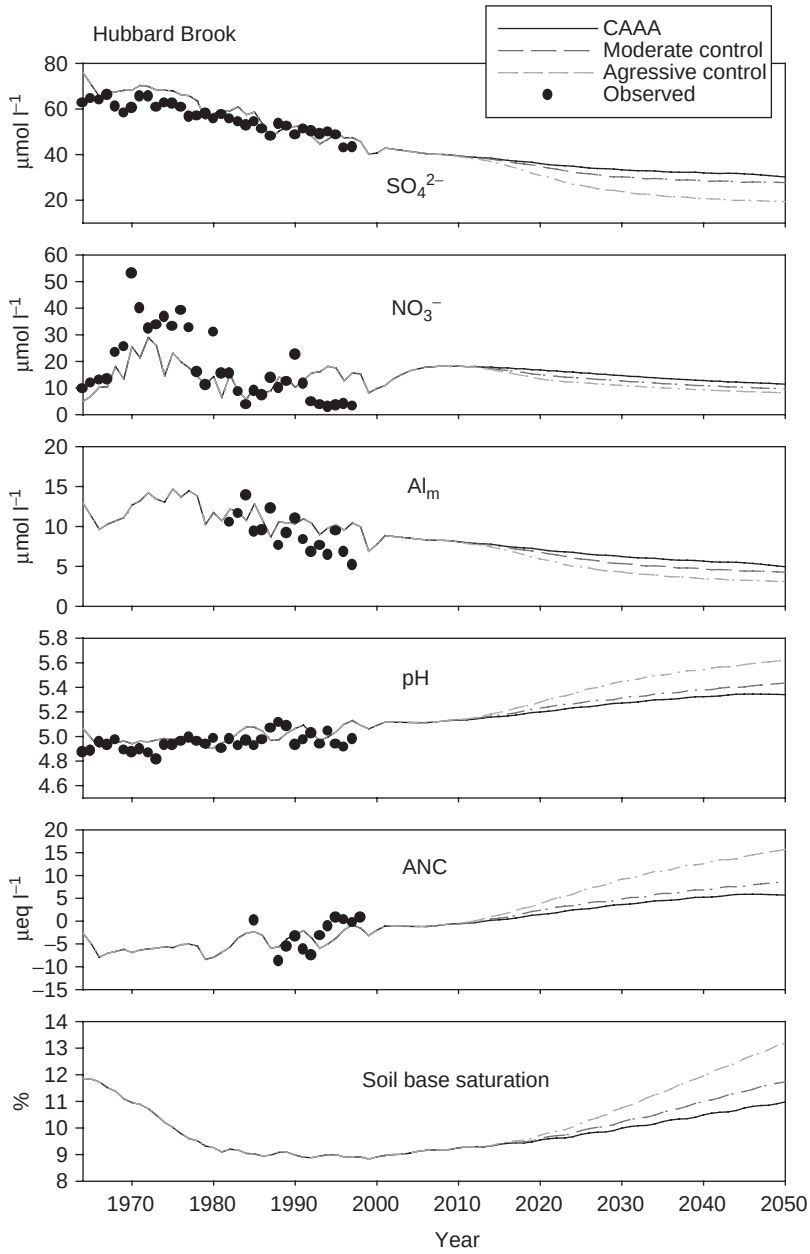

Figure 10 Time series of predictions with the acidification model PnET-BGC of changes in stream chemistry at Hubbard Brook to changes in past and potential future emissions of sulfur dioxide and nitrogen oxides, including the 1990 Amendments of the Clean Air Act and moderate and aggressive emission control scenarios. Shown are model-predicted stream concentrations of sulfate, nitrate, acid-neutralizing capacity, pH and dissolved inorganic aluminum, and soil percent base saturation. Measured values are indicated for comparison. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

20 to 25 years. By 2050, the concentration of aluminum and the base cation content of the soil in these watersheds would begin to approach recovery thresholds or preindustrial levels.

The model results suggest that full implementation of the 1990 CAAA will not bring about substantial improvements in chemical recovery at Hubbard Brook. The results further demonstrate that the process of recovery will be slow, particularly for sensitive systems such as Hubbard Brook. Similar analyses have been conducted at regional scales using PnET-BGC for the Adirondack region of New York (Chen and Driscoll, 2005) and northern New England (Chen and Driscoll in press), with similar results obtained. Other analyses have been conducted to evaluate the response of watersheds in Canada and Europe to future emission reductions (Wright, 2003).

In sum, acidic deposition is a pervasive problem that has had a greater impact on soils, terrestrial vegetation, surface waters, and aquatic biota than previously projected. Although abatement strategies in Europe and North America have had positive effects, emissions remain high compared to background conditions. Given the accumulation of acids and loss of buffering capacity in the soil, many areas are now more sensitive to acidic deposition and have developed an inertia that will delay recovery. Nevertheless, calculations from computer models show that deeper emission cuts will lead to greater and faster recovery from acidic deposition.

Acknowledgment

This article was developed as part of the Hubbard Brook Research Foundation Science-Links program, funded by Jessie B. Cox Charitable Trust, Davis Conservation Foundation, Geraldine R. Dodge Foundation, McCabe Environmental Fund, Merck Family Fund, John Merck Fund, Harold Whitworth Pierce Charitable Trust, the Sudbury Foundation, and the Switzer Environmental Leadership Fund of the New Hampshire Charitable Foundation. Support was also provided by the W. M. Keck Foundation and the National Science Foundation. We are indebted to Gene Likens for the use of long-term precipitation and steam chemistry data at Hubbard Brook. This is a contribution of the Hubbard Brook Ecosystem Study.

96: Nutrient Cycling

ANTHONY C EDWARDS[1] AND ROBERT G WETZEL[2†]

[1]Formerly of: Catchment Management Group, Macaulay Institute, Aberdeen, UK & Currently at: Nether Backhill, Aberdeen, UK
[2]Department of Environmental Sciences and Engineering, The University of North Carolina, Chapel Hill, NC, US
[†]Deceased April 18, 2005

Nutrient concentrations within aquatic ecosystems have increased markedly during the last fifty years due to a variety of causes. Significant changes to the rates of nutrient cycling, particularly of nitrogen and phosphorus, have influenced their biological availability on a global scale. Three broad groupings of processes that directly influence nutrient cycling within freshwaters are described. Retention modifies the availability of nutrients for transport, while selectivity between individual chemical species results in preferential uptake and/or transport, and finally transformation processes alter the physical state or reactivity of particular nutrients. Differences in spatial and temporal dynamics of delivery and transport mechanisms among individual nutrients have caused variable relative changes in nitrogen and phosphorus concentrations and fluxes. These composite dynamic factors make it difficult to couple causal relationships between nutrient sources and their impacts.

INTRODUCTION

Human activity has developed within the geographical constraints imposed by the physical landscape with the result that intensive agriculture and high urban densities tend to be concentrated toward the flatter, floodplain coastal regions. Where demand for land has been historically high, such as Western Europe, few lowland areas exist that have not been extensively exploited. These developments have often been accompanied by the straightening of watercourses and many other impacts, such as abstraction, on water resources (*see* **Chapter 91, Water Quality, Volume 3**; **Chapter 191, Environmental Flows: Managing Hydrological Environments, Volume 5**). In some situations, this exploitation has been so extreme that rivers that were once constantly flowing are now dry for extended periods or flow is maintained only through effluent discharges. Anthropogenic pollution, together with modifications of the environment and climate, are now so pervasive that no aquatic system of the biosphere can be considered as truly pristine or unaltered in some manner (*see* **Chapter 93, Effects of Human Activities on Water Quality, Volume 3**). A current estimate of the global riverine flux of total nitrogen is suggested to be double that of the preindustrial era (Green *et al.*, 2004). It is within this background of multiple and complex stresses that nutrient cycling in aquatic systems is now considered.

An improved prediction of the impact of nutrient enrichment on ecosystem community structure and function requires an understanding of the mechanisms that are responsible for nutrient enrichment and subsequent cycling (*see* **Chapter 90, Lake Sediments as Records of Past Catchment Response, Volume 2**). Increased concentration and flux of individual nutrients have been most apparent during the last five decades although it is likely that systems were suffering from nutrient enrichment well before this (de Jonge *et al.*, 2002). For example, paleolimnological studies of a closed lake of volcanic origin in Italy demonstrated the marked effects of alterations to the drainage basin area by the construction of a road alongside the lake in early historical times (Hutchinson *et al.*, 1970). Increased eutrophication in the sedimentary records coincided precisely with the major disturbance of the drainage basin by the construction of a Roman road, the Via Cassia, about 171 B.C. when a large increase in inputs of phosphorus (P) and alkaline earths, particularly calcium, resulted and the lake

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Table 1 Examples of biotic or abiotic processes that influence nutrient availability and transport within terrestrial and aquatic systems

	Terrestrial systems		Aquatic systems	
	Biotic	Abiotic	Biotic	Abiotic
Retention	Immobilization of N and P in organic matter	Sorption processes involving both organic and inorganic surfaces	Microbial retention totally dominates	Deposition of suspended material onto floodplain
Selectivity	Preferential plant uptake of particular solutes	Particle-size separation during erosion events	Increasing recalcitrance of DOM by selective utilization of labile compounds	Preferential exchange of NH_4^+ and PO_4^{3-} by stream bed sediment
Transformation	Nitrification and the generation of the mobile nitrate anion	Increased crystalinity of amorphous Fe/Al minerals during drying cycles	Denitrification and utilization of inorganic N Turnover rates are inversely proportional to organism size	Redox cycles involving Fe/Mn minerals and release/uptake of associated P under reducing conditions

rapidly became eutrophic, causing the deposition of much organic matter.

Anthropogenic sources of nutrients vary widely in their composition and mode of delivery to aquatic systems. Actual responses will depend greatly upon the type and individual properties of receiving waters. Direct inputs of industrial and domestic effluent (*see* **Chapter 94, Point and NonPoint Source Pollution, Volume 3**) contribute significant quantities of both nitrogen (N) and P and continue to be responsible for many local and regional-scale impacts (e.g. Smith *et al.*, 2003). Many intensive agricultural production systems are currently experiencing a surplus of nutrients as a consequence of excessive use of fertilizers and the inefficient utilization and recycling of the resulting animal waste products (Steele, 1995; Smaling *et al.*, 1999). Even remote "pristine" environments do not escape being impacted by the growing global atmospheric N cycle and the possibility of long-range N transport thought to be responsible for the nutrient imbalances implicated by the N saturation hypothesis (Galloway, 1998; Galloway and Cowling, 2002). Much of the recent increase in atmospheric N is directly attributable to emissions from automobiles and animal waste products which means that nutrient enrichment and the resulting environmental impacts are a shared human responsibility (*see* **Chapter 184, Global River Carbon Biogeochemistry, Volume 5**).

Various physically, chemically, and biologically mediated processes act to modify profoundly nutrient concentrations and fluxes. Establishing the combined significance of these processes hampers attempts to understand the fundamentals of "nutrient cycling" or measure the extent of impact that various human driven perturbations have on aquatic systems. Ecosystem level expression of these processes occurs through three quantifiable responses. The first involves *retention* which influences the availability of nutrients for transport; second is the *selectivity* shown by individual process for a particular chemical species leading to preferential uptake and/or transport; and finally there are *transformation* processes that result in a physical change in either state or reactivity of a particular chemical species. These responses will be referred to in the sections that follow and together contribute to a sequence of interlinked mechanisms that operate to buffer downstream nutrient losses by introducing selective and seasonal lag times. Table 1 provides examples of processes that may operate within terrestrial and aquatic systems.

Although nutrient retention is virtually always only temporary, timescales can vary from minutes to thousands of years depending upon local circumstances. The net result is a damping of system response and a modification of the timing, chemical form, and quantity of chemicals available either for transport or uptake.

NUTRIENT CYCLING WITHIN TERRESTRIAL AND AQUATIC SYSTEMS

Here nutrient cycling is considered in a broad context that recognizes the importance of a "terrestrial component" as the ultimate source for most of the water and many of the nutrients that enter surface and groundwater. Meyer *et al.* (1988) suggested three reasons a greater understanding of elemental cycling within streams could help improve understanding of ecosystem behavior. These are as follows:

1. nutrients regulate ecological processes in streams, especially when a nutrient is limiting;
2. nutrients link terrestrial and aquatic ecosystems; and
3. stream processes alter the timing, magnitude, and form of elemental fluxes and thereby nutrient availability to downstream communities.

Terrestrial and aquatic ecosystems are therefore linked through the essentially unidirectional movement of water and substances that occur in response to hydrological events across the drainage basin. Strong relationships between particular attributes of terrestrial ecosystems (such as land cover) and the chemical composition of drainage water have been regularly reported. As the downgradient receivers of terrestrial land drainage, most aquatic systems are especially sensitive and therefore highly responsive to changes that affect either runoff quality or quantity. For this reason, water that drains from terrestrial land often provides a useful indicator of perturbation. Regular sampling and analysis can usefully be employed as a diagnostic integrator and indicator of wider ecosystem damage (e.g. Aber *et al.*, 2003).

The routing and residence time of water within individual system components are influenced by geomorphological features of the landscape. The proportion of incident precipitation that ultimately contributes to surface or groundwater flow varies widely among ecosystems and also seasonally. For example, only about one-third of the incoming precipitation of many forested drainage basins leaves as runoff and groundwater seepage to streams and rivers during active growth seasons (*see* **Chapter 186, Water and Forests, Volume 5**). Changes to land management such as the removal of existing vegetation, greatly increase the amount and accelerate the flow rate of runoff (e.g. Likens and Bormann, 1995). Vegetation type and soil composition influence not only the amount of runoff but also the composition and quantity of allochthonous organic matter and nutrients that enter streams and lakes. The duration of contact with soil and associated microbiota influence the content of dissolved salts and organic products conveyed in the water.

Although it might be considered that once in the drainage network most nutrients move unidirectionally to the nearest large lake or ocean, this is not always necessarily the case. The composition of surface waters reflects the influence of terrestrial and in-stream processes and therefore represents the net balance between processes that either consume or generate a particular solute. For example, inorganic forms of N may be utilized as a substrate for in-stream denitrification. A recent example from Hubbard Brook demonstrated this situation, where in-stream demand for nitrate appeared to outstrip nitrification, resulting in a reduction of downstream nitrate export (Bernhardt *et al.*, 2002). During periods of high precipitation, runoff volumes may in some cases exceed the storage capacity of river channels resulting in the inundation of floodplains, often for long periods of time. As a consequence of the reduction of energy caused by overspilling the channel, suspended solids (SS), organic matter, and many associated nutrients can be returned to the flooded land and result in highly productive adjacent habitats (*see* **Chapter 84, Floodplain Sedimentation – Methods, Patterns, and Processes: A Review with Examples from the Lower Rhine, the Netherlands, Volume 2**). Channel engineering and progressive urbanization of the river plain increases the risk of flooding, while growth of macrophytes can reduce in-stream flows resulting in localized sedimentation (e.g. Haslam, 1978; Dodds and Biggs, 2002). Rivers act as effective redistributors of nutrients and sediment from upstream to downstream locations which may include standing waters.

Because of their geographical situation, estuaries are considered to be especially sensitive to nutrient enrichment. Conley (2000) recently reviewed data for a geographically wide range of riverine inputs to estuaries and highlighted a number of underlying issues that relate to nutrient cycling. It was demonstrated that N and P loading has increased by 6–50 and 18–180 times, respectively, compared to "pristine" conditions. Interestingly, this enrichment demonstrates that not only have quantities increased over time but because the rate of change has differed between nutrients, the ratio of N to P delivered to these estuaries has narrowed over time which may have important implications for the timing and nature of nutrient limitations. This conclusion is supported by other investigations, which have also shown that chemical composition and bioavailability has also altered. Under "pristine" conditions, it has been argued, for example, that a selective preference and utilization of inorganic N forms will result in their depletion and a relative increase in the leaching of organic forms of N for primary forests in temperate South America (Hedin *et al.*, 1998; Perakis and Hedin, 2002). Organic forms of both N and P can also contribute significantly to total losses derived from agriculturally managed systems (Howarth *et al.*, 1996).

PHOSPHORUS AND NITROGEN CYCLES IN FRESHWATER ECOSYSTEMS

Ecological interest in P stems from its major role in biological metabolism and the relatively small amounts of P available in the hydrosphere. In comparison to other major nutritional and structural components required by biota (carbon, hydrogen, nitrogen, oxygen, and sulfur), P is the least abundant, and most commonly is the first element to limit biological productivity of fresh waters. Nitrogen is also a major constituent of cellular protoplasm of organisms and a major nutrient that affects and sometimes limits the productivity of fresh waters.

Nutrients enter the food chain initially through uptake (autotrophs or heterotrophs), the efficiency of which requires the three conditions:

1. they should be present at concentrations that are sustained during biologically active uptake periods above some ecological threshold value (usually defined by a membrane transport system);
2. they should be in a labile (readily bioavailable) chemical form;
3. they should be present in pools which are physically accessible to the biota.

For many natural ecosystems, one or both of these conditions (together with many other physical/chemical limiting factors) are not met and result in suboptimal conditions for growth. The global nutrient enrichment of aquatic ecosystems means that one type of limitation that has restricted productivity levels below the system potential maximum, in many cases, has been removed. For example, the role of elemental imbalances that occur between trophic levels has been reviewed recently (Frost *et al.*, 2002) for benthic systems their potential to affect population dynamics, trophic interactions, and gross transfer efficiencies has been demonstrated.

Types of Phosphorus

Much quantitative data exist on the seasonal and spatial distribution of P in streams and lakes, as well as the loading rates to recipient waters from drainage basins (Wetzel, 2001). Orthophosphate (PO_4^{3-}) is the only directly utilizable form of soluble inorganic P. Phosphate is extremely reactive and interacts with many cations (e.g. Fe and Ca) to form, especially under oxidizing conditions, relatively insoluble compounds that precipitate out of the water. The immediate bioavailability of phosphate is also reduced by its adsorption to inorganic colloids and particulate compounds (e.g. clays, carbonates, and hydroxides).

Much of the organic P resides in living and senescent plant organic matter or is associated with organic compounds immobilized with soil particles (Wetzel, 1999). Mineralization rates are masked by this large pool, from which a small but critical quantity of labile organic P is rapidly recycled among the soil, plants, and microbes. The organic P transformations are controlled by a combination of P concentrations in solution and biological activities, the most important of which are microbial alterations of redox and bonding to particles. As the concentrations or biological availability of the inorganic pool decreases, much of the P resides in organic compounds and polyphosphates, usually resulting in an increase in the relative rate of recycling between the inorganic and organic P pools.

In aquatic ecosystems, P availability depends to a great extent on its delivery from the drainage basin. Both physical and biotic processes in lakes, streams, and wetlands tend toward concentration of P in inorganic and organic pools of the sediments. Exchange rates between various deposits of P and the interstitial water of the sediments depend on local adsorption and diffusion coefficients and their alteration by enzyme-mediated reactions of the microbiota (Wetzel, 2001). In organic-rich sediments not illuminated by sunlight, high sediment demand for oxygen results from microbial respiratory metabolism, which may be exacerbated by slow rates of diffusion from the overlying water and inorganic elements such as Fe(II) that accumulate in reduced form. On a molar ratio of P liberated per unit of organic carbon mineralized by bacteria, the availability of alternate electron acceptor compounds such as sulfate largely control mineralization rates and release of sorbed and bonded P from sediments.

Algal photosynthesis on sediment surfaces, as well as oxygen release from the roots of emergent aquatic plants of wetlands into the rhizosphere, markedly alters redox conditions of the sediments on a distinct diurnal basis (Roden and Wetzel, 1996; Wetzel, 1999, 2001; Reddy *et al.*, 2005). These rapid (minutes) shifts in the depth of the oxidized microzone, by as much as a factor of 100, and redox conditions in the sediments, in turn, form a highly dynamic sediment system that rapidly alter both mineralization rates of organic P pools and inactivation of inorganic P by oxidative reactions (Carlton and Wetzel, 1988). Of the several fractions of organic P, a low molecular weight fraction cycles rapidly (hours) with soluble forms. Dissolved and colloidal organic P fractions released from microbiota are cycled much more slowly, particularly if sorbed to inorganic and detrital organic particles.

Distribution and Balance of Phosphorus

The range of total P in fresh waters is large, from $<5\,\mu g\,L^{-1}$ in very unproductive (oligotrophic) waters to $>100\,\mu g\,L^{-1}$ in highly eutrophic waters. Most uncontaminated fresh waters contain 10–50 μg total P/L. Concentrations of total and soluble P tend to increase markedly in the lower strata (hypolimnia) of productive lakes that are thermally stratified, largely from the release of soluble P from the stores of accumulated sediments.

Dissolved P concentrations in rivers are generally higher than in lakes, and often increase markedly following rainfall and snowmelt events on land in the drainage basin. At low concentrations in streams, P can be limiting, and microbial productivity often increases with greater loading of P. In addition to biological uptake, P abundance is influenced also by abiotic adsorption and desorption reactions with organic and inorganic particles. Where dissolved organic P compounds are less chemically active they can be exported downstream for considerable distances. Most recycling of P (>95%) is associated with microbiota attached to particles.

The P content of groundwater is generally low (average ~20 μg P/L) even in areas where soils contain relatively

large quantities of P. The low P content is a result of the relatively insoluble nature of phosphate-containing minerals and efficient scavenging of soluble P by biota and soil particles. However, certain situations can arise where groundwater experiences high concentrations of P as a consequence of localized contamination arising from effluents derived from septic systems or agricultural feedlots (Maule and Fonstad, 2000).

P uptake and kinetics in numerous temperate lakes show that turnover times are extremely rapid (5–100 min) during summer periods of high demand and low loading inputs, and efficient uptake systems can reduce P concentrations to well below analytical detection limits (Hudson *et al.*, 2000). During winter periods, turnover rates slow by as much as 2 orders of magnitude. P turnover rates are generally faster under more oligotrophic conditions of lower P availability. Sedimentation of particles results in constant losses of P from the upper strata of water (*see* **Chapter 88, Reservoir Sedimentation, Volume 2**). As a result, fresh supplies of P must enter the ecosystems in order to maintain or increase productivity.

Phosphorus enters fresh waters from atmospheric precipitation and from groundwater and surface runoff. Small amounts of P in atmospheric precipitation and particulate material fallout originates from fine particles of soil and rock, particularly from agriculture, from living, and dead organisms (particularly as volatile compounds released from plants), and from natural fires and the burning of fossil fuels. The loading rates of phosphorus in surface waters vary greatly with patterns of land use, geology and morphology of the drainage basin, soil productivity, human activities, pollution, and other factors (Table 2). When P is added to unproductive fresh waters, either experimentally or as a result of human activities, a common response is a rapid (days) increase in algal and bacterial productivity. Because of numerous sites of rapid sequestering and losses, inputs must be more or less continuous, however, in order to maintain a higher level of productivity. For this reason priority is often given to the management of P inputs.

Numerous mass balance models have been developed to predict, on the basis of P loading and hydraulic retention times, the anticipated responses of algal biomass and less commonly productivity. The models yield a reasonably accurate estimate of permissible P loading needed to achieve a certain level of lake productivity if loading is reduced. In certain shallow lakes with greater than average turbulence, large littoral areas, and small anaerobic hypolimnia, reduced productivity does not always occur as rapidly in response to decreased P loading as predicted from the models. In these lakes, P release from sediment sources ("internal loading") is much greater than common values (10–30% of total loading) for deeper, more intensely thermally stratified lakes.

Types of Nitrogen

The nitrogen cycle is a complex biochemical process in which N in various forms is altered by nitrogen fixation, assimilation, and reduction of nitrate to N_2 by denitrification. The nitrogen cycle of fresh waters is essentially microbial. Dominant forms of nitrogen in fresh waters include (i) dissolved molecular N_2 and N_2O, (ii) ammonium nitrogen (NH_4^+), (iii) nitrite (NO_2^-), (iv) nitrate (NO_3^-), and (v) various organic compounds, such as amino acids, amines, nucleotides, proteins, and humic compounds of modest N content.

Table 2 General ranges of primary productivity of phytoplankton and related characteristics of lakes of different trophic categories (From Wetzel (2001) after numerous sources cited therein)

Drainage basin type	Total dissolved inorganic nitrogen losses (kg N km^{-2} $year^{-1}$)	Total phosphorus losses (kg P km^{-2} $year^{-1}$)
Undisturbed temperate forest	ca. 200	ca. 2
Undisturbed boreal forest	90–160	3–9
Cleared forest, igneous watershed	–	ca. 5
Cleared forest, sedimentary watershed	–	ca. 11
Cleared forest, volcanic watershed	–	72
Pasture, low intensity	100–1000	8–20
Pasture, high intensity	2000–25 000	–
Arable, cereals	4000–6000	–
Arable, cash crops	4000–<10 000	–
Arable, intensive (UK, USA, Netherlands)	–	7–190
Mixed upland (Northern UK)	530–630	ca. 34
Groundwater leachates	427–638	35–93
Urban runoff	ca. 1000	ca. 100
General soil productivity		
Low	<500	<20
Medium	500–2500	20–50
High	>2500	>50

Distribution and Balance of Nitrogen

The nitrogen cycle consists of a balance between N inputs to and nitrogen losses from aquatic ecosystems. Sources of N include (i) N contained in particulate "dry fallout" and in precipitation, (ii) N_2 fixation both in the water and the sediments, and (iii) inputs of N from surface and groundwater drainage. Reduced forms of N are a major constituent of the effluent from sewage treatment works and livestock wastes. Biological fixation of N_2 by soil bacteria can be a major source of N. In lakes and streams, N_2 fixation by heterotrophic bacteria and certain cyanobacteria is quantitatively less significant, except under certain conditions of severe depletion of combined inorganic N compounds. N_2 fixation by cyanobacteria is usually much greater than fixation by heterotrophic bacteria, and in particular, in wetlands surrounding or adjacent to surface waters can add significant amounts of combined N to freshwater ecosystems.

Ammonia is generated by heterotrophic bacteria as the primary nitrogenous end product of decomposition of proteins and other nitrogenous organic compounds. Ammonia concentrations are usually low as it is readily assimilated by plants, strongly retained by sediment, and oxidized in nitrification to NO_2^- and NO_3^-. Under anaerobic conditions of productive waters, as in the lower strata of a thermally stratified lake, large concentrations of NH_4–N can occur. Nitrate is assimilated and aminated into organic nitrogenous compounds within organisms. During metabolism of these organisms, and at death, much of the N is liberated as ammonia or organic nitrogenous compounds that are degraded to ammonia and related compounds.

Dissolved organic nitrogen (DON), largely as complex amino nitrogen compounds in polypeptides and humic substances, often constitutes over 50% of the total soluble N in fresh waters having both autochthonous and allochthonous origins (Egeberg *et al.*, 1999). Organic carbon-to-nitrogen ratios (C : N) indicate an approximate state of resistance of complex mixtures of organic compounds to decomposition, because proteolytic metabolism by fungi and bacteria removes proportionally more N than C. Wider C : N ratios commonly occur in residual organic compounds which are more resistant to decomposition. Organic materials from terrestrial and wetland sources commonly have C : N ratios from 45 : 1 to 50 : 1, and contain many humic compounds from plant structural tissues of low N content. Changes in the protein-carbohydrate-lipid ratios alter the particulate C : N ratio as a result of P or N limitation.

Increased loading of both inorganic and organic N to rivers and lakes frequently results from agricultural activities, effluent from sewage treatment works (STW), intensive livestock enterprises, and anthropogenic atmospheric pollution (Table 2). In unproductive oligotrophic lakes, P availability is often the principal limitation nutrient for plant growth. As P loading to fresh waters increases and they become more productive, P requirements become saturated with high P availability. Nitrogen availability then becomes more important as a limiting nutrient (Maberly *et al.*, 2003).

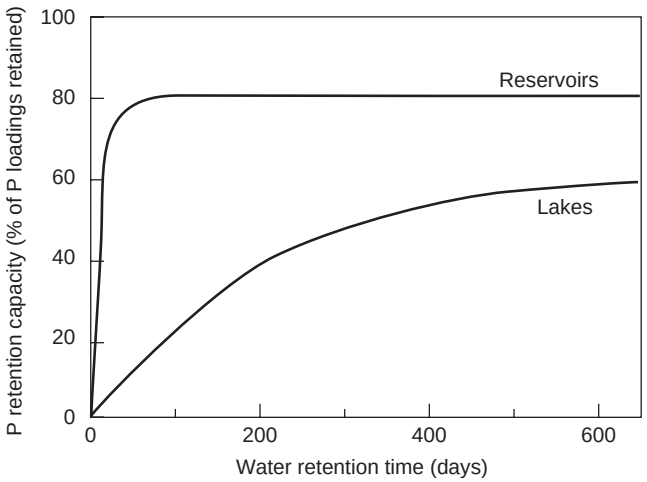

Figure 1 Phosphorus retention capacity of lakes and reservoirs as a percentage of total phosphorus loading retained in relation to water retention times. (Modified from Straškraba, 1996)

Retention capacities for nutrients can differ considerably between stratified natural lakes and reservoirs (*see* **Chapter 109, Reservoirs, Volume 3**), largely as a function of marked differences in water retention times (e.g. Figure 1). Although P retention times are similar when comparing water retention times of a year or longer, the water retention times of lakes are much longer (1–7 years on the average) than those of reservoirs (often <100 days and highly variable).

In running waters, N is used repeatedly and released back to the water as it passes downstream. The rate of utilization and release depends upon physical and biological retentiveness, largely by the microbiota attached to the streambed. The average distance a nutrient molecule travels downstream during one cycle through the water, biota, and substrata compartments is the *spiraling length*. Nutrient limitations to biotic productivity are not common in small rivers and streams, where nutrients are efficiently retained and recycled. As rivers become larger, nutrient retention is less and nutrient limitations can become less significant.

The processes of N cycling in the water of streams and rivers are similar to those of lakes and are influenced to a large extent by bacterial, fungal, and other microbial metabolism. Once nitrogen is loaded to a stream or river, the attached bacteria, fungi, and algae are the primary organisms controlling the spatial and temporal variations within the water. The processes of nitrification and denitrification often function simultaneously and reciprocally in running water sediments, where many microzones of steep redox

gradients occur in the hyporheic zone of the streambed. The highly dynamic longitudinal pattern of N_2O outgassing from streams draining agricultural areas has been demonstrated by Reay *et al.* (2003).

RELATIONSHIP BETWEEN DRAINAGE BASIN FEATURES AND WATER CHEMISTRY

Land Cover and Terrestrial Process

Concentrations and the resulting flux of dissolved and particulate material vary greatly both spatially between locations and temporally at individual sites (Johnes and Butterfield, 2002). While differences in in-stream utilization can account for some of the observed variability, much can be traced backward and explained by differences in the geology, soils, vegetation cover, and land use existing within the contributing terrestrial catchment area (*see* **Chapter 115, Landscape Element Contributions to Storm Runoff, Volume 3**; **Chapter 202, Use of Climate Information in Water Resources Management, Volume 5**). The significance of any single attribute may well vary seasonally. A study by Johnson and Gage (1997), for example, demonstrated that drainage basin factors accounted for much of the observed variation in total dissolved solids; however, during autumn, geological factors and shared influence of geology/landscape structure plus land use exerted more influence than with land use only. It is reasonable to expect that a relationship should exist between certain catchment attributes (through their combined influence upon key transformation processes), the composition of drainage water, and consequently the structure and functioning of aquatic systems they maintain.

The important role which transformation processes have upon nutrient retention through their influence upon the chemical form and fluxes of N is demonstrated in Table 3. In this example an upland seminatural, highly "organic" soil is compared to a lowland "mineral" agricultural soil. Although each has a similar soil N capital of $\sim$5000 t ha^{-1}, which in the case of the organic soil has collected over thousands of years, these two situations represent the extreme of conditions. The principle factor that ultimately governs N composition of drainage waters is the balance, which exists among immobilization, mineralization, and nitrification processes. Although both terrestrial systems appear to display a net retention of N, the much greater inputs and associated losses of nitrate that occur from the agricultural site results from the dominance of nitrification.

It is possible to develop these general relationships in two ways. The first considers the attributes of the total hydrologically contributing land area, while the second approach requires an increasing level of sophistication where relationships are developed using a greater awareness of spatial partitioning. The first situation using the "whole" contributing area assumes that areas having a similar range of attributes all contribute equally, irrespective of their distance from the water course, whereas the latter approach implies some degree of spatial weighting. Johnson and Gage (1997) compared the strength of relationships for individual determinants obtained with either the whole drainage basin area or a spatially weighted definition, such as just the attributes of a 100-m buffer strip immediately adjacent to the river. While river nitrate concentrations were better related to the whole catchment, total phosphorus (TP) and SS were best described during the summer with land use in the buffer zone. Observations of this nature elucidate how catchments operate while also demonstrating the independent and temporal nature of transport mechanisms for individual substances.

The Terrestrial–Aquatic Interface

It has been reasonably argued that the area immediately adjacent to a river, which encompasses both riparian and hyporheic zones, represents the interface and site of connectivity between terrestrial and aquatic systems. The transient interface between surface and groundwater is an important point linking lateral nutrient fluxes

Table 3 A comparison of N capital, transformation processes, and fluxes of N between extensively managed seminatural upland and intensive low land agricultural systems

Attribute	Upland seminatural	Lowland agriculture
Soil N capital and chemical form	$\sim$5000 t ha^{-1}, reduced (organic and ammonium)	$\sim$5000 t ha^{-1}, reduced (organic and ammonium) and nitrate
Sources of N input	Atmosphere, biological fixation	Atmosphere, biological fixation, fertilizer/manure
Dominant transformation processes	Immobilization	Mineralization and nitrification
Stream water composition	Organic N and ammonium $<$1 mg N L^{-1}	Nitrate $\sim$7 mg N L^{-1}
Annual N flux	$\sim$2 kg N ha^{-1}	$>$25 kg N ha^{-1}

from terrestrial systems and the longitudinal processes in streams (Dahm *et al.*, 1998). A constant exchange of water and solutes occurs between the hyporheic zone and the river (*see* **Chapter 113, Hyporheic Exchange Flows, Volume 3**). Typical lengths of hyporheic zone range from centimeters to meters (Harvey and Wagner, 2000) and where this interaction leads to an improved supply of substrate, this zone contributes significantly to in-stream metabolism and recycling. Important processes include redox cycles and denitrification. Recent reviews have summarized the importance of the biological and physicochemical processes (Pusch *et al.*, 1998; Wetzel, 2001) operating within it that can retain and transform (Table 1) nutrients, ultimately modifying delivery. For these reasons, this zone, in particular, receives special attention often being the focus of attempts to "manage" nutrient transport from the wider landscape. Hedin *et al.* (1998) highlight the importance of the soil–stream interface as an area with high potential for removing dissolved N by denitrification and suggest that the process is limited by the availability of oxidizable carbon via shallow flow paths. Support for management policies that concentrate on "this last line of defense" in the protection of water quality is debatable, although the critical role of the riparian corridor to overall river health and function is undeniable.

NUTRIENT TRANSPORT AND DELIVERY TO AQUATIC ECOSYSTEMS

Sources of Nutrients

Convention usually distinguishes between "point" and "diffuse" nutrient sources (*see* **Chapter 94, Point and Non-Point Source Pollution, Volume 3**). While this distinction may well represent an oversimplification of the actual situation, it does enable some basic differences between the attributes of the dominant delivery mechanisms to be made (*see* **Chapter 117, Land Use and Land Cover Effects on Runoff Processes: Urban and Suburban Development, Volume 3**; **Chapter 118, Land Use and Land Cover Effects on Runoff Processes: Agricultural Effects, Volume 3**). Classical examples of point sources (such as STW effluent) tend to have a constant and concentrated composition relative to the receiving waters with a semicontinuous delivery that may be independent of catchment hydrological processes. Importantly, the delivery of nutrients from point source origins can completely overwhelm naturally occurring short-term or seasonally associated dynamics of in-stream N and P cycles. In contrast to point sources, which are comparatively easy to locate and quantify accurately, diffuse sources usually have poorly defined and variable points of delivery. These basic differences are now considered for diffuse and point sources separately, and various specific case study examples can be found in Haygarth and Jarvis (2002).

Diffuse Sources

The significance of waterborne transport means that the physical linkage or degree of "hydrological connectivity" that exists between terrestrial and aquatic systems is an important feature that helps define nutrient delivery from diffuse sources. River composition and downstream nutrient transport vary considerably between steady and storm flow hydrological conditions. The former is most likely to be dominated by water originating from deeper soil horizons and groundwater, while the latter will be typified by episodic, high-energy events reflecting the increasing proportion of runoff derived from near-surface soil horizons and overland flow. Some of the implications arising from these differences between these two states are summarized in Table 4.

Point Sources

Despite ongoing and extensive regulation, nutrient inputs from point sources continue to have pronounced impacts on aquatic ecosystems (Haggard *et al.*, 2001). The often high concentrations of reactive P in STW effluent usually results in an intense zone of physicochemical and biological activity, tending to favor adsorption downstream of point sources (*see* **Chapter 97, Urban Water Quality, Volume 3**). This situation has been well demonstrated by Owens and Walling (2002) where the TP content of SS varied from $<2000\,\mu g\,g^{-1}$ for headwater areas located upstream of the main urban and industrialized regions to concentrations in excess of $7000\,\mu g\,g^{-1}$ at downstream sites. Phosphorus inputs from point sources may also widen the inorganic to organic P ratio from <2 in the headwaters to >4 in the lower reaches.

Regional-scale Relationship Between Point and Diffuse Sources

An example of how P export from a catchment having both urban and rural land uses can be separated on the basis of source, transport, and potential availability has been summarized by Dorioz *et al.* (1998). Export regimes were defined using a unique set of hydrological conditions (Table 5), TP inputs, in-stream TP retention, and bioavailability. The first hydrological condition experienced an extended period of stable and low flows where surface runoff was negligible and nutrient supply dominated by those originating from point sources. The overall system balance was toward nutrient accumulation through sedimentation and the selective adsorption of P. Conditions 2 and 3 (Table 5) are typified by increasing amounts of rainfall occurring against a background of stable low flows, but some overland flow may be generated especially from low-permeability urban areas. The system balance moved

Table 4 A comparison of the changing conditions likely to affect nutrient cycling during periods of steady and changing flow conditions

Attribute	Reducing/steady river flow	Increasing/event based river flow
Proportion of time	Long duration giving rise to regular flow conditions	Episodic, short-term dynamic flow events
Energy conditions	Low–medium	High
Hydrological connectivity/routing	Deeper longer residence time soil drainage and groundwater	Increasing proportion of rapid near-surface/overland flow
Nutrient transport	Primarily as soluble forms	Tendency for dominance of particulate associated forms
Seasonal occurrence	Summer and winter periods where soils are frozen	Spring and autumn
Biological production potential	High, as a result of clear water and greater light penetration during summer months	Reduced, as a result of poor light transmission and physical damage (e.g. abrasion) and low temperatures
In-stream processes and the balance between export or import conditions	Sediment deposition, nutrient retention, shorter spiraling distances, biotic uptake, and transformations	Sediment resuspension, nutrient export, longer spiraling distances
Drainage water composition	Solute dominated with composition being reflective of geochemical and in-stream biological processes	Particulate dominated with composition being more reflective of terrestrial biogeochemical processes

Table 5 Four reoccurring hydrological conditions in relation to P transport and catchment export dynamics (Dorioz *et al.*, 1998)

	Flow conditions	Surface runoff	Dominant P source	P form	System P balance
1	LF, constant, or decreasing flow for >7 days	None	Point sources	Soluble & bioavailable	In > Ex
2	LF, small storm event, so that 7-day flow greater than preceding weekly average	Urban	Point sources, and in-stream stores	Particulate & highly bioavailable	Ex > In
3	HF, substantial rainfall follows at least 7-day period of constant or decreasing flow	Urban	Diffuse urban sources and all stored P is exported	Highly bioavailable, high conc., and fluxes	Ex > In
4	HF, prolonged periods of rainfall	Urban and agricultural land	Diffuse agricultural sources	Conc. are low but fluxes high	In = Ex

Note: LF – low flow, HF – high flow, In – input, Ex – Export.

toward a net export of the previously accumulated in-stream nutrients. The final condition occurred where rainfall was prolonged and stream flow was increased to the extent where there was little possibility of retention and imports essentially equaled exports, but some storage might be possible if the system floods and sedimentation occurred over the floodplain.

Contrasting the Sources and Behavior of N and P: Catchment-scale Implications

The previous sections have highlighted differences between nutrient sources and some of the implications these might have for their delivery to and retention within river systems (*see* **Chapter 69, Solute Transport in Soil at the Core and Field Scale, Volume 2**). The widescale and well-documented increase in surface and groundwater nitrate concentrations provides an excellent example with which to further develop this theme and demonstrate the strong linkage that can develop between the products of "terrestrial" process and the composition of surface waters (*see* **Chapter 188, Land Use and Water Quality, Volume 5**). Transformation of DON via NH_4^+ to NO_3^- by mineralization and nitrification processes (Table 1) is sensitive to certain soil properties that include pH and texture

in addition to a constant supply of N and C substrates. Particularly favorable conditions for nitrification arise after soil cultivation, which combined with nutrient amendments and periodic liming means that there is often a strong relationship between the area of cultivated agricultural land and NO_3^- concentration. This situation is demonstrated in Table 6, which shows the strong positive relationship that can exist between averaged NO_3^- concentrations and the proportion of agricultural land (which ranged from 0 to >90% of the total catchment area) for 57 rivers located throughout Scotland and sampled at their lowest nontidal point. Phosphate (and NH_4^+) concentrations correlated much better to human population densities (which ranged from essentially <1 to >1000 capita/km^2).

The actual data are plotted in Figure 2 where some of the scatter for NO_3^- may be attributable to and explained by the very general nature of the land cover classification (arable plus all grassland). The relationship between PO_4^{3-} and agricultural land was poor (Table 6) but much better correlated to the census derived population density within each catchment, which suggests a predominantly point (assuming a reticulated STW system) source for P (Figure 2b). Together, these catchments account for over half the land area and half the population of Scotland. The N : P ratio (NO_3^--N and PO_4^{3-}-P) varied widely, but only at population densities >100 people/km^2 did it fall below 10; below this population density, the ratio was always greater than 10, and on occasions reached 100.

Transport of N and P

The nutrient flux that occurs from terrestrial ecosystems displays a high degree of spatial and temporal variability with the principle transport mechanism differing fundamentally between N and P (*see* **Chapter 89, On the Worldwide Riverine Transport of Sediment – Associated Contaminants to the Ocean, Volume 2**). The short-term retention and therefore capacity for downstream transportation of nutrients is the product of the attributes of delivery (chemical form, quantity, and timing) coupled with those related to the efficiency of various in-stream processes. Nutrient dependent limitations on productivity develop when biological demand exceeds local rates of supply. The annual cycle of increasing productivity often coincides with conditions of reduced summer discharge, and three properties of the local environment become central to the continued resupply of nutrients:

1. the buffering capacity and degree to which the immediate local environment has become saturated for individual nutrient species;
2. the quantity and biological availability of nutrients supplied from "external" sources; and
3. the local efficiency with which nutrients are being recycled.

Nutrients are transported either fully dissolved or in some association with SS (*see* **Chapter 140, Transport of Sediments, Volume 4**). The extent of partitioning between

Table 6 Matrix of correlation coefficients (r) between various nutrient and SS concentrations for 57 river water samples collected throughout Scotland on a monthly basis and averaged over a single year. (Samples were collected and analyzed by the Scottish Environment Protection Agency)

	Agricultural land use	Population density
SS	0.46***	0.34*
NH_4^+	0.15^{ns}	0.52***
NO_2^-	0.23^{ns}	0.48***
NO_3^-	0.77***	0.31*
PO_4^{3-}	0.28*	0.61***

Note: ns – not significant, $*P < 0.05$, $***P < 0.001$.

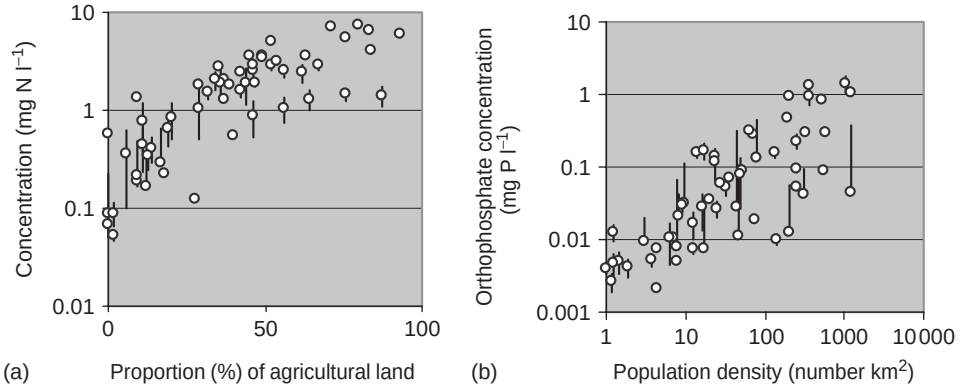

Figure 2 Annually averaged (a) NO_3^--N and (b) PO_4^{3-}-P concentrations (with SD) for samples collected at approximately monthly time intervals over a single year by the Scottish Environment Protection Agency and plotted against the proportion of agricultural land (a) or population density (b) in each catchment. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

these two phases is a function of the solute involved, physicochemical properties of the sediment, and the prevailing environmental conditions. Physical form has a direct implication for nutrient cycling through its influence upon "accessibility" for uptake, which occurs primarily from solution, whilst also influencing general mobility and residence times. Changes in environmental circumstances, such as redox status, discharge, or large point source inputs may alter the state of dynamic equilibrium existing between solid and solution phases.

Together, these factors combine to profoundly influence nutrient cycles, through the contrasting behavior and properties of NO_3^- and PO_4^{3-} in surface waters. Importantly, these fundamental differences help explain the tendency for PO_4^{3-} to be widely considered as the nutrient most likely to be limiting in fresh waters. The greater reactivity of PO_4^{3-} results in a high selectivity for sorption onto solid phases and therefore the maintenance of low soluble P concentrations. This situation is the opposite to that which exists for NO_3^-, which generally has a poor affinity for solid phases and explains why NO_3^- concentrations are commonly 2 orders of magnitude greater than those of PO_4^{3-} (Table 7).

These differences in physicochemical behavior also means that while concentrations of PO_4^{3-} should be subjected to strong (internal) buffering from sorbed P, the reverse would be true for NO_3^- where concentrations reflect a combination of terrestrial (external) sources and the balance between in-stream utilization and production. An example of the changing conditions for low and high flows is shown in Table 7. Although NO_3^- concentrations remained similar to those for PO_4^{3-}, TP and SS increased by ~10, 50, and 290 times respectively at the high flow. The resulting change in instantaneous load was only 1 order of magnitude for NO_3^- compared to more than 3 orders of magnitude for P and SS and demonstrates the tendency for most P to be mobilized during episodic events often associated with SS. In situations without significant point sources, it might be expected that, during periods of extended steady flow, conditions will favor soluble forms of N and P leading to a widening of the N : P ratio compared to storm flow, where high SS and the associated P causes a narrowing of the N : P ratio. For the example illustrated in Table 7 the NO_3-N : TP ratio narrows from 762 at low flow to 17.6 at high flow. These values are largely for transport, and do not connotate biological availability, because many chemical states of the transported materials are relatively recalcitrant to biotic utilization.

Timing of N and P Delivery with Biological Requirement

The simple comparison made in Table 7 can be extrapolated to provide insight into the differing transport mechanisms that operate at the catchment scale. The effective delivery of nutrients from "diffuse sources" that occurs during episodic storm events introduces a strong temporal component to the dynamics of annual transport of N and P by rivers. High rates of nutrient flux tend to be associated with periods of greatest storm frequency, although it is unlikely that these high flow conditions are particularly favorable for productivity and uptake. This potential mismatch between the timing of nutrient supply and demand means that system retention times become important. With increasing retention times, as in lakes and reservoirs, a greater proportion of these episodically delivered nutrients will remain potentially available for biological uptake.

Attempts to fully understand the dynamics of nutrient availability requires a good understanding of the physicochemical differences in the reactivation and transport mechanisms that together modify the timing of delivery and composition of nutrient fluxes to drainage waters. The seasonality of biological uptake means that only a proportion of the total annual flux of nutrients constitutes the "biologically significant" fraction. With increasing catchment size and overall complexity, it becomes difficult to separate and quantify the precise contribution that individual sources make and therefore also where the most effective remediation strategies should be targeted. An extreme example of this situation has regularly been described for large, strongly retentive standing water bodies (also large slow flowing rivers), where "internal" cycling of existing nutrients is well capable of sustaining biological activity over long time periods. The size of an internal nutrient supply will influence the effectiveness of management strategies that focus only on reducing fresh inputs of nutrients.

By way of contrast to nutrient loading, the highest nutrient concentrations of impacted waters often occur under conditions of low flow where groundwater sources may dominate, dilution of point sources is minimal, and efficient recycling of existing nutrients in lakes becomes important. These different situations have lead to confusion

Table 7 Comparison between concentrations ($mg\,L^{-1}$) and instantaneous flux ($mg\,s^{-1}$) of nutrients between low and high stream discharge of a small second-order stream (Bronie Burn) draining agricultural land in NE Scotland

	Flow	SS		NO_3^--N		TP		PO_4^{3-}-P	
	($L\,s^{-1}$)	($mg\,L^{-1}$)	($mg\,s^{-1}$)	($mg\,L^{-1}$)	($mg\,s^{-1}$)	($mg\,L^{-1}$)	($mg\,s^{-1}$)	($mg\,L^{-1}$)	($mg\,s^{-1}$)
Low flow	2	4.64	9.28	12.2	24.4	0.016	0.032	0.016	0.032
High flow	72	1335	96 120	13.2	947.5	0.75	54	0.17	12.2

as to whether a nutrient loading or concentration should be considered when determining impact assessments. As a result, targeting of the most appropriate remediation actions in order to minimize impacts is difficult.

BIOLOGICAL EFFECTS OF NUTRIENT ENRICHMENT

Introduction

The productivity and internal metabolism of aquatic ecosystems are driven by energy acquired by photosynthesis from solar radiation. Inland waters receive organic products of photosynthesis directly from their aquatic flora and indirectly from the drainage basins as particulate and dissolved organic matter from terrestrial and wetland plants imported by stream water, storm runoff, groundwater, and the atmosphere (*see* **Chapter 102, Trophic Dynamics, Volume 3**).

Light is attenuated exponentially with increasing depth in water. The ultraviolet wavelengths are absorbed strongly by water and dissolved organic compounds in the water. The blue portion (400–500 nm) of the visible spectrum penetrates most deeply in relatively clear waters. Infrared wavelengths are absorbed rapidly by the molecular structure of the water molecules and much of this energy is dissipated as heat. Because water is less dense as temperature increases above 4 °C, less dense warmer water floats upon the more dense cooler water. The density stratification separates the lake into a warmer, less dense stratum (epilimnion) that overlies a cooler, denser zone (hypolimnion). The interface zone (metalimnion) between these strata is a region of rapid thermal discontinuity, often several degrees change per meter.

The resulting density stratification affects not only the thermal structure and water mass stratification, but also the hydrodynamics of lakes and reservoirs. Patterns of density-induced stratification influence physical and chemical properties and cycle both spatially within the water body and seasonally. These properties structure aquatic habitats and have marked effects on all chemical cycles, metabolic rates, and the population dynamics of organisms and their productivities (reviewed in detail in Wetzel, 2001).

In large lakes and reservoirs, the volume of water with sufficient light to support photosynthesis (euphotic zone) is small in relation to the total volume of water containing stored dissolved oxygen that can be used for heterotrophic respiration. In small and relatively shallow lakes, however, the proportion of water supporting photosynthesis is large relative to total lake volume, and respiratory demands can exhaust oxygen dissolved in the lower strata of the lake. The process of eutrophication exacerbates the exhaustion of dissolved oxygen in large portions of lake ecosystems. Eutrophication is the increased loading of organic matter to an aquatic ecosystem. Often in lakes and reservoirs, eutrophication results in increased photosynthetic production of organic matter in response to excessive loading of nutrients, particularly phosphorus, to the water from external sources (*see* **Chapter 108, Lake Ecosystems (Stratification and Seasonal Mixing Processes, Pelagic and Benthic Coupling), Volume 3**).

In flowing waters where individual nutrient retention times may be extremely short and sustained high concentrations are not typical, aquatic biota must display high uptake and utilization efficiencies in an almost opportunistic approach to nutrient acquisition. Periods of greatest nutrient loading are usually associated with storm events where physical conditions are not always conducive to active growth. It is likely that under these circumstances, periods of low flow and concentrations of individual nutrients become more important (Dodds *et al.*, 1996). The complexity of full ecosystem responses to nutrient additions has been demonstrated experimentally by Peterson *et al.* (2001). The first year of N additions resulted in a large increase in primary productivity, which was followed during the second year by secondary grazers, which resulted in a return to clear water conditions. Such studies have important implications with respect to the capacities for stream ecosystems to store and retain nutrient loads received from the catchment areas.

Succession of Eutrophication

Increased inorganic nutrient loading, particularly of P and combined N species, is fundamental to initial eutrophication and to the maintenance of high, sustained productivity by the phytoplankton communities. Low rates of productivity in oligotrophic lakes are maintained to a large extent by low inputs of organic matter, concomitant with slow rates of decomposition. Oxidizing hypolimnetic conditions are thus maintained and result in low rates of nutrient release from the sediments in a cyclical causal system. Dissolved organic compounds from both internal and external sources are usually low, which results in limited availability of organic micronutrients and reduced complexing capabilities for essential inorganic micronutrients.

Under eutrophic conditions, the loading rates of nutrients, especially P and combined N, are relatively high. As rates of photosynthetic productivity and organic loading to lower strata increase, nutrients are released from sediments into anoxic hypolimnia, increasing recycling rates. Phytoplanktonic productivity of eutrophic lakes and reservoirs increases markedly. In increasingly eutrophic lakes, dense algal communities reduce light penetration and thereby compress the depth of the trophogenic zone. Some partial circumvention of the effects of self-shading can be achieved by buoyant species (e.g. gas-vacuolated cyanobacteria) or even flagellated species. Light limitations caused by self-shading set an upper boundary to the phytoplanktonic photosynthetic productivity, beyond which further

increases are not possible, regardless of increased nutrient availability. Further increases in photosynthetic productivity are possible only by extending the length of the growing season (e.g. in the tropics) or by increasing turbulence and frequency of exposure to available light, as in artificially mixed sewage lagoons.

Impacts of Nutrient Enrichment

Nutrient enrichment can modify both biomass productivity and community structure (see Harper, 1991; Moss, 1998) often being associated with a decrease in species biodiversity. Rates of algal production increase, as nutrient limitation of the phytoplankton of infertile waters are increasingly relieved by sustained nutrient inputs. As the densities of the phytoplankton community progressively reduce the available light and thickness of the trophogenic zone, productivity per unit surface area is usually lower under these hypereutrophic conditions than under less productive conditions where a thicker trophogenic zone exists.

Certain characteristic phytoplankton associations occur repeatedly in lakes of increasing nutrient enrichment. Although variance is high, there is a general tendency to shift from a dominance of diatoms, dinoglagellates, chrysophytes, and cryptophytes in oligotrophic waters to a dominance of cyanobacteria, euglenophytes, and diatoms and green algae among eutrophic waters (Table 8).

The ranges of primary productivity of phytoplankton commonly associated with oligotrophy and eutrophy are large (Table 8). The primary productivity of phytoplankton is commonly used as a major criterion for determining trophic state of a lake or reservoir. This criterion, however, assumes that dissolved and particulate organic matter inputs from littoral and external terrestrial sources are small relative to those of the phytoplankton. In many cases on a global basis, littoral productivity and allochthonous organic inputs are much larger than inputs produced by phytoplankton productivity (Wetzel, 1990a). In such cases, phytoplankton productivity alone is a poor estimator of the trophic state of a lake or reservoir. The primary productivity of phytoplankton must be viewed as a variably important contributor to overall aquatic metabolism (Table 9).

Remediation via Nutrient Reduction

Eutrophication is a process leading to increased biological productivity and decreased basin volume from excessive addition of dissolved and particulate inorganic and organic materials to lakes and reservoirs. Although much of the earlier emphasis on eutrophication was on the basis of increased growth of phytoplankton algae, a broader context would include the rapid alterations to the basin morphometry caused by siltation. Increased littoral areas lead to rapid increases in the development of aquatic macrophytes of high productivity and accelerated internal loadings of organic matter. As lakes become shallower, the exchange of nutrients that are remineralized in the sediments within the productive trophogenic zone becomes more likely.

Enhanced P availability is most frequently the cause of enhanced productivity in lakes and reservoirs. Although other elements, particularly N, can become the dominant limiting nutrient for phytoplankton growth in certain waters when P supplies are sufficient, on a global basis P is the foremost nutrient limiting to autochthonous photosynthesis on a sustained long-term basis. Lake and reservoir restoration efforts have, as a result, been directed largely toward reducing the loading of P, and to a lesser extent N, to the surface waters by advanced wastewater treatment, diversion, land management, or reducing the P load in wastewater by restricting the P content of detergents. If releases of sediment P stores become significant, in part stimulated by low redox potentials that have resulted from organic matter loading, production, and deposition, attempts are often made to control the availability or recycling of nutrients by physical (e.g. aeration) or chemical (e.g. P inactivation, sediment oxidation) methods within the lake or reservoir (Cooke *et al.*, 1993; Eiseltová, 1994; Wetzel, 1990b, 2001).

Lake and reservoir management and restoration have focused on problems particularly associated with excessive nutrient loading and poor land management. Prevention of nutrient pollution and eutrophication is clearly the most prudent long-term solution. Reductions in nutrient loadings often require evaluation of diffuse and point sources within the drainage basin and a systematic multifaceted program of reduction and control. Once the loadings of nutrients and water are known, a nutrient budget can be used to evaluate the dynamics of annual inputs and outputs of substances. The budget permits the estimation of changes in algal biomass that could result from increases or decreases in nutrient loadings, water residence time, or increased mean depth as may occur from sediment removal.

Phosphorus release from sediments can be very high in lakes with anoxic hypolimnia. This release can delay the predicted reduction in phytoplankton biomass following reductions in external nutrient loading. The internal loading can be estimated and incorporated into nutrient budget data and models.

Nine common methods are used, singly or in combination, to reduce nutrient availability or suitable habitat for photosynthesis (Klapper, 1991; Cooke *et al.*, 1993).

1. Nutrient removal by advanced treatment and land management
2. Nutrient diversion of external nutrient loadings away from receiving rivers, reservoirs, or lakes
3. Hypolimnetic withdrawal of nutrient-enriched hypolimnetic water by siphoning, pumping, or deepwater discharge

Table 8 General ranges of primary productivity of phytoplankton and related characteristics of lakes of different trophic categories[a]

Trophic type	Mean primary productivity ($mg\,C\,m^{-2}\,day^{-1}$)[b]	Phyto plankton density ($cm^3\,m^{-3}$)	Phyto plankton biomass ($mg\,C\,m^{-3}$)	Chloro phyll a ($mg\,m^{-3}$)	Dominant phyto plankton	Light extinction coefficients (m^{-1})	Total organic carbon ($mg\,L^{-1}$)	Total P ($\mu g\,L^{-1}$)	Total N ($\mu g\,L^{-1}$)	Total inorganic solids ($mg\,L^{-1}$)
Ultraoligotrophic	<50	<1	<50	0.01–0.5		0.03–0.8		<1–5	<1–250	2–15
Oligotrophic	50–300		20–100	0.3–3	Chrysophyceae, Cryptophyveae	0.05–1.0	<1–3			
Oligomesotrophic		1–3			Dinophyceae, Dinophyceae, Bacillariophyceae			5–10	250–600	10–200
Mesotrophic	250–1000		100–300	2–15		0.1–2.0	<1–5			
Mesoeutrophic		3–5						10–30	500–1100	100–500
Eutrophic	>1000		>300	10–500	Bacillariophyceae, Cyanobacteria	0.5–4.0	5–30			
Hypereutrophic		>10			Chlorophyceae, Euglenophyceae			30–>5000	500–>15 000	400–60 000
Dystrophic	<50–500		<50–200	0.1–10		1.0–4.0	3–30	<1–10	<1–500	5–200

[a]Modified from Wetzel (2001), after many authors and sources.
[b]Referring to approximately net primary productivity, such as measured by the ^{14}C methods.

Table 9 Comparative characteristics of phytoplankton and their productivity among river, reservoir, and natural lake ecosystems[a]

Property	Rivers	Reservoirs	Natural lakes
Phytoplankton diversity	Very low in low-order streams; increasing in high-order large rivers	Low in riverine zones; increasing in lacustrine zone	High diversity in oligotrophic lakes, decreasing in eutrophic lakes; similar in tropical and temperate lakes
Phytoplankton biomass	Very low in low-order streams; increasing in large rivers, although often light-limited	Moderately high in response to high nutrient supply in riverine sections; less in lacustrine zone where nutrients often limiting	Highly variable (to 5 orders of magnitude) in temperate lakes seasonally; much less variable in tropical lakes
Phytoplankton productivity	Low, often light-limited by advective flows and turbidity	Highest in transitional zone; reduced in riverine zone by light availability and often in lacustrine zone by nutrients; marked horizontal gradients; volumetric productivity (P_{max}) decreases from headwaters to dam; areal productivity relatively constant horizontally	Low in comparison to littoral productivity; increasing with moderate nutrient loading; declining at very high nutrient loading; seasonal and vertical gradients predominate; small horizontal gradients; light and inorganic nutrient limitations predominate

[a]Modified from Wetzel (2001) derived from numerous sources cited therein.

4. Dilution and flushing of a reservoir by a source of nutrient-poor water
5. Phosphorus precipitation and inactivation due to adsorption or precipitation after the addition of aluminum compounds, or natural clay and carbonate particles
6. Sediment oxidation by the additions of an alternative electron acceptor, such as nitrate to delay the reduction of iron and release of P
7. Aeration of the anoxic hypolimnia of lakes and reservoirs
8. Sediment removal in shallow eutrophic lakes to remove nutrient accumulations and increase mean depth
9. Food-web manipulations of zooplankton and fish and their efficiencies of herbivory on algae, animal predation, and nutrient recycling.

River Management and Restoration

From a geographical context, two general approaches are employed to reduce the flux of nutrients deriving from terrestrial sources. Attention has been placed upon management options that result in the interception and retention of nutrients within the riparian zone or through the use of more general blanketed catchmentwide actions that favor measures aimed at reducing the nutrient surplus of agricultural systems (e.g. Öborn *et al.*, 2003). Successful action measures require the simultaneous and integrated management of both aspects in order to deliver the best options for long-term restoration of rivers (*see* **Chapter 185, Integrated Land and Water Resources Management, Volume 5**).

The Riparian Zone

A fundamental tenet of both river management and restoration is to protect or restore the riparian floodplain areas of streams and rivers. In many cases, streams and rivers have been channelized by straightening and deepening the channel, particularly in lowland agricultural areas to increase drainage. Accompanying the loss of stream length and meandering is a loss of riffles and pools, a loss of riparian floodplains and wetlands, and a loss of riparian vegetation (*see* **Chapter 107, Natural and Constructed Wetlands, Volume 3**). As a result, hydraulic head is increased when energy dissipation is reduced. Increased flows reduce habitat diversity, particularly in the sediments and adjacent wetland, with a catastrophic reduction in habitat diversity and biodiversity (e.g. Gore, 1985; Petersen *et al.*, 1992; Eiseltová and Biggs, 1995). Loss of riparian floodplains and wetlands decreases water tables, increases rates of water runoff, enhances nutrient losses from adjacent land, and increases scouring and sediment yield to the channel. Water retention capacities are greatly reduced and as a result, during high precipitation events, flooding is very common and much more severe that would be the case if portions of the riparian and floodplain environments were retained.

Several means of river management and restoration measures include:

1. allowing the river channel to migrate laterally with periodic inundation of the floodplain above river bank capacity;
2. encouraging and developing buffer strips of plant and microbial communities along each side of the river channel to function in bank stabilization and as a metabolic filter for effective sequestering and retention of nutrients;
3. encouraging the development of natural wetlands, particularly at juncture points of tributaries to the main channel; and

4. reducing of slope gradient at the edge of the channel to encourage channel meandering and floodplain regeneration.

The Wider Catchment Area

Unfortunately, while it is possible to effectively reduce the flux of nutrients derived from terrestrial sources, it is difficult to envisage a general situation in the near future where these losses approach levels that existed prior to the recent (last 50 years) phase of agricultural intensification. The reasons for this lack of response relate to the range of retention and transformation processes described earlier, together with the accumulated increased nutrient capital of many terrestrial and aquatic ecosystems and the extent of "chronic" background enrichment experienced by many surface and groundwaters. This rather pessimistic observation means it is even more important to agree to the prioritization and introduction of appropriate catchmentwide management objectives. A good discussion of this rapidly developing area is available at USEPA (2003a) and Water Framework Directive (2000).

The often very site-specific nature of many nutrient driven biological impact means that a wide range of catchment-scale management options exist that might prove to be effective. These may tackle either the direct input of nutrients or indirectly through modifying the hydrological transport pathways and connectivity to river systems. Some of the options are listed here.

1. Reduce sources of rapid storm runoff from industrial/urban areas by increasing infiltration and short-term storage.
2. Reduce nutrient capital of soil-plant systems, through improved efficiency of nutrient use and/or change of land use.
3. Attempt to minimize production of soil nitrate.
4. Develop natural barriers (e.g. hedgerows) to dissipate energy and generation of surface runoff and soil erosion.
5. Follow and enforce strict best management agricultural practices.

MODELING

Models aid in the identification and quantification of nutrient sources both spatially and temporally across an individual catchment (*see* **Chapter 17, Hydrological and Environmental Modeling of Transport Processes in Rivers and Estuaries, Volume 1**; **Chapter 100, Water Quality Modeling, Volume 3**). The complexity and range of issues involved in the modeling of nutrient supply, transport, and impact has meant that a variety of approaches have been adopted (see Haygarth and Jarvis, 2002). As with most modeling exercises, the appropriate choice depends greatly upon the amount of temporal and spatial resolution that is considered necessary together with the availability of reliable data for parameterization. Often the choice has to be made between those models that are complex, data hungry, process based, and single element specific, and those that have both poor temporal and spatial resolution, but that are easily parameterized and often employ simple regression-type relationships. While the former provide a high degree of spatial and temporal understanding, they are not necessarily robust or easily used among different geographical situations. Examples of the second approach include loss coefficients defined for particular landcover/soil-type/climatic combinations (*see* **Chapter 15, Digital Elevation Model Analysis and Geographic Information Systems, Volume 1**) using relationships developed between certain catchment level attributes and the N and P losses.

A variety of process-based models is available, which, because of the fundamental differences between N and P, tend to emphasize biologically mediated aspects of the N cycle as compared to those physicochemical process that are important for P. This coupling helps to explain why many of the process-based models tend to be nutrient specific. A review of current modeling efforts can be found at Benchmark Models (2003), where the objective is to establish a set of criteria to assess the appropriateness of integrated models for use in the implementation of Water Framework Directive. Other approaches prefer to focus upon the transport and delivery aspects of nutrient transfer to aquatic systems, and therefore include a strong underlying hydrological component.

One particularly important modeling goal is the accurate apportioning of nutrient sources that contribute to both total and biologically significant losses. As the size/area of a catchment increases it becomes difficult to resolve individual sources because of the compounding effects of damping and retention. Source apportioning is therefore an important component of the effective targeting of nutrient management. One recent approach that should be transferable between river systems and uses the natural hierarchical stream order structure combined with a hydrological and biogeochemical model has been described for the River Danube by Garnier *et al.* (2002).

Models that improve the system-level understanding of increased nutrient supply and impacts together with the linked attempts to better define system threshold or target concentrations have been developed. The most successful and widely used models were developed and applied to standing waters. Being able to identify the key role that physical factors such as water depth and turnover time play within broad classes of standing waters has been central to this success. The lack of a similar understanding and an ascribed series of generalized physical criteria are perhaps the reasons for the much poorer prediction capacities for

flowing waters. River systems function as both a conduit for nutrient transport as well having the potential to be impacted in their own right.

THE FUTURE EMPHASIS

The contribution individual potential sources of nutrients make at both local and whole catchment scale requires further quantification. The accumulated impacts of nutrient enrichment on ecosystems immediately down gradient and ultimately coastal/marine systems remains a major research objective. Central to this requirement is the development of target or threshold values for individual nutrients which must reflect their relationship to realistically set conditions for "background" states. The use of ecoregions is one way forward and this approach can be investigated further at USEPA (2003b). A similar level of understanding of the relationship that exists between nutrient supply and biological impact that has been established for standing waters is required for flowing systems. Unfortunately, terrestrial nutrient cycles are inevitably "leaky", which is particularly so for NO_3, while point sources are often major contributors of P. Even when apparently achievable objectives have been decided upon, the buffering mechanisms operating within soil-plant nutrient cycles introduce a strong hysteresis into the recovery. An example of the difficulties that this can introduce has become evident for the Baltic Sea where responses to management action plans were slower than anticipated (Grimvall *et al.*, 2000).

For many river situations, it is not always the total nutrient loss that determines a potential impact; the matching of periods of nutrient supply with those of biological demand needs much greater consideration. To achieve this requires a greater understanding of the particular aquatic system attributes that help to modify retention times of individual nutrients. A recent example of this situation has been described by Edwards *et al.* (2003) for a eutrophic estuarine system. An estimated 70% of the terrestrially derived nitrate passes through the estuarine system of the River Ythan, NE Scotland, during the biologically dormant period when algal growth is at a minimum.

The central role that hydrologically mediated transport plays in the delivery of N and P means that changes in either the frequency of storm events or quantity of rainfall can have very significant implications for nutrient cycling. Periods of low summer flows can be associated with poor dilution of point sources and high river concentrations (*see* **Chapter 34, Climate Change – Past, Present and Future, Volume 1**; **Chapter 189, Land Use and Water Resources Under a Changing Climate, Volume 5**). The possibility that climate change might be altering rainfall-runoff patterns requires consideration. The tremendous seasonal and annual variability in climate, which influences nutrient supply and retention means that many aspects relating to eutrophication, especially for the shorter residence time riverine environments, remain poorly understood.

FURTHER READING

The following sections provide an overview of the essential attributes and factors that are responsible for regulating nutrient cycling in both standing and flowing water bodies. In such a short text it is difficult to cover all topics or eventualities adequately, therefore the following books are recommended to provide a more comprehensive overview in general (Moss, 1998; Harris, 1999; Lewis, 2000; Wetzel, 2001; Smith, 2003) and specific (Brezonik, 1993; Stumm and Morgan, 1996) issues.

Steady growth of population, due to overall population increases and continuing migration from rural to urban areas, creates enormous demands and stresses on urban waters with respect to water supply, drainage, flood protection, wastewater management, and beneficial uses of receiving waters and groundwater. Urban water issues are therefore in the forefront of water management priorities in practically all regions of the world, though often for broadly varying reasons. Key issues of urban water management are discussed in this article, which focuses on the evolution of urban drainage infrastructure, characterization of urban drainage, urban runoff impacts on receiving waters, urban drainage management, water, and wastewater reuse and future perspectives and priorities. The discussion focuses on the collection and transport of urban effluents (sewer systems), characterization of urban drainage provided by combined or storm sewers (flows and their quality), impacts of urban drainage effluents on receiving waters, and groundwater and impact mitigation by integrated urban drainage management with the emphasis placed on the management of surface runoff and water/wastewater reuse. While the progress in integrated engineering science, watershed-based management and new water technologies is impressive, the challenges of maintaining and improving urban water services, particularly in low-income countries, are formidable and may be further exacerbated by demographic, social, and climate change.

INTRODUCTION

Flood protection, drainage, and sanitation have always ranked highly in the needs of most societies, and, even in early civilizations, cities such as Ur and Babylon of the second century millennium B.C. Mesopotamian Empire possessed sophisticated wastewater collection and stormwater drainage systems, the remains of which can still be found. Significant advances in urban drainage technology were introduced during the period of the Roman Empire with roadway drainage, underground conduits, and sewer networks primarily intended for flood mitigation and the drainage of lowlands. The collection of rainwater for household and public use was also considered important especially given that domestic water consumption during the Roman period reached very high levels of 300 to 500 L per person per day.

Sanitation practices deteriorated after the decline of the Roman Empire with surface drains and streets being used in the Middle Ages as the only means of conveyance and disposal of all kinds of water-borne wastes. Water consumption declined to less than 15 L per head per day with already polluted urban waters being abstracted for further use in paper, fabric, and leather industries. Stormwater and foul sewage streams thus became indiscriminately mixed, becoming so noxious that they had to be covered and turned into sewers, giving rise to the birth of the "combined" sewer principle. The first beginnings of modern urban drainage practices were intended for stormwater control and were initiated in European cities during the nineteenth century, particularly following the numerous epidemics of typhoid and cholera in Europe and the United States in the 1830–1870 period. Inlets, gutters, and sewers replaced open street channels in Paris during 1810 to 1839 under the efforts of the engineers Bruneseau and Emmery, and, in 1843, the first comprehensively planned sewerage system for a major city was undertaken in Hamburg, Germany. The London sewer system designed by Bazalgette was introduced between 1859

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

and 1865, and, in the United States, main urban drainage systems were introduced in Chicago (1850s) and New York (1880). A good review of the history of urban drainage in the United States is given in Burian *et al.* (2000) with information on recent urban pollution control strategies provided in the chapter by Loagne and Lorin (*see* **Chapter 94, Point and NonPoint Source Pollution, Volume 3**).

The perspective of urban drainage also changed from a design standpoint during the late nineteenth century. Intuitive reasoning about conversion of rainfall into runoff led to the emergence of the Rational Method through the work of Mulvaney (1851), Kuichling (1889) and Lloyd–Davies (1906). By the end of the late nineteenth century, engineers possessed various design concepts and methods for wastewater disposal systems, and, for the next 100 years, these would become the standard tools used in urban drainage design throughout the world. Since the 1960s, rapid developments have occurred in urban drainage practice and this can be directly linked to the introduction of the computer and associated electronics such that it is now possible to calculate flows in sewer and drain networks with high precision and resolution to support cost-effective design, analysis, and operation.

Whilst these advances have helped in coping with urban flooding and have substantially improved the health of urban citizens, progress in water quality considerations and particularly those addressing the impact of increasing urban populations and their activities upon both surface and groundwaters have been much slower. Unfortunately, the processes that control water quality in drainage systems are much more complex and less deterministic than those which control flow rates (see McCutcheon, **Chapter 100, Water Quality Modeling, Volume 3**). More recently, major changes in drainage design and operation philosophy have been introduced as a result of

- the introduction and adoption of the concepts of ecological integrity and sustainable approaches to environmental and water resources management set within a watershed-wide framework;
- acceptance of the need to consider urban drainage, wastewater systems, and receiving waters in a holistic, integrated manner;
- the continuing development of computing power and an associated range of new analytical and real-time control techniques.

However, almost two-thirds of the world's population has no inherited sewered infrastructure, and many struggle with recurrent flooding and the daily need to find a place to carry out the most fundamental personal ablutions. Many would argue that the techniques and paradigms on which the wastewater disposal systems were developed in the developed nations are totally irrelevant to the needs and circumstances of developing urban populations and that new urban drainage paradigms are required. The major objectives for urban drainage remain public hygiene, flood protection, and environmental enhancement, although the emphasis in developed countries has been firmly placed to date on flood and pollution control. However, at the beginning of the twenty-first century, urban drainage has evolved to become much more than the simple transport and treatment of urban runoff and the time is ripe for the introduction of new paradigms based on more long-term sustainable strategies.

CHARACTERIZATION OF URBAN DRAINAGE

Introduction

Urban runoff includes dry weather sewage baseflow, stormwater, combined sewer overflows (CSO), as well as industrial effluent discharges and has been identified as a source of receiving water pollution for nearly 50 years. However, it is only in the last 20 years that national efforts within North America, Europe, Japan, and Australia have been made to identify and quantify the various pollutants and urban land uses responsible for such contamination. Surface Water Outfalls (SWOs) are essentially generated by storm rainfall conveying stormwater over impermeable urban surfaces to the separate surface water sewer system although non-wet weather flow can occur due to blockages, line breaks, vandalism, or misconnections. CSOs represent the combined volume of wastewater and stormwater runoff entering combined sewer systems, which exceeds the conveyance and treatment capacity of the drainage network, and is diverted to the receiving water by overflow regulators.

Urban Surface Water Pollutants

The range of pollutant concentrations and loadings associated with stormwater runoff from impermeable urban surfaces indicates that such surface water discharges can be highly variable in quality (Table 1), with standard deviations frequently being 75% (equivalent to a coefficient of variation, C_v, of 0.75) of the average event mean concentration (EMC) value. Table 1 would suggest that EMCs are frequently close to, if not exceeding the minimum NOEL (no observable effects limit) value and thus potentially present a problem to receiving water ecology. However, land use pollutant loading relationships do have a high degree of site specificity, and regional extrapolations on a continental scale cannot be readily applied. Further, the impact is varied with organism; some are victim to chronic low level exposure, others to acute higher concentration flushes. Nevertheless, the land use mean EMC value $\times$ Runoff Volume approach provides a convenient and appropriate screening-level methodology for estimation

Table 1 Pollutant concentrations and loadings for urban stormwater runoff

Pollutant parameter	Event mean concentration and range (mg L^{-1})		Load per unit area (kg imp.ha^{-1} $year^{-1}$)		Minimum concentration causing observable biological effects

of annual loads and their confidence limits (Marsalek, 1991; Ellis and Mitchell, 2005). Mean EMCs can be calculated from observations or transported from existing databases such as the US NURP database (USEPA, 1983); runoff volume is produced by hydrological modeling. The volume is then multiplied by the mean EMC to obtain the loading, and estimate bounds derived from multiplication by the upper and lower confidence limits.

Properties of EMCs are of further interest in load and impact estimations. Firstly, the US NURP data indicate that geographic location and land use were of little utility in explaining site-to-site variability, or predicting data for unmonitored sites (US EPA, 1983). Under such circumstances, best EMCs are obtained by pooling data for all sites. Secondly, EMCs were found to be statistically independent of runoff event volumes, which implies that loads can be derived by multiplication of the mean EMC by runoff volume, and, furthermore, when sampling runoff events, randomly selected events of any magnitude are acceptable. Thirdly, analysis of EMC data in the NURP program (US EPA, 1983) and in other studies indicated that stormwater constituent concentrations as well as their EMCs are log-normally distributed. This fact can be used in estimating means of censored concentration data, and in estimates of loads and quantiles (Van Buren *et al.*, 1997). Many urban water quality planning and design tasks require spatially and temporally distributed data on stormwater, municipal sewage, and combined sewage flows in urban areas, for the analysis of existing sewerage systems or planning and design of new ones. Such tasks require the use of urban simulation models, which have greatly evolved during the past 30 years. There are many such models currently in use, but several broadly used software packages stand out in the modeling practice (listed alphabetically):

InfoWorks CS (collection system) of Wallingford Software (**http://www.wallingfordsoftware.com**), MOUSE of the Danish Hydraulic Institute (**http://www.dhi.com**), and the Storm Water Management Model of the US Environmental Protection Agency (**http://www.epa.gov/ceampubl/**). These models are modularly structured, and, in general, they calculate runoff and wastewater flows, their quality, route the flows and water quality constituents through transport, storage, management, and treatment facilities, and simulate the fate of effluents in receiving waters. Modules for simulation of real-time control of sewer systems are also available. In general, the available modeling tools serve well the needs of urban modelers and facilitate easy input data import from GIS or other databases (Zoppou, 2001).

Combined Sewer Overflow (CSO) Pollutants

Table 2 shows the range of pollutant concentrations associated with global CSO discharges, which are not that dissimilar between the various countries quoted, given the variation in geographic and climatic situation for the differing data locations. The pollutants in CSOs come from domestic sources (especially BOD_5, TSS and nutrients), trade effluents (especially fats, grease, metals, and synthetic organic compounds), as well as from atmospheric washout and impermeable surface water runoff during wet weather events. Concentrations can vary substantially on a diurnal basis, both within and between stormflow events, as well as from community to community. These pollutants impact the aquatic environment in various ways, as indicated later in the article, with solids, for example, aggravating fish gill tissue, increasing turbidity, and entombing embryos in the bed gravel. Oil can severely affect wildlife through ingestion following preening as well as from loss of external waterproofing, whilst both organics and metals can induce toxic effects upon the biota.

Aesthetic pollutants such as sanitary products, toilet tissue, and faeces also characterize CSO discharges with loads, depending on the magnitude and frequency of overflow events, watershed characteristics, as well as population size and character. Floatables, including sanitary products, litter, and detritus are also characteristic of CSOs and can have an adverse impact on wildlife, primarily through entanglement or ingestion as well as having adverse aesthetic impacts. A recent concern has arisen over the incidence of sewage contaminants associated with pharmaceuticals and personal care products (PPCPs) such as chelating agents (e.g EDTA), antibiotics, antiinflammatories, steroids, and endocrine disrupters that are being found at levels well above the widely accepted $1\,\mu g\,L^{-1}$ limit (Marsalek *et al.*, 2002).

Combined sewer networks should not be regarded simply as conveyance systems as they also serve as physical and chemical reactors having the potential to alter and modify the quality of received urban runoff. The sudden flow influx into a CSO brought on by a rainfall (or snowmelt) event can create a first-flush effect, which occurs when pollutants washed from impermeable urban surfaces combine with pollutants resuspended from in-pipe sediment. Studies of sewer entry–exit mass loads have shown that exchanges with in-pipe pollutant stocks make up a principal source of wet weather flow pollutants for solids, BOD/COD, hydrocarbons, and soluble metals such that they present a prime source of acute oxygen depletion in the receiving water (Ashley *et al.*, 2004).

Construction and Urban Runoff

The increases in sediment load associated with urbanization have been well documented, and it has been suggested that construction causes 50% of the urban sediment yield with as much as 10 tonnes per capita per annum (and averaging between 116 to 157 tonnes $ha^{-1}\,year^{-1}$) being transported in receiving waters during the initial construction phases (D'Arcy *et al.*, 2000). This sediment yield declines substantially as the urban area matures such that TSS concentrations can decline (especially for small urban watersheds) below levels observed in rural catchments.

Table 2 CSO pollutant concentrations

	TSS ($mg\,L^{-1}$)	BOD ($mg\,L^{-1}$)	COD ($mg\,L^{-1}$)	Cd ($\mu g\,L^{-1}$)	Cu ($\mu g\,L^{-1}$)	Pb ($\mu g\,L^{-1}$)	Zn ($\mu g\,L^{-1}$)	P_{total} ($mg\,L^{-1}$)	N_{total} ($mg\,L^{-1}$)	*E. Coli* (100 mL)
US	237–635	43 – 95	120–560			150–290			2.9–4.8	
Canada	190							1.4	8.3	
UK	***425***	***90***				***250***	***870***	***10***	***8.3***	
	176–647	43–225	260–507			80–450	100–1070	6.5–14.0	2.1–28.5	$10^6 - 10^8$
Europe	105–721	39.9 – 200	148–530	1.1–9.6	37–170	42–450	357–1070	2.4–4.0	2.1–14.4	$10^7 - 10^8$

(Table compiled from: Ellis J. B. (1986) Pollutional aspects of urban runoff. *Urban Runoff Pollution, NATO Technical Series,* Torno H. Marsalek J. and Desbordes M. Highway construction can result in equally large increases in sediment yield. For example, in addition to recorded illegal off-site discharges, TSS concentrations of between 3235 and 20 340 mg L^{-1} and 8635 and 46 800 mg L^{-1} have been recorded respectively for the Annan and Kirtle Water over the period April 1993 to May 1995 during the construction of the M74 motorway in Scotland, UK (D'Arcy *et al.*, 2000). The cumulative effect of these nonpoint sediment discharges resulted in 3.9 km of the River Annan and 16.2 km of the Kirtle Water being downgraded from the highest water quality classification standard.

Urbanization and Surface Runoff Flows

The transformation of a watershed from a rural to an urban condition produces three major changes in the hydrological characteristics of receiving streams:

- An increase in flow volume primarily due to the reduction in infiltration following increases in impermeable surfacing with increases in runoff volume being greatest for frequently occurring small, intense storms.
- A decrease in lag time due to a combination of impervious surface runoff and the expansion of the urban drainage net, which reduces hydraulic roughness and increases the velocity of overland flow.
- An increase in peak discharge; this is the combined result of increases in runoff volume and decreases in lag time. A full urbanized watershed with some 50% impervious cover will increase the peak discharge of a 2-year storm by approximately four times.

The relative increase in 0.01 through 0.2 probability storms for runoff peaks and volumes, that is, 100 through 5-year return period storms are 1.8 to 3.0 times the runoff from undeveloped land (for example, see `http://udfcd.org/techpapers.htm`). As the recurrence probability increases to 0.5, that is, a 2-year storm, the runoff after urbanization is about 40 to 60 times or more the undeveloped rate. However, it is the annual (or 1.5-year recurrence interval flow) and more frequently occurring smaller storms that are the dominant channel forming events and which generally shape the watercourse along with being responsible for delivering the majority pollutant load to the receiving water. Further detail on flow effects and related urban drainage design arising from urbanization is also provided by Endreny in **Chapter 117, Land Use and Land Cover Effects on Runoff Processes: Urban and Suburban Development, Volume 3**.

Given the need to capture and convey large floods up to the 100 RI storm event that result from increased surface runoff, traditional engineering of urban waterways has been to employ straightened concrete-lined channels with safety walls or gabion buttresses. Flows along these watercourses are flashy and potentially hazardous to local residents, thus longitudinal slopes need to be reduced using grade control drop structures, low/trickle flow channels, on-line riffle/pool sequences, sinuous low-flow paths, and so on.

Flow and Quality Pathways

Figure 1 illustrates the various source inputs (heavy-bordered boxes), outputs (or sinks shown by dashed boxes) and pathways of water and pollutants for both natural and anthropogenic sources that are encountered within an urban catchment. There may be unintentional pathways whereby flows leave the sewer pipes via exfiltration or where elevated groundwater levels act as a source and add water into the sewer system via pipe infiltration. The former loss is generally of a small scale and less than 2 to 3% of total flow volume due to joint sealing by sediment and biofilm growth in the sewer pipe (Ellis *et al.*, 2004). The latter gains by infiltration can be much more substantial, particularly following prolonged rainfall periods that elevate the catchment water table above the level of the sewer pipe invert.

URBAN RUNOFF IMPACTS ON RECEIVING WATERS

Introduction

The various impacts of urbanization on the water cycle are independent, and they have a synergy that reinforce each other and lead to a general deterioration and loss in water use. This yields the paradox that it is urban areas, which have the greatest requirements in terms of water and aquatic amenity use, water quality, and flood protection, but are characterized by the highest flood and pollution risks and have the most highly degraded aquatic environments. Some detail on the relationship between infrastructure and resulting water quality is also given by Baker in **Chapter 188, Land Use and Water Quality, Volume 5**.

The most significant urban receiving water impacts are caused by discharges from both separately sewered SWOs and CSOs with the nature and magnitude of the impact being dependent on the characteristics of the generating watershed and the interactions with the receiving waterbody. Such impacts need to be evaluated in terms of specific characteristics at each site, including physical habitat changes, water quality changes, sediment and toxic pollutant impacts, impacts on biological communities, and groundwater impacts. Discharges of fecal bacteria also pose health risks, particularly during and immediately after wet weather events. Such physical, chemical, and biological effects will operate at varying temporal and spatial scales. Temporal scales correspond to the nature of acute (short-term) and chronic (long-term accumulative) impacts with intermittent water quality criteria normally related to exposure duration and return period of the impact-causing event

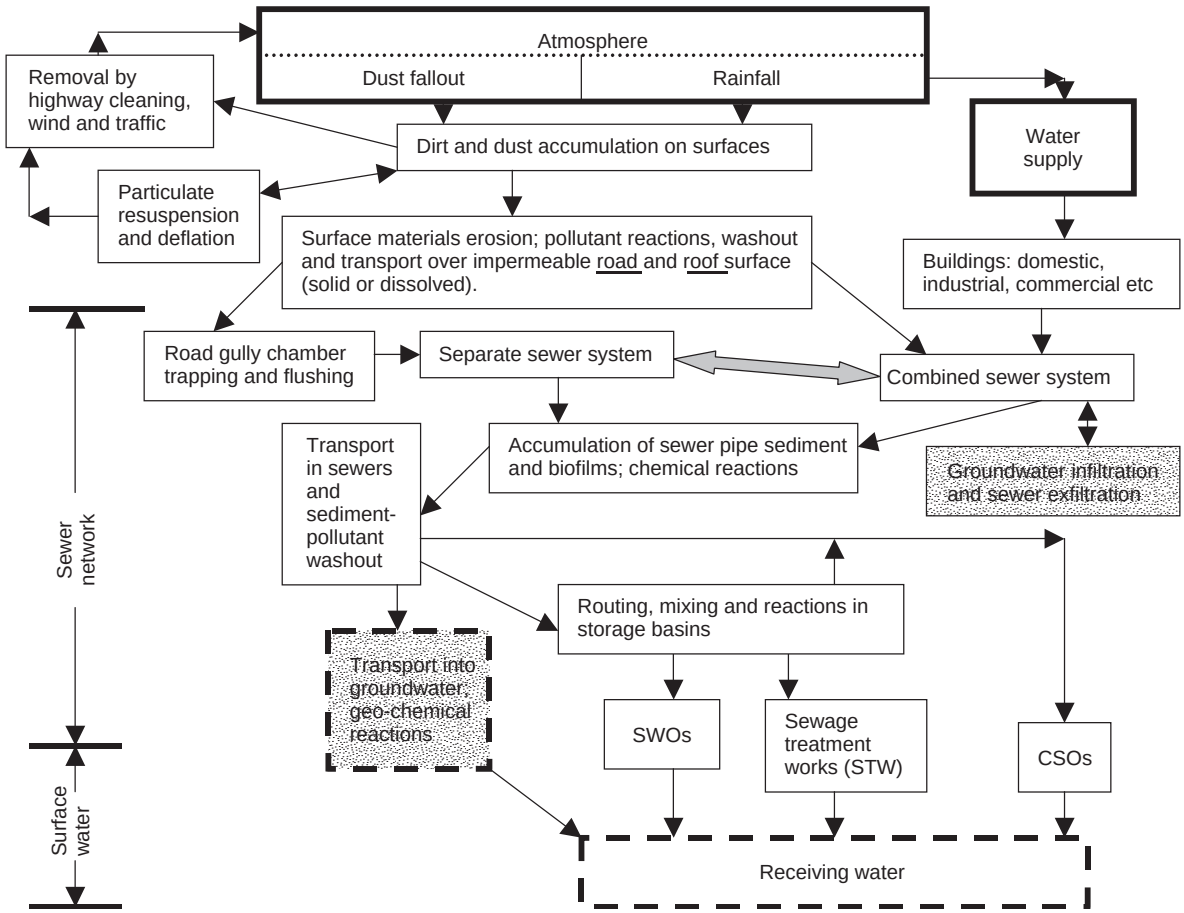

Figure 1 Urban runoff pathways

as well as the pollutant concentration. The typical recovery time after a CSO event is on the order of 5 to 7 days. However, it cannot be concluded that compliance with such criteria will provide guaranteed long-term protection as continued episodic exposure and perturbation can lead to a permanent weakening of the aquatic ecosystem and prevent ultimate recovery.

Receiving Water Impacts

Physical habitat changes Urbanization can permanently modify the nature, form, habitats, and behavior of receiving water bodies that are frequently "canalized" or heavily modified to contain the flood channel and improve storm flow conveyance. Such regulated channels will have altered fluvial dynamics typified by increased sedimentation and high erosion potential, which, in turn, influences stream morphology and channel characteristics as well as in-stream habitat and substrate conditions. Bed sedimentation also limits exchange between surface and underground waters across the hyporheic zone.

Water quality changes Dissolved oxygen (DO) depletion from intermittent urban discharges is a well recognized phenomenon with the soluble organics transported in the water phase exerting an immediate DO depletion with the scouring effect of increased flow on basal sediments adding to this effect, which can be further exacerbated by the presence of ammonia. Settleable solids accumulate on the bed and can result in delayed DO depletion due to an increase in the sediment oxygen demand (SOD) as well as facilitating anoxic conditions under ice cover during winter months. Pollutants discharged from both CSOs and SWOs contribute a range of adsorbable and settleable pollutants derived from sewer deposits, wastewater effluents, and urban surfaces. Owing to the nature and amount of biodegradable organics, anaerobic conditions may prevail in receiving water sediments and accumulated metals, hydrocarbons, and bacteria can then impose long-term, chronic impacts on the sediment community. Approaches to multidimensional water quality modeling of waterbodies receiving polluting discharges are outlined by Lin and Falconer in **Chapter 17, Hydrological and Environmental Modeling of Transport Processes in Rivers and Estuaries, Volume 1**.

Ecological changes The generic characteristics of urban receiving water ecology are habitat instability and ecotoxicity. The urban stream is dominated by taxa, which can tolerate successive erosional–depositional sequences and transient, low-quality food sources with limited leaf decomposition and short retention times for organic matter. Numerous studies have demonstrated the adverse biotic effects resulting from episodic urban discharges with suppression of ecological diversity occurring downstream of outfalls. The analysis of ecological diversity and associated community structures, together with benthic toxicity testing, provide powerful tools for assessing urban runoff impacts (Rochfort *et al.*, 2000; Ellis, 2000). However, many urban drainage studies have failed to demonstrate with any statistical certainty that water concentrations downstream of SWOs are any more toxic than upstream of the discharge. Acute toxicity tests undertaken by the Canadian National Water Research Institute (Marsalek *et al.*, 1999) on 58 stormwater and 65 CSO samples showed the majority to be nontoxic or only potentially toxic at 67% and 93% for stormwater and CSOs respectively. Similar results have been obtained in studies of highway runoff in the United Kingdom (Moy *et al.*, 2003).

The inhibition of acute toxicity observed by many stormwater studies may simply reflect the pollutant-complexing and binding effects, which occur in the presence of organic rich effluent. Genotoxicity and longer-term chronic toxicity may present more severe problems for urban waterbodies receiving stormwater runoff and CSO discharges. Bioavailability can be locally enhanced by sediment organic carbon content and pH as well as particle size, with interstitial waters being the principal route of uptake for sediment-associated contaminants. It may be the cumulative and interactive effects of water and toxic sediment quality as well as fluctuating flow and physical habitat constraints, which collectively lead to patterns of reduced biotic community status and diversity in urban receiving waters.

Public health risks The design of CSOs and SWOs means that untreated sanitary waste and contaminated effluents discharge to urban receiving waters, and it is widely recognized that urban runoff contains a wide variety and frequently high numbers of pathogenic bacteria and viruses which raise potential public health risks. During 2002, 21% of US beach closures were due to bacterial discharges associated with stormwater runoff in comparison to CSOs, which were responsible for only 1% of closures (US EPA, 2004).

Groundwater impacts There is little clear evidence of any substantial or widespread impact of urban runoff or sewer exfiltration on groundwaters (Ellis *et al.*, 2004), although both winter salting and herbicide applications in urban areas can generate levels above the drinking water standard in adjacent groundwaters.

Aesthetic deterioration Research into the public's perception of urban receiving water quality and the potential for the sustainable management of water uses for amenity, recreation, and nature conservation has shown that they generally perceive most urban rivers as being polluted, even when the chemical and ecological quality may be acceptable (House, 1996).

INTEGRATED URBAN DRAINAGE MANAGEMENT

Concepts and Main Issues

Urban discharges may cause numerous adverse effects on receiving waters with the impacts being exacerbated by traditional drainage systems and end-of-pipe solutions, which often appear to be expensive and inefficient. Increased concerns about such impacts have led to the development of new solutions based on the general concept of integrated urban water management (Figure 2), which provides a holistic integration of flood protection, water supply management and protection, groundwater quality, wastewater management, and receiving water quality. Such total urban water cycle management must be firmly linked to the question of urban sustainability (Lawrence *et al.*, 1999; Marsalek and Chocat, 2002). The emerging issue is probably to minimize the impacts of construction through better planning and design of the urban development itself. This idea is central in the concepts of low impact development (LID), sustainable development design (SDD), and "smart growth" planning (SGP). A characteristic of SDD/SGP smart growth development is a reduced footprint, leaving intervening and adjoining land available for open space, habitat development, and off-site drainage controls such as wetlands or detention basins.

Different Kinds of Actions

Sustainability implies an equilibrium among the three sets of demands; the needs of environmental protection, economic needs, and the needs of the society. So far, most attention has focused on environmental needs (e.g. attenuation of increased flows, sediment exports, chemical and bacteria fluxes). Relatively little is known about the economic and social aspects of new water and wastewater management systems needed to facilitate a full development of urban water resources to meet the needs of society. However, the introduction of sustainable principles for future urban developments being required by many regional and national planning administrations is driving new agendas and approaches for strategic urban infrastructure including the implementation of alternative drainage designs and integrated water resource management approaches, as indicated in Figure 2.

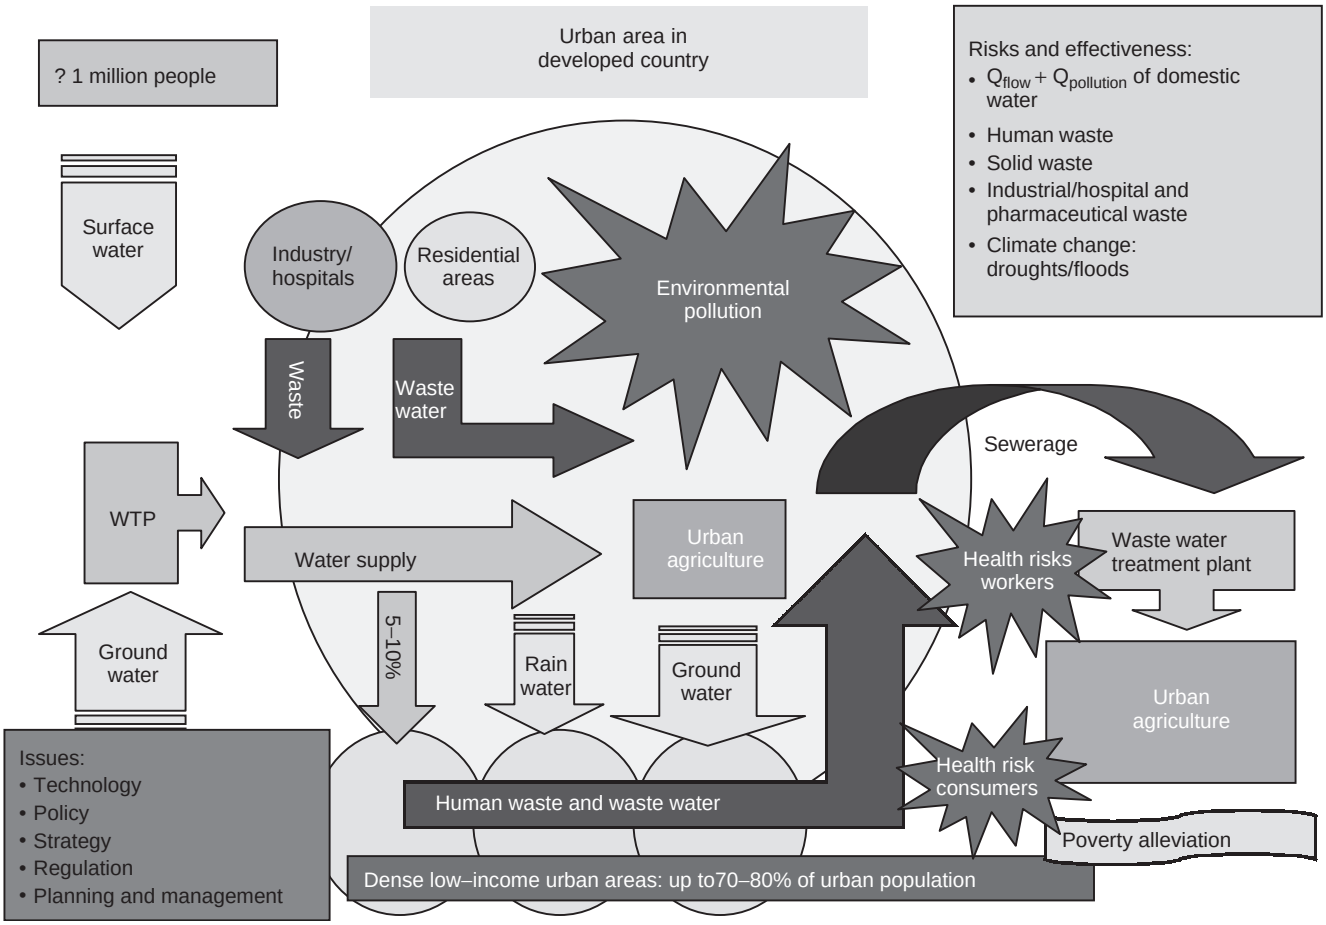

Figure 2 Sustainable urban drainage management. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Integrated Urban Water management implies actions at four levels, which can be referred to as follows:

1. *Policies and nonstructural controls*: These proactive measures are generally highly cost-effective, and for that reason are considered in all stormwater management plans and include public awareness/education/participation; urban development planning; management of material use, exposure, and disposal controls; spill prevention and cleanup; prevention/elimination of illegal dumping and illicit connections; and street and stormwater facilities maintenance (ASCE, 1998). These approaches require a close cooperation between planners, drainage designers, and community stakeholders from the early stages of land development.
2. *Best Management Practices* (BMPs) *for stormwater control and treatment*: These include a variety of reactive structural source and site controls offering cost-effective flow and quality control performance (**www.bmpdatabase.org**; **www.wsud.org.au**) as well as potential ecological and amenity benefits (**www.ciria.org.uk/suds**):

- Lot-level source controls; such measures include enhanced rooftop detention, flow restrictions at catchbasins to enhance local storage/detention, measures to slowdown runoff flow and enhance infiltration along with implementing stormwater harvesting and reuse.
- Local stormwater storage either on roofs or in small cisterns or reservoirs.
- Biofiltration by grass filters, swales, and pocket wetlands; these measures reduce runoff volume by infiltration and enhance runoff quality by such processes as settling, filtration, adsorption, and biouptake resulting in TSS reductions of at least 50%.
- Infiltration facilities; these BMPs serve to reduce the volume and rate of runoff, reduce pollutant transport and recharge groundwater.
- Permeable and porous pavements; introduced within urban areas in order to reduce runoff from impermeable surfaces. Total outflow TSS

concentrations for such structures are typically 10 to 20 mg L^{-1} with both solid metals and organics being reduced by 60 to 80%.

- Water quality inlets, which provide some stormwater treatment by sedimentation and skimming of floatables and oil. French and UK experience with these systems indicates very low effectiveness, except for interception of accidental oil spills with low pollutant removal rates and release of captured pollutants being reported (Bardin *et al.*, 2001).
- Filters; stormwater sand filters have been introduced in the United States with considerable success, although reports from Australia and New Zealand have been less encouraging. They are effective in removing pollutants (Urbonas, 1994), but, to maintain their effectiveness, they may have to be back-washed regularly and the risk of clogging should be reduced by stormwater pretreatment.

3. *Community-level BMPs:*

- Community infiltration facilities; these facilities comprise infiltration trenches and basins of somewhat larger scales than those provided at the site level.
- Stormwater management ponds; stormwater ponds (or wet retention basins) are used widely in Australia, Canada, Western Europe, and the United States to provide various types of controls, including flow control (reduction of flow peaks), sedimentation, and removal of dissolved pollutants by marginal aquatic plants. Outflow pollutant concentrations from these facilities are normally a function of the influent concentrations, but reductions of an order of magnitude are feasible for solids and solid-associated pollutants. Ponds may accumulate large quantities of contaminated sediments, which may be polluted with heavy metals and persistent organic pollutants, including polycyclic aromatic hydrocarbons (PAHs). Both metals and PAHs in deposited sediments may be released into the water column in response to changes in the water quality and flow-through rates.
- Constructed wetlands; wetland BMPs provide stormwater detention and treatment by various processes, including filtration, infiltration, and biosorption, and serve as cost-effective treatment systems for both particulate and dissolved pollutants.
- Extended detention (dry) basins; such basins are widely applicable and can provide stormwater settling in those areas where it is difficult to maintain wet facilities.

These BMPs are often used within multiple (treatment-train) systems. In these hybrid systems, two or more BMPs may be stacked vertically or in a series, to increase the system performance or reliability, or to reduce the maintenance. Such multiple treatment train systems are rapidly becoming the norm in new greenfield and brownfield urban developments as they provide an effective approach to full effluent treatment.

4. *Watershed-level Measures*: The watershed or catchment is a logical unit for water and wastewater management planning and forms the basis, for example, for most European drainage regulation and management. Urban drainage and stormwater management strategy should be included in watershed plans, developed in a hierarchical manner, using an ecosystem approach and providing a basis for the development of more detailed drainage management plans. Yet, in many countries, such an approach is difficult to implement efficiently since organizations involved in urban management are frequently different from those involved in watershed management. The development of new strategies or technologies is strongly impeded by economic problems (costs, financing), sociological problems (acceptance by the public, fragmentation of duties and responsibilities), urban planning challenges (integration into the landscape), organizational cooperation, problems with policies and regulations, and so on. Nevertheless, such integrated, source-control strategies represent a sustainable approach for both developed and developing countries, enabling the adverse effects of urbanization to be addressed at an affordable cost.

WATER AND WASTEWATER REUSE

Background

The concept of total water cycle management in urban areas provides a logical context for water reuse and recycling (Lawrence *et al.*, 1999). The extent to which such measures are practiced depends on water availability, economic incentives, regulatory feasibility, and public acceptance. Reuse can be either direct (reclaimed water is transported to the points of reuse), or indirect, whereby reclaimed water is first discharged into receiving waters or aquifers and then reused (see Figure 2).

Wastewater Effluent Reuse

Stormwater Reuse: Rainwater/stormwater reuse is currently practiced in many countries as a result of the widespread use of stormwater management, which often involves various forms of rainwater/stormwater reuse and thus provides double benefits – mitigation of runoff and its pollution, and provision of subpotable water supply. Typical examples of stormwater reuse include collection and reuse of residential and commercial roof runoff for irrigation or toilet flushing, collection of roof water from dome stadiums for toilet

flushing and landscape irrigation, and treated stormwater reuse for industrial processes, boiler feed, or cooling waters. In stormwater reuse, the most feasible source appears to be roof runoff, which represents the source with the best water quality; other sources of stormwater, particularly runoff from streets and highways, may be too polluted and expensive to treat for reuse. Even in the case of roof runoff, there are concerns (Eriksson *et al.*, 2002) about its quality, mostly due to heavy metals (from roofing materials, depending on the rainwater pH), chemicals in dry atmospheric deposition (depending on local or remote sources and air transport), and fecal bacteria (bird droppings). Collected roof water is usually treated, using such processes as filtration, screening, settling, and UV disinfection.

Greywater Reuse: In the management of domestic wastewater, one of the options receiving much attention in recent years is the at-the-source separation into two separate flows; blackwater, or toilet waste, and greywater representing all remaining household wastewater. Greywater has been studied as an alternative source of water for nonpotable applications, including irrigation, and toilet flushing. Examples of greywater reclamation and reuse include subsurface irrigation, greywater treatment, and disinfection for toilet flushing, greywater reuse in experimental housing, and a major in-building water recycling scheme at the Millennium Dome (UK), where the system provided 55% of the water demand at the site in the form of greywater from washroom sinks, rainwater from the Dome roof, and groundwater (Hills *et al.*, 2002).

Unseparated Wastewater Reuse: General wastewater reclamation and reuse has been called "the greatest challenge of the twenty-first century" (Asano, 2002). It has the potential to bring about two great benefits – (i) provide a reliable source of water and (ii) keep wastewater pollutants out of receiving waters. Basic principles of wastewater reuse include three underpinning principles (i) providing reliable treatment corresponding to the intended reuse, (ii) protecting public health, and (iii) winning public acceptance (Asano, 2002). The approach taken to wastewater reuse depends on the intended category of reuse, with seven types of reuse commonly practiced: (i) agricultural irrigation, (ii) landscape irrigation, (iii) groundwater recharge, (iv) industrial process water, (v) environmental and recreational uses, (vi) subpotable urban uses, and (vii) indirect or direct potable reuse.

Recharge and Direct Reuse

Groundwater recharge is another large-scale application practiced by spreading/infiltration basins or direct injection to groundwater aquifers. The ideal soils for soil-aquifer treatment (SAT) balance rapid recharge (i.e. a coarse-textured soil) with efficient contaminant adsorption and removal. Recreational and environmental (ecological) uses involve nonpotable uses related to land-based water features such as the development of recreational lakes, wetlands, and stream augmentation (Asano, 2002). Nonpotable urban uses include fire protection, air-conditioning, toilet flushing, construction water, flushing of sanitary sewers, heat source or sink (in heating, air-conditioning or snowmelting), snow making, and landscape irrigation.

The most challenging category of wastewater reuse is potable reuse, practiced either by replenishment of water supply storage, or by direct input of highly treated reclaimed water into the water distribution system. Although direct reuse has been demonstrated in the City of Windhoek, Namibia (Harhoff and van der Merwe, 1996), similar applications in industrial countries are highly unlikely, mostly because of the lack of public acceptance and concerns about a safe and complete removal of new chemicals of concern (e.g., endocrine disruptors, pharmaceuticals, personal care, and therapeutic products) and pathogens from the reclaimed water (Marsalek *et al.*, 2002).

FUTURE PERSPECTIVES

Today it is generally accepted that urban surface water, groundwater, and wastewater should be considered in relation to each other and to their interactive impacts on water flows, receiving water pollution and aquatic ecology. This is recognized in the very high investment effort being made in many countries to reduce urban flooding and pollution risks and to provide sustainable urban drainage systems. Since the passage of the US Clean Water Act in 1972, the EPA, states and local water pollution control agencies have undertaken numerous actions and initiatives to reduce both CSO and SWO impacts. Some $11 billion has been invested since 1998 on injunctive relief schemes and $75 million on urban drainage improvement schemes (US EPA, 2004). The Urban Wastewater Treatment Directive and forthcoming Water Framework Directive within Europe is likewise driving stepwise improvements for urban drainage infrastructure with capital investment within the United Kingdom alone reaching £2.8 billion over the 2000–2005 period.

However, in any analysis of future trends and drivers affecting urban water systems, sustainable development is only one, albeit important, influencing factor. Population and demographic trends are of equal significance. The number of megacities with greater than 10 million inhabitants is expected to increase to over 20 by 2050 (with 80% being located in developing countries), with some 70% of the world population living in urban areas. Inevitably such large-scale urbanization has severe implications for urban water conditions and requirements, particularly given that on a global scale, only about 15% of wastewater is treated (**www.thewaterpage.com**). In western cities,

although major demographic shifts including ageing populations and falling average household occupancy are likely to keep population levels relatively stable, such trends are also likely to lead to higher per capita water and wastewater infrastructure demands. The rise of consumerism, individualism, and increased disposable incomes in western societies will also generate new drivers for future water and wastewater resource supply and management as exemplified by the substantial rise in bottled water supplies, water-using domestic appliances, separated waste streams and waste recycling schemes.

A major influencing factor on future urban water resource management will be climatic change. Such change will have major implications for water resources, urban flooding, and receiving water pollution as predicted in the recent UK government Foresight Future Flooding report (OST, 2004). This analysis of urban drainage risk was conducted within the context of scenarios of differing socioeconomic futures, as depicted in Figure 3. The vertical dimension shows the system of governance, ranging from autonomy where power remains at the regional/national level to globalization or interdependence where power increasingly moves to other institutions such as the European Union. The horizontal dimension in the figure shows social values, ranging from individualistic values to community-oriented values. Central to the scenario identification is the recognition that different mechanisms of state and market regulation will influence decision-making. The driver with the greatest influence on future urban drainage was precipitation and its spatial and temporal change. Other important physical drivers were identified as urban creep, increases in groundwater infiltration, and receiving water pollution in addition to regulation, public attitudes to flooding and the ability/willingness to pay for future infrastructure improvements.

Chocat *et al.* (2004) have proposed the evolution of four possible future scenarios for urban drainage. The "green" scenario, dominated by decentralized source-control approaches with minimum sewer connections and extensive wastewater recycling and water conservation, is equivalent to the community-based, local stewardship quadrant of Figure 3. The conservative "technocratic" scenario adopting centralized advanced technology, monopolistically retained, and managed within the public sector, reflects the regionalized, national enterprise socioeconomy of Figure 3. The "privatization" scenario is clearly consumer and world market oriented and represents the predominant strategy operating within many developing countries at present. The final scenario suggested by Chocat *et al.* (2004) is that of "business-as-usual" which stumbles between the technocratic tradition and green ideas as well as picking up varying degrees of privatization.

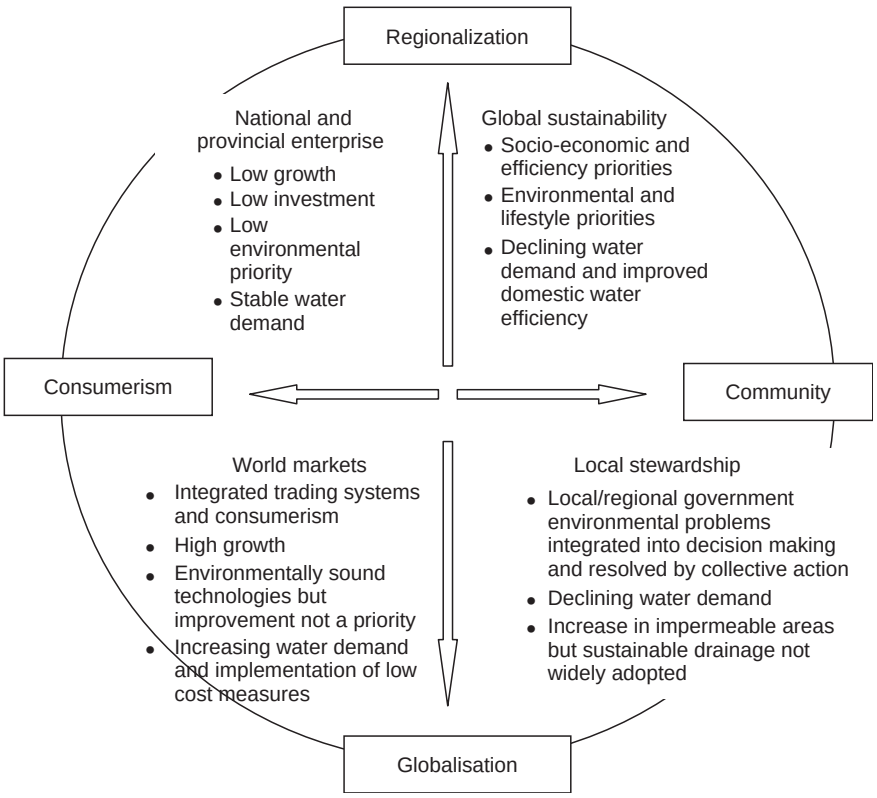

Figure 3 Socioeconomic futures

The scenario analysis approach provides no firm indication of which future might be more probable than another, although it is important to note that technical solutions do not map clearly to particular socioeconomic futures and that the high existing sunk asset value of urban drainage means that there is always likely to be considerable inertia and conservatism in the water industry. Thus, it is feasible to visualize a "no-change" (or little change) future scenario with urban water resource managers having a lack of control with respect to land use planning and chemical usage as well as being underfunded.

Alternative perspectives have been widely canvassed, with some indicating a complete revolution in future urban water systems in terms of new paradigms, new contexts, and new methodologies (Maksimovic and Tejada-Guibert, 2001). This thinking is based on the introduction of multidisciplinary, integrated approaches to urban drainage incorporating sustainable principles, the adoption of network, risk, and vulnerability analysis, complex modeling, incorporation of educational and social values as well as anticipatory and contingency scenarios for addressing new impacts such as climate change.

98: Pathogens

CHARLES P GERBA

Department of Soil, Water and Environmental Science, University of Arizona, Tucson, AZ, US

Water plays a major role in human disease by serving as the vehicle for the transmission of disease-causing microorganisms (pathogens), and as a habit for some of their insect hosts. Worldwide, it is estimated that a child dies every 8 s from water-related diseases. New pathogens, which are transmitted by water, are recognized on a continuing basis providing challenges to both watershed management and water treatment technologies. Microorganisms transmitted by the fecal-oral route or waterborne pathogens are the most widespread since many may occur in the feces of both infected humans and animals. All surface waters can be expected to contain waterborne pathogens at one time or another. Feces from animals and sewage discharges contaminate surface waters. Groundwater may be contaminated from infiltration from land disposed human and animal wastes or water contaminated with these wastes, septic tanks, and unlined landfills. Contamination of surface and groundwater is always greatest after rainfall events due to the flushing of accumulated animal feces and infiltration of soils. Waterborne pathogens may survive for days to months in the environment. Survival of pathogens in the water environment is largely dependent on temperature and sunlight exposure.

INTRODUCTION

Disease-causing microorganisms are referred to as *pathogens*. A very small number of microorganisms are capable of causing disease in man and animals, but they have a major impact on human health. Pathogenic microorganisms are still the leading cause of death worldwide, and pathogens in which water is related to their spread are major contributors to mortality and morbidity. The World Health Organization estimated in 1996 that every 8 s a child died from water-related disease and that each year more than five million people died from illness linked to unsafe drinking water or inadequate sanitation (WHO, 1996). Waterborne outbreaks of disease continue to occur as well in the developed world. New waterborne pathogens have been discovered almost yearly over the last 20 years, while others have been introduced into the developed world from increased globalization of travel and food resources. This has created an increased awareness of the importance of watershed and water treatment management for their control. Control of diseases spread by water will continue to be a major challenge in the foreseeable future.

Waterborne diseases are those transmitted through the ingestion of contaminated water (Table 1). They are usually excreted in the feces of infected persons in large numbers and can survive in the water environment from a few days to many weeks. Thus, waterborne diseases are transmitted through the fecal-oral route, from human to human or animal to human. Waterborne diseases include the agents of cholera, typhoid fever, and infectious hepatitis.

Water-based diseases are caused by pathogens that either spend all (or essential parts) of their lives in water or depend upon aquatic organisms for the completion of their life cycles. Examples of such organisms are the parasitic helminth, Schistosoma and the bacterium *Legionella pneumophila*, which cause schistosomiasis and Legionnaires diseases respectively.

Water-related diseases, such as West Nile, yellow fever, St. Louis encephalitis, dengue, and malaria, are transmitted by insects that breed in water (e.g. mosquitoes that carry malaria) or live near water (e.g. the flies that transmit the filarial infection onchocerciasis). The major waterborne and water-based pathogens and diseases they cause are shown in Tables 2–5. Viruses consist solely of nucleic acid (which contains the genetic information) surrounded by a protective protein coat called a *capsid*. The nucleic acid may be either ribonucleic acid (RNA) or deoxyribonucleic acid (DNA). They cannot grow outside of living cells

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Table 1 Type of water-related illnesses associated with pathogens

Type	Cause	Example
Waterborne	Pathogens that originate in fecal material and are transmitted by ingestion	Cholera, typhoid fever, *Giardia*
Water-based	Organisms that originate in water or spend part of their life cycle in aquatic animals and come in direct contact with humans in water or by inhalation	Schistosomiasis, *Legionella*
Water-related	Organisms with life cycles associated with insects that live or breed in water	Yellow fever, West Nile virus

Table 2 Major waterborne enteric viruses

Virus group	Serotypes or types	Some disease caused
Enteroviruses Poliovirus	3	Paralysis, fever, aseptic meningitis
Coxsackievirus	29	Herpangia, paralysis, aseptic meningitis, heart disease, fever
Echovirus	34	Respiratory illness, aseptic meningitis, diarrhea, heart disease, rash
Enteroviruses (68–71)	4	Meningitis, eye infection, respiratory illness
Astroviruses	5	Diarrhea
Hepatitis E	1	Hepatitis
TT virus hepatitis	1	Hepatitis
Reoviruses	3	Respiratory illness
Rotaviruses	5	Diarrhea
Adenoviruses	49	Respiratory disease, eye infections, diarrhea

(animals, plants, bacteria) and do not need food to survive. Viruses transmitted by the fecal-oral route are capable of surviving for long periods of time in water. Viruses that infect bacteria are called *bacteriophages*, and those bacteria that infect coliform bacteria are called *coliphages*. Bacteria are single-celled organisms surrounded by a membrane and cell wall. Bacteria that grow in the human intestinal or gastrointestinal (GI) tract are referred to as *enteric bacteria*. Enteric bacterial pathogens usually cannot survive for prolonged periods of time in the environment. Protozoa are single-celled animals. Protozoan parasites that infect humans are capable of producing environmentally resistant cysts or oocysts. These cysts or oocysts have very thick walls, which make them very resistant to disinfection. Helminths (literally worms) are multicellular animals that parasitize humans. They include roundworms, hookworms, tapeworms, and flukes. Helminths lay eggs that are excreted in the feces of infected persons. These eggs are capable of prolonged survival in water and soil.

Table 3 Major waterborne bacteria

Bacterium	Major disease
Salmonella typhi	Typhoid fever
Salmonella paratyphi	Paratyphoid fever
Salmonella spp	Diarrhea
Shigella	Bacillary dysentery
Vibrio Cholerae	Cholera
Pathogenic *E. coli*	Diarrhea, Hemopytic uremic syndrome
Yersinia enterocolita	Diarrhea
Campylobacter jejuni	Diarrhea
Helicobacter pylori	Common ulcer
Leptospira	Leptospirosis (Weil's disease)

Table 4 Major water-based pathogens

Organism	Major disease
Legionella pneumophila	Acute respiratory illness (Legionnaires' disease) Pontiac fever
Mycobacterium avium	Respiratory illness
Pseudomonas aeruginosa	''Swimmer's ear'' skin infections
Naegleria fowleri	PAM[a]

[a]PAM – Primary amoebic meningoencephalitis.

TYPES OF PATHOGENS

Viruses

More than 140 different types of viruses are known to infect the human intestinal tract and are excreted in the feces. Viruses that multiply in the intestines are referred to as *enteric viruses*. Some enteric viruses are capable of replicating in other organs such as the liver, heart, eye, skin, respiratory tract, and nerve tissue. For example, hepatitis

Table 5 Some characteristics of waterborne/water-based transmitted parasites

Organism	Infective form	Mechanism of transmission	Reservoirs
Giardia lamblia	Cyst	Person – person Waterborne Foodborne	Humans, beavers, muskrats, voles
Cryptosporidium parvum	Sporulated oocyst	Person–person Waterborne Foodborne	Many vertebrates, especially cattle
Entamoeba histolytica	Cyst	Person–person Waterborne Foodborne	Usually humans (potentially pigs, primates, and dogs)
Naegleria fowleri	Trophozoite	Trophozoite swims up nasal cavity	None: free living in aquatic or soil environment
Cyclospora cayetanesis	Sporulated oocyst	Waterborne Foodborne	None known
Enterocytozoon bieneusi	Spore	Fecal-oral	None known
Encephalitozoon hellem	Spore	Urine-oral	None known
Encephalitozoon cuniculi	Spore	Fecal/urine-oral	Laboratory rabbits, rodents, dogs
Encephalitozoon intestinalis	Spore	Fecal/urine-oral	None known
Toxoplasma gondii	Sporulated oocyst	Oral ingestion from soil or litterbox (oocyst) Undercooked meats (tissue cysts)	Cats: definitive host humans, sheep, goats, pigs, cattle, birds, intermediate hosts
Ascaris lumbricoides	Embroynated egg	Oral from soil contact	Humans
Tricuris Trichiura	Embroynated egg	Waterborne Foodborne	Humans
Necator americanus	Filariform	Skin penetration	Humans
Schistosoma mansori	Cercariae	Penetrate skin	Humans Intermediate host: snail

A virus (HAV) infects the liver, causing hepatitis. Enteric viruses are generally very host-specific; therefore, human enteric viruses cause disease only in humans and sometimes in other primates.

Enteroviruses have been the most studied waterborne viruses because of the ease at which they can be grown in the laboratory. The more common enteroviruses include poliovirus (3 types), Coxsackieviruses (30 types), and the echoviruses (34 types). Although these pathogens are capable of causing a wide range of serious illness, most infections are mild. Infectious viral hepatitis is caused by HAV and hepatitis E (HEV). These viruses are very common causes of infections in the developing world. HEV has been associated with large waterborne outbreaks in Asia and Africa, and cases of high mortality in pregnant women (20 to 30% of those ill). Noroviruses and Saporoviruses are members of the calicivirus family. These viruses are now believed to be the major cause of adult viral diarrhea in the world. They are believed to be the major cause of food-borne diarrhea and have been responsible for numerous outbreaks of waterborne diseases worldwide. Human caliciviruses are only known to infect humans and have never been grown in the laboratory. They cause a diarrhea lasting from one to three days with a low mortality. Rotaviruses are the major cause of acute diarrhea in children under two years of age and a major cause of childhood deaths in the developing world and have been responsible for water- and food-borne illness in adults. Adenoviruses have been responsible for recreational water outbreaks of eye and throat infections associated with swimming pools. Drinking water outbreaks have recently been documented.

The ingestion of just a few viruses are capable of causing infection and for this reason low numbers of viruses in water are considered a potential public health hazard. For this reason, large volumes of water are usually processed for their detection. For example, from 10 to 1000 L of water must be processed. Viruses are concentrated from the water by adsorption onto pleated cartridge filters (Hurst *et al.*, 2002). The viruses are then desorbed from the filters in 1 to 2 L of an eluent, which is concentrated to a few milliliters. Next, the concentrate is assayed by using cell culture or molecular methods, such as the polymerase chain reaction (PCR). The viruses are detected by the destruction of the cell culture (called *cytopathogenic effects* or *CPE*), but this may require days to weeks. PCR can detect and identify viruses in less than a day, but cannot be used to assess their viability (ability to cause infection).

Bacteria

Unlike most enteric viruses, enteric bacteria usually infect man and a wide variety of animals. The exception is bacteria of the genus *Shigella*, which infect only humans. Major waterborne bacteria and the illnesses they cause are shown in Table 3. Food is the most common source of infection in humans, although untreated drinking water (or break downs in water treatment) and recreational waters are also sources of infection.

Campylobacter jejuni is one of the most common identified causes of bacterial diarrhea in the United States. It is a common infection of birds, which is believed to be the major source of human exposure. It has been isolated from 22% of coastal and estuary waters ranging from 10 to 230 campylobacters per 100 mL (Bolton *et al.*, 1982). It has been found in 10 to 44% of pond water samples (Carter *et al.*, 1987). It is thought that virtually all surface waters contain *Campylobacter*. Recovery rates from surface waters are highest in the fall and winter months and lowest during the spring and summer months. *C. jejuni* dies off rapidly at warm temperatures (37 °C), but may survive for over 120 days at 4 °C.

Salmonella is a very large group of bacteria comprising over 2400 known types. All these types are pathogenic to humans and can cause a wide range of symptoms from mild diarrhea to severe illness and death. They are capable of infecting a large variety of both cold- and warm-blooded animals. Typhoid fever, caused by *S. typhi*, and paratyphoid fever caused by *S. paratyphoid*, are both enteric fevers that occur only in humans and primates. *Salmonella* can be detected in almost any nondisinfected domestic sewage or animal wastes.

Escherichia coli is found in the GI tract of all warm-blooded animals and is usually considered a harmless organism. However, several strains are capable of causing diarrhea. One group referred to as enterohemorrhagic *E. coli* (EHEC) is capable of causing serious life-threatening illness in young children and the elderly. EHEC is now recognized as a serious problem in developed countries. EHEC almost always belongs to the single serological type 0157 : H7. The illness usually includes severe cramping and diarrhea, which is initially watery, but becomes grossly bloody. The illness usually lasts only eight days, but, in some individuals, it develops into hemolytic-uremic syndrome or HUS, which results in permanent kidney failure. Cattle feces are the major source of human exposure.

Shigella is closely related to *E. coli. Shigella sonnei* causes a mild diarrhea and is the type most often causing illness in the United States. *Shigella* is a common cause of recreational waterborne outbreaks associated with swimming in lakes and rivers. They do not survive long in natural waters and are very sensitive to inactivation by disinfectants.

The genus *Vibrio* comprises a large number of species, but only a few of these species cause illness in humans. The most famous member of the group is *Vibrio cholerae*, the bacterium that causes cholera. Cholera remains prevalent in many parts of South America, Asia, and Africa. *V. cholerae* serotype 01 produces a toxin, which causes severe diarrhea and, in some cases, can cause death in a few hours because of rapid dehydration. Humans are the only known natural host, although environmental reservoirs may exist, apparently in association with copepods or phytoplankton.

Helicobacter pylori is the major cause of stomach ulcers in humans. The bacterium colonizes the stomach mucosa and produces a layer of mucus to protect itself from the low pH and digestive enzymes present in the stomach. Long-term infection may lead to stomach cancer. While person-to-person transmission is possible, several epidemiological studies have suggested that swimming in and drinking nondisinfected water are associated with infections of this organism (Klein *et al.*, 1991). Studies have shown that drinking untreated groundwater was related to infection with this organism (Baker and Hegarty, 2001).

Legionella pneumophila is the causative agent of Legionnaires disease and Pontiac fever.

Legionnaires disease is a severe respiratory infection, which has a 15% fatality rate in hospitalized cases. Pontiac fever is a milder infection characterized by fever and headache. *Legionella* occurs naturally in water, but appears capable of causing the disease only after growing in water above 20 °C. *Legionella* survives well above 50 °C. Hot water systems, air-conditioning cooling towers, hot tubs, and decorative fountains have been traced to outbreaks of *Legionella*. The bacterium survives for months in tapwater. The primary route of transmission is thought to be through the inhalation of aerosols.

Detection of pathogenic bacteria in water is difficult and time consuming and is not done routinely. The recent developments of molecular methods such as the PCR have made identification more practical. Traditional methods involve the use of enrichment media to select for the growth of the pathogen followed by growth on selective media followed by biochemical tests and the use of specific antibodies. Usually 100 to 1000 mL volumes are tested.

Protozoa

Although first described in 1907, *Cryptosporidium* was not recognized as a human pathogen until 1980. Since that time, it has been responsible for numerous outbreaks of waterborne diseases in the United States and the United Kingdom. In 1993, it was responsible for the largest waterborne outbreak ever documented in the United States. The outbreak, which occurred in Milwaukee, WI, resulted in 400 000 cases of diarrhea and almost 100 deaths (Mackenzie *et al.*, 1994). The source of the outbreak was traced to the occurrence of the organism in treated drinking water.

The protozoan parasite produces an environmentally stable oocyst that is resistant to inactivation at chlorine levels normally used in drinking water treatment. The oocysts range in size from 3 to 6 μm in diameter. After they are ingested, they release four sporozoites, which invade cells in the intestines and cause diarrhea. Cattle and other animals are major sources of oocysts in the environment and commonly occur in surface waters. *Cryptosporidium* can be expected to occur in all types of surface freshwater environments. In the United Kingdom, all finished drinking water treatment plants are continuously monitored for the presence of *Cryptosporidium* to ensure treatment performance. In the United States, limited monitoring of water sources for drinking water treatment plants is conducted every five years to ensure that the treatment process can reduce the oocysts to levels considered safe. Because of the resistance of the oocysts to chlorine, adequate filtration is needed to control the occurrence of the oocysts in treated drinking water. Ultraviolet light has been found to be an effective disinfectant for the control of this organism in water.

Giardia lamblia is the most frequently identified intestinal parasite in the United States (Adam, 1991). Humans become infected with *G. lamblia* by ingesting the environmentally resistant stage, the cyst. Once ingested, it passes through the stomach and into the upper intestines, releasing two trophozoites, causing diarrhea. When *Giardia* cysts enter the environment, they can survive for prolonged periods of time. They have been documented to survive for up to 77 days at 8 °C in distilled water (Bingham *et al.*, 1979). Beavers and muskrats are believed to be sources of *Giardia* in surface waters, but humans are also likely to be a major source. The cysts, measuring 8 to 16 μm, are significantly more resistant to chlorine and ozone disinfection than enteric bacteria and viruses, and outbreaks have been associated with unfiltered drinking water and recreational waters. *Giardia* is also very sensitive to inactivation by ultraviolet light. Because of its large size, it is easily removed by filtration.

Entamoeba histolytica is the cause of amebic dysentery. Humans are the main host, although pigs, monkeys, and dogs have also been found to serve as reservoirs. There are two cysts, small (5–9 μm) and large (10–20 μm) with each cyst producing eight trophozoites. This organism is generally only a problem in developing countries where sanitation is substandard. No waterborne outbreaks have occurred in the United States in more than 30 years. It is easily inactivated by common disinfectants.

Waterborne outbreaks of *Cyclospora cayetanesis*, Microsporidia, and *Toxoplasma gondii* have been documented, but how important water is in the transmission of these protozoa is currently uncertain.

Naegleria fowleri is a protozoa changing between a cyst, amoeba, and flagellate with the amoeba being dominant. The free-living protozoa are ubiquitous and found in fresh waters throughout the world (John, 1982). Cysts are usually present in low numbers, but when the water temperatures exceeds 35 °C (hot springs and warm stagnant waters), the amoeba transforms to the flagellated form rapidly, which enables the organism to swim. Infections are usually associated with children swimming in warm nondisinfected natural springs, lakes, and swimming pools. The flagellate swims into the nose of humans and makes its way via the nerves to the brain, producing a toxin that liquefies the brain, causing death. Infection usually occurs in children. Fortunately, it is a fairly rare infection.

Protozoan parasite detection in water involves collecting the organisms from 10 to 100 L of water by passage through cartridge filters, which collect them by size exclusion (Hurst *et al.*, 2002). The organisms are then eluted from the filters and further concentrated through centrifugation and capture on magnetic beads coated with antibodies for the specific organism to be detected. The organisms are then stained with fluorescently labeled antibodies specific for the organism to be detected. The cyst or oocyts are identified under an ultraviolet light microscope for the fluorescing organism and further characterized by shape, size, and internal structures.

Helminths

Helminths are multicellular animals that are transmitted by water and are parasitizing to humans. They include the Nematoda (roundworms) and the Platyhelminths, which are divided into two subgroups: the Cestoda (tapeworms) and the Trematoda (flukes). In these parasitic helminths, ova or eggs constitute the infectious stage. Excreted in the feces of infected persons and spread by water, soil, or food, these ova are very resistant to environmental stresses and to disinfection. The most important parasitic helminths are listed in Table 5. The ones causing the most common infections are largely transmitted by contact with fecally contaminated soil or food, although transmission by contaminated water may occur.

Ascaris is a large intestinal roundworm and a major cause of infections in humans worldwide. Worldwide estimates indicate that between 800 million and one billion people are infected, with most infections being in the tropics and subtropics. In the United States, most infections tend to occur in the Gulf Coast. Although most infections are mild, death can result from intestinal blockage. The life cycle of this parasite includes a phase in which the larvae migrate through the lungs and the throat before being swallowed. Although the eggs are dense, and hence readily removed by sedimentation in wastewater treatment plants, they are very resistant to the action of chlorine.

Schistosoma spp. are worms (trematodes or flukes) that have two deep suckers, which are used for attachment. The life cycles are complex, requiring an intermediate host (snail) to complete their life cycle; humans are the definitive host, excreting eggs in the feces. *S. mansoni* is the most important worldwide and is responsible for more than 200 million infections worldwide and causes up to 200 000 deaths annually (Hopkins, 1992). Cercariae are released from infected snails into the water environment and penetrate the human skin and migrate from the lungs to the liver. The adult worms then migrate to the circulatory system to other organs. The eggs are excreted in the feces or urine.

Helminths are detected in water by centrifuging a 100-mL to 1-L sample and resuspension in a smaller volume, which is examined under the microscope for specific ova or eggs characteristic of the individual species (Ayres and Mara, 1996).

INDICATOR MICROORGANISMS

Because of the difficulty and time necessary for the detection of waterborne pathogens, more easily detected enteric bacteria or bacteriophages (viruses which infect enteric bacteria) are used as indicators of fecal contamination and potential presence of enteric pathogens. Developed at the beginning of the twentieth century, the indicator concept depends on the fact that certain nonpathogenic bacteria occur in the feces of all warm-blooded animals. These bacteria can easily be isolated and quantified by simple laboratory techniques. The coliform group has been used as the standard for assessing fecal contamination of drinking water for almost a hundred years. This group includes all aerobic and facultatively anaerobic, gram-negative, nonspore-forming, rod-shaped bacteria that produce gas upon lactose fermentation in prescribed culture media within 48 h at 35 °C. Through experience it has been learned that absence of these organisms in 100 mL of drinking water ensures the prevention of enteric bacterial disease outbreaks. However, it has been learned that threats of disease may still exist from enteric viruses and protozoa, which have a greater resistance to disinfectants and survive longer in the environment. In addition, coliforms may originate from nonfecal sources and regrow in water under some conditions. Fecal coliforms include the genera *Escherichia* and *Klebsiella*, and are differentiated in the laboratory by their ability to ferment lactose with the production of acid and gas at 44.5 °C within 24 h. Fecal coliforms have been used as standards to indicate the quality of recreational waters. *E. coli* and enterococci (another group of enteric bacteria found in human feces) have been shown to be more specific indicators of fecal contamination, and concentrations of them in recreational water have been shown to be related to risk of gastroenteritis from swimming in surface waters (Cabelli *et al.*, 1982).

Because of their constant presence in sewage and polluted waters, the use of bacteriophages as appropriate indicators of fecal pollution has been proposed (Havelaar *et al.*, 1993). Bacteriophages have also been suggested as indicators of human pathogenic enteric viruses and have been used as models to assess human enteric virus behavior during water treatment and in the environment. Bacteriophages of *E. coli*, referred to as *coliphages*, have been the ones most commonly studied. The use of coliphages as indicators of fecal pollution is based on the assumption that their presence in water denotes the presence of bacteria capable of supporting the replication of the phage. Two groups of phage have been studied: the somatic coliphage, which infects *E. coli* strains through cell wall receptors, and the F-specific RNA coliphage, which infects strains of *E. coli* through the F+ or sex pili. Most F+ coliphages are similar in shape and size, as most of the waterborne enteric viruses and tests have been developed to specifically detect this type of coliphage.

FATE AND TRANSPORT IN THE ENVIRONMENT

Once released from the infected host, waterborne pathogens must survive long enough to infect another host. Enteric pathogens may survive from a few days to many months in the environment, depending on a number of important factors. Generally, helminths eggs survive the longest followed by viruses, protozoa, and bacteria. Enteric bacterial survival is the most limited because they need nutrients and have difficulty in competing with indigenous microflora outside the host. Since water is their natural habit, water-based pathogens increase in number under the proper environmental conditions.

Temperature is the most important factor controlling waterborne pathogens. Generally, the lower the temperature, the longer is the survival time of pathogens. Freezing is detrimental to the survival of helminths eggs, bacteria, and protozoa. However, at freezing conditions, viruses may survive for many years.

Surface Waters

Sources

Enteric pathogens in surface waters primarily originate from runoff during rain events and sewage discharges. Livestock is the primary source of pathogens on agricultural land (Khaleel *et al.*, 1980). Rainfall results in the movement of accumulated animal fecal material on land to nearby water bodies. In some urbanized areas, runoff is collected by the sewage collection systems during major rainfall events and the ability of sewage treatment plants to treat these combined wastes may be exceeded, resulting in the release of untreated sewage.

Table 6 Percentage of animals shedding selected waterborne zoonotic pathogens

Pathogens	Cattle	Calves	Sheep	Pig	Rodents	Waterfowl
Cryptosporidium sp.		20–90	8–40	5 – 20	30	13–100
Giardia sp.	57–97					
Campylobacter spp.					10–95	6–50
Salmonella spp.	13		4–15	7 – 22	1–10	1–10
E. coli O157 : H7	2–3.5		2	1.5 – 9		

Modified from Medema *et al.* (2003).

Livestock are a well-known source of waterborne pathogens (Table 6). There is a direct relationship between the presence of cattle on agricultural land and fecal coliforms in surface waters and direct animal access may have more of an impact on streams than stocking densities (Tiedemann *et al.*, 1987). Wild animals, largely mammals and birds, are another source of human pathogens. In well-protected surface water catchments, upland reservoirs, and mountain streams, wildlife may be the most important source of fecal pollution. In the Netherlands, it has been shown that reservoirs are at greatest risk during late winter/early spring, when bird numbers on the (partly frozen) reservoirs are high. When thaw sets in, the bird feces that have collected on the ice enter the water, leading to a peak contamination with *Campylobacter, Cryptosporidium*, and *Giardia* (Medema *et al.*, 2003).

The concentration of pathogens in raw sewage is dependent upon the incidence of infection within the population, time of year, per capita water usage, and the socioeconomic status of the population. The concentration of pathogens found in feces of infected persons is shown in Table 7. The peak incidence of many enteric infections is seasonal in temperate climates. Thus, the highest incidence of enterovirus infection is during the late summer and early fall; rotavirus infections tend to peak in the early winter, and *Cryptosporidium* infections peak in the early spring and fall. A greater incidence of enteric infections occurs in lower socioeconomic groups, particularly where lower standards of sanitary conditions prevail. The concentration of pathogens in raw sewage in the developed world and polluted surface waters is shown in Table 8. Concentrations of enteric pathogens are much greater in sewage in the developing world than the industrialized world. Sewage treatment by activated sludge or stabilization ponds may reduce the concentration of pathogens by 90 to 99%. Disinfection with chlorine can significantly further reduce the concentration of bacterial pathogens, but significant concentrations of viruses and protozoan parasites may remain. Filtration to remove turbidity, cysts, and oocysts and reduction of organic matter by chemical flocculation and extended disinfection are necessary to reduce pathogens below detection levels.

Table 7 Concentration of enteric pathogens indicator microorganisms in feces

Organism	Per gram of feces
Protozoan parasites	
Helminths *Ascaris*	10^4–10^7
Enteric viruses	
Enteroviruses	10^4–10^5
Rotavirus	10^{10}
Enteric bacteria	
Salmonella spp.	10^4–10^{10}
Shigella	10^5–10^9
Indicator bacteria	
Coliform	10^7–10^9
Fecal coliform	10^6–10^9

Table 8 Estimated levels of enteric organisms in sewage and polluted surface water in the United States

Organism	Raw sewage	Polluted stream water
Coliforms	10^7–10^9	10^5
Fecal coliforms	10^6–10^7	–
Fecal streptococcus	10^5–10^7	–
Entercocci	10^4–10^5	–
Coliphages	10^2–10^3	–
Enteric viruses	10^2	1–10
Giardia	10–10^2	0.1–1
Cryptosporidium	1–10	0.1–10^2

Modified from U.S. Gerba (2000).

Transport

In temperate lakes, thermal stratification may occur during summer and winter. This reduces the exchange of water between the upper and lower layers of lake water. In summer, the quality of the water at the bottom slowly deteriorates due to settling. When de-stratification occurs in autumn, water from the upper and lower layers mixes. This process causes settled particles with coliforms to reenter the water. In one lake, for example, it was reported that autumn de-stratification led to a 10-fold increase in coliform densities for several weeks; from a level consistently below 10/100 mL in summer to more than 100/100 mL (Geldreich *et al.*, 1989).

The concentration of pathogens and indicator bacteria is closely linked to rainfall events. Rainfall and rainfall intensity are important factors in the release of pathogens from

fecal matter and the subsequent mobilization into surface waters (Ferguson *et al.*, 2003). Higher land-surface slopes generally have more overland transport (Tate *et al.*, 2000).

Global climate change has resulted in an increase in heavy rainfall events. This increase has a direct impact of pathogen loading in watersheds. A significant statistical relationship between the increase incidence of rainfall and waterborne disease has been demonstrated in the United States (Curriero *et al.*, 2001).

Pathogens tend to accumulate in sediments due to direct settling or attachment to suspended particulates, which form sediment deposits. Survival of pathogens in sediments can be significantly greater than in surface waters. As long as pathogens remain adsorbed to sediments, there is little threat to public health. However, resuspension of the upper levels of sediments may increase the concentration of pathogens in the water. Sediment resuspension may occur through boat activity, swimming, currents, dredging, storm events, or animal activity. Studies in coastal areas indicate that 10- to 10 000-fold greater concentrations of enteroviruses may occur in sediments than in the overlying seawater on a volume basis (Gerba *et al.*, 1977). Fecal coliforms have been found in freshwater sediments at concentrations 100 to 1000 fold higher than the overlying water (Geldreich, 1970). In duckweed ponds and multispecies wetlands used to treat activated sludge effluents, the concentration of *Giardia* cysts was found to be 150- to 550-fold greater in the sediments than the overlying water (Karim and Gerba, 2002). *Cryptosporidium* oocyst concentrations were 50 to 70 times greater in the sediments than the overlying water. Settling is probably the major mechanism of cyst and oocyst accumulation in sediments. This explains the greater concentration of the larger *Giardia* cysts in the sediments compared to the oocysts.

Survival

Temperature and sunlight intensity are major factors controlling the survival of pathogens in surface waters (Table 9). In general, survival is prolonged when water temperatures are low. In a study in Alaska, little enterovirus inactivation over a distance of 150 miles under the ice in an Alaskan River in the winter was observed (Dahling and Safferman, 1979). Enteric bacteria are sensitive to inactivation by ultraviolet light in sunlight and predictive models for fecal coliform survival in surface waters have been developed (Kapuscinski and Mitchell, 1982). Adsorption of enteric bacteria and viruses to particles prolongs their survival probably through protection from antagonistic factors in water and, in the case of viruses, enhanced thermostabilization (Liew and Gerba, 1980). Survival of poliovirus in marine sediments was found to be 4- to 96-fold greater than in seawater (LaBelle and Gerba, 1980). In contrast, *Giardia* cyst survival was found to be less in duckweed pond sediments than the overlying water (Karim and Gerba, 2002). Indigenous bacteria and protozoa have been found in both marine and freshwater antagonistic to enteric bacterial and viral survival. In general, pathogen survival in marine waters is less than that in freshwater and greater in the presence of sewage. Typical die-off rates of waterborne pathogens in surface waters are shown in Table 10.

Table 9 Factors affecting the persistence of pathogens in soil

Factor	Comments
Temperature	Longer survival at low temperatures; longer survival in winter than in summer.
Water-holding capacity	Survival is lower in sandy soils with lower water-holding capacity.
Light	Lower survival at soil surface because of UV lights
Soil texture	Clays and humic materials increase water retention by soils and thus enhance microbial survival.
pH	May indirectly control survival by controlling adsorption to soils, particularly for viruses.
Cations	Some (e.g. Mg^{2+}) may thermally stabilize viruses
Organic matter	May influence bacterial survival and regrowth. Virus survival is longer in the presence of organic matter.
Biological factors	
Antagonism from soil microflora	Increased survival in sterile soils. No clear trend as regards the effect of soil microflora on viruses.

Adapted from Gerba and Bitton (1984).

Table 10 Die-off rates and reduction time for selected microorganisms in surface water

Microorganism	Die-off (Log_{10} day^{-1})
Parasites	
Cryptosporidium sp	0.0057–0.046
Giardia sp.	0.023–0.23
Viruses	
Enteroviruses	0.01–0.2
Hepatitis A	0.05–0.2
Rotavirus	0.24–0.48
Bacteria	
Salmonella spp	1–7
E. coli	0.23–0.46
Coliforms	0.77
Enterococci	0.17–0.77

Modified from Medema *et al.* (2003).

Subsurface Environments

Sources

Almost half of all the waterborne disease outbreaks documented every year in the United States are due to contaminated groundwater (Lee *et al.*, 2002). Pathogens enter

the groundwater from septic tank leachfields, land application of wastewater for irrigation and disposal, landfills, riverbank infiltration, leaking sewer lines, waste oxidation ponds, and direct injection into the groundwater. Septic tanks are believed to be the major cause of outbreaks and a recent epidemiological study found a direct relationship between diarrhea and septic tank density in communities served by septic tanks (Borchardt *et al.*, 2003). In a nationwide study of utility drinking water wells in the United States, viruses, coliphages, and indicator bacteria were found in 31, 21, and 15% of the samples respectively (Abbaszadegan *et al.*, 2003).

Transport

Microorganisms are colloids (biocolloids) that behave as particulates in their transport in the subsurface. Because of this, their movement may be much different than solutes, depending on the nature of the subsurface matrix. In uniform material, they may experience greater retardation than solutes; however, where fractures are present, they may travel at much greater rates (Hinsby *et al.*, 1996).

Owing to their size, helminths ova, protozoa, and bacteria are easily filtered out during their transport through soil. Bacterial removal by soils is inversely proportional to the particle size of soils. Bacteria may also adsorb to soil. The degree of adsorption is influenced by a number of water quality and soil properties, which are listed in Table 11. Rainfall significantly influences the transport of bacteria through soil and greater numbers are seen in wells after rainfall events. Under field conditions, pathogenic bacteria are efficiently retained by most soils and rarely detected in groundwater. Factors controlling transport of microorganisms in the subsurface are shown in Table 11.

Because of their small size, viruses may travel further than any other pathogen in the subsurface. The major factor controlling virus transport through soil is adsorption. Both electrostatic and hydrophobic interactions are involved in virus adsorption. The charged carboxyl and amine groups on the surface of the viral protein coat are involved in electrostatic interactions and aliphatic groups in the hydrophobic interactions (Gerba, 1984). Clay soils generally have a greater capacity than sandy soils. Greater virus removal occurs near the soil surface because of virus retention onto iron oxides and other metal oxides that form in the presence of oxygen (Chu *et al.*, 2001). Adsorption varies with the type and strain of virus (Goyal and Gerba, 1979). Some viruses (poliovirus type 1) adsorbs very well to most soils, while others (echovirus 1 and coliphages MS-2) adsorb poorly. Viruses adsorb poorly to soils in low ionic strength conditions and rainfall causes viral desorption promoting transport. Transport is also promoted by the presence of organic matter. Thus, virus adsorption is less when suspended in sewage. Virus transport is greater above pH 7.0. Changes in pH can also result in viral de-adsorption (Bales *et al.*, 1995).

Both laboratory and field studies have shown that sewage sludge (biosolid) application does not result in virus transport to groundwater. Viruses have never been detected in groundwater beneath sludge application sites (Straub *et al.*, 1993). Viruses appear to be tightly bound to the sewage sludge because of the presence of proteins produced by bacteria, which have a high affinity for binding viruses (Sano, 2003).

Several models have been proposed for predicting viral and bacterial transport through soils and aquifers (Yates and Ouyang, 1992). These models vary in complexity and require environmental (temperature), soil/hyrogeologic (texture, adsorption coefficient for the organism), and microbiological transport (e.g., microbial type, inactivation rate). Most of these models simulate microbial transport under saturated flow conditions.

Survival

The main factors controlling the survival of pathogenic bacteria in soil are temperature, moisture content, sunlight, pH, organic matter, bacterial type, and antagonistic microflora, which include indigenous soil bacteria and predatory protozoa. Soil desiccation is probably the major

Table 11 Summary of the main factors governing the transport of pathogens through soil

Factor	Comments
Soil Type	Fine-textured soils retain microorganisms more effectively than light-textured soils. Iron oxides increase the adsorptive capacity of soils.
Filtration	Straining of bacteria and protozoan parasites at soil surface limits their movement.
pH	Generally, adsorption increases when pH decreases.
Cations	Adsorption increases in the presence of cations. Rainwater may desorb viruses from soil owing to its low conductivity.
Soluble organics	Generally compete with microorganisms for adsorption sites. Humic and fulvic acid reduce virus adsorption to soils.
Microbial type	Adsorption to soils varies with microbial type and strain.
Flow rate	The higher the flow rate, the lower the microbial retention.
Saturated versus unsaturated flow	Virus movement is less under unsaturated flow conditions.

Modified from Gerba and Bitton (1984).

Table 12 Die-off rates of enteric microorganisms in groundwater

Microorganism	Die-off rate (log_{10} day^{-1})
Viruses	
Hepatitis A	0.10–0.33
Poliovirus 1	0.013–0.77
Coxsackievirus	0.19
Rotavirus SA11	0.36
Coliphage MS-2	0.063–0.75
Bacteria	
E. coli	0.063–0.36
Faecal streptococci	0.03–0.24
Salmonella typhimurium	0.13–0.22

Modified from Medema *et al.* (2003).

factor controlling bacterial survival in soils. Indicator bacteria (coliforms, fecal coliforms, *E. coli*) often increase in soil after rainfall events (Pepper *et al.*, 1993).

Temperature and soil moisture are the major factors controlling virus survival in soil. Viruses in land applied sewage sludge were found to survive for 23 weeks during the winter in Denmark, but only for 2 to 4 weeks in the summer and fall in Florida (Bitton, 1999). Die-off rates for waterborne enteric pathogens in groundwater are shown in Table 12.

CONCLUDING REMARKS

The rapid emergence of new waterborne pathogens in recent decades has created a greater need to better understand their fate and transport in aquatic environments. Pathogens are opportunistic and will always find means to coexist with humans. Applications of molecular methods to identify and track the source of water-related pathogens provide better insight into the exposure via surface and groundwaters. This in combination with microbial risk assessment should provide better means to control their occurrence in our water supplies.

99: Salinization

JOHN RUPRECHT AND SHAWAN DOGRAMACI

Department of Environment, Salinity and Land Use Impacts Branch, Resource Science Division, East Perth, Australia

Salinization of land and water resources is a major environmental and economic problem facing many parts of the world. Soil salinization and the consequent degradation of agricultural land are proceeding so fast that many countries may not be able to achieve sustainable agriculture to feed their population in the foreseeable future. Furthermore, many important ecosystems and internationally recognized wetlands are under serious threat from the increased salinity.

Salinization is the process by which the concentration of total dissolved solids in water or soil is increased because of natural or human-induced processes.

Many aspects of hydrological science underpin the understanding of salinization. The knowledge and understanding of the movement of water and salt from the atmosphere, through landscapes and rivers are essential to understanding salinization.

The main approaches to assessing the impacts of land and water salinization and to evaluating potential solutions include process studies, catchment studies, modeling, and statistical analysis. Each of these is discussed in more detail in the article. A summary of the models available for salinity studies is also outlined.

INTRODUCTION

Salinization of land and water resources is a major environmental and economic problem facing many parts of the world. One of the essential elements to sustain human life on earth is the capacity of the soil to produce sufficient food for the population. Soil salinization and the consequent degradation of agricultural land are proceeding so fast that many countries may not be able to achieve sustainable agriculture to feed their population in the foreseeable future. Furthermore, many important ecosystems and internationally recognized wetlands are under serious threat from the increased salinity.

Many aspects of hydrological science underpin the understanding of salinization. The knowledge and understanding of the movement of water and salt from the atmosphere, through landscapes and rivers, are essential. The aims of this section are to describe the salinization of soil and water, to present a synopsis of the chemical and physical processes causing the increased salinity levels, and to describe the tools and approaches that are available to evaluate and manage these degraded resources.

SALT ON THE LAND

Physical and chemical processes such as weathering, erosion, flooding, and deposition together with climatic aridity cycles have occurred throughout the history of the Earth. These processes are responsible for the concentrations of salt in various parts of the landscape. Extensive salt accumulation over time has occurred in the lower parts of landscapes resulting in saline soils and salt lakes. Salinization has also been a reversible process, with natural ecosystems flushing out the salt during periods of wetter climatic conditions.

In recorded history, several major occurrences of human-induced salinity (secondary salinity) have affected societies. The earliest and most serious occasion occurred in the latter part of the fourth millennium BC in ancient Mesopotamia, now southern Iraq (Jacobsen and Adams, 1958). Development of agricultural land in semiarid Mesopotamia required massive investments in major engineering schemes such as diversion canals. Large volumes of water were diverted from the Euphrates and Tigris rivers through canals to fields leading to increased seepage, flooding, and a consequent

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

rise in the watertable. Declining wheat production and cultivation of more salt-tolerant species, such as barley, were associated with an increase of soil salinity. Yield reduction, and the resulting inability to meet the needs of the population, devastated these old centers of civilization. Other historical examples of the impacts of irrigation salinization on the decline and depopulation of agricultural areas have occurred in China, the Indus River Basin, and South America (Casey, 1972).

More recent examples of the impacts of large-scale irrigation schemes and land clearing on the salinity development include the San Joaquin Valley in California, Australia, Pakistan, and the Amu Darya and Syr Darya rivers in Turkmenistan and Uzbekistan (Ghassemi *et al.*, 1995). In Australia alone, approximately 5.6 million ha of arable land are currently affected by salinity, and approximately 12 million more ha are threatened by increased salinity in the next 100 years (Australian Agriculture Assessment, 2001).

SALT IN WATER

Approximately 97% of the water on the Earth occurs as saline water in the seas and oceans. Neglecting the amount of the freshwater held in polar ice caps and glaciers, groundwater accounts for approximately half of the remaining freshwater resources on a global scale. The water in rivers, streams, and lakes that contributes frequently and actively to rainfall, evaporation, and stream flow accounts for only a small percentage (0.3%) of the global total freshwater resources (Todd, 1970; Freeze and Cherry, 1979). Most groundwater on the continents is meteoric in origin, that is, it has been derived from the atmosphere as rain or snow.

Naturally occurring saline groundwater may occur in sediments deposited in the ocean where seawater is trapped between the grains; or during weathering where highly saline water is formed and chemically combined in the weathered products; or during volcanism and metamorphism. An example of the latter case is the carbon-dioxide-rich springs in California, which contain significant a component of metamorphic water (Barnes, 1970).

Most of the groundwater resources globally are affected by extensive and intensive anthropogenic activities such as land clearing and irrigation, resulting in secondary salinization. This is particularly true in dry regions of the world, in hyper-arid and subhumid regions that are mostly warm to hot, and the potential evaporation far exceeds rainfall (Ghassemi *et al.*, 1995). For example, Datta and Jong (2002) describe the impacts of irrigation by groundwater pumping on the accumulation of salt in the root zone in the northwest region of Haryana in India. Funakawa *et al.* (2000) discuss the salinization caused by irrigation schemes and diversion of river water in Central Asia. In Australia, clearing and irrigation have caused substantial increases in groundwater and stream salinity (Australian Agricultural Assessment, 2001). Salinization of groundwater has been part of the water resource problem over the last 2000 years in southern Iraq (Jacobsen and Adams, 1958). Overpumping of aquifers and changing groundwater budgets in the coastal areas have resulted in salinization of groundwater by seawater intrusion (Ergil, 2000), and mixing of saline aquifers with fresher aquifers as a result of the groundwater head change (Hopkins and Richardson, 1999; Marie and Vengosh, 2001).

Significant changes to the nature of many inland waters have occurred over the last 200 years. Many inland waters, particularly in semiarid and arid regions, are becoming more saline from human activity.

The need for better recognition of the costs of salinization and its social and environmental effects and more effective managements is stressed by the many publications over the last decade (Ghassemi *et al.*, 1995; Dogramaci and Waterhouse, 2004).

DEFINITION OF SALINIZATION

The term salinity refers to the presence in soil and water of various electrolytic mineral solutes. Most common among these solutes are the dissociated cations Na^+, K^+, Ca^{2+}, Mg^{2+}, and the anions Cl^-, SO_4^{2-}, NO_3^-, HCO_3^-, and CO_3^{2-}. In addition, hypersaline waters may contain trace concentrations of the elements B, Se, Sr, Li, Rb, F, Mo, Mn, Ba, and Al, some of which may be toxic to plants and animals (Tanji, 1990; Hillel, 2000).

Salinization is the process by which the concentration of total soluble salts (TSS) in water or soil is increased because of natural or human-induced processes. Natural and human-induced salinization are also called *primary and secondary salinization* respectively. Salt-affected soils of primary origin are formed as a result of the long-term influence of natural processes leading to an accumulation of salts within a landscape. The presence of salts can be the result of gradual weathering, submergence of soils under seawater, and accession of salts bought inland by rainfall. All continents have extensive areas affected by primary salinization (Ghassemi *et al.*, 1995).

Secondary salinization of land is also the result of an increased concentration of salts (TSS) in the soil profile. This occurs primarily because of the evapotranspiration of recharge, then mobilization by groundwater. The salt stored at the root zone in the soil profile is being mobilized because of excess recharge from human activities such as irrigation or land clearing. The additional water raises watertables or creates an upward pressure on semiconfined or confined aquifers. When the watertable is within 1–2 m of the ground surface, groundwater evaporates, or capillary action brings water to the surface where it evaporates leaving salts behind. The salt stored in a soil profile can be dissolved

and moved laterally or vertically by groundwater and surface runoff towards watercourses, and increase salinity in streams, rivers, or terminal lakes.

Units of Salinity Measurement

Stream and groundwater salinity refers to the concentration of TSS in water. The term *salinity* is also used interchangeably with *salinization* to mean the effects of saline water. Peck (1983) provided a stricter definition of salinity as the concentration of the major ions (Na^+, K^+, Ca^{+2}, Mg^{+2}, Cl^-, HCO_3^-, CO_3^{-2} and SO_4^{-2}) in a solution.

Salinity may be expressed in a number of ways depending on the method of measurement. The most accurate method of determining the salinity of a particular water sample is to sum the measured quantities of the individual ions, which is expressed as TSS. Another method of expressing salinity is to weigh the evaporated residue of a given sample after filtering it to remove sediments. Salinity can also be expressed as Total Dissolved Solids (TDS). Both methods are expressed in units of milligrams per liter ($mg\,L^{-1}$).

For reasons of analytical convenience, a practical index of salinity is electrical conductivity (EC), usually expressed in units of milliSiemens per meter ($mS\,m^{-1}$). Electrical conductivity values are always expressed at a standard temperature of 25 °C to enable comparisons of readings taken under varying climatic conditions. A descriptive classification of water salinity is shown in Table 1.

Stream and groundwater salinity can be measured by:

- Intermittent sampling: samples taken on an ad-hoc basis to measure baseline salinity levels.
- Regular sampling: daily, weekly, or monthly samples. Regular sampling can also encompass automatic pump samplers that sample water at predetermined times, or with rate of rise in water level.
- Continuous monitoring: the continuous measurement of electrical conductivity with values stored on a data logger at regular time intervals, usually ranging from less than 5 min to more than 24 h. The conductivity meters most commonly used are either toroidal cells or four electrode.

Soil salinity can be extremely heterogeneous within short distances horizontally and vertically (Moore, 1998). Soil salinity can be measured in a laboratory by soil testing or with geophysical methods (e.g. electromagnetic induction meters). Soil salinity is measured by extracting liquid from a saturated soil paste and TSS measured as for water. However, because this method is laborious and expensive, a cheaper alternative is to measure electrical conductivity of a 1:5 soil-water mixture (ECe). A calculated ECe can be derived by multiplying the EC (1:5) by a factor related to soil texture (Moore, 1998). Soil salinity can also be defined by the effects on plants (Table 2).

Soil salinity on a large scale can be mapped with an electromagnetic (EM) conductivity meter that estimates the bulk electrical conductivity of the soil, which depends on the salinity of the soil solution, its water content, and the type and amount of clay in the soil.

Table 2 Assessment of saline land with soil salt content (Adapted from USSL, 1954)

Soil salinity ($mg\,L^{-1}$)	Rating	Effect on plants
0–1000	Non – saline	Salinity effects mostly negligible
1000–2100	Slightly saline	Yield of sensitive crops reduced
2100–4500	Moderately saline	Yield of many crops reduced
4500–9200	Highly saline	Only salt-tolerant crops yield satisfactory
>9200	Extremely saline	Only very salt-tolerant plants yield satisfactory

Table 1 Descriptive classification of water salinity (Adapted from Hillel (2000))

Water quality	TDS ($mg\,L^{-1}$)	Comment
Fresh	<500	Regarded as good quality drinking water based on taste Acceptable for most irrigation
Slightly brackish	500 to 1000	Acceptable as drinking water based on taste Acceptable for most irrigation – The acceptable level for irrigation will range with type of crop, type of soils, and level of drainage.
Brackish	1000 to 2000	Acceptable for most stock and some irrigation. The acceptable level for irrigation will range with type of crop, type of soils, and level of drainage.
Moderately saline	2000 to 5000	Primary drainage
Saline	5000 to 10 000	Limited farm use – unacceptable for most stock unless as an emergency supply
Highly saline	10 000 to 35 000	Very saline groundwater
Hypersaline	>35 000	Seawater, may have use in industry or mining.

In saline areas, the depth to the watertable can be used as an alternative method of assessing potential increase in soil salinity levels. The critical depth is the depth of the watertable from which water can reach the soil surface by capillary rise in sufficient quantities to cause a salt problem. The critical depth, which ranges from 1–6 m under dryland conditions (Nulsen, 1981), will vary with the concentration and composition of the solutes, the frequency and amount of rainfall, soil physical properties, and type of crop (Table 3).

CAUSES OF SALINIZATION

Sources of Salt

The major natural sources of salt are considered to be:

- *Marine sedimentary rocks or seawater intrusion*

Marine salt can be derived from seawater intrusion or ancient marine sedimentation. The chemistry and the ionic composition of seawater are distinctive; therefore, the relative contributions of salt sources can be derived from proportional relationships. If marine salts from recent intrusions or connate salt are the primary sources of salt in sediments or groundwater, then the concentration of specific anions and heavy isotopes in the mixture will vary according to the degree of mixing (Herczeg *et al.*, 2001).

- *Weathering of rocks*

Host rocks experience both physical and chemical weathering. Physical weathering may produce larger soil particles than chemical weathering, which may produce soluble ions, colloidal gels, microcrystalline substances, and clay minerals. The soluble ions may then be leached from the weathering profile, or bound to clay minerals. The chemical composition of soil water and groundwater can be related to the weathering products if the hydrochemistry and the geology is well known (Szabolcs, 1989). The correlation between concentrations of anions and cations produced by chemical weathering should be strong if chemical weathering is the main source of dissolved salts in groundwater (Sami, 1992). The lack of chloride ions can be used as an indication of salinity source more likely to be from weathering, as chloride rarely originates from the weathering processes (Herczeg *et al.*, 1993).

Table 3 Critical depth to saline water table (from Nulsen, 1981)

Depth to saline groundwater (m)	Effect of salinity on ground cover
>2	Negligible effect
<1.8	Wheat yield decreased
<1.5	Barley yield decreased
<1.2	Ryegrass growth affected, replaced with salt – tolerant species.

- *Deposition of sea salt carried in rain and wind*

Marine salt may be transported by the wind as an aerosol and deposited by rainfall or dry fallout. This salt is often referred to as *meteoric salt*. In semiarid to arid areas and near-coastal areas, this can be the dominant source of salt. A portion of this salt is dissolved again in subsequent rainfall, which may recharge aquifer systems. Such contribution of salt is limited by distance from the sea (see Figure 1). In Australia, the rate of meteoric salt fallout ranges from 130–175 kg ha^{-1} y^{-1} at or near-coastal areas to 30–70 kg ha^{-1} y^{-1} 300 to 500 km inland.

Meteoric salt is characterized by an ion composition similar to that of the ocean (dominated by Na and Cl ions) from which it originated (Mazor and George, 1992; Dogramaci and Yesertener, 2001). Hingston and Gailitis (1976) and Blackburn and McLeod (1983) provided detailed mineral ion ratios for rainfall and dry fallout for Western Australia and the Murray–Darling Basin (Australia), respectively.

Salt Accumulation and Leaching

Anthropogenic activities, such as irrigation and clearing native vegetation for dryland agriculture, may result in mobilizing salt in the landscape and groundwater, which can lead to salinization through:

- dissolution of naturally occurring salts in the soil
- salts applied to the soil in artificial and natural fertilizers
- the accumulation of salt in the soil profile as applied water is lost by evaporation and evapotranspiration
- capillary action where groundwater rises and evaporates leaving salts in the upper soil profile.

Salt in the soil solution moves by molecular or ionic diffusion in response to the concentration gradients within the solution and by advection due to the mass flow of the soil solution. The processes of diffusion and advection can occur simultaneously, either in the same direction or in the opposite direction. The transport of salt is further complicated by hydrodynamic dispersion, which is the mixing process during flow due to different flow velocities through the pore spaces. The differences in flow velocities and diffusion in the direction of decreasing concentration result in the dispersion of solutes. Transport of salts may also be affected by the exchange or adsorption onto the surfaces of soil particles. For soil water that is dominated by chloride and sodium ions, chloride is generally regarded as nonreactive while sodium undergoes exchange in some soils.

Salt Balance in Soil

Salt from the surface is transported into the soil by infiltrating water. Salt output from the soil is via throughflow and groundwater discharge or through very minor absorption by

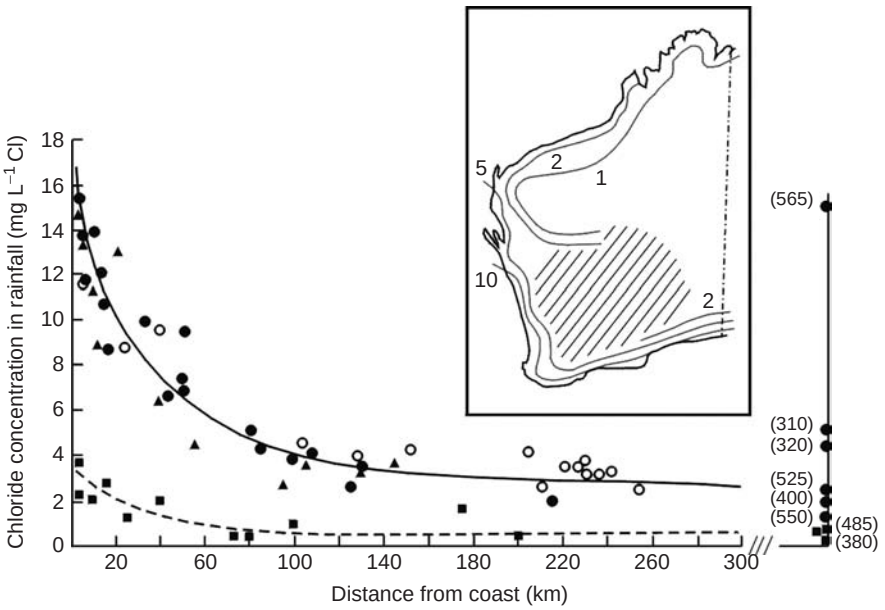

Figure 1 Decrease in concentration of chloride (mg L^{-1} Cl) in rainfall with shortest distance from the coast. The insert map is the chloride concentration in rainwater in western Australia. Hatched area indicates the region of variable values (2–10 mg L^{-1} Cl) (After Hingston and Gailitis, 1976 reproduced by permission of CISRO publishing) A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

plant roots. Transport of salt through uptake by vegetation and its return of salt to the soil are largely cyclic. The salinization of soil occurs when salt input exceeds salt output and salt accumulates in the soil. The distribution of salt in the soil profile is influenced by factors that include magnitude of salt input, average annual rainfall, depth of soil, presence or absence of saturated zones, slope, and soil properties such as texture, structure, and permeability. Because the uptake of salt by vegetation is very small in saline areas, it can generally be ignored in the soil salt balance.

The salt balance is the summation of all salt inputs and outputs for a defined volume of soil during a specified period. If salts are conserved, in that they are neither generated nor decomposed chemically in the soil, then the difference between total input and output must equal the change in salt content of the soil zone assessed.

The following simple equation applies to the amount of salt in the liquid phase of the root zone per unit area of land:

$$\Delta M_s = \Delta_w(V_r c_r + V_i c_i + V_g c_g - V_d c_d) \qquad (1)$$

where ΔM_s is the change in mass of salt in the root zone; V_r, V_i, V_g, V_d are the volumes of rain, irrigation, groundwater rise, and drainage respectively, with corresponding salt concentrations of c_r, c_i, c_g, c_d.

As an example, assume:

- Rainfall with a salinity of 20 mg L^{-1} occurred in winter of 350 mm.
- Capillary rise from saline groundwater in spring and autumn totaled 100 mm at a concentration of 2000 mg L^{-1}.
- Irrigation was applied during the summer season and amounted to 900 mm with a salinity of 400 mg L^{-1}.
- Drainage during the irrigation season amounted to 200 mm with a salinity of 800 mg L^{-1}.
- Assume the salt applied in the fertilizer and possible dissolution of soil minerals and salts within the soil are negligible.

Using the above data, the root zone is accumulating salt at a rate of 0.52 kg m^{-2} per year.

Several recent models have been proposed to relate the concentration of drainage water to some clearly definable value of salinity that affects the crop directly. Hoffman and van Genuchten (1983) determined the linearly averaged mean root zone salinity by solving the appropriate equation for one-dimensional vertical flow of water through soil, assuming an exponential soil water uptake function.

The ratio of the linearly averaged concentration of the root zone (c) to the concentration of the irrigation water (c_i) is:

$$\frac{c}{c_i} = \frac{1}{L} + \frac{d}{ZL} + \ln(L + (1\text{-}L))e^{-Z/d} \qquad (2)$$

where L is the leaching fraction, Z is the depth of the root zone, and d is the empirical constant set to 0.2Z.

When more water is applied than can be held by the soil in the crop root zone, the excess water drains below the root system, leaching salts with it. The more water applied in excess of the crop water requirements, the less salt is left in the root zone despite the fact that more salt has actually been added to the field. The term leaching fraction is used to relate the fraction or percent of water applied to the field that actually drains below the root zone. Leaching and drainage are the main mechanisms for removing of salts from the root zone as the uptake of salts by crops contributes little to the removal of salts.

The effectiveness of leaching salt from the root zone in irrigation areas is measured by % efficiency. Surface irrigation systems have leaching efficiencies ranging from 50–80%, and most irrigation systems have leaching efficiencies of 60% or less. The higher the salinity of the irrigation water, the larger the volumes and more frequent applications of water are required. The normal inefficiencies of irrigation systems are often more than sufficient for adequate leaching of salts out of the root zone. However, salt buildup in the root zone resulting from the presence of shallow water tables can lead to salinization despite high theoretical leaching rates.

The leaching of salts and other chemicals out of the root zone needs to be managed in an environmentally responsible way to avoid undue rises of groundwater levels and contamination of underlying groundwater, and to protect surface water into which drainage water is eventually discharged after it leaves the aquifer through natural drainage or constructed drainage or pumping systems (Bouwer, 2002).

In the context of a whole catchment, leaching refers to the time for soil salt to be leached to a stream or river after a change in the net input of water. Peck and Hurle (1973) and, more recently, Hatton *et al.* (2002) estimated leaching times from some of the salinity-affected catchments in Western Australia to range from 30 to more than 500 years.

EFFECTS OF SALINIZATION

Effects on Soil Physical and Chemical Properties

The accumulation of salts in soils can lead to irreversible damage to soil structure. The effects are most extreme in clay soils, where the presence of sodium can result in sodic soils. This occurs by adsorption of sodium ions to clay particles, which, in severely affected soils, can bring about collapse of the soil structure. Sodic soils make growing conditions very poor, soils very difficult to work, and prevent reclamation by leaching using standard techniques. Gypsum in the irrigation water or mixed in the soil can be used to reduce the sodium content of sodic soils.

Quirk and Schofield (1955) proposed the concept of a threshold concentration of irrigation water, which is defined as the concentration of solutes required to maintain soil permeability at an acceptable level relative to that measured with a strong salt solution for a particular value of Sodium Adsorption Ratio (SAR).

$$\mathrm{SAR} = \frac{\mathrm{Na}}{(\sqrt{(\mathrm{Ca} + \mathrm{Mg})/2})} \tag{3}$$

where the ion concentrations are expressed in millimoles per liter.

Problems in soil structure occur when there is excess sodium relative to calcium and magnesium ions in the water applied or in rainfall. Calcium and magnesium ions are divalent cations and are more tightly associated with clays than monovalent sodium cations, and are preferentially adsorbed onto most clays, which generally have negative surface charges.

The excess sodium ions will displace cations from the clay surface because of the law of mass action. This will cause the dispersion of clays and result in the collapse in pore structure. The resultant decreased pore size will decrease the soil permeability and increase the potential for waterlogging. Consequently, the combination of a high EC and a high SAR can create poor soil conditions for agriculture.

Effects on Plants

The effects of salts on plants have been reviewed by Maas (1990) and Pessarakli (1993). Salt-affected plants are usually stunted and may have darker green leaves. As the salt concentration increases above a threshold level, both the growth rate and ultimate size of the plant decrease (Maas and Hoffmann, 1977).

A plant exposed to a high concentration of salts in the root zone will respond almost immediately by reducing the rate of leaf expansion (Moore, 1998). This rapid response is due to the increased osmotic potential hindering water uptake by the roots. Over the long term, excess salt in soils results in a buildup of salt in the leaves, especially the old leaves, resulting in death (necrosis). Salt also causes nutrient deficiencies by hindering nutrient uptake in the root zone because of reduced root growth, water uptake, and competitive displacement by sodium ions.

The salt tolerance of agricultural plants and crops varies widely (Tables 2 and 3). In general, crops tolerate salinity to a threshold level, beyond which yields decrease approximately linearly with increasing salt concentrations. In addition, the combination with other factors such as waterlogging can exacerbate the impacts of salinity.

Effects on Ecosystems

The remaining terrestrial and aquatic ecosystems are threatened by secondary salinization. The overall biological effects are considered to be:

- changes to the natural character (processes and structure)
- loss of biodiversity
- taxonomic replacement (less salt-tolerant species are replaced by more tolerant species).

All of these effects are undesirable and largely irreversible: they cause more or less permanent degradation. The loss of biodiversity is probably greater than generally realized since recent work on both the naturally fresh and saline waters in semiarid and arid regions indicates they have much greater biodiversity than was thought (Williams, 1999). Recent investigations into the impacts of increased salinity on the biodiversity of southwestern Australia suggest that the richness of most biological groups show an inverse relationship with salinity (Hammer, 1986). With respect to shallow lakes, salinization has resulted in the loss of freshwater species of submerged macrophytes and the dominance of a small number of more salt-tolerant species (Davis, 2004).

Many rivers of southwestern Australia have suffered a 20-fold increase in salinity (Schofield *et al.*, 1988), which has led to changes to the biological communities of aquatic ecosystems (Halse *et al.*, 2003). Recent data confirms these trends and further substantial changes are likely to occur, despite the flora and fauna of the southwest of Australia being comparatively well adapted to the existence of salinity in the landscape. Possibly, one-third of wetland and river invertebrates, large numbers of plants, and a substantial proportion of the waterbird fauna will disappear because of the impacts of salinization (Halse *et al.*, 2003).

Other examples of increasing salinity include the Colorado River (southwestern United States) and the Syr and Amu Darya, Central Asia, which discharge into the Aral Sea (Williams, 1999). The salinity of the lower reaches of the Syr Darya has increased by sevenfold in the past 90 years. Ecological effects are largely similar to those for freshwater lakes and wetlands. It is often difficult to separate ecological effects because of secondary salinization from those resulting from the other two major anthropogenic disturbances to rivers and streams in drylands, flow regulation, and diversion. Economic effects are more easily distinguished, when salinities reach 1000 mg L^{-1}. At this level, the water becomes unsuitable as drinking water. Thus, the economic costs may be very large. Managers become alarmed when even small rises occur, as they are, for example, with regard to the River Murray (southeastern Australia), a major source of irrigation water and public water supplies for the city of Adelaide (Ghassemi *et al.*, 1995).

CURRENT EXTENT OF SALINIZATION

Land Salinization

The estimation of the extent of salinization is very difficult due to the dynamic nature and lack of data and inconsistencies between the data provided by various organizations. FAO (2000) provided a global estimate of approximately 400 million ha of land considered to be salt-affected (Table 4). Nearly 50% of the salt-affected land is within Asia, Pacific, and Australia region and includes China, India, and Pakistan, which have the highest portion of irrigation salinity. Australia on the other hand is one of the worst affected by dryland salinity with approximately 5.7 Mha already saline, and it is predicted that a further 17 Mha will be salt-affected in the next 100 years.

River Salinization

The salinity of surface waters is naturally highly variable and there is no global reference value to assess the level of salinity. The average salinity of some of the world's major rivers in the global dataset for rivers (Walling and Webb, 1983) is ~250 mg L^{-1} TDS. Some rivers, such as the Blackwood and Avon rivers in Australia, have high natural salinities or have experienced great increases due to human-induced change (Table 5). In temperate regions, rivers originate in high rainfall zones and the salinity increases from up-gradient to the discharge areas. However, salinity variations along rivers in southwest Australia highlight an atypical characteristic of rivers rising in low rainfall regions – they become fresher as they reach the coast due to fresh tributaries diluting the more saline water coming from inland.

Eighty percent of the rivers within the global dataset have a chemical composition made up of four ions (HCO_3, SO_4, Ca, and SiO_2), which indicate mineral weathering as the major source of salts. Calcium is the most common cation found in the surface waters of many European rivers, and its dominance is mainly a function of geology, especially when carbonate or gypsum deposits are present in the watershed.

Table 4 Extent of salt-affected land in million hectares Mha (After FAO, 2000)

Continent	Land area (Mha)[a]	Salinity-affected(Mha)
Africa	1900	39
Asia, the Pacific, and Australia	3107	195
Europe	2011	7
Latin America	2039	61
Near east	1802	92
North America	1924	5
TOTAL	12 783	399

[a]Mha denotes million hectares.

Table 5 Salinity and constituent concentrations for major rivers worldwide (From GEMS/WATER and Hatton and Ruprecht, 2001)

River	Discharge	TDS	Constituent concentrations ($mg\,L^{-1}$)							
	($10^9\ m^3$)	($mg\,L^{-1}$)	Na	K	Ca	Mg	Cl	SO_4	HCO_3	SiO_2
South America

Avon	0.4	5200	1383	31.2	120	250	2746	234	302	99

Rivers in Australia, on the other hand, are notable for their marked difference from this global average. In particular, the rivers of southwest Australia are very saline, with the dominant components being Na and Cl. Generally, the concentrations of sodium and chloride are highly correlated in the surface waters in coastal areas, particularly in arid and semiarid regions, indicating marine origin (Herczeg *et al.*, 2001) (Table 5, Figure 2).

Stream salinity in the coastal areas in Australia ranges from 100 in fully forested areas to over $20\,000\,mg\,L^{-1}$ TDS depending on the extent of native vegetation clearing, mean annual rainfall, and geomorphic characteristics (Schofield *et al.*, 1988; Schofield and Ruprecht, 1989). Globally, the mean annual salt load in river discharge to the ocean is $39.5\,t\,km^{-2}$ (Figure 2), though for specific areas there are significant variations. For example, the mean annual salt load can vary from less than $10\,t\,km^{-2}$ to more than $250\,t\,km^{-2}$ for cleared Western Australian catchments in low-rainfall areas (<350 mm). The relatively higher salt load discharging in Australian rivers is mainly due to disturbance to the natural water balance by clearing of native vegetation for agriculture development (Figure 3).

The secondary salinization of rivers and streams is closely related to land salinization. This is because rivers and streams either arise in salinized catchments and discharge salt into lakes and wetlands or flow from them with additional salt loads. Both small streams and large rivers may be subject to secondary salinization. The Blackwood River in southwestern Australia provides a well-documented example of a river that has been salinized during the past 80 years by catchment changes; its catchment has been extensively cleared for agricultural purposes. Less than a century ago, its salinity was $<500\,mg\,L^{-1}$, it is now mostly $>3000\,mg\,L^{-1}$.

Lake and Wetland Salinization

Many freshwater lakes and wetlands occur in semiarid and arid regions and may also suffer secondary salinization after extensive changes to land use in their catchments (Williams, 2001a). Irrigation and clearance of the natural vegetation are the most important reasons. Both processes commonly mobilize subsurface salt that salinizes freshwater lakes and wetlands. Rising saline groundwaters may threaten floodplain wetlands in certain regions. Examples of secondarily salinized freshwater lakes and wetlands include Lake Qarun, a formerly freshwater lake in southwest of Cairo, Egypt, which has become saline because of salt inflows in drainage water from nearby agricultural land (Williams, 2001b). Increases in the salinity of some freshwater lakes in the Rift Valley of Ethiopia have been attributed to irrigation, river diversions, and deforestation (Williams, 2001b).

Many large and permanent salt lakes have also been modified and affected by secondary salinization. The human-induced increase in salinity of these salt lakes is also caused by diversion from inflowing rivers: with decreased freshwater inflows, lake volumes decrease and so solutes may become more concentrated (Kefford, 2000).

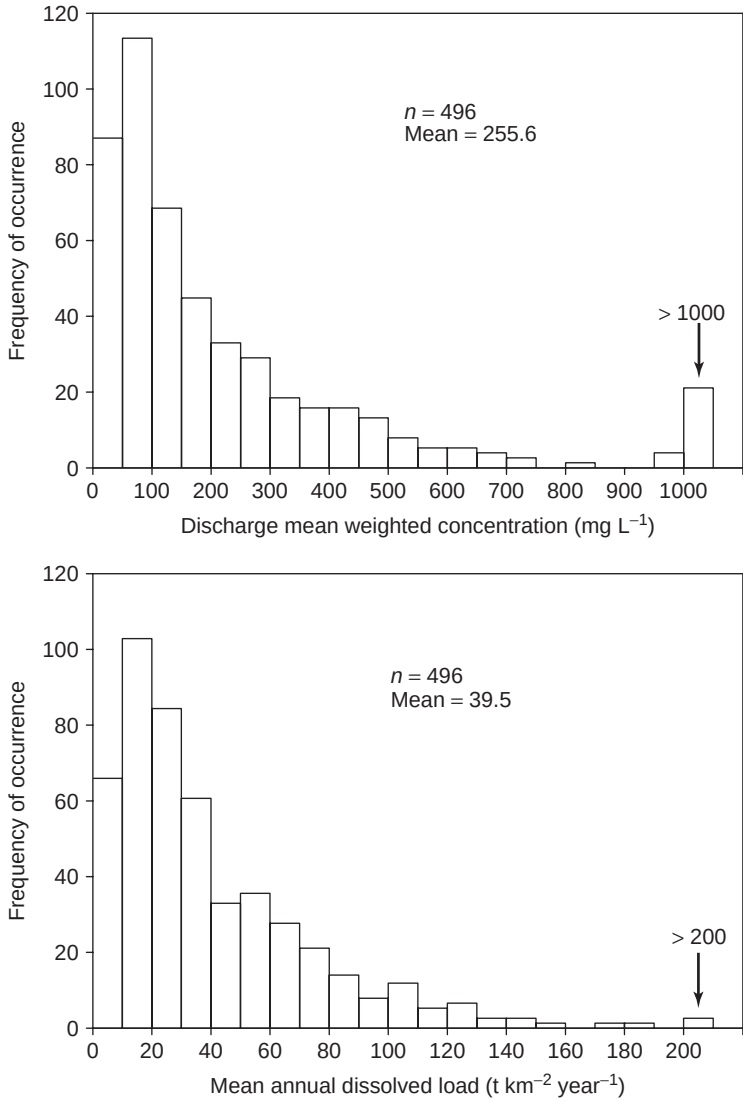

Figure 2 Frequency distribution of discharge-weighted mean total dissolved solids concentration and mean total dissolved load for a sample of 496 world rivers (Adapted from Walling and Webb, 1983)

A few examples of human-induced change on ecosystems are also known from temperate regions. Some of the artificial lakes created by open-cast coal-mining in Germany are now being salinized by saline groundwater, and salt mines have salinized several freshwater lakes in Cheshire, UK. Reservoirs too can be threatened by secondary salinization. Waters impounded by the Imperial Dam on the lower reaches of the River Colorado in the United States, will soon have salinities $>1100\,\mathrm{mg\,L^{-1}}$ (Ghassemi *et al.*, 1995). Salinity is a major environmental problem for this river and its many impoundments. Even small salinity rises can be significant for freshwater lakes and wetlands since their biota generally has a limited salt tolerance. The disappearance of macrophytes and riparian trees is one of the first signs of secondary salinization.

Apart from ecological damage (changes in natural character, biodiversity loss, taxonomic replacement), secondary salinization causes many other problems. Economic losses include the loss or reduced value of the lake or wetland for water supplies. Decreases in conservation, amenity, aesthetic, and general environmental values also occur. For floodplain wetlands, losses include degradation of the riverine system as a whole because of the close hydrological and ecological relationship between floodplain wetlands and rivers (e.g. Davies *et al.*, 1994).

MANAGEMENT OF SALINITY

Throughout many salinity-affected areas (irrigation and dryland salinity), the change in water balance has raised

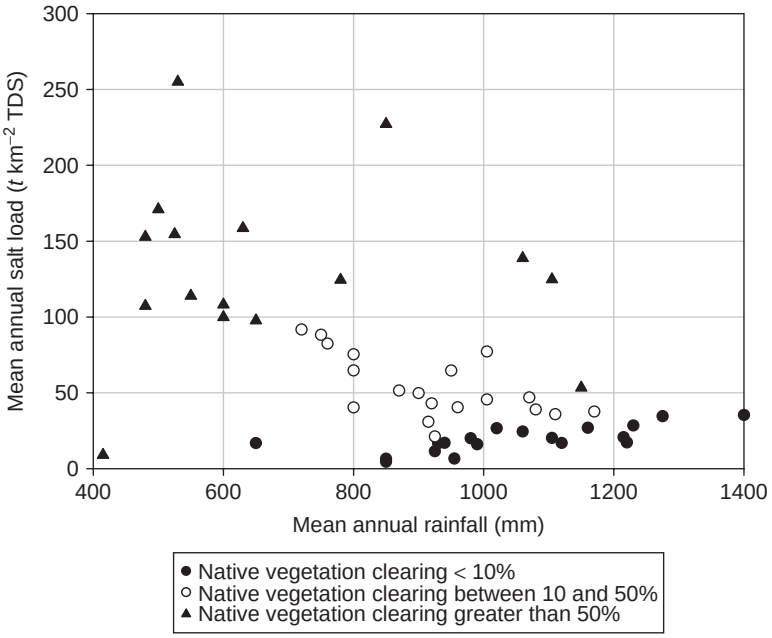

Figure 3 Relationship between mean annual rainfall and mean annual salt load for rivers in southwest Australia

saline groundwater levels, resulting in groundwater discharging to the surface and into natural waterways. These discharge areas become saline, often waterlogged, support only salt-tolerant vegetation, and suffer from soil erosion. Shallow watertables are as much an environmental problem as an issue to agriculture and infrastructure. Management of saline watertable in these areas aims to:

- stabilize watertables at harmless levels in irrigation areas with good quality groundwater,
- significantly retard rising groundwater by control of groundwater recharge, and, where necessary, adapt to higher saline conditions in irrigation areas with saline groundwater,
- significantly reduce accessions to the groundwater systems and to substantially improve salinity problems associated with localized groundwater systems
- protect, and where appropriate, rehabilitate high-value wetlands and other significant environmental features.

The main purpose of salinity management options is to restore the water balance by either reducing the infiltration of excess water (recharge management), increase discharge by engineering options, or combining both approaches. Because irrigation salinity is intrinsically associated with increased recharge, the primary management option is to enhance discharge by engineering work such as drains and groundwater pumping. For more discussion on irrigation management for salinity control, see the reviews of Kruse *et al.* (1990) and Hillel (2000).

Engineering Options

Drainage

Drainage has been essential for managing rising watertables in most irrigation schemes around the world. It is considered necessary for irrigation to maintain plant growth, and prevent waterlogging and soil salinization. The major types of surface drainage are seepage interceptor drains, horizontal subsurface drains, and vertical or tube-well drains. One of the major problems associated with drainage is the loss of water by leakage resulting in inefficient management of groundwater. Up to 40% of drainage water is lost via evaporation and leakage in some drainage schemes (Ghassemi *et al.*, 1995). Improving irrigation water efficiency by means such as irrigation channel lining or piping, land forming, and grading, changing the method of irrigation, or by irrigation scheduling can all reduce land and water salinization substantially.

The ranges of depth and spacing generally used for the placement of drains in field practice are shown in Table 6.

Groundwater Pumping

There is a growing awareness of the salinity management benefits of groundwater pumping and the need for integrated groundwater and surface water solutions. Thousands of groundwater pumping bores have been installed to lower the watertable in most of the irrigation schemes of Pakistan and India (Ghassemi *et al.*, 1995). In areas where a river drains saline aquifer, interception schemes can be used to reduce the discharge of the saline groundwater to the river.

Table 6 Prevalent depths and spacing of drains in different soil types (After Hillel, 2000)

Soil type	Hydraulic conductivity (m day^{-1})	Spacing of drains (m)	Depth of drains (m)
Clay	1.5	10–20	1–1.5
Clay loam	1.5–5	15–25	1–1.5
Loam	5–20	20–35	1–1.5
Fine, sandy loam	20–65	30–40	1–1.5
Sandy loam	65–125	30–70	1–2
Peat	125–250	30–100	1–2

The basic design principle assumes that the extraction of groundwater from an aquifer hydraulically connected to the river, using a line of pumping wells positioned close and roughly parallel to the river, will decrease the hydraulic gradient of the aquifer toward the river.

The release of freshwater from reservoirs in a river basin during periods of low river flow that coincide with high river salinity can also reduce river salinity (Schofield *et al.*, 1988).

Disposal of Saline Water

- *Reuse option*

Drainage water can be reused repeatedly to irrigate more salt-tolerant crops. Drainage water can also be reused for repeated irrigation to the extent that it still has value for use by a crop of higher salt tolerance (Rhoades, 1984). When the drainage quality is such that its potential for reuse is exhausted, then the drainage water could be disposed of to evaporation ponds.

- *Disposal to rivers and lakes*

This option is widely practiced by either controlled or uncontrolled means. In controlled disposal, the volume, salinity, and time of disposal are managed. Effluent from the drainage facilities is collected into holding basins or evaporation basins and released to the river during periods of high river flow.

- *Disposal to evaporation basins*

Drainage water can also be disposed directly to naturally occurring evaporation basins or ponds, (formed from natural depressions, saline lakes) or constructed ones. They can vary in size from a few hectares serving individual farms to very large basins. The design, maintenance, and cost-benefit analysis of evaporation basins have been the focus of a detailed investigation in the Murray Darling Basin in Australia (Leaney *et al.*, 2000; Jolly *et al.*, 2000; Dowling *et al.*, 2000). Leakage, laterally or vertically, is a major problem for evaporation basins. Lateral leakage is often the principal undesired consequence because of its effect on surrounding land within a relatively short period of time. Vertical leakage beneath a basin creates a groundwater mound that may raise groundwater levels next to the basin. It is important to note that the evaporative capacity of the saline disposal basins is reduced with increasing salinity due to evaporation (Table 7).

Agronomic and Vegetation Options

Agronomic Practices

The water balance of a catchment can be manipulated to some extent by altering the agronomic practices. One of the best documented examples is the replacement of shallow-rooted grasses with deep-rooted alfalfa on recharge areas of the Northern Great Plains of the United States (Halvorson and Reule, 1980). Saline seeps that affected a large area of productive dryland agriculture in the region have been controlled with an intensive cropping system and deep-rooted crops. Alfalfa, when grown on about 80% of the recharge area, reduced the deep percolation of soil water and provided hydrologic control within one year of establishment (Halvorson and Reule, 1980).

Productive Use of Salt-Affected Soils and Saline Water

There has been considerable research into the productive use of saline land by revegetation and other means. Salt-tolerant crops and pastures (grasses and legumes) have considerable potential for the adaptation of saline land. Saline aquaculture is also a productive option for the safe storage of saline water.

Revegetation Options

Tree-based land management strategies can contribute significantly to minimizing the spread of salinity and even to recovering land from salinization. The hydrological response of catchments to tree planting varies enormously, making it difficult to provide specific advice on strategies to achieve salinity benefits. In some catchments previously cleared for agriculture, local strategic plantings can have significant and almost immediate effects on waterlogging and groundwater discharge. In others, afforestation of the majority of the catchment is required to significantly limit salinization, and the timescale to do so may be very long: up to hundreds of years (Hatton *et al.*, 2002).

Revegetation can control salinization by either reducing recharge or by increased water use at discharge sites.

Table 7 Reduction of evaporation potential of water with different salinity

Salinity (mg L^{-1} TDS)	Percentage of freshwater evaporation (%)
Freshwater	100
30 000 (seawater)	99
140 000	90
300 000 (saturation)	59

Revegetation strategies can include discharge plantings, dense plantations covering a high proportion of area, wide-space plantations, and strips or small blocks strategically placed but covering a small proportion of area.

Hatton *et al.* (2002) described the key diagnostic properties of a catchment with respect to its hydrologic response to tree planting to be:

- the discharge capacity of the aquifer
- the nature of the recharge process: diffuse compared to localized recharge, its spatial distribution, and the rainfall environment
- the size of the groundwater system
- the salinity of the soil and the groundwater.

Policy and Management Options

Policy options such as water pricing, transferable water entitlements, and integrated natural resource or catchment management are also important and should be considered in any strategy of salinity mitigation for both dryland and irrigation salinity.

Possible economic instruments for addressing salinity include tradable emissions permits, auction-based systems for allocating rights, charges, and subsidies, regulations, or voluntary programs (Pannell, 2000).

In Australia, a recent initiative has been the National Action Plan for Salinity and Water Quality, which is a partnership between Commonwealth and State governments, and regional management bodies (Australian Agricultural Assessment, 2001). The purpose of the action plan is to identify high priority, immediate actions to deal with salinity, particularly dryland salinity, and deteriorating water quality in key catchments and regions across Australia. The plan includes:

- targets and standards for natural resource management
- integrated catchment/regional management plans
- capacity building for communities
- an improved governance framework
- clearly articulated roles for the Commonwealth, State/Territory, local government, and the community
- a public communication program.

ASSESSING LAND AND WATER SALINIZATION

The main approaches to assessing the impacts of land and water salinization and to evaluating potential solutions include process studies, catchment studies, modeling, and statistical analysis.

Process Studies

Process studies identify the hydrologic processes causing the increased land and water salinity. This approach is used to evaluate the impacts of salinity management on the various components of the hydrological balance at small paddock and large catchment scale. For studies of water quantity and quality and the required measurements and methods, see Calder (1992). Process studies may include studies of the effectiveness of vegetation or engineering options to manage salinity such as:

- Afforestation
- Agronomic options
- Deep drainage
- Groundwater pumping
- Siphon wells

Process studies are particularly valuable when associated with properly designed catchment experiments so that the reasons for the observed changes to the hydrology and salinity can be determined.

An example of a process study is one conducted near Kyabram in Victoria (Australia), which monitored a tree plantation with groundwater conductivity in the range 3000 to 5000 $\mu S\,cm^{-1}$ for more than 20 years (Silberstein *et al.*, 1999). Over this time, the trees lowered the watertable from 1 to 5 m below the natural surface. The local depression in the watertable continued to deepen as long as groundwater use exceeded the rate of lateral inflow from the surrounding irrigated pasture. Tree water use estimates over the initial 10 years indicated that the trees used approximately 730 mm per year, of which 430 mm came from the watertable (Silberstein *et al.*, 1999). However, sap flow readings five years later suggested that groundwater use was falling as salt accumulated in the root zone. If this trend continued, the watertable would start to rise again. These field studies, when combined with process modeling, indicate that the tree plantation at the Kyabram site is unsustainable due to salt accumulation. In addition, Silberstein *et al.* (1999) suggest the general rule that, in situations where the accumulated salt cannot be exported, tree plantations grown in areas with a groundwater salinity of 3000 $\mu S\,cm^{-1}$ or greater should be considered as unsustainable.

Catchment Experiments

Catchment studies are designed to investigate the effects or define major processes of salinization at a catchment scale. Paired catchment studies that use a control to evaluate the impacts of salinization are preferable. In a single-catchment experiment, the effects of a land use change are measured by comparing measurements made before and after the change occurred. In a paired catchment experiment, land use is held constant on the control catchment and changed on the treatment catchment. The differences in the hydrologic response and water quality can then be compared with catchments experiencing the same weather patterns. In single-catchment experiments, it

may be difficult to separate the effect of land use change from the effects of different weather patterns before and after the land use change. Paired catchment studies are more costly, but provide more accurate results because the effects of change are being measured under the same weather conditions on the two catchments.

It is critical in the design of catchment experiments, particularly those concerned with the water and salt balance, that the experimental error attached to the effect being studied is not larger than the effects themselves (Calder, 1992).

Catchment Experiment – Case Study

Long-term coupled experimental catchment studies are fundamental in understanding the long-term impact of clearing on the development of land and stream salinity. In 1973, the Western Australian Government and CSIRO (Commonwealth Scientific and Industrial Research Organisations) established five experimental catchments (Table 8) to quantify the salinity impacts of agricultural development. Three of the catchments were cleared in 1976 using a range of clearing strategies and the other two catchments were left untreated and considered as control catchments.

The major research findings, summarized in Peck and Williamson (1987), Ruprecht and Schofield (1989) and Ruprecht and Schofield (1991a, b) are considered to include:

- a rapid rise in groundwater level following clearing, even where the preclearing level was more than 10 m from the ground surface. Although the response time-lag varied, groundwater levels at the range of depths and landscape positions responded rapidly to land clearing in both the high and medium rainfall zones.
- preferred flow paths were the dominant routes for water recharging aquifers postclearing
- the characteristic shape of salt profiles identifies the nature of infiltration in the unsaturated zone and groundwater recharge
- groundwater discharge areas are source areas for runoff and streamflow. The increase in streamflow following clearing was strongly correlated with the development of areas of saturated soil associated with groundwater seepage (Ruprecht and Schofield, 1989).
- streamflow and salt load increased immediately after clearing at the high rainfall site (Wights), with a fourfold increase in streamflow and a 15-fold increase in salt load compared to preclearing levels
- streamflow and salt load from the Lemon Catchment increased dramatically when saline groundwater reached the soil surface in the valley of the catchment (Ruprecht and Schofield, 1991a).

Table 8 Summary of Collie research catchments

Catchment	Treatment	Rainfall zone / salt risk
Salmon	Control	High – low salt risk
Wights	100% cleared	High – low salt risk
Ernies	Control	Medium – high salt risk
Lemon	50% cleared	Medium – high salt risk
Dons	38% cleared in parkland and strips	Medium – high salt risk

Geophysical Approaches to Salinity Mapping

Airborne geophysical techniques, primarily magnetic and radiometric, have been used as the primary methods of mineral exploration since the 1950s. The development of new geophysical technologies, namely, *airborne electromagnetic systems* (AEM) and significant improvements in AEM data processing software and data visualization technique provided the possibility of rapidly obtaining salinity related data over large areas that could assist in dryland salinity investigations. Electromagnetic surveys provide data on the nature of the regolith and the distribution of salt in the landscape. Application of these datasets for land management began in the mid-1980s, although significant analysis and interpretation for farm and catchment planning has been undertaken since 1993 (Rhoades *et al.*, 1997; George, 1998).

Airborne geophysical datasets provide a cost-effective method for mapping, monitoring, and providing better understanding of the surficial geology, particularly when dealing with high-value assets. Research has primarily been concentrated in identifying high conductivity areas, which may suggest the presence of high salt concentrations and the detection of geological structures that impede or facilitate enhanced groundwater flow. These areas can be targeted as priority areas in managing dryland salinity on catchment scale.

Modeling Approaches

Modeling approaches that describe and quantify basic hydrological processes and phenomena under a range of conditions are very useful in salinity investigations, particularly in the assessment of management options. Jakeman *et al.* (1987) delineated the types of models required, and discussed some problems in their construction and calibration.

Groundwater models are useful if a management strategy is required to consider the effects of rainfall, irrigation, cropping activity, groundwater pumping, and land use change on groundwater levels, and on land and stream salinity. Hydrologic routing and surface water quality models can be used to predict downstream salinity concentrations, for management strategies such as salinity dilution by release of additional discharge from upstream storages; to provide advance warning of salinity levels that are too high for irrigation usage; and for quantifying saline inflow within a river reach.

The complexity of model development for specific cases and the lack of required field data are major reasons why some models are used more frequently than others. For example, groundwater, stream routing, and surface water models are used more frequently than complex groundwater solute transport models and unsaturated flow and transport models.

The response of salinity or salt concentration to changes in stream and river flow has been studied in several ways, but investigation of rating relationships between salinity concentration and streamflow represents the traditional approach (Walling and Webb, 1986). Such relationships typically take the form:

$$c = aQ^b \tag{4}$$

where c is solute concentration, Q is streamflow, a is the regression constant, and b is the regression exponent. Examples of more complex relationships of salinity to streamflow are given by Walling and Webb (1986).

Several factors may influence the form and timing of stormy-period chemographs and, in turn, generate hysteretic behavior. In particular, a "flushing effect" has been noted in many rivers (e.g. Walling and Foster, 1975) by which soluble material accumulated during the prestorm period is mobilized and transported to the stream where it influences solute concentrations during the early stages of a storm event. In some cases, dilution in solute concentrations associated with a storm event may be preceded by increasing concentrations. Solute accumulation before a flood event will be affected by evaporation of soil moisture, capillary rise, and the buildup of dry fallout deposits, leaf residues, and dead plant material (Walling and Foster, 1975). Flushing effects are particularly pronounced in autumn storms following solute accumulation over the summer period, and Klein (1981) has demonstrated that solute concentrations in overland subsurface flows are systematically related to the length of the dry period preceding a storm.

In contrast to the flushing effect, solute stores within a catchment may exhaust during a sequence of closely spaced flood peaks (Walling and Webb, 1986). Progressive exhaustion of solute stores may cause a systematic shift in the position of the hysteretic loop as reported by Cornish (1982) from an investigation of German's Creek catchment in New South Wales.

The form and timing of solute responses may be significantly affected by contrasts in the chemical concentration of surface and subsurface flow components (Anderson and Burt, 1982). Water flowing by different routes over and through the soil at varying rates in separate phases of a storm event will have differential access to soluble material distributed unevenly within the soil profile (Walling and Webb, 1986).

There are several examples of models developed in South Africa to simulate the salinity of river inputs to reservoirs (Hall and Gorgens, 1979) in which solute pickup subroutines have been added to existing runoff models.

The exponential form of leaching was used by Hall and Gorgens (1979) for a large catchment in South Africa. The basic equation of leachate concentration was:

$$C = C_o e^{(-R.t/W)} \tag{5}$$

where R is recharge
W is the soil water storage
C is instantaneous leachate concentration
C_o is initial leachate concentration

Soil Water Modeling

At a more detailed level, Bresler (1981) and Raats (1981) reviewed the process of transport and residence times of salt and water through soil systems. Raats (1981) considered the input–output relationships for a two-dimensional saturated soil system and found an exponential distribution of arrival times. It has also been used in theoretical discussions of input/output relationships (Eriksson, 1971), leaching of solutes from a laboratory model (Peck, 1973), and the chloride balance of some farmed and forested catchments in southwestern Australia (Peck and Hurle, 1973).

Process models of water and solute movement include steady-state soil salinity models to predict salinity in the root zone from irrigation application and associated water salinity (Oster and Rhoades, 1990); models that simulate the dynamics of salt movement (accumulation and leaching) in the soil profile and plant response to salinity (Simunek and Suarez, 1994; Huston *et al.*, 1990; Simunek *et al.*, 1994); models that simulate irrigation return flow and its salinity (Aragues *et al.*, 1990); and models that simulate solute transport in the saturated zone (Table 9).

Catchment Modeling

Although there has been considerable progress in understanding the complexity of water and salt flows, most models are site specific and do not have wider applicability. In particular, more work is still required in the validation of models and on increasing their applicability for management decisions.

Small-scale, physically based catchment models that include salinity processes include TOPOG (Vertessy *et al.*, 1996) and WEC-C (Croton and Barry, 2001). In Australia, TOPOG and WEC-C have been applied to small experimental catchments (Silberstein *et al.*, 1999; Bari and Croton, 2002). LASCAM (Sivapalan *et al.*, 1996b) is a conceptual hydrology model that can represent the dryland salinity processes following land use changes of large catchments (applied on catchments up to 100 000 km^2 in area). This model has been applied to catchments affected by dryland salinity in Australia (Sivapalan *et al.*, 1996a, b).

More recently, the groundwater flow model MODFLOW (Michael *et al.*, 1988) has been used to predict the extent

Table 9 Summary of some models applicable to salinization

Model group and name	Description	Reference
Process models		
AgET	1-D soil water model for various vegetation and soil profiles	Argent and George (1997)
UNSATCHEM	2-D transport model for variably saturated porous media with major ion chemistry	Simunek and Suarez, 1994
LEACHM	Leaching estimation and chemistry model – A process-based model of water and solute movement, plant uptake, and chemical reactions in the unsaturated zone	Wagenet and Hutson, 1992
DRAINSAL	Two-dimensional, finite element model that provides long-term predictions of the desalinization of a tile-drained soil and the associated changes in the quality of groundwater and drain effluent	Kamra and Rao (1994)
Hydrus 2D	HYDRUS-2D is a Windows-based modeling environment for analysis of water flow and solute transport in variably saturated porous media.	Simunek and van Genuchten, 1999
SALTMOD	Predicts soil salinity and salt content of groundwater and drainage effluent in irrigated agricultural land.	Rao *et al.* (1992)
DRAINMOD	Simulate the hydrology of poorly drained, high-watertable soils on an hourly or daily basis.	Skaggs (1980)
Catchment models		
CATSALT	Water balance and salt transport modeling at property and catchment scales	Beale *et al.* (2000)
LASCAM	Large-scale catchment model that predicts daily water volume and salt loads	Sivapalan *et al.* (1996 a, b)
WEC-C	Physically based small catchment model that predicts movement of water and salinity	Croton and Barry (2001)
TOPOG - DYNAMIC	Daily time-step model that describes how water moves through landscape. Includes solute movement	Vertessy *et al.* (1996)
IHACRES	Catchment scale rainfall-runoff model based on unit hydrograph approach	Jakeman *et al.* (1990)
MODFLOW	Groundwater flow model	Michael *et al.* (1988)
MIKE SHE	MIKE SHE is a modeling system describing the flow of water and solutes in a catchment in a distributed physically based way.	Refsgaard and Storm (1995)
GIS other related models		
MAGIC	GIS-based steady-state water and salt catchment model	Mauger (1996)
WSIBal	Lake model that models water and salt balance	Barr *et al.* (2000)
IQQM	River basin model of water and salt flows and stores for regulated and nonregulated systems	DLWC (1995)
SWAGMAN	Models impacts of management options and climate on watertable, salinization, and yield.	Meyer *et al.* (1996)
Flowtube	Simple groundwater model to allow evaluation of management options	Clarke *et al.* (1999)

of saline land and evaluate the various engineering options such as drains and groundwater pumping to control land salinization (Salama *et al.*, 1993; Dogramaci *et al.*, 2002). The results of these studies indicate that MODFLOW is a powerful tool to delineate and map areas underlain by a shallow watertable (the salinity risk area).

To cover all processes that contribute to salinity development in large-scale catchments with one model, the MIKE SHE (Refsgaard and Storm, 1995) modeling system can be utilized. The model is an integrated and distributed, physically based, finite difference model. MIKE SHE comprises a number of flow modules, which may be combined to describe integrated surface water–groundwater dynamics and flow within the entire land-based part of the hydrological cycle, or tailored to studies focusing on areas of particular interest.

Statistical Approaches

Helsel and Hirsch (1992) provide a summary of applied statistical methods appropriate for river salinity analysis. The approaches include comparison of datasets, describing uncertainty, several approaches to developing relationship between variables such as flow and salinity (including nonlinear regression and LOWESS), and trend analysis.

Richter *et al.* (1993) provide a comprehensive discussion of both graphical and statistical techniques of data analysis that can be utilized to analyze the water quality data and aid in identification of sources of groundwater salinization.

CONCLUDING COMMENTS

Salinization of land and water resources is a major environmental and economic problem facing many parts of the world. Soil salinization and the consequent degradation of agricultural land are proceeding so fast that, unless policies and approaches change, many countries will not be able to achieve sustainable agriculture to feed their populations in the foreseeable future. Many important ecosystems and internationally recognized wetlands are also under serious threat from the increased salinity.

Research on the fundamentals of managing land and water resources threatened by salinity through anthropogenic activity needs to be advanced to guarantee a sustainable environment. This research needs to be solution focused, leading to the development of sustainable land and water management practices that meet not only production goals, but also good social and environmental outcomes.

100: Water Quality Modeling

STEVEN C MCCUTCHEON

Faculty of Engineering and Warnell School of Forest Resources, University of Georgia on assignment from the US EPA National Exposure Research Laboratory, Athens, GA, US

Water quality forecasts are vital to determining limitations for point source waste loads and diffuse or nonpoint source loads required to meet water quality standards in streams, lakes, and estuaries. Only mechanistic water quality modeling is widely applicable for forecasting. Although surface water quality modeling has a sound interdisciplinary scientific basis, the use of these analysis tools are limited in regulatory and resource decision making by a lack of a professional consensus defining model application protocols. To analyze water quality problems, (i) the uses for a water body must be evaluated, (ii) models must be calibrated and tested to relate impaired water quality to the waste sources, (iii) a formal uncertainty analysis must define a margin of safety to protect human and ecological health, and (iv) when necessary, an economic analysis must be performed to determine if the designated uses are reasonably achievable.

SCIENCE AND ART

The engineering art of surface water quality modeling has a sound interdisciplinary scientific basis, but the use of these analysis tools for forecasts are limited in decision making by a lack of a professional consensus defining what application protocols should be followed. Model forecasts are important elements of determining point source waste loads and nonpoint source loads required to meet water quality standards in streams, lakes, and estuaries. *See* **Chapter 10, Concepts of Hydrologic Modeling, Volume 1** for a broader discussion of these modeling arts for all of hydrology.

At least three fundamental principles are used to formulate mechanistic water quality models for forecasting. These include Newton's Second Law from which the conservation of momentum equation is derived and three other conservation principles – water continuity, constituent mass conservation, and conservation of energy in temperature simulations and occasionally, turbulence closure. Fundamental to all mechanistic water quality models is the conservation of water and the conservation of constituent mass, whether dissolved or particulate. The most primitive models do a simple accounting for water and constituent mass present in the water body. Less primitive models use the continuity equation for water, and the hydraulic slope and water body morphometry to derive flows or velocities at a point and to account for changes in water volume due to flows entering and leaving the water body. Most state-of-the-art models also solve the conservation of water momentum and continuity equations to actually simulate flows from a specification of inflows, outflows, boundary roughness, and wind drag. The most advanced hydraulics and hydrodynamics models use conservation of energy and other semiempirical turbulence closure techniques to simulate the dynamic distribution of water volumes and flows throughout the water body. The allied water quality algorithms or separate models are based on the conservation of mass equations and Fick's law to derive a separate advective-diffusion equation for each dissolved or particulate constituent. The advective-diffusion equation uses simulations or specifications of water velocity and semi-empirical or empirical expressions of each important kinetic process that creates or destroys constituent mass. Lin and Falconer (**Chapter 17, Hydrological and Environmental Modeling of Transport Processes in Rivers and Estuaries, Volume 1**) write each one of these governing equations. On the horizon of applied science and expected to become a part of practice in the coming decade is the use of the Second Law of Thermodynamics to define unit stream power and simulate changes in channel geomorphology. These stream and

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

watershed geomorphology models are expected to add a fifth fundamental principle to practical water quality modeling.

Although the empirical and semiempirical relationships are well known in water quality modeling, the practical procedures for defining the overall limitations of simulations at a particular site are not defined as well as necessary to support sound decision making. A high degree of experience in the art of water quality modeling is necessary to collect, compile, and derive water quality, flow, morphometric and meteorological data and parameters. The art of collecting, compiling, and selecting this information is driven by the specific resource management decisions to be made for the water body. Because resource management and environmental decision making are dynamic arts as well, the highest degree of practice requires iterative, interactive communication with resource managers, as project and program needs and objectives mature and change. *See* (**Chapter 14, Hydroinformatics and its Contributions to Hydrology: From Computation to Communication, Volume 1**) for a broader view of the experience necessary in hydrologic modeling.

The empirical and semiempirical parameters and coefficients used in water quality modeling must by definition be selected by calibration. Although, some data collection protocols and laboratory analysis of samples can be used to specifically determine some parameters, almost all of these numerical values still need to be confirmed during model calibration. Given the large number of empirical parameters involved, all calibrated water quality models require testing to define, at least in a limited sense, the range of applicability for a particular water body. Terms such as "verification" and "validation" have been used to describe the testing procedure. Occasionally, only calibration may be required for some modeling projects. When less precision and accuracy is needed, hydrodynamic and hydraulic models of water movement and conservative tracers may only require calibration checks of roughness coefficients and dispersion parameters, especially in large water bodies in which boundary friction and small-scale mixing is not vitally important.

Despite the general agreement on the need for calibration and testing (Thomann and Mueller, 1987), few well-defined calibration, testing, and hind casting or forecasting protocols have been agreed upon. This fact alone requires a high degree of art and experience in modeling. Thus, the most important element in water quality analysis is not the computer codes applied, but the expertise of the modeler to interpret the calculations and translate the numerical results into information which decision makers and mangers can use. Perhaps the most significant lag in the development of practice is the failure to agree upon and use statistical tests to define the precision and accuracy or uncertainty of all model applications. Guessing and then labeling water quality model calibrations as "good," "good enough," or in similar qualitative terms is not sufficiently informative for decision makers. Formally defining scientific uncertainty for decision makers is not an easy task, but is one that is vital to overcoming past misuses of water quality models in resource management. Plus, there are unknowable events in water quality analysis as in any analysis that is beyond the current imagination of humankind. However, this reality must not prevent practitioners from consistently and reliably describing the known limitations of models and simulation uncertainty for each application. Furthermore, because very few water quality models used in practice have been formally peer reviewed, site-specific definition of simulation uncertainty and definition of model limitations will remain necessary and vital.

Probabilistic modeling can also be linked to a formal uncertainty analysis. Like the statistical testing of calibrations and other simulations, the practical use of probabilistic approaches (Reckhow and Chapra, 1983) is significantly overdue in water quality forecasting (NRC, 2001).

The following two sections support this introduction to the science and art of water quality modeling. The next section reviews some of the practical models in use today to illustrate that uncertainty analyses are not adequately applied in practice. The final section briefly clarifies an application protocol for these models when used to determine a waste load allocation for point sources or nonpoint sources, or both, to illustrate procedurally when and how statistical testing and uncertainty analysis should be applied in water quality modeling.

PRACTICAL COMPUTER CODES

Table 1 lists representative practical models used in water quality analysis. These represent a consistent set of models for simulating the steady state and dynamic water quality of streams and rivers, lakes and reservoirs, estuaries, and watershed loads. This selection was limited to those US codes in the public domain or available to most government agencies, for which misapplication may be most probable. As practice in Europe and elsewhere avoids some misuse by mostly relying upon custom model formulations for each site investigated (*see* **Chapter 14, Hydroinformatics and its Contributions to Hydrology: From Computation to Communication, Volume 1**), Table 1 was limited to public domain codes to illustrate the weakness in US water quality modeling practice. Shanahan *et al.*, (1998) notes the lack of standard model development protocols that currently limit European practice in water quality modeling (**`http://harmoniqua.wau.nl`**).

Most striking from Table 1 is that only one practical model includes a formal first order uncertainty analysis,

Table 1 Some practical water quality models

Water body and dynamics	Model	Creation date	Uncertainty analysis	Comments
Steady state one-dimensional streams	QUAL2EU	1973	1st order error analysis	Developed by the US Environmental Protection Agency and is in the public domain at (**http://www.epa.gov/ceampubl/swater/qual2eu/**). The original code QUAL-II (Roesner *et al.*, 1973) has undergone (i) line by line peer review of the code and manual (NCASI, 1980) and (ii) peer review of the manual and testing using diverse data from three rivers (McCutcheon, 1983).
Dynamic one-dimensional streams and rivers (RIV1)	CE-QUAL-RIV1	1985	None	Developed by the US Army Corps of Engineers and available upon request (**http://el.erdc.usace.army.mil/products.cfm?Topic=model&Type=watqual)**. No known peer review of code and manual but the governing equations, solution schemes, and some simulation results has been published in the peer-reviewed literature.
Dynamic one-dimensional, two-dimensional, and three-dimensional lakes and estuaries	WASP7	1981	None	Developed by the US Environmental Protection Agency (Di Toro *et al.*, 1981; Connolly and Winfield, 1984; Ambrose *et al.*, 1988) and in the public domain (**http://www.epa.gov/ceampubl/swater/wasp**) and (**http://www.epa.gov/athens/wwqtsc/html/wasp.html**). Earlier version peer reviewed by NCASI (1987).
Dynamic one-dimensional lakes and reservoirs (R1)	CE-QUAL-R1	1985	None	Developed by the US Army Corps of Engineers from the Water Quality for River-Reservoir Systems computer code derived from the original slab model by Orlob (HEC, 1978) and available upon request but no longer maintained by the Army (**http://el.erdc.usace.army.mil/products.cfm?Topic=model&Type=watqual**). No known peer review of code and manual.
Dynamic two-dimensional water bodies (lakes and estuaries, W2)	CE-QUAL-W2	1975	None	Developed by the US Army Corps of Engineers from the Laterally Averaged Reservoir Model (Buchak and Edinger, 1981) and available upon request (**http://el.erdc.usace.army.mil/products.cfm?Topic=model&Type=watqual**). No known peer review of code and manual but (**http://www.ce.pdx.edu/w2/index.html?workshop.html**) indicates that over 516 applications of the code are known, many of which are independent of the Corps of Engineers.
Dynamic three-dimensional estuaries	CE-QUAL-ICM (Integrated Compartment Model)	1982 and 1989	None	Developed by the US Army Corps of Engineers and some versions are in the public domain (**http://el.erdc.usace.army.mil/products.cfm?Topic=model&Type=watqual**). CE-QUAL-ICM derived from the same box-model approach as WASP using a different numerical solution. No known peer review of code and manual but the Chesapeake Bay simulations have been reviewed by at least two independent panels and also published in the peer-reviewed literature.
Dynamic three-dimensional estuaries	EFDC (Environmental Fluid Dynamics Code)	1992	None	Developed by the US Environmental Protection Agency and in the public domain (**http://www.epa.gov/ATHENS/wwqtsc/html/efdc.html**). No known peer review of code and manual but Beach *et al.* (2002) documents a peer review of the conceptual basis of EFDC to simulate polychlorinated biphenyl fate and remediation in the Housatonic River.

(*continued overleaf*)

Table 1 (*continued*)

Water body and dynamics	Model	Creation date	Uncertainty analysis	Comments
Dynamic watersheds	HSPF11 (Hydrologic Simulation Package-Fortran)	1966	Has been used with Monte Carlo analysis (Golder Associates, 2003)	Developed by the US Environmental Protection Agency and US Geological Survey (Donigian *et al.*, 1984; Bicknell *et al.*, 1993) and is in the public domain at (`http://www.epa.gov/ceampubl/swater/hspf/`). No known peer review of code and manual. Independent experts tested the model with both field data and model experiments (Sullivan and Schueler, 1982; Schueler, 1983; Song *et al.*, 1983; Hicks *et al.*, 1985; Nichols and Timpe, 1985; Weatherbe and Novak, 1985; Udhiri *et al.*, 1985; Motta and Cheng, 1987; Moore *et al.*, 1988; Chew *et al.*, 1991; Chen *et al.*, 1998a,b).

Notes: Much of the information is from Martin and McCutcheon (1999). This table focuses on practical US water quality models. Rosbjerg and Madsen (**Chapter 10, Concepts of Hydrologic Modeling, Volume 1**) discuss select European models that are equally practical.

and only two codes have been formally peer reviewed. Yet, despite being the first and only model that includes the necessary uncertainty analysis, the QUAL2EU code has not been adapted to a Windows™ environment, and the US Environmental Protection Agency has developed a newer version that does not include uncertainty analysis (`http://www.epa.gov/athens/wwqtsc/html/qual2k.html`). While all other practical models should be used in an uncertainty analysis framework, only the HSPF seems to have actually been used in this manner (Table 1) in North America. A Monte Carlo analysis was used to generate probabilistic distributions of simulated and forecast water quality conditions (Golder Associates, 2003). This lack of formal uncertainty analysis tools incorporated into all practical software used for water quality modeling makes it vital in the following section to clarify that sound protocols must include uncertainty analysis and development of objective margins of safety in modeling practice. Rosbjerg and Madsen (**Chapter 10, Concepts of Hydrologic Modeling, Volume 1**) review the methods of uncertainty analysis for modeling.

The very limited number of peer reviews of water quality computer codes and manuals is disturbing and inefficient. Furthermore, the two codes, QUAL-II and Water Quality Analysis Simulation Program (WASP), which were peer reviewed, were examined in 1980–1983 and 1987. Since that time, both codes have been updated several times and these updates have not been peer reviewed and the revised codes independently retested. Thus, the scientific credibility of water quality modeling derives almost exclusively from independent case studies by experts in the field. These case studies, more extensive for some models than others, form only an irregular patchwork of *ad hoc* credibility for model use over the full simulation domains. Thus, almost all water quality modeling must only be undertaken by experts who understand the extent of the *ad hoc* credibility and are scientifically qualified to extend the patchwork credibility on a case-by-case basis. This requirement leaves few applications that can be undertaken by neophytes who have not mastered the history and practice. Much standardization and rigorous review are necessary to accommodate widespread use of water quality models in significant resource management and environmental protection decisions. The following protocol for water quality modeling stresses how these shortcomings must be overcome until the scientific bases can be updated, some standardization put in place, and resulting computer programs and manuals independently peer reviewed and tested over the full domain of intended use.

CLARIFICATION OF APPLICATION PROTOCOLS

The art of water quality modeling predominantly comes into play in applications of models to specific sites to address specific management issues. There are two dominant reasons why the relatively complete science of water quality modeling requires considerable art and experience. First, there is a lack of consensus on procedures to calibrate, test, and apply water quality models for a given quantity and quality of data. Practitioners typically ignore some procedures such as model testing and rarely describe the limitations of calibrated and applied models in terms that resource managers understand. Second, statistical criteria

to judge model calibrations and tests are diverse and are rarely used in practice. Sensitivity and uncertainty analysis are rarely used. When applied, analyses are not applied holistically with statistical testing to define well understood margins of safety that are now required for total maximum daily load analysis to be considered scientifically valid in the US (NRC, 2001) and should be required for all water quality design work. Instead, limited knowledge and investigation of conservative assumptions in model conceptual frameworks are typically used to assume that the required margin of safety is qualitatively covered. This implicit assumption is rarely stated, much less discussed in terms that resource managers seem to comprehend for use in decision making.

To overcome these severe limitations, the following general protocol should be followed for water quality analyses, such as a waste load allocation or total maximum daily load calculation for nonpoint source pollution:

1. Evaluate the designated uses for a water body or segment. The water quality criteria that define these uses typically define the water quality issues to be investigated. Designated uses may include water supply, provision of habitat, irrigation water use, recreation, industrial use, and other uses. The water quality criteria to protect the designated uses have typically been translated into standards by the responsible State, Tribe, or Environmental Protection Agency Region in the US. If the water segment has been classified as impaired and listed on the US 303(b) list [40 CFR (Code of US Federal Regulations) Part 130], then the evaluation should look at the reasons for listing, including the quantity and quality of data used for this purpose. Delisting should be an option when current assessment data no longer indicate impairment (Thomann and Mueller, 1987; Shabman and Smith, 2003).
2. Relate potential or existing water quality impairments of a water segment to the point and nonpoint source loads (Chapra, 2003), including legacy sources due to past waste and land management practices that might include contaminated sediments. Development of rational cause-and-effect models for forecasting requires data collection, model calibration, and testing to define model limitations and uncertainty using well-defined sensitivity and statistical testing (*see* **Chapter 10, Concepts of Hydrologic Modeling, Volume 1**; **Chapter 17, Hydrological and Environmental Modeling of Transport Processes in Rivers and Estuaries, Volume 1**; **Chapter 14, Hydroinformatics and its Contributions to Hydrology: From Computation to Communication, Volume 1**). The data used to test a model must be independent of the data used to calibrate the program. Sensitivity analysis is used to define an operational model for forecasting within the defined limits, or other analyses so as to hindcast causes of problems. The limits of an operational or calibrated model are defined by the conditions used in the calibration and testing of the model. However, no protocols seem to have been agreed upon to define the limits of a calibrated and tested model. Statistical evaluation using consistent statistics (McCutcheon *et al.*, 1990) and preselected levels of allowable error in decision making is required to determine when a model is adequately calibrated and to test a model with independent data sets. Alternatively, the level of significance for the calibration and independent testing can be determined statistically and used to convey the level of uncertainty to decision makers. If they deem the uncertainty too high, then adaptive management can be employed to make some load reductions, collect more calibration and testing data, and repeat the calibration, testing, and formulation of an operation model.
3. Application of the calibrated and tested model involves iterative simulations of scenarios that represent decreases in point and nonpoint sources to ensure that water quality standards and criteria are met. A formal uncertainty analysis must be used to define the vital margin of safety or factor of safety (Thomann and Mueller, 1987; NRC, 2001; Reckhow, 2003; Walker 2003), along with knowledge of the resource management and environmental protection objectives. This objective margin of safety is generally defined in terms of the following:
   (a) Reserve waste assimilation of the water body
   (b) Potential for acute and chronic human health effects associated with certain designated uses (the greater the risks, the larger the margin of safety should be)
   (c) Life history of all important aquatic species effects for certain designated uses
   (d) Habitat effects for certain designated uses
   (e) Known uncertainties in water quality simulations
   (f) Risk of upsets in point source treatment plants leading to occasional discharge of untreated waste waters
   (g) Reliability of best management practices that may be selected for nonpoint source control.
4. Where required, an economic analysis should be performed to determine the impact on waste load allocations and total maximum daily load allocations. Basic data should be provided for water quality managers to weight costs of achieving or maintaining water quality standards compared to the benefits of the designated uses, consistent with the antidegradation or nondegradation policies associated with the US Clean Water Act [see 40 CFR §131.12 and (**`http://www.epa.gov/OCEPAterms/nterms.html`**)].

Acknowledgments

The reviews of Tim Wool of the US Environmental Protection Agency Watershed and Water Quality Modeling Technical Support Center, the editor, and anonymous reviewers are appreciated. Mark S. Dortch, Tom Cole, and Dotty Tillman of the Water Quality and Contaminant Modeling Branch of the US Army Waterways Experiment Station provided information on the availability and peer review of the Army models in Table 1. Dr. Earl Hayter of the US Environmental Protection Agency National Exposure Research Laboratory provided information on the EFDC. The electronic software templates for this article were prepared from information on the web sites of the Water Quality and Contaminant Modeling Branch of the US Army Waterways Experiment Station and Portland State University, and from the sites of the US Environmental Protection Agency Center for Exposure Research Modeling and the Watershed and Water Quality Modeling Technical Support Center. This paper has been reviewed in accordance with the US Environmental Protection Agency peer and administrative review policies and approved for publication. PART 9

Ecological and Hydrological Interactions

101: Ecosystem Processes

ALAN P COVICH

Institute of Ecology, University of Georgia, Athens, GA, US

Biological production in inland waters is limited by flows of energy and nutrients across landscapes that undergo complex spatial and temporal dynamics driven by hydrological processes. Primary production (by photosynthesis or chemosynthesis), nutrient uptake and cycling, and decomposition of organic matter are all interconnected by the movement of water and organisms among interconnected ecosystems. Hydrology influences rates of transport, deposition, and recycling of inorganic materials, which, in turn, influence the various species and their associated ecosystem processes. Ratios of nutrients limit productivity and influence foraging behavior of consumer species. The ratio of carbon to nitrogen to phosphorus (C:N:P) available to plants often limits rates of photosynthesis. In many inland aquatic ecosystems, the scarcity of phosphorus limits plant productivity, although nitrogen or light are often limiting factors in lakes and shaded streams. Suspended sediment transported by runoff carries adsorbed nutrients and influences light penetration that, in different combinations, can limit rates of photosynthesis.

Dispersal of individuals to high-quality habitats and assembly of natural communities sustain functional groups of species and ecosystem processes following disturbances (such as severe floods and droughts or accidental spills of toxins). This dispersal is often limited by hydrologic connections among different habitats. Some "fugitive species" are especially well adapted for dispersal, and may include other nonaquatic modes of movement. These highly mobile species rapidly colonize new habitats or disturbed habitats and are widespread, generalist species in terms of their roles in ecosystem functioning. Other species have more specialized ecosystem roles in particular habitats and are less adapted for dispersal. These species have restricted distributions and different adaptations for persistence, in relatively isolated ecosystems with limited habitat connectivity.

If population densities increase beyond carrying capacity in optimal habitats, the movement of species from their high-quality habitats to low-quality habitats creates sink populations where individuals survive but do not reproduce and cannot sustain ecosystem services. Source populations are those that continue to reproduce in high-quality habitats and to produce individuals who disperse to locations with lower or variable habitat quality. The occasional flow of genes among these usually isolated subpopulations (metapopulations) influences the long-term evolution of species and aggregations of partially isolated communities (metacommunities). These biotic processes and their associated ecological services depend on sustainable flows of water throughout habitats in entire drainage networks. However, high degrees of connectivity also allow introduced, nonnative species to spread and possibly displace native species. Over time, the loss of native species which are well adapted for long-term variability in environmental conditions can, in some catchments, lead to instability and unreliable provisioning of ecosystem services by nonnative species.

INTRODUCTION

A close look at any drainage basin reveals significant spatial heterogeneity that can influence both hydrological and ecological processes. From micro- to macroscales, there are different distributions of horizontal and vertical elements of the landscape that are important to the structure and function of aquatic ecosystems. These elements influence how water flows across the terrain's surfaces and subsurfaces as well as the distributions of species that perform essential ecosystem processes. Discharge, infiltration, and residence times of water are all influenced by

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

these surfaces. Their combined flowpaths affect weathering, sediment transport, nutrient cycling, as well as biological diversity and productivity. Thus, geological, hydrological, and biological interactions all determine the distributions and dynamics of plants and animals over time and space. The succession of biological communities has predictable patterns of nutrient retention and storage that can be best understood once the underlying physical template is defined and examined in terms of eco-hydrological connectivity.

This review focuses primarily on biological structure and productivity within and among aquatic habitats that are interconnected within drainage networks. The relevance of aquatic connectivity for the dispersal of species and the assembly of plant and animal communities is widely recognized and well documented. The determination and understanding of these general relationships of ecosystem structure and function are the result of more than a century of field studies and analyses of complex natural systems. However, conceptualization of numerous hierarchical linkages in both horizontal and vertical dimensions among aquatic ecosystems has developed most rapidly in the last 10 years.

The varied degrees of isolation and connectivity among populations of aquatic species are strongly influenced by hydrology and topography. Following disturbances, numerous factors determine how species reassemble into the biological communities that influence ecosystem-level processes. The patchy distributions of many aquatic ecosystems (ponds, floodplain lakes, wetlands) result in some degree of spatial separation for varied periods of time. Frequently, however, isolated components of aquatic and terrestrial ecosystems are interconnected by floods or by the ways water resources are managed. For example, flood control can eliminate connections among rivers and floodplain habitats and alter groundwater connections.

The loss of native species which are well adapted for long-term environmental conditions can lead to instability and unreliable provisioning of ecosystem services (Giller *et al.*, 2004a). Water management decisions that alter hydrologic regimes can increase the loss of native species and replacement by nonnative species. Sometimes, these species can functionally substitute for the native species for periods of time. However, these nonnative species may not be well adapted in the long run as conditions continue to change. The intrinsic variability of natural ecosystems often requires a complex mix of species that are capable of sustaining ecological processes in a wide range of conditions. In some cases, there are species interactions that facilitate ecological process through serial processes that favor mutual interactions among species. The loss of one of these species can result in a cascading chain of losses or declines in rates of ecological processes (Covich *et al.*, 2004a). Thus, the distributions of specific producer and consumer species in biotic communities influence rates and types of biological productivity of inland waters (Table 1). This spatial complexity of drainage basins (Table 2) is essential for sustaining the natural processes and ecological services provided by aquatic ecosystems.

Ecosystem Characteristics

Inland aquatic ecosystems are open, self-organized, potentially resilient systems composed of interacting abiotic and biotic components (Wetzel, 2001). Internal ecosystem dynamics of nutrient cycling and flows of energy are regulated by a complex series of interactions among species within food webs and by physical and chemical controls. The biological productivity and biodiversity of any lake, river, or wetland reflect their locations within a drainage network and their histories of disturbances. The rates and timing of abiotic inputs of energy, water, and nutrients to aquatic ecosystems are determined by regional climate, geology, and topography. Erosion, transport, and deposition of sediments in drainage basins regulate complexity of substrata used by the aquatic biota (Amoros and Bornette, 2002; Malard *et al.*, 2002). Assembly of biotic components is determined by evolutionary adaptations, biogeographical relationships, and modifications of habitats over time. Colonization by species from within the region and by introductions of nonnative species influence species composition and their cumulative effects on productivity. Major species losses can occur from overharvesting of certain species and by diseases spread by introduced species (Malmqvist and Rundle, 2002; Holeck *et al.*, 2004; Giller *et al.*, 2004b; Padilla and Williams, 2004).

Interactions among distinct inland aquatic ecosystems emerge as characteristics associated with catchment-scale relationships often driven by climate, geology, and hydrology across a topographic landscape (Montgomery, 1999; Prosser *et al.*, 2001; Church, 2002; Richards *et al.*, 2002; Benda *et al.*, 2004). The physical template that determines how species move through habitats is dynamic and responsive to natural climatic variability and managed flows. Water diversions, channelization, dam construction, agricultural and urban land development greatly modify flows of water and materials while potentially reducing species diversity (Malmqvist and Rundle, 2002; Pringle, 2003a; Meyerbeck, 2004).

Conceptual Developments

Although early studies (Forbes, 1887; Forel, 1892) usually focused on single ecosystems and provided detailed analysis of a particular lake, river or wetland, this initial perspective clearly recognized that connections between terrestrial and aquatic components were important. For example, Forbes (1887) emphasized that lakes represented a natural "microcosm" with a great deal of internal, self

Table 1 Ecosystem terminology

Biogeochemical cycles: Flows of nutrients such as carbon, nitrogen, and phosphorus through distinct pathways within ecosystems.

Chemoautotrophy: Primary production by some microbes is based on energy-yielding chemical reactions as an energy source (rather than solar energy used by photoautotrophs) when synthesizing organic matter from inorganic materials.

Decomposition: The breakdown of dead organic matter (detritus) by bacteria and fungi that recycles nutrients.

Ecosystem: The set of interacting abiotic and biotic components in a spatially defined location where operational boundaries determine measurements of terrestrial, aquatic, and atmospheric inputs and outputs. A concept often used for examining specific questions regarding large-scale changes in the physical environment or shifts in assembly of species within a biotic community.

Ecosystem processes: Flows of energy, cycling of materials, and production of plants and animals are related to determine how ecosystem functioning reflects structure.

Food webs: Species are connected by flow of energy and cycling of materials from producers to consumers in ''flow maps'' composed on multiple food chains (single pathways through the entire food web).

Functional groups: Those species that perform similar roles in an ecosystem process as ''primary producers'' or ''decomposers''.

Heterotrophy: Production based on consumption of externally synthesized organic matter produced by other organisms (such as by herbivores, carnivores, and detritivores).

Photoautotrophy: The most common form of primary production (by green plants such as algae, macrophytes, and by certain bacteria) is based on solar energy when synthesizing organic matter from inorganic materials (carbon dioxide or bicarbonate ions).

Productivity: Organic synthesis by plants (primary productivity) and animals (secondary productivity) per unit area per unit time (annual productivity is usually expressed in units of Kcal m^{-2} $year^{-1}$) provides a basis for general comparisons across different ecosystems and over time.

Succession: Patterns of change in biotic assemblages within ecosystems from one season to another or over longer time periods (years, decades).

Trophic cascades: Changes in the presence or absence (or shifts in abundance) of predators results in altered production at lower trophic levels: primary and secondary productivity is alternately constrained or unconstrained by feeding activities of consumers at upper trophic levels (top-down control).

Trophic levels: Groups of organisms that share similar roles in food chains and food webs defined by the input and output of a shared-source energy. Energy transfers among adjacent groups provide measures of efficiency that are viewed as, sometimes, limiting the length of food chains (primary producers, primary consumers, secondary consumers, etc). A single species may be represented on multiple trophic levels if sources of energy change as a result of changes in their life history and modes of foraging.

Table 2 Drainage basin structure and consequences

Attributes	Measurements	Effects
Basin size	Large versus small area	Amount of runoff increases with basin size
Basin shape	Elongate versus circular	Runoff is faster in narrow basins
Network Pattern	Reticulate versus linear	Runoff is faster in linear drainage networks
Drainage Density	High versus low	Runoff may lag in high-density networks
Channel	Wide versus narrow width	Runoff begins in narrow tributaries (low-order) channels, flows into wider channels (higher-order) channels. Shading limits light in forested narrow channels, and primary productivity is relatively lower than in wide channels.

regulation of their biotic communities. Yet, he also noted that some lakes in Illinois (located within the Mississippi, Illinois, and Ohio River drainages in the central United States) were often isolated in small drainage basins while others were closely interconnected with rivers: "The fuviatile lakes. . .are appendages of the river systems. . . being situated in the river bottoms and connected with the adjacent streams by periodic overflows. Their fauna is, therefore, substantially that of rivers themselves, and the two should, of course, be studied together". Regional studies of lake districts made other early contributions to a landscape perspective. For example, Juday and Birge (1933) compared numerous lakes in northern Wisconsin that shared a glacial origin but differed in morphometry (depth, volume, shape, surface area), species composition and productivity. Thus, regional studies recognizing spatial and temporal dynamics at multiple scales have a long history in aquatic ecology.

Field studies of phosphorus cycling in inland waters by Hutchinson and his colleagues (Hutchinson and Bowen, 1947, 1950) in Connecticut, northeastern USA, used

isotopic tracers to quantify rates of primary productivity and cycling of the phosphorus available for plant uptake (dissolved orthophosphate) in the context of lake biogeochemistry. Related field studies of inland waters contributed additional fundamental concepts regarding biogeochemical relationships between ecosystem structure and function relative to energy flow. Lindeman (1942) provided an innovative framework for comparing how energy flows through food webs based on linked trophic levels; this work continues to stimulate studies that focus on how components within and among ecosystems are connected by energy flows. Odum (1957) quantified energy flows, mineral cycling, and productivity with methods that continue to integrate whole ecosystem dynamics by measuring dissolved oxygen production (photosynthesis) and oxygen uptake (respiration). Many studies began to use isotopes of carbon to measure rates of primary production (photosynthesis) and cycling of carbon.

Light availability and ratios of available nutrients can limit growth of primary producers, composed of suspended algae (phytoplankton) and rooted plants (littoral vegetation). Secondary producers, the herbivores and carnivores, compose the open-water (zooplankton), bottom-dwelling (zoobenthos), and fish communities, that are, in turn, limited by the availability of primary production. Redfield (1958) and his colleagues demonstrated relatively consistent ratios of carbon, nitrogen, and phosphorus that characterized open-water marine organisms (biomass). These ratios are based on the unifying concept of stoichiometry in which all biomass is composed of biochemically well-defined proteins, lipids, carbohydrates and nucleic acids that require basic elemental building materials. Such relationships provide reliable means for predicting where and when consumers might likely forage in different locations to obtain essential nutrition (Sterner and Elser, 2002). In general, these fundamental ecological and biogeochemical processes are often limited by nutrient transport, suspended sediments, and dispersal of organisms that are all interconnected by hydrological processes. For example, suspended sediments transport adsorbed nutrients and limit light penetration; concentrations of dissolved nutrients are altered by the quantity and source areas of runoff.

The importance of viewing lakes and rivers as integrated ecosystems composed of interacting groups of producers and consumers is now widely recognized as being based on coupled energy flows and cycling of nutrients. These ideas of a common energy currency coupled to nutrient cycling emphasize that lakes, river drainages, and wetlands are clearly linked to terrestrial and aquatic ecosystems with flows of energy and nutrients moving in different directions at different times. Odum (1969) determined the ways in which ecosystems change over time. He emphasized that early phases of biological community development are characterized by high rates of primary productivity with relatively few species and linear food webs. These early ecosystems generally have few mechanisms for retaining nutrients, and biomass storage is low. As the community increases in species diversity, the food web becomes further reticulated and rates of primary productivity decline. The more mature ecosystems have additional mechanisms for recycling and retaining nutrients as biomass storage increases.

On the basis of detailed local studies, conceptual advances have examined patterns of productivity by integrating analyses of nutrient budgets, trophic levels, and mass balances of energy (following the first law of thermodynamics). These energy and nutrient budgets also required detailed hydrologic budgets for comprehensive interpretations. Ecologists have had considerable success defining and integrating these budgets in relatively small catchments where sufficient data were available to provide reliable inputs. For example, Mirror Lake, in the Hubbard Brook Valley of the White Mountains, New Hampshire, USA, is one of the best-studied lake basins. Long-term hydrological and limnological studies provide a solid basis for placing biotic relationships in a well-documented ecosystem context that makes this glacial lake basin a testing area for ecological concepts (Likens, 1985, 2004). Information on tributary and atmospheric inputs of nutrients as well as surface and groundwater inputs are integrated over decadal timescales and related to biological productivity and biodiversity. Values of inputs and outputs provide nutrient and water balances that clearly document the important role of Mirror Lake as a key integrator of inflow relative to its outflow to Hubbard Brook.

Large-scale studies in limnology provided opportunities for ecologists, hydrologists, geologists, and atmospheric scientists to work together because interdisciplinary approaches were recognized as essential for a comprehensive analysis. For example, inputs of nitrogen and carbon from precipitation and wind-blown dust often provide sufficient amounts of these essential elements to entire regions within a lake district or large watershed. In contrast, phosphorus is usually scarcely distributed in catchments because of the localization of its geological deposits. Consequently, phosphorus is often the limiting nutrient in many inland waters because it has no atmospheric gas phase like carbon and nitrogen and can enter only as particulates or as runoff (Wetzel, 2001). Phosphorus limitation also results when this nutrient is stored in plant biomass and taken out of circulation until herbivores consume the plant biomass and recycle the organic phosphorus back into solution as orthophosphate. Also, there is considerable inorganic storage in lake sediments where phosphorus remains as an insoluble form (often bound by colloids and by chelates such as ferric hydroxide, or in various mineralized forms such as calcium phosphate in oxidized sediments). Frequently, phosphorus, nitrogen, and carbon are also available from locations of

human-derived, point sources (e.g. sewage-treatment plant effluent) and nonpoint sources (diffuse fertilizer-enriched runoff) in many drainage areas that require even more interdisciplinary perspectives on land use and water management.

The emerging conceptual framework of landscape-level ecosystem dynamics connected to hydrologic processes provided important insights for understanding and managing entire drainage basins (Cummins, 1974; Hynes, 1975). Terrestrial inputs of water and nutrients alter productivity of aquatic ecosystems in complex direct and indirect relationships. Food-web connections modify how energy flows affect nutrient cycling as well as nutrient storage in populations of the top-trophic level consumers. Fish biomass (standing stocks) can be managed to modify nutrient cycling and thus provide biological control of excessive plant productivity. For example, the presence of certain fish predators are know to alter their prey which in turn can alter the rates of consumption by their prey (herbivorous zooplankton feeding on phytoplankton) that alter plant productivity, nutrient cycling, and storage (Carpenter *et al.*, 2001). These indirect linkages among trophic levels are termed *trophic cascades* and provide a means for controlling nutrient levels and rates of eutrophication by managing fish populations. Regulating the harvesting and stocking of certain types of predatory fish results in different types and quantities of herbivores and plants predominating in biological communities. This biomanipulation of food webs is an important tool for maintaining water quality for recreation and drinking water supplies (Shapiro, 1990).

In summary, managing land use in riparian areas and in entire land-water food webs has become an important ecosystem-level, concept-based approach for controlling nutrient availability in aquatic habitats that are highly interconnected with terrestrial habitats through hydrologic processes (Malmqvist and Rundle, 2002; Power and Dietrich, 2002; Thoms and Parsons, 2003). The effects of wetland, floodplain, and groundwater connections emerge as critical links in understanding a landscape-level framework of analysis (Ward and Stanford, 1995; Smith, 1998; Benke *et al.*, 2000; Junk and Wantzen, 2004). Ecologists and hydrologists continue to explore in-depth connections among ecosystems (Hershey *et al.*, 1999; Benke, 2001; Ward *et al.*, 2002) and emphasize that landscape-level network connections (Rodriguez-Iturbe, 2000; Gomi *et al.*, 2002; Fisher *et al.*, 2004) are critical to understanding how changes in land use or climate alter whole drainage basins (Winter, 2001; Likens, 2004). Although many land-water connections were recognized in earlier studies, important linkages within drainage networks were rarely documented relative to rapidly changing land use or at the scale of nested catchments. The increased use of spatially explicit modeling has provided a means to incorporate patchiness and degrees of isolation into more comprehensive analysis of catchment connections (Gergel *et al.*, 2002; Poole, 2002).

THE PHYSICAL TEMPLATE AS CONTROLS ON ECOSYSTEMS

The geologic origins, landscape topography, and connections among inland aquatic ecosystems all form the physical template for processes that alter residence times of water as well as light and nutrient availability. These physical processes influence biological productivity within any drainage basin. The origin of aquatic ecosystems by geologic or other means (Hutchinson, 1957) often determines topographic locations and connectivity to biogeochemical processes within natural landscapes (Swanson *et al.*, 1988; D'Angelo *et al.*, 1997; Grimm *et al.*, 2003; McClain *et al.*, 2003). Subsequent events further connect different ecosystem components (e.g. rivers, lakes, groundwaters, and wetlands) so that coupled physical, chemical, and biological interactions develop over time (Bishop, 1995; Winter, 2001; Richards *et al.*, 2002; Likens, 2004). Atmospheric inputs, runoff, and residence times of water within drainage basins are bounded by the topographic template that constrains species distributions and biological productivity (Hynes, 1975). Thus, the directions, rates, and quantities of water movements influence patterns of species diversity, food-web structure, and function, which, in turn, regulate ecosystem dynamics such as biological productivity, decomposition, and cycling of nutrients and other materials.

Spatial relationships within landscapes strongly control biogeochemical nutrient cycling and biotic productivity (Sorrano *et al.*, 1999; Hershey *et al.*, 1999; Kling *et al.*, 2000). Recent studies on these coupled physical and biological relationships have stimulated new research perspectives (Rice *et al.*, 2001a,b; Poole, 2002; Fisher *et al.*, 2004). As a result, the International Hydrological Program recognized the importance of eco-hydrological connectivity as a major focus for research and management (Janauer, 2000). The interdisciplinary conceptual integration needed to understand how drainage networks can regulate ecosystem processes and biological productivity is emerging as an important area of synthesis. This review first considers how individual streams and rivers are hydrologically linked and then includes the additional complexity of connected lakes and floodplains. Finally, isolated standing waters are considered as additional components that have indirect hydrologic connections.

River Drainage Networks

Running waters are organized in a hierarchy of flow paths from small streams to large rivers so that their combined erosive energy creates a drainage network regulated by the geology, climate, and disturbance history of a catchment

basin (Nakamura *et al.*, 2000; Osterkamp, 2002; Kinner and Stallard, 2004). Drainage density (the ratio of the total stream channel lengths of a drainage network relative to the drainage basin area) is one indicator (Table 2) of how water moves across a landscape, altering runoff and infiltration over geological timescales (Osterkamp, 2002). Along with climate, the topology of the network controls rates of sediment, nutrient transport, and routes of dispersal by many species, which, in turn, influences species distributions.

Drainage networks are dynamic in space and time with surface and subsurface waters interconnected vertically and horizontally. Channel locations at the confluences of tributaries (nodes) have physical attributes that are different from sections of river channels (links) within the drainage network. These confluences result in the combined transport and deposition of sediments that are abrupt and nonlinear in terms of the sizes and amounts of substrata (Benda *et al.*, 2004). The size distributions of substrata and their residence times (stability of organic and inorganic deposits) influence biotic habitats and abundances of bottom-dwelling (benthic) species.

A multidimensional framework is needed to integrate the flows within the network because of the complex horizontal linkages among pools and riffles within the channel and many types of lateral connections with floodplains (discussed in the following sections). Vertical connections within many sediment-filled river channels also link subsurface flows through groundwater and the porous sediments within channels (the hyporheic zone) to create a highly complex set of flow paths through interstitial deposits (Boulton *et al.*, 1998; Poole, 2002; Fisher *et al.*, 2004; Poole *et al.*, 2004). This subsurface zone is often an active site for exchange of water, dissolved nutrients, and organic matter that contains a high diversity of benthic invertebrates and microbes. Up-welling waters typically contain dissolved nutrients that increase algal production at the channel surface. Down-welling zones often transport dissolved oxygen and organic matter into depths where microbial and invertebrate communities process the materials (Stead *et al.*, 2004).

Drainage network characteristics provide numerous other conceptual bases for linking physical and biotic characteristics. One of the first examples was the River Continuum Concept (RCC). The RCC considered tributary sizes and linkages (stream order) together with channel widths as predictors of biotic community composition and function (Vannote *et al.*, 1980). Although this initial emphasis on a linear profile in the RCC was useful as a basis for forecasting the distributions of functional feeding groupings of invertebrate species (primarily aquatic insects) along some rivers, it was insufficient for understanding how other riverine food webs functioned (Perry and Schaeffer, 1987; Thorp and Delong, 1994; Fisher, 1997; Fisher *et al.*, 1998). One of the main features of the RCC was a focus on connectivity between riparian forest inputs of leaf litter and headwater stream energy sources for detritivores. Another feature was the longitudinal coupling of species based on stream orders. The pattern of organic-matter processing emphasizes that species (shredders) in headwaters (upper tributaries that comprise first- and second-order streams) break down coarse leaf material into fine suspended particulates that are consumed by downstream, filter-feeding species. These processing chains in forested headwaters depend on adequate flow and turbulent transport. These biotic linkages provide an example of flow-mediated ecosystem processing that is drought sensitive, in temperate-zone streams (Whiles and Dodds, 2002) and even in tropical rain forests (Crowl *et al.*, 2001; Covich *et al.*, 2003).

Rice *et al.* (2001a,b) developed the Link Discontinuity Concept (LDC) on the basis of the distribution of distinct habitats along elevational profiles of river drainages that are associated with sediment grain sizes resulting from various types and sizes of tributary confluences. These nodes in the drainage network are characterized by distinct substrata that are preferred by certain species. The differences in substrata identified in the LDC were not previously examined in detail within the RCC. The LDC conceptualization does not compress various stream orders into a linear elevational gradient (as in the RCC). Rather, the LDC emphasizes disjunct distributions of stream power as a framework for predicting species distributions in the drainage network as was also recognized by earlier studies (Ward and Stanford, 1995; Montgomery,1999).

There are numerous case studies describing how drainage networks are structured and how local geomorphic features influence ecological productivity (Hershey *et al.*, 1999; Gomi *et al.*, 2002; Parsons *et al.*, 2003). A general pattern occurs among drainages in high-relief, montane catchments where the particular locations of waterfalls create barriers for upstream migrations of fish, crustacean, and molluscan species (Covich and McDowell, 1996; Covich *et al.*, 1996; Smith *et al.*, 2003). For example, in the Luquillo Long Term Ecological Research Project in the Luquillo Mountains of Puerto Rico, the locations of the first waterfalls as a function of distance from the coast are the best predictors of biotic communities and food-web structure (Figure 1). Numerous species of predatory fishes live in the coastal estuaries and many can move various distances upstream into freshwater rivers (Covich and McDowell, 1996). Other predators such as wading birds and large decapod crustaceans (freshwater crabs and shrimps) are important consumers that are most diverse at low elevations, and some species are widely distributed in upstream portions of the drainage network. The abundance and size distributions of invertebrates in many headwater pools results from a large number of juveniles that migrate upstream from estuaries. As these invertebrates move upstream and grow, they are subject to fish predation

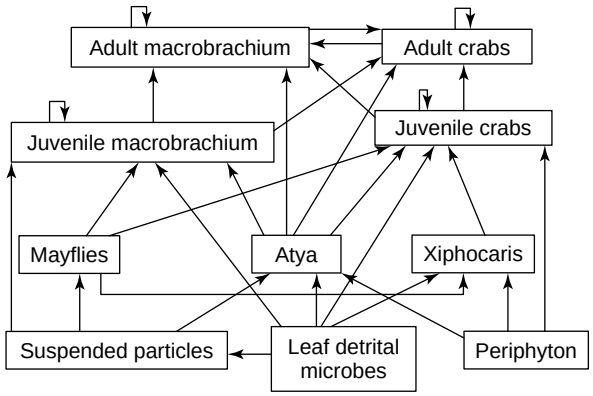

Figure 1 Food-web connections in headwater tropical streams of the Luquillo Mountains, Puerto Rico (Modified from Covich and McDowell, 1996) Arrows indicate how energy flows from in-stream primary production by algae (periphyton) and from riparian inputs of leaf litter (processed by bacteria and fungi) to consumers (insects and decapods). Loops indicated cannibalism by different ages of freshwater shrimp (*Macrobrachium carcinus*) and crabs (*Epilobocera sinuatifrons*)

by mountain mullets (*Agonostomus monticola)* and eels (*Anguilla rostrata*) at lower elevations. However, the upstream distribution of these two dominant fish predators are limited by the location of steep waterfalls ($>8-10$ m in height) that create barriers. Typically, the lowest-elevation waterfalls are relatively small and many are submerged during floods. These periods of inundation allow for upstream movements by migrating fishes. However, a threshold exists in the height of waterfalls that forms persistent barriers. Those waterfalls that are too high to be submerged are the primary geomorphic features that spatially limit assembly of food webs and cause upper tributaries to differ from lower portions of the drainage network. Thus, the local, spatial differences of topographic barriers in various catchments can modify upstream dispersal and formation of food webs. Generally, geomorphic features can help forecast ecosystem structure and processing rates by the ways terrain controls distributions of various key species.

River Drainage Networks with Standing-Water Connections

Direct, visible connections among flowing-water and standing-water habitats form complex patterns that have critical linkages with terrestrial habitats. The complex digitations of shorelines formed by reservoirs and many natural lakes increase the terrestrial transfers across these zones of runoff and organic detritus. These land-water connections are altered by changes in water levels that occur frequently in lakes, rivers, and wetlands during periods of seasonal floods and droughts. Longer-term, climate-induced drying out of springs, tributaries, and other habitats further change patterns of connectivity as a result of changing annual water balances. River inflows from drainage areas, inflows from groundwaters, and direct precipitation (on their lake surface areas) are the total annual inputs while evaporation and outflows are the main outputs that determine the annual lake water balance. Water balances are also modified by vegetative cover and land use that influence sediment transport and infilling of lakes and reservoirs, especially during peak periods of runoff and flood pulses.

The number and distribution of in-flowing and out-flowing rivers and the management of dams, diversions, and reservoirs are major variables that determine lake levels, water quality, flood control, and connectivity with shoreline habitats. For example, the impact of metropolitan Atlanta on the downstream river channel of the Chattahoochee River (Figure 2) provides a case study of one of the most impacted rivers in North America. Models of reservoir productivity and complex food-web dynamics provide useful predictions needed for management and decision making (Osidele and Beck, 2004). The reservoirs upstream and downstream of Atlanta have extremely different levels of nutrient cycling and productivity. These complex hydrological interactions among multiple reservoirs and linked rivers within a drainage network create challenges for management of alternative uses of the reservoirs for recreation, flood control, hydropower production and municipal water supplies (Couch *et al.*, 1996). These challenges are especially acute during periods of floods and drought.

The capacity for water storage and long-term continuity of outflows in rivers and lakes is decreased as suspended materials are transported by rivers and deposited in channels and lake basins. These rates of sedimentary infilling are especially high in steep terrain with sparse vegetative cover, intensive land use, and extremes in precipitation. Reservoirs are often prone to rapid sedimentation in drainage areas with poorly managed land and, thus have a limited lifetime storage capacity. A few large stormflows can transport large inputs of sediments and require expensive dredging to restore the storage capacity. Changes in climate and alterations of vegetative cover and land use can result in major shifts in erosion (from weathering and landslides) that alter rates of sediment and nutrient accumulation, water storage capacities, and turbidity (Waters, 1995; Turner *et al.*, 2003). Particulates with absorbed phosphorus, nitrogen, and carbon as well as trace elements are transported downstream into lakes and reservoirs (Waters, 1995; Smith, 1998). The delivery of sediments to lakes or from one lake to another along river connections is hydrologically determined by variations in precipitation and runoff.

Large proportions of the total nitrogen and phosphorus inputs to a drainage basin are retained in small headwater streams by sediments and microbes through a process of nutrient spiraling in which nitrogen and phosphorus move in and out of a series of abiotic and biotic components within

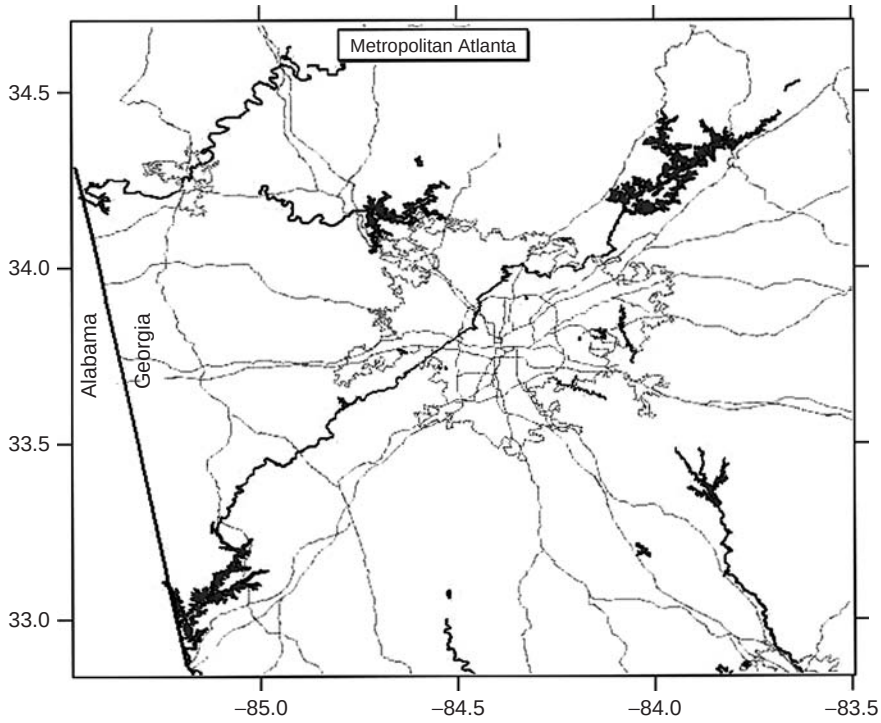

Figure 2 Effects of multiple reservoirs on downstream ecosystems. The Chattahoochee River in northeast Georgia flows from Lake Sidney Lanier through Atlanta to West Point Lake on the border with Alabama. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

the channel (Newbold *et al.*, 1983; House, 2003). Nutrients are also transported by animals as they move from one habitat to another; some species of fish and other consumers travel considerable distances within drainages (Hobbs, 1999; Fry, 2002; Vanni, 2002; Vanni and Headworth, 2004). Significant percentages of nitrogen are transformed through the process of denitrification into ammonia gas and released into the atmosphere (Alexander *et al.*, 2000; Thomas *et al.*, 2001). Locations (termed "hot spots") with relatively rapid nutrient transformations by microbial communities are associated with hydrologic zones characterized by relatively low dissolved oxygen and warm water (Grimm *et al.*, 2003; McClain *et al.*, 2003).

River-connected Oxbow Lakes and Floodplain Lakes

Differences in locations among rivers, lakes, and wetlands greatly influence how nutrients and organisms move within drainage basins. River-connected lakes associated with floodplains (parafluvial habitats) have distinct associations with seasonal flooding that inundate their otherwise isolated basins (Benke *et al.*, 2000; Junk and Wantzen, 2004). Floodplain-associated wetlands are spatially and temporally interconnected in complex ways that reflect geology, terrain, and management of surface and groundwaters. Floodplains are among the most intensively studied wetlands because the frequency and duration of inundation clearly alters transport and deposition of nutrient-enriched sediments and inflows of river waters, often reflecting predictable annual patterns of seasonal inundation (Lewis *et al.*, 2001; Knowlton and Jones, 2003; Hamilton *et al.*, 2004). These predictable seasonal processes increase access to both standing- and flowing-water habitats by fishes and other organisms that are well adapted to seasonal migrations and dispersal (Bornette *et al.*, 1998; Amoros and Bornette, 2002). The spatiotemporal complexity of flooding events also creates increased habitat heterogeneity that is critically important in maintaining high biodiversity and productivity (Benke *et al.*, 2000; Junk and Wantzen, 2004). Floodplain lakes and cutoffs of river-meander channels (ox-bowl lakes) are usually shallow and highly productive ecosystems, especially for fish that can readily move among these inundated habitats at different times of years to forage and reproduce. The development of lake stratification and subsurface flows among floodplain lakes and wetlands adds to habitat complexity and results in variable nutrient cycling and plant productivity.

The cessation or alteration of the timing and extent of natural flood events by flow management (such as channelization, diversions of river water and construction of locks and dams) greatly alters the natural flow regime and downstream biotic productivity (Poff *et al.*, 1997; Pringle, 2003b; Tockner *et al.*, 2000; Tockner and Stanford, 2002;

Thoms, 2003; Thoms and Parsons, 2003; Lytle and Poff, 2004). Cumulative effects of wetland drainage and water diversions result in losses of ecosystem services naturally provided by ecological processes that sustain wildlife populations, filter nutrients, and reduce risks of flooding to society (Kiker *et al.*, 2001; Covich *et al.*, 2004b).

River-connected Lake Chains and Lake Outflows

Some drainage basin networks are characterized by chains of interconnected lakes and rivers (Kling *et al.*, 2000; Webster *et al.*, 2000) and chains of reservoirs (Elser and Kimmel, 1985). In montane regions, these chains have hydrologic connections based on major differences in elevation that create complex spatial and temporal relationships in terms of water temperatures, transparency, nutrient concentrations, conductivity, salinity, and biotic productivity. Lakes connected by large, low-gradient rivers often have significant lags in transport of materials and residence times of nutrients. These lags are especially important in those lakes and reservoirs that are modified for flood control, navigation, and other purposes. For example, the upper Mississippi River (from Minneapolis, Minnesota to St. Louis, Missouri, USA) has been converted into a series of 29 reservoirs through construction of locks and dams for regulating water levels that enhance barge navigation. This section is quite different from the free-flowing lower Mississippi River (from the confluence of the Ohio River to the Gulf of Mexico) where the channel is constrained by flood-control levees. High discharge in naturally unconstrained rivers that connect a series of lake basins can create backflows, over-bank flooding of wetlands, and complex groundwater flowpaths in watersheds with low-gradients. Low-gradient connections that depend primarily on groundwater or small tributaries have complex but predictable down-slope patterns of water chemistry and productivity. Large-river ecosystem models are available to compare continuous flowing reaches (Thorp and Delong, 1994) with those that have distinct interruptions of managed flows (Ward and Stanford, 1995; Thoms and Parsons, 2003).

The Northern Lakes Long Term Ecological Research project in Wisconsin, USA, provides some of the first studies to document these surface and subsurface connections in low-relief terrain (Kratz *et al.*, 1991; Kratz *et al.*, 1997; Sorrano *et al.*, 1999; Baines *et al.*, 2000; Riera *et al.*, 2000; Webster *et al.*, 2000). Another well-studied example of a natural chain of lakes is located in the Arctic Long Term Ecological Research project in the northern foothills of the Brooks Mountain Range, Alaska, USA. The Toolik Lake catchment drains 66.9 km^2 in several subbasins. The largest subbasin covers 46.6 km^2 and its longest river drainage network contains 10 lakes and these flows are linked prior to entering Toolik Lake. The mean depths of these 10 lakes range for 4.9 to 25 m and have distinct differences in residence times and water balances during the spring thaw. Each inlet and outlet alters the downstream connections among these linked ecosystems through changes in alkalinity, pH, conductivity, nutrients, and dissolved organic carbon. As the drainage area increases along the downstream locations, there are predictable coherent relationships among abiotic variables and material processing (Kling *et al.*, 2000).

The Kissimmee River is another example of a complex natural river ecosystem that historically connected Lake Kissimmee with Lake Okeechobee in Florida. The flows among these connected ecosystems, the Kissimmee Chain of Lakes, were altered between 1962 and 1971 as part of the Central and Southern Florida Food Control Project. The meandering river was channelized so that 167 km of its natural channel was transformed into a 90-km-long drainage canal (9-m deep and 100-m wide). This project drained more than 21 000 ha of floodplain wetlands. Flow between lakes was regulated by canals, drainage ditches, levees, and pumping stations to provide water for irrigation as well as flood control, creation of pastures, and diversions of out-flowing nutrients to minimize eutrophication of downstream wetlands in the Everglades. Meeting the demands for urban and rural water uses resulted in greatly modified discharge to coastal zones, estuaries, and associated wetlands. Although the natural flow regime was altered, it was not irreversible. It is expensive to attempt restoration of both ecosystem structure and function and to reestablish a natural community again. A 70-km section of the river that influences 11 000 ha of wetlands is being restored to attempt to recreate a more natural flow regime (Dahm *et al.*, 1995; Steinman and Rosen, 2000; Warne *et al.*, 2000).

The Colorado River is another example of a large, complex river system in North America that now contains two of the largest reservoirs in the United States (Lake Mead, Lake Powell). These reservoirs in the lower Glen Canyon and Grand Canyon were designed to regulate complex flow regimes for generating hydropower and water storage to supply agricultural and municipal demands for water. A controlled flood in 1996 was used to restore substrata downstream of Glen Canyon Dam and Lake Powell by moving sediments and recreating beaches and backwater habitats (Patten *et al.*, 2001; Schmidt *et al.*, 2001). This experiment was well designed and documented, but the results indicated that relatively brief, infrequent, small floods are insufficient as a management solution for restoring the coarse-grained habitats needed by endemic species of fishes for spawning or for restoring the riparian vegetation dynamics needed by endangered wildlife (e.g. the southwestern willow flycatcher). This event was also insufficient to create persistent beaches for recreational uses such as river rafting. The study also helped in determining how the loss of volume in the reservoir altered water quality (Hueftle and Stevens, 2001) as well as loss of ecosystem services such as hydropower generation. Additional studies

were conducted to learn more about sediment transport and how dam operations can be used to manipulate downstream water quality. In general, restoration of river drainage connections within chains of lakes and reservoirs requires a perspective that recognizes that multiple, habitat-forming hydrologic events are needed at large spatial and temporal scales (Clarke *et al.*, 2003; Robinson *et al.*, 2004; Ewel, 2001).

Precipitation and weathering of rocks and soils within a drainage basin contribute inorganic elements to flowpaths that converge as surface or subsurface network flows into channels and basins. Webster *et al.* (2000) defined 3 functional classes among spatially connected lake networks: (i) spatially uniform lakes have a high degree of synchrony; (ii) spatially structured lakes have local synchrony among those within similar elevations; (iii) unstructured lakes lack synchrony. Thus, downstream flows among interconnected lakes create a wide range of variability in synchronous responses to disturbances based on differences in lake-basin morphometry and residence times (Kratz *et al.*, 1997; Sorrano *et al.*, 1999). One of the major characteristics of lake chains is that the inflows to rivers from lake outlets differ from inflows derived from tributaries within the drainage basin. Lake outlets are characterized by dynamic changes in water temperatures, nutrient concentrations, algal production, and suspended organic matter from density-stratified lakes and reservoirs (Richardson and MacKay, 1991; Cattaneo, 1996; Robinson and Burgher, 1999).

Closed Lake Basins and Wetlands

Depending on locations and shapes of closed lake basins (those with no outflows), these standing waters differ significantly with regard to their annual water balances. These basins lose water volume primarily through evaporation and sometimes through groundwater seepage. There is a great deal of research focused on vernal pools, wetlands, and closed lakes because they are important components in the hydrologic cycle (Bullock and Acreman, 2003). However, their water quality is changing and they are vanishing from many landscapes as a result of draining natural basins, diversions of water to urban uses, and infilling of these habitats during dry periods (Leibowitz, 2003; Whigham and Jordan, 2003). The hydrologic dynamics of these ecosystems also take on legal considerations as legislation is passed that is intended to protect them under "no net loss" guidelines or to devalue their ecological importance because they do not fit in certain classifications (Winter and LaBaugh, 2003). Smaller closed basins are particularly sensitive to drought and other changes in precipitation (Fritz *et al.*, 2000; Winter, 2001). However, many larger lacustrine and wetland habitats are also seasonal with varied periods of persistence ranging from weeks to months each year. Playa lakes and wetlands in the semiarid western USA are examples of isolated, closed aquatic habitats that vary greatly in size and permanence with complex dispersal mechanisms controlling species diversity (Hall *et al.*, 2004).

The duration of wetland habitats (hydroperiod) influences how many species can consistently survive in these temporary waters (Schneider and Frost, 1996; Spencer *et al.*, 1999; Batzer *et al.*, 2004). These species typically have adaptations such as resting stages for long diapause or rapid dispersal and short life spans that allow them to reestablish in these isolated sites once water levels rise (Jeffries, 1994). Although drying out of these wetlands limits the dispersal of some species, this factor alone is not sufficient to account for the distributions of species in these communities. Community structure, particularly the presence or absence of predators and the diversity of predators, also often determines total species diversity and how these ecosystems function (Wissinger, 1999; Batzer *et al.*, 2004).

Large closed basins reflect long-term changes in climate as the ratios of evaporation and precipitation shift and result in major changes in lake levels, such as are recorded in the geologic record of closed basins such as the Great Salt Lake in Utah and Mono Lake in California, USA. Because many features influence water balances within lake districts composed of closed drainage basins and variable precipitation, some lake levels may decrease while others increase even if they experience identical annual precipitation. For example, the seasonal distribution of rainfall and snowfall alters rates of infiltration and runoff as do the types of vegetation and land use. Disturbances such as fire and landslides further interact with the geomorphically modified terrain to control inflows to closed basins. The shapes and sizes of the lake basins also control what proportion of the lake's volume is open to evaporation from its surface so that changes in lake levels are complex but predictable (Hutchinson, 1957).

Seeps and groundwater flows transport nutrients in various directions within rivers, lakes, and wetlands in response to floods and droughts as well as human impacts such as water diversions, groundwater pumping, and water storage in surface and subsurface reservoirs. Water quality in closed basins reflects the increased salinities and concentrations of toxins that accumulate from long periods of evaporation. For example, draining wetlands has concentrated wildlife in remaining habitats. However, diversion of irrigation waters to create wetlands, such as the Kesterson Refuge in the San Joaquin Valley of California, resulted in evaporative accumulation of selenium, a toxic metal that was lethal to many species of waterfowl. The geologic deposits of selenium are distributed widely in the arid western United States and these sites have similar risks for waterfowl. These natural processes can have detrimental consequences for managed wetlands (Pringle, 2003c).

HYDROLOGY AND ECOSYSTEM STRUCTURE

Ecosystem processes in aquatic ecosystems are often regulated by flow rates, water temperatures, and water balances that reflect regional patterns of precipitation and runoff regimes. Thus, hydrology influences how biotic components form functional groups of species that perform specific ecosystem processes such as primary and secondary productivity. Water-transported nutrients and sediments control production of plant matter, which then controls food availability for grazers and omnivores. Food webs provide maps of energy flows within the ecosystem and indicate how particular species interact to play key roles in the context that results from different degrees of hydrologic connectivity.

Primary and Secondary Productivity

Total or gross productivity is the amount of dry biomass (or energy equivalents) accumulated per unit area per unit time. Units for annual productivity are usually expressed in terms of biomass ($kg\,m^{-2}\,year^{-1}$) or energy ($Kcal\,m^{-2}\,year^{-1}$). The energy stored as biomass and which is not lost when some maintenance energy is allocated to respiration is termed *standing stock biomass* or net productivity. This harvestable material can be used to calculate the total energy fixed by also measuring respiration rates in plants and respiration and assimilation rates in animals, then adding those values to obtain the gross or total productivity. This plant and animal biomass and its associated storage of nutrients can be retained in the same location where primary and secondary production occurred. A portion is often transported downstream by river discharge to lakes or estuaries. Moreover, some of the productivity moves upstream as fish biomass. Many types of invertebrates migrate upstream to disperse and reproduce in headwater reaches. Some amount of the productivity flies or crawls off as insects and other invertebrates disperse throughout the catchment, thereby linking the aquatic and terrestrial ecosystems.

The large diversity of riparian and aquatic plants and animals play major roles in primary and secondary productivity within aquatic ecosystems. Dominance by a few species is typical of many aquatic communities, especially those that are physiologically stressful such as those with low dissolved oxygen, high salinity, high temperature, and high nutrients. Thus, the relationships between species diversity and ecosystem processes are important because changes in connectivity influence population and community dynamics. These changes, in turn, can alter rates of productivity (Wallace and Hutchens, 2000; Naeem and Wright, 2003; Covich *et al.*, 2004b; Giller *et al.*, 2004a; Morin and McGrady-Steed, 2004). Inland aquatic ecosystems provide potentially good testing areas for conceptual frameworks relating dispersal, biodiversity, and ecosystem functioning because of their different degrees of connectivity and varied community structure.

Aquatic Productivity, Nutrient Cycling, and Ecosystem Connectivity

The total amounts and proportions of available macro- and micronutrients that limit plant and animal productivity are derived from catchments and delivered by distinct flow paths (Smith, 1998; Sterner and Elser, 2002; Dodds *et al.*, 2004). The resulting changes in plant and animal productivity are measurable, visible signs of how ecosystems respond to hydrologic inputs and associated nutrient transport and cycling. Rates of plant productivity are also influenced by nutrient cycling (external and internal to specific ecosystems) that is regulated by microbial processes, sediment reworking, and grazing by herbivores at different locations within the drainage network (McClain *et al.*, 2003; Poole *et al.*, 2004).

Periods of high nutrient availability (eutrophication) are often accompanied by low flows that prevent dilution and flushing of excessive nutrients. This low-flow condition can cause algal blooms and massive growths of aquatic vegetation that undergo rapid population growth by a few dominant plant species (Smith, 1998). Plant material accumulates if not consumed by herbivores or washed out of the channel or basin. Plant matter also increases because often the dominant, fast-growing plant species are distasteful to consumers and some are toxic so that rates of removal by grazing often decrease. Pulses of excessive plant productivity can lead to oxygen depletion as plants die off and decompose. Microbial respiration during decomposition can require oxygen, yet dissolved oxygen in density-stratified waters is not mixed from the uppermost surface to these lower layers. The lack of dissolved oxygen, in turn, can result in death (and decomposition) of fish and other consumer species, depleting oxygen even further. This process of excessive growth and decay continues until the lake or pond stratification is broken down by seasonal changes in temperatures that mix the entire volume and more dissolved oxygen enters the water from the atmosphere or until some major inflow of water with different densities (determined by relative temperatures and salinities of the river inflows and the standing waters) destabilizes the density stratification and washes out accumulated nutrients in the basin or channel. As a result of these spatial and temporal relationships, fisheries' yields and the quality of fish harvests can differ markedly from one site to another on the basis of geologic origins, geographic locations, sizes of drainage areas, nutrient inputs, and specific composition of food webs (Cabana and Rassmussen, 1996; Power and Dietrich, 2002; Rassmussen and Vander Zanden, 2004).

Dispersal and Colonization

The assembly of species in a biotic community initially reflects colonization from a regional pool of species that is further modified over time as the assembly is subject to hydrological and geomorphic changes (Lamouroux *et al.*, 2002; Merigoux and Doledec, 2004). Changes in the number of species and their relative abundance within a biotic community reflect spatial relationships among suitable habitats (Osborne and Wiley, 1992; Poff, 1997; Matthews and Robinson, 1998; Olden *et al.*, 2001). Thus, biotic communities are subsets of species that occur in local habitats and move from one location to another in response to disturbances and in search of high-quality habitats (Holt, 2002, 2004). As some species become locally extinct, other species are likely to replace them. The history of how different species disperse among alternative high-quality habitats provides important insights regarding assembly and persistence of natural communities. For example, dispersal of species through drainage networks provides for rapid recovery following disturbances (such as floods and droughts as discussed in the following sections). Following disturbances, especially those that can lead to local extinctions of subpopulations, mobility is essential for reassembly and for sustaining these functional units together with their associated ecosystem processes. Subpopulations in productive habitats have the potential to be source populations. Source populations have access to high-quality resources and can reproduce a surplus of individuals who provide dispersing individuals to locations with variable habitat quality. The movement of species to low-quality habitats creates sink populations where individuals survive but do not reproduce and cannot sustain ecosystem services throughout the entire drainage.

The flow of genes among subpopulations (metapopulations) influences the long-term evolution of species. Populations that are isolated for periods of time but disperse and reproduce among subpopulations from time to time form interconnected metapopulations in complex drainage networks (Gotelli and Taylor, 1999). Similarly, aggregations of partially isolated communities (metacommunities) that perform key ecosystem processes may be altered by degrees of connectivity and flow of genetic information and capacity for adaptation to changing environmental conditions (Pulliam, 1988; Holt, 2002). These interacting local communities comprise a larger-scale metacommunity that includes multiple species capable of dispersing and recolonizing available habitats (Cottenie *et al.*, 2003; Mouquet and Loreau, 2003).

On the basis of means of dispersal, the biotic components of inland aquatic ecosystems consist of two major groups: (i) Species that require interconnecting streams and rivers for active or passive aquatic dispersal and colonization. These include mostly vertebrates and invertebrates such as certain mussels that rely on fish for dispersal; and (ii) Species that are adapted to overland dispersal during some phase of their life history. These include amphibious vertebrates and highly mobile groups of invertebrates, such as some crustacean species, as well as those that have aerial dispersal as adults, such as many aquatic insects (Bilton *et al.*, 2001). Distances and rates of passive dispersal are not well documented among most aquatic species but some long-distance transport is known (Bohonak and Jenkins, 2003).

Migratory movements of consumer species (such as many types of fishes and decapod crustaceans) generally result in a long-term biotic integration of spatially defined subsystems (Schindler and Scheuerell, 2002; Vadeboncoeur *et al.*, 2002). Thus, the species composition of any ecosystem is initially determined by dispersal abilities of species within a regional pool of colonizers and then their persistence depends on successful competition or coexistence with resident species and avoidance of predators. Sources of replacement species are influenced by connectivity, dispersal adaptations, frequency and intensity of disturbances, and the resulting heterogeneity characteristic of aquatic habitats.

Surface and subsurface connections serve as dispersal routes for many aquatic species and specialized propagules that are adapted for buoyancy and resistant to desiccation. These adaptations affect the dispersal of species that form new biotic communities as additional species are added or lost over time. For example, small habitats (such as isolated ponds or headwater streams above high waterfalls or low-water dams) typically have fewer species of fish because the absence of horizontal riverine connections or high vertical barriers prevent dispersal to these sites (Cumming, 2004). Because movements by fish dispersal also affect dispersal of some invertebrate species (such as some riverine mussels that rely on fish for transporting their larvae), these isolated communities often have fewer total species and are distinct from other similar, but spatially interconnected ecosystems. However, many of these isolated ecosystems are characterized by species capable of migrating from nearby locations without direct aquatic connections (Bilton *et al.*, 2001; Bohonak and Jenkins, 2003). For example, many small ponds and intermittent streams have diverse assemblages of invertebrates, in part because of the ability of these species to use other means (such as aerial dispersal) to colonize the habitats that do not require continuous aquatic connectivity (MacKay, 1992).

Studies of zooplankton distributions and genetics in small ponds indicate a combination of mechanisms and result in rapid colonization of new habitats, as well as recolonization of persistent ponds from other local ponds (Figuerola and Green, 2002; Havel *et al.*, 2002; Cohen and Shurin, 2003; Louette and De Meester, 2004). Geographic location and the length of time since the origin of a habitat greatly influence species richness, especially in larger lake and river

ecosystems that generally are more persistent over geologic and evolutionary timescales (Malmqvist, 2002).

The oldest lakes and rivers are centers for speciation as well as refugia from regional extinctions (Wilson *et al.*, 2004). These communities differ markedly from younger assemblages in having higher numbers of species in certain groups that have radiated over millennia and are specialized in their functions and with uniquely restricted distributions (Cohen, 2000; Lundberg *et al.*, 2000). These specialized, endemic species are thought to be at risk from drainage basins changes, especially from eutrophication and deposition of eroded sediments at the mouths of rivers flowing into ancient lakes, such as Lake Tanganyika in the African Rift Valley (Donohue and Irvine, 2004).

ECOSYSTEM RESPONSES TO HYDROLOGIC CONDITIONS

Changing water quality such as depletion of dissolved oxygen, warmer temperatures, or increased turbidity can alter habitats for species that require certain conditions. Unlike many terrestrial or marine habitats, most continental waters are often transitory, impermanent habitats that may dry out during drought (Stanley *et al.*, 1997; Fritz and Dodds, 2004; Stanley *et al.*, 2004), greatly altering their ecosystem processes (Dahm *et al.*, 2003; Lake, 2003). Shallow basins may fill in with sediments following decades of erosion and deposition by variable flow regimes (Fritz *et al.*, 2000). Rates of erosion are especially sensitive to management practices and natural events such as climate change associated with intense rainfall during wet years or prolonged drought during extremely dry years. The effects of insect damage or fire on terrestrial vegetation can lead to severe erosion and increased nutrient loading that affect riparian, river, and lake ecosystems, thereby altering fish distributions (Dunham *et al.*, 2003). Organisms adapted to persist in inland waters, thus, usually have some mechanism for dispersing among continental and insular habitats. These different adaptations are relevant for understanding the rates of recolonization following chronic disturbances and catastrophic loss of species that occur in response to extreme natural events as well as to human-caused disturbances.

Functional Resilience and Species Dispersal

The ways in which species have evolved life histories in response to natural flow regimes and drought over millennia are known to alter their patterns of dispersal and their abilities to respond and persist following disturbances (Lake, 2003; Lytle and Poff, 2004). To resolve local and regional issues of water management as well as protection of rare species throughout their distributions, it is widely recognized that a comprehensive, landscape-level approach to management is needed (Poiani *et al.*, 2000; Gergel *et al.*, 2002; Pringle, 2003b).

The biotic changes associated with chronic pollution such as eutrophication or climate change can lead to major shifts in dominance of resident species or to gradual evolutionary changes among species in habitats with relatively restricted access by dispersing species. Recovery rates of biotic communities and their associated ecosystem functions following a catastrophic event (e.g. extreme floods, droughts, or accidental spills of toxins) are especially influenced by the degree of connectivity among similar habitats and their associated hydrological processes and residence times. The downstream drift or upstream migrations of various species generally result in rapid recovery (Gjerlov *et al.*, 2003). Stream communities are typically resilient to infrequent, local disturbances but may be less capable of recovery following frequent and intense disturbances (Resh *et al.*, 1988). Location and distance from sources, along with other factors such as age of the ecosystem are known to be very important for recolonization. For example, small lakes are often more isolated than streams, and natural rates of extinctions within fish communities are known to be greater than rates of colonization or recolonization (Tonn, 1990; Magnuson *et al.*, 1998; Cumming, 2004).

The physical locations and number of connections among habitats at the landscape level also greatly influence how flow-based disturbances modify food-web composition and function (Schlosser, 1991; Fausch *et al.*, 2002; Power and Dietrich, 2002; Woodward and Hildrew, 2002). For example, effects of extreme flood events are usually of short duration (days to months) because many species either: (i) resist washout from floods by occupying microhabitats such as structurally complex woody or rocky substrata (Townsend *et al.*, 1997); or (ii) rapidly recolonize interconnected habitats within the drainage network (MacKay, 1992; Covich *et al.*, 1996). However, effects of extreme drought and other persistent low-flow events (such as water diversions) on stream food webs can persist for several years (Stanley *et al.*, 1997; Covich *et al.*, 2003; Lake, 2003). Lowered discharge can dry out waterfalls, disrupt upstream migrations, and restrict flow-based chemical communication (Crowl and Covich, 1994). Similarly, low discharge greatly decreases habitat quality and availability by decreasing pool volumes and hydrologic connectivity (Bencala, 1993; Fausch *et al.*, 2002). Reduced flows lead to accumulations of organic and inorganic materials that further decrease pool volumes and quality by infilling with deposits.

As water moves across a landscape and through a drainage network, chemical characteristics are modified with varied concentrations of dissolved and suspended materials being transported downstream and utilized by the biota (Wallace and Hutchens, 2000; Whiles and Dodds,

2002). These transported materials reflect various combinations of geologic history, current and past land use as well as direct and indirect effects of pollution. Deposits of these materials accumulate in lake basins and wetlands that record changes over time in how the drainage network functions in response to atmospheric acidification, climate change and land uses (Fritz *et al.*, 2000).

Connectivity and Vulnerability to Invasive Nonnative Species

Invasive species can spread quickly across continents if the drainage network of freshwater habitats is highly interconnected (Malmqvist and Rundle, 2002; Gido *et al.*, 2004; Holeck *et al.*, 2004; MacIsaac *et al.*, 2004). The ability of nonnative species to disperse rapidly through a drainage network depends on the structure of the network, the location of the initial introduction, the dispersal ability of the nonnative species, and its competitiveness. Once established, nonnative species can modify the habitat, eliminate native species, and set in motion a series of changes that favors complete competitive dominance by nonnative species through alteration of water quality or substrata. All these features are being widely studied as a result of increased global trade and movement of many species in the ballast water of ships and aquarium trade shipments (Kolar and Lodge, 2002; MacIsaac *et al.*, 2004; Padilla and Williams, 2004). Models predicting spread of species with planktonic larvae such as nonnative zooplankton and mussels (especially from the Caspian Sea) incorporate measures of habitat connectivity and variable habitat quality. These models usually also consider transport by people associated with recreational uses of isolated lakes (dumping of bait buckets or movement of boats) as well as other nonintentional, passive types of dispersal. Intentional introductions of fishes and crayfishes for aquaculture production as well as fish (such as trout) for recreational fishing have occurred repeatedly in many parts of the world with numerous impacts on native species of fishes, amphibians, and aquatic invertebrates (Englund and Polhemus, 2001; Pilliod and Peterson, 2001; Knapp, 2005). These species can disperse into locations where they are not wanted, especially in locations with variable flows (Light, 2003). They often outcompete native species, alter relative abundances of persistent coexisting species, or spread diseases that result in differential mortality among native species.

Introductions of species that migrate upstream (such as trout, carp, and crayfish) or drift downstream (such as zebra mussels, *Dreissena polymorpha*) can rapidly disperse and alter substrata, food webs, and ecosystem processes (Beekey *et al.*, 2004). If the nonnative species are introduced at nodes in complex drainage networks with multiple linkages (such as interconnected lake chains and dendritic patterns of tributaries), the dispersal from these point sources can be relatively rapid and difficult to control. However, in some cases, restoration of native species is possible (Vredenburg, 2004).

Determining the sources of nutrition for individuals and documenting where they are capable of growing rapidly within a drainage area can be improved by the use of stable isotopes (Fry, 2002). For example, Fry and Allen (2003) sampled zebra mussels in the Mississippi River along a north–south transect from Minnesota to Louisiana. They detected "local zones of influence" by measuring stable isotopes of carbon, nitrogen, and sulfur in these filter feeders and by relating the sources of nutrients to land use in different tributaries. These connectivities were especially evident in the upper Illinois River that was influenced by municipal point sources of nutrients while other sections of tributaries were most likely influenced by agricultural nonpoint sources of nutrients.

The connectivity among floodplain lakes (as recognized very early for distributions of native fishes by Forbes, 1887) within river networks takes on considerable importance in ongoing studies of invasive species such as Asian carp that are moving upstream within large rivers of North America (Chick and Pegg, 2001; Pegg *et al.*, 2002). For example, the high degree of connectivity among tributaries, floodplain lakes, and off-channel wetlands with the main channels of the Upper Mississippi River and of coastal rivers in the southeastern United States provides a large-scale illustration of a complex drainage basin where native species are at risk because of their need for interconnected habitats (Fry, 2002). Predicting the probabilities of dispersal among communities of existing native species and developing strategies for protection of isolated rare species require careful consideration of aquatic connectivity (Scheerer, 2002; Koel, 2004; Cooke *et al.*, 2005). Other well-connected habitats include vast wetlands such as the Everglades in southern Florida. Models of fish dispersal and persistence also include the importance of various degrees of spatial complexity across large areas of low relief. Small differences in topography have large effects during periods of floods and droughts because refugia are limited to specific sites that reflect geological history and biotic modifications of the terrain (DeAngelis *et al.*, 1997).

Because most oceanic islands are relatively isolated and geologically young, they generally have fewer native freshwater species than continental drainages; their drainage areas are also smaller and less complex, so that predictions based on these relatively simple systems are more likely to be useful in forecasting ecosystem-level changes (Smith *et al.*, 2003). For example, geologically recent, insular drainages on the Caribbean and South Pacific islands, typically, have fewer than 10 fish species (Covich and McDowell, 1996; March *et al.*, 2003). These insular streams are likely to be vulnerable to multiple additions of nonnative

species because some of the more specialized mainland species may be able to outcompete the natives species if they have a wider niche than the invading species (Sax and Brown, 2000). Invasive nonnative species can rapidly find niches in these relatively small drainage networks and some can potentially displace native resident species, especially where refugia for native species or food resources are limited. Release from predators, parasites, and diseases found in mainland rivers may allow nonnative species to spread rapidly throughout the drainage basin. These types of displacements of native species by introduced species are commonly observed in island drainages (Englund and Polhemus, 2001; Brasher, 2003; Craig, 2003; Smith *et al.*, 2003). In some cases, however, the native species can persist because they are often especially well adapted for highly variable flows that may occur only rarely but have significant impacts on the invasive species. For example, crayfish (*Procambarus clarkii*) was introduced to Hawaii from the United States and occurs in numerous small streams on some islands but this species has not yet dispersed into larger, fast-flowing rivers in the mountains; similarly, the Tahitian prawn (*Macrobrachium lar*) occurs widely in low-gradient coastal rivers but has not yet dispersed into steeper montane channels where high flows appear to limit its distribution and where native decapod species persist (Larned *et al.*, 2003). However, in other much older islands and those that were once connected to continents with high species richness, the number of endemics (native species restricted to a single island) is higher (such as in Madagascar), and some nonnative fish species have also been able to disperse widely and rapidly even though 143 native fishes in 54 genera and 21 families occur there and 65% are endemic (Benstead *et al.*, 2003).

Large, continental river basins contain numerous species of fishes reflecting the size and complexity of inland drainage networks. This heterogeneous, physical template has been critical for the evolution of fishes and other freshwater species. Structural heterogeneity of freshwater habitats and reshuffling of species during flood events have led to the evolution of a disproportionate number of inland fishes (Lundberg *et al.*, 2000; Hoeinghaus *et al.*, 2003). Despite the very low proportion of freshwater (0.01%) relative to the planet's total amount of water, freshwater fishes now number more than 10 000 species. This number is approximately 40% of all fish species (Lundberg *et al.*, 2000). Many of these species are in ancient tropical rivers, such as the Amazon River, the largest river in the world. Here the locations of tributaries and floodplain lakes are important over evolutionary timescales because geological and hydrological controls alter habitat availability (Costa *et al.*, 2001; Fritz *et al.*, 2004). For example, 43 species of electric fishes are known to occur within the Amazon River drainage network and recent analysis indicates that their localized diversity is enhanced by tributaries. The number of species in the main channel increases downstream of tributary confluences, representing a nodal model of community organization within the drainage network (Fernandes *et al.*, 2004). However, the expanding rates of deforestation, agricultural growth, road construction, dams, diversions, and growth of cities will have cumulative effects on dispersal and function of these diverse tropical species of fishes (Bojsen and Barriga, 2002; Wright and Flecker, 2004). Loss of species diversity of fishes and other freshwater biota over time will likely have irreversible consequences for ecosystem processes on very large scales (Giller *et al.*, 2004a,b; Meybeck, 2004).

CONCLUSIONS

Biological production in inland waters is limited by flows of energy and nutrients across landscapes that continually undergo complex dynamics driven by hydrological processes. Primary production (by photosynthesis or chemosynthesis), nutrient uptake and cycling, and decomposition of organic matter are all connected by the movement of water and organisms among coupled ecosystems. Inputs of water from precipitation, runoff, and infiltration to groundwater all combine to influence rates of transport, deposition, and recycling of inorganic materials which, in turn, influence habitat quality. The relative and absolute abundance of various species and their roles in functional groups that regulate ecosystem processes are controlled by a large number of hydrological variables that relate to habitat quality.

Distances among aquatic habitats, as well as the types and numbers of hydrologic linkages connecting them, influence the timing of different amounts of water and nutrients that enter and cycle through aquatic ecosystems. Flowing-water habitats (streams, rivers, estuaries) are linked to standing-water habitats (ponds, lakes, wetlands) by horizontal surface and subsurface connections in lake chains, lateral floodplains, and salt marshes. Rates of flows among these connected habitats are often more complex and variable than among small, isolated standing-water ecosystems (marshes, bogs, ponds) where residence times are often longer.

The dispersal of species through drainage networks provides for rapid recovery following disturbances (such as extreme floods and droughts). Dispersal to high-quality habitats by many species that comprise natural communities is essential to sustain reassembly of these functional units and their associated ecosystem processes, following disturbances. Source populations are those that continue to reproduce and, thus, provide dispersing individuals to locations with variable habitat quality. The movement of species to low-quality habitats creates sink populations where individuals survive but do not reproduce and cannot

sustain ecosystem services throughout the entire drainage. The flow of genes among subpopulations (metapopulations) influences the long-term evolution of species. Similarly, aggregations of partially isolated communities (metacommunities) that perform key ecosystem processes are also altered by degrees of connectivity and flow of genetic information, and capacity for adaptation to changing environmental conditions.

High degrees of connectivity also allow introduced, nonnative species to spread throughout a catchment. If the introduced species displace native species, rates of critical ecosystem processes can change. These processes and their associated ecological services depend on sustainable flows of water as well as on well-managed catchments where flow management, land use, and introductions of nonnative species can rapidly alter ecosystem productivity. Over time, the loss of native species which are well adapted for long-term variability in environmental conditions can lead to instability and unreliable provisioning of ecosystem services.

Management of drainage basins for hydropower, stormflow runoff from urban landscapes, and rapid economic development typically alter these critical natural connections by modifying the ecohydrology of riverine networks, especially headwater tributaries (Walters *et al.*, 2003). Loss of habitat and species are increasing as a result of these changes on a global scale (Meyer and Wallace, 2001; Pringle, 2003b). For example, reductions in stream density (stream length per drainage basin area) occur when natural stream channels are lost by substituting subsurface pipes for natural fluvial geomorphology. These areas are often then developed and paved so that infiltration of groundwater from channels is lost as are the natural processes that break down organic matter and retain organic matter *in situ* (Paul and Meyer, 2001). Increased surface runoff increases in paved-over areas of the catchment as the proportion of impervious surface increases. Continued paving of roads and building of rooftops, driveways, and parking lots all combine to increase peak flows, severity of flooding and bank erosion (Arnold and Gibbons, 1996; Gergel *et al.*, 2002; Brattebo and Booth, 2003). The integration of hydrology and aquatic ecology may help resolve some of these issues through enhanced environmental understanding and more coherent planning of biospheric and hydrospheric connections.

Acknowledgments

The manuscript has benefited from comments by Wyatt Cross, and an anonymous reviewer. Figures were prepared by Tamara Heartsill-Scalley and Gretchen Loeffler. Research on food webs, species functions, and drainage networks in Puerto Rico and Hawaii was supported by the US National Science Foundation.

102: Trophic Dynamics

CORY C CLEVELAND, ALAN R TOWNSEND AND DIANE M MCKNIGHT

Institute of Arctic and Alpine Research, University of Colorado, Boulder, CO, US

The carbon (C) and water cycles are intimately linked in terrestrial ecosystems. Thus, an understanding of the processes regulating transfers of water in terrestrial ecosystems requires an understanding of the carbon cycle, and in particular, the factors constraining carbon movement in the soil-plant-atmosphere continuum and through trophic levels in ecosystems. The linkages between the C and the water cycles are mediated primarily through biological processes, and are bidirectional in nature. For example, precipitation (and hence ecosystem water availability) strongly regulates plant growth and biogeochemical cycling in soils. Subsequently, plant growth and soil biogeochemistry strongly influence evaporation and atmospheric water vapor (and hence precipitation). Plant growth and soil processes are also cyclically linked. Thus, plant and soil interactions can have important implications for water cycling. However, while major climatic variables (including precipitation) may drive biological patterns and processes at large scales, other ecological interactions also regulate both plant and soil processes. An appreciation of these ecological factors is important to understanding the relationship between C and water, and to predicting how global environmental change is likely to affect the interactions between the C and water cycles.

INTRODUCTION

From an ecological perspective, plant photosynthesis regulates the carbon balance and productivity of the biosphere, controls fluxes of C between the biosphere and the atmosphere, and is responsible for virtually all of the biochemical production of organic matter. From an anthropomorphic perspective, biomass produced by autotrophic organisms via photosynthesis is the source of all food, fiber, and fuel in the biosphere, and thus sustains all other life on earth, including humans. Of all the carbon fixed by plants (gross primary production; GPP), some is stored and some is respired. The fraction of C that is fixed but not respired represents net primary production (NPP). Much of the biomass produced by plants is consumed by individuals of higher trophic levels, or moves into soil where it provides substrate for heterotrophic organisms (net ecosystem production; NEP). Inputs of organic matter from plants to soil influence nutrient cycling and soil water retention, and therefore affect further plant production. Understanding the ecological controls on organic matter cycling in terrestrial ecosystems is fundamental to our understanding of ecosystem water balance, both at present and in the future.

PRIMARY PRODUCTION

Gross Primary Production

In 1942, Lindeman outlined the fundamental ecological concepts of energy flow in ecosystems. At any trophic level, from producer to consumer, energy flow is mediated through the individual organism. Energy is consumed, some is lost as feces, urine, or gas, and part is assimilated and respired or used for the production and growth of new biomass. During each transfer from a lower to a higher trophic level, ~10% of the consumed biomass is directly converted to new biomass; the balance is respired (Smith, 1996). Primary plant production is conceptually similar. Photosynthetically active radiation (PAR; radiation in the 400–700 nm wave band in the visible light spectrum that is utilizable by plants during photosynthesis) may be intercepted by a plant and used to drive photosynthesis. Ultimately, only a tiny fraction of total available light energy is used to convert inorganic carbon to organic molecules

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

within plants; the majority is lost as long-wave radiation and through sensible and latent heat fluxes. However, this small fraction is sufficient to drive plant production that sustains all organisms occupying higher trophic levels. The total organic carbon produced during plant photosynthesis is known as *gross primary production* (*GPP*).

Net Primary Production

The concept of energy flow through ecological trophic levels suggests that not all C fixed by plants during photosynthesis is allocated to growth and biomass production (Figure 1). Plant respiration is also necessary to maintain the energy demands of biomass autotrophic organisms.

Plant respiration, which involves the mitochondrial oxidation of carbohydrates to form ATP, the most important energetic molecule in cells, is the necessary cost of maintaining nonphotosynthetic plant biomass (at all times) and photosynthetic leaves (at night; Chapin *et al.*, 2002); roughly half of the C fixed by any given individual plant during GPP is respired directly by plants as carbon dioxide (CO_2) back into the atmosphere (Figure 1). The difference between total plant C fixed (GPP) and the C lost through plant respiration represents plant net primary production (NPP). Odum (1971) defined NPP as "the rate of storage of organic matter in plant tissues in excess of the respiratory utilization by plants". By this definition, NPP includes increases in plant biomass (e.g. growth of roots, shoots, and leaves), incidental losses of fixed C through roots (i.e. root exudation), transfers of fixed C to symbiotic or associated microorganisms (e.g. mycorrhizal fungi and rhizosphere bacteria), and plant production and losses of biogenic hydrocarbons. In Lindeman's energy transfer model, NPP also represents the amount of photosynthetically fixed C that is available to the first heterotrophic level in an ecosystem (Lindeman, 1942).

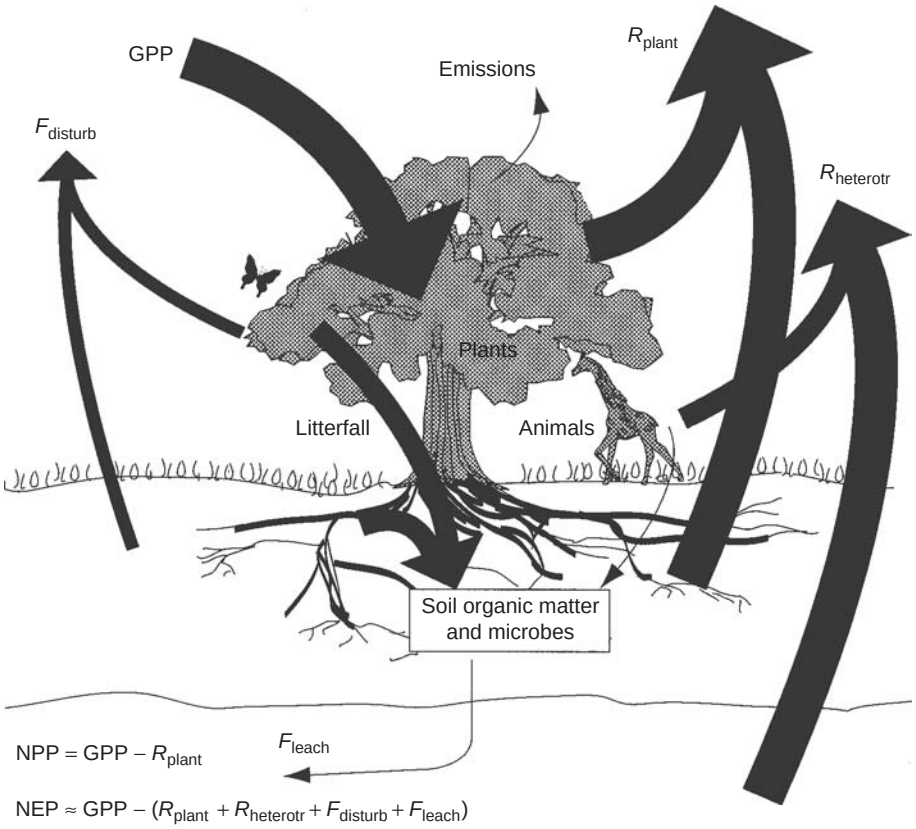

Figure 1 Overview of the major carbon fluxes in an ecosystem. Carbon enters an ecosystem as gross primary production (GPP) through plant photosynthesis. Roots and aboveground plant parts return roughly half of this carbon back to the atmosphere as plant respiration (R_{plant}). Net primary production (NPP) is the difference between GPP and R_{plant}. Most of NPP is transferred to soil organic matter as litterfall, root death, root exudation, and root transfers to symbionts; some NPP is lost to higher trophic levels (e.g. animals). Most carbon entering the soil is lost through microbial respiration, which together with animal respiration, is called *heterotrophic respiration* (R_{hetero}). Additional carbon is lost from soils through leaching and disturbance. Net ecosystem production (NEP) is the net carbon accumulated by an ecosystem; it equals the carbon inputs from GPP minus the various avenues of carbon loss (Reproduced from Chapin *et al.*, 2002 by permission of Springer)

Table 1 Productivity of different ecosystems per day and per unit leaf area

Biome	Season length (d)	Daily NPP per ground area ($g\,m^{-2}\,d^{-1}$)	Total LAI ($m^2\,m^{-2}$)	Daily NPP per leaf area
Tropical forests	365	6.8	6.0	1.14
Temperate forests	250	6.2	6.0	1.03
Boreal forests	150	2.5	3.5	0.72
Mediterranean shrublands	200	5.0	2.0	2.50
Tropical savannas and grasslands	200	5.4	5.0	1.08
Temperate grasslands	150	5.0	3.5	1.43
Deserts	100	2.5	1.0	2.50
Arctic tundra	100	1.8	1.0	1.80
Crops	200	3.1	4.0	0.76

Data from Gower, 2002.

Global Distribution of NPP

NPP is usually measured at the scale of the ecosystem and is expressed in grams of biomass or C per square meter per year (Sala and Austin, 2000). An accurate estimate of NPP represents one of the most fundamentally important characteristics of an ecosystem, and as such, estimates of NPP both within and between ecosystems are plentiful (but see Clark *et al.*, 2001a for discussion of problems in estimating NPP). On the global scale, NPP is spatially heterogeneous, but growing season length is the most important factor explaining differences in biome-specific NPP (Chapin *et al.*, 2002). Like most enzymatic biological processes, photosynthesis is sensitive to extremes in temperature and moisture, and many ecosystems experience times that are too dry, too wet, too cold, or too hot to allow photosynthesis and plant growth to occur. However, when biome-level estimates of NPP are adjusted for growing season length, NPP in different forested ecosystems are nearly identical ($\sim 5\,g\,m^{-2}$ $year^{-1}$), and NPP in the most productive systems (tropical rain forest ecosystems) is only three times NPP in the least productive systems (desert ecosystems; Table 1). These calculations suggest the importance of growing season length in controlling rates of NPP on a global scale (Chapin *et al.*, 2002).

The Fate of NPP: Plant Allocation

What is the fate of NPP? Plant allocation of the products of NPP varies in both space and time, and from species to species. For example, climatic variability over the range of a single plant species influences the timing of C allocation for leaf bud production and foliar growth, leaf senescence, and flowering and fruiting times, among others. Similarly, allocation patterns in deciduous tree species that annually grow new leaves differ from allocation patterns in evergreen species in an area experiencing identical climatic conditions (e.g. aspens in the spruce-fir ecotone). Thus, while generalizations about plant C allocation are difficult, in general, plants allocate carbon to minimize limitation by any single resource (Chapin *et al.*, 2002). The relative demand for different resources regulates the direction and flow of carbon through plants (Aber and Melillo, 2001). Plants allocate resources to roots, shoots, or leaves depending on the relative availability of aboveground and belowground resources. When belowground resources (e.g. water or nutrients) are most limiting to plant production, plants may allocate a greater percentage of C to the production and maintenance of belowground biomass. For example, in deserts, water is often the most limiting resource, and light availability is high. Thus, many desert plants produce extensive root systems that include roots at the surface to capture episodic precipitation, and deep roots that effectively capture more consistent water supplies at depth (Chapin *et al.*, 2002). In contrast, plants growing in closed canopy, light limited forests may partition more C to aboveground tissues to maximize their ability to reach the canopy and capture available light (Table 2).

Abiotic Controls on NPP

As discussed, growing season length explains much of the variability in NPP between different ecosystems. What other factors influence rates of NPP? As the driver of the photosynthetic process, light availability strongly regulates ecosystem NPP. Early work by Montieth (1977) demonstrated that the productivity of well-watered and well-fertilized crop plants was linearly related to the amount of light they absorbed. This basic concept has much utility; it combines meteorological constraints of light impinging on a surface with the physiological constraints of light absorption and use by a leaf (Sala and Austin, 2000). Energy absorbed by a leaf (absorbed PAR; APAR) integrates seasonal and diurnal variation in sunlight and climate, and also implicitly includes the quantity of vegetation that is absorbing radiation, or the leaf area index (LAI; Sala and Austin, 2000). A conversion efficiency factor can then be used to convert APAR to growth, or biomass produced.

Table 2 Components of NPP in 12 old-growth tropical rain forest sites

Site	Aboveground biomass (Mg C/ha)	Component of aboveground NPP (Mg C/ha/y)			
		Fine litterfall	Losses to consumers	Volatile organic C	Estimated aboveground NPP
Ivory Coast: L'Anguédédou Forest	151.5	9.3	1.1	0.2	14.3
Thailand: Khaochong	167.0	5.9	0.7	0.2	9.9
USA: Hawaii (Puu Kolekole)	68.5	4.4	0.5	0.2	7.6
Columbia: Magdelena slope	162.9	4.4	0.5	0.3	7.5
Brazil: Egler Reserve	203.0	3.7	0.4	0.2	6.4
Puerto Rico: Colorado Forest	84.8	3.4	0.1	0.2	5.6
Venezuela: San Carlos	118.7	2.8	0.3	0.3	5.2
Jamaica: Blue Mountain Mull Ridge	156.0	2.8	0.3	0.2	5.0
India: Kagneri	230.0	2.0	0.2	0.3	3.9
Mexico: Chamela	40.0	1.7	0.4	0.2	3.2
Puerto Rico: Pico del Este	23.8	1.6	0.1	0.2	2.9
USA: Hawaii (Site 5)	61.5	0.9	0.1	0.2	1.4

Data from Clark *et al.*, 2001b.

Table 3 Primary production and biomass estimates in global terrestrial ecosystems

Ecosystem type	Area (10^6 km)	Mean NPP (g C/m^2/year)	Mean biomass (Kg C/m^2)
Tropical rain forest	17.0	900	20
Tropical seasonal forest	7.5	675	16
Temperate evergreen forest	5.0	585	16
Temperate deciduous forest	7.0	540	13.5
Boreal forest	12.0	360	9.0
Woodland, shrubland	8.0	270	2.7
Savanna	15.0	315	1.8
Temperate grassland	9.0	225	0.7
Tundra	8.0	65	0.3
Desert scrub	18.0	32	0.3
Rock, ice, sand	24.0	1.5	0.01
Cultivated land	14.0	290	0.5
Swamp, marsh	2.0	1125	6.8
Lake, stream	2.5	225	0.01

Data from Whittaker and Likens, 1973.

Because APAR can be used to generate estimates of NPP on large scales, combined with the ability to obtain values of APAR using remote sensing, estimates of APAR measured from space are routinely used to generate estimates of plant production.

Large-scale (e.g. biome- to global-scale) patterns in terrestrial primary productivity can also be well explained by climatic variables, most notably average annual temperature and precipitation. In general, primary production is high in ecosystems with warm, moist climates, and low in ecosystems characterized by cold, dry climates (Table 3). Analyses of the empirical relationships between NPP and climate (Schuur, 2003; Lieth, 1975) further validate this observation, and suggest the importance of temperature and precipitation in regulating NPP (Figure 2). Across a temperature gradient ranging from $<10\,^{\circ}$C to $\sim30\,^{\circ}$C, NPP increases linearly with increases in temperature (Schuur, 2003). However, precipitation is also highly correlated with ecosystem NPP (Figure 2). This strong positive relationship between ecosystem annual precipitation inputs and NPP represents the first link between C and water cycles depicted in Figure 3.

The relationship between NPP and precipitation has also been verified experimentally. Sala *et al.* (1988) found that mean annual precipitation explained 90% of the variability in mean aboveground NPP in 100 major land resource areas across the central grassland region of North America. These observations illustrate the overwhelming importance of water availability as a control on NPP, at least in some ecosystems. However, while increases in precipitation in

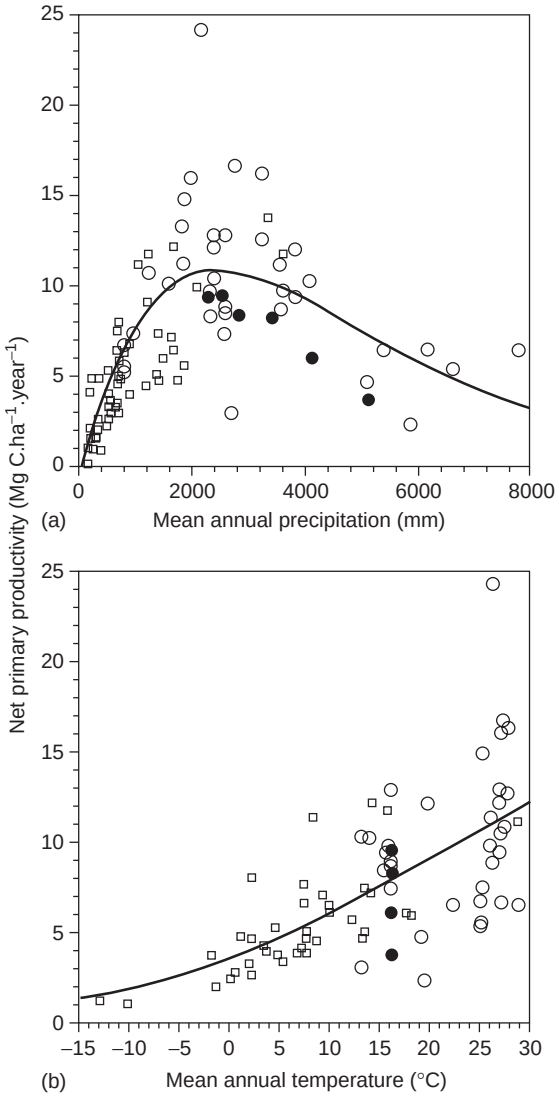

Figure 2 Relationships between net primary production and (a) mean annual precipitation and (b) mean annual temperature in temperate ecosystems (Reproduced from Schuur, 2003 by permission of Ecological Society of America)

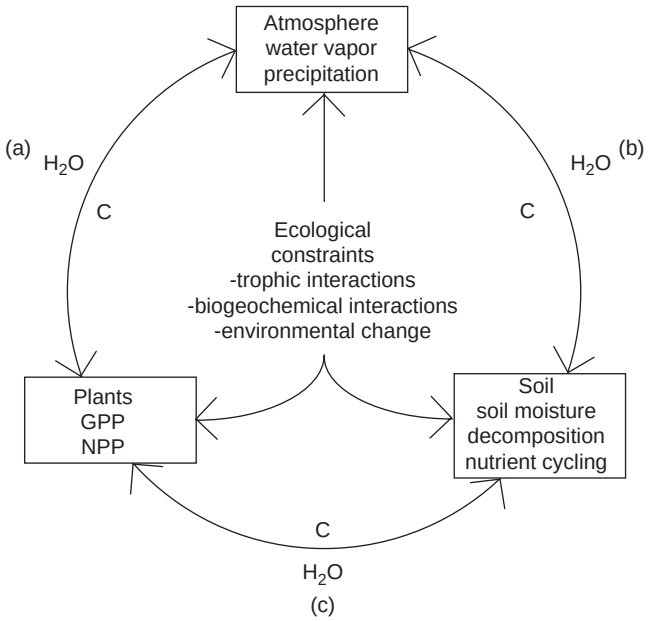

Figure 3 Schematic illustration of the coupling of the carbon and water cycles in terrestrial ecosystems. (a) NPP and evapotranspiration regulate the flow of water and C between plants and the atmosphere; (b) decomposition and evaporation control the flow of water and C between the soil and the atmosphere; and (c) biogeochemistry and soil processes regulate fluxes of C and water in the plant–soil continuum. However, ecological constraints also strongly regulate the fluxes of C and water in terrestrial ecosystems

many arid and semiarid ecosystems correlate with dramatic increases in NPP, in extremely mesic ecosystems, excessive precipitation inputs may actually correlate with decreases in NPP (Schuur, 2003). Together, these data suggest interesting interactions between precipitation and NPP. Namely, NPP increases with temperature and precipitation, but this effect diminishes in wet, warm ecosystems, where further increases in precipitation or temperature may not be balanced by increases in NPP (Figure 2). The fact that NPP decreases in ecosystems characterized by extremely high precipitation inputs suggests that excessive water availability either directly or indirectly affects plant growth through other feedback mechanisms.

Evapotranspiration: The Return of Water to the Atmosphere

The emerging linkages between C and water cycling, which include the strong correlation between water availability and NPP, suggest that the relationship may also operate in reverse. In other words, high NPP may also affect atmospheric water content. Empirical evidence suggests a strong relationship between NPP and ecosystem water losses, and these losses, in turn, complete the cycle connecting plant C cycling with atmospheric water content (e.g. Schimel *et al.*, 1997). Respiratory losses of CO_2 are not the only resource costs of maintaining an autotrophic lifestyle; losses of water via evapotranspiration link primary production (C cycle) with the hydrological cycle (*see* **Chapter 42, Transpiration, Volume 1**). Losses of water from terrestrial ecosystems to the atmosphere occur via two pathways: evaporation, or the direct return of water to the atmosphere from open water bodies and from the land surface (mainly from rock and soil and plant surfaces); and transpiration, the incidental loss of water through plant leaf stomatal openings (*see* **Chapter 70, Transpiration and Root Water Uptake, Volume 2**). During photosynthesis, plants obtain atmospheric CO_2 for fixation in photosynthesis through their stomata, small pores in the leaf surface.

The size of the stomatal opening regulates stomatal conductance, and high stomatal conductance equates with high fluxes of CO_2 available for photosynthesis. However, as a consequence of high stomatal conductance, a decreasing moisture gradient from the inside of the leaf to the outside creates a flux of water out of the leaf, thus resulting in plant water loss to the atmosphere. Thus, in maximizing CO_2 uptake for photosynthesis, plants necessarily subject themselves to high water losses via transpiration.

Together, transpiration and evaporation are known as *evapotranspiration*, and rates of actual evapotranspiration (AET) are very well correlated with NPP (Figure 4). The high correlation between NPP and AET represents an important feedback loop connecting water and carbon cycling in ecosystems. High rates of precipitation and inputs of solar radiation (energy) stimulate high NPP. Subsequently, high rates of NPP in mesic ecosystems lead to high rates of water loss to the atmosphere via evapotranspiration, which have been shown to complete the feedback system by fueling precipitation into ecosystems. The importance of this feedback between NPP, soils, and precipitation is illustrated by an example from tropical rain forests. In Amazonia, the climate and vegetation are tightly coupled. High rates of evapotranspiration from Amazon forests provide water vapor to the atmosphere. Through convective processes, evaporated and transpired water vapor becomes cumulus clouds and precipitation (Nobre *et al.*, 1991). Much of the daily rainfall in the Amazon Basin is quickly reevaporated and transpired into the atmosphere, maintaining high atmospheric humidity and generating clouds that provide the following day's rain. Without forest vegetation, most rainfall would enter rivers, resulting in progressive drying of the air, and affecting NPP.

Net Ecosystem Production

With respect to organic C balance, ecosystems can be aggrading (i.e. C accumulating in soils and vegetation), degrading (i.e. net loss of C), or in equilibrium (i.e. carbon inputs matched by carbon losses). The balance between carbon entering and leaving an ecosystem is net ecosystem productivity (NEP; also known as *net ecosystem exchange* [NEE]), and represents the difference between NPP and heterotrophic respiration by animals and microorganisms (Figure 1). Most carbon enters an ecosystem though NPP, and the majority of C that enters an ecosystem is eventually lost through respiration. However, in some ecosystems, leaching of dissolved organic carbon (DOC) or dissolved inorganic carbon (DIC) through soils and into aquatic ecosystems may be important loss vectors for C (Neff and Asner, 2001). This is particularly true in arctic terrestrial ecosystems, where roughly 20% of the CO_2 produced in soils is lost as CO_2 from lakes, streams, or groundwater (Chapin *et al.*, 2002). Losses of fixed C via methane or plant produced hydrocarbon emissions are also significant loss pathways for C in some ecosystems. For example, in wetland systems, or systems where anoxic conditions prevent the aerobic decomposition of organic matter, ecosystem losses of C *via* methanogenesis can be significant. Similarly, many plants have been shown to produce C-rich secondary compounds that are lost as volatile hydrocarbons from ecosystems. Volatile organic carbon (VOC) emissions (e.g. terpenoid and isoprenoid compounds from plants) may account for C losses up to 5% of NPP (Figure 1; Chapin *et al.*, 2002).

DECOMPOSITION

Soil Organic Matter Decomposition

In most ecosystems, the majority of the C fixed during NPP leaves the ecosystem through the activity of heterotrophic microorganisms (Figure 1). The most important conversions of ecosystem organic C to CO_2 (i.e. real losses) occur during heterotrophic respiration; microorganisms utilize dead plant biomass and detritus to respire and build biomass. Decomposition is a fundamental ecological and biogeochemical process; it returns fixed C to the atmosphere, and also returns critical nutrients stored in organic matter back to the soil, thus providing the main source of

annual plant nutrient availability (Paul and Clark, 1996) (*see* **Chapter 96, Nutrient Cycling, Volume 3**). Organic matter decomposition is also tightly linked to water inputs, and represents another important link between the C and the water cycles (Figure 3).

Following litterfall and litter accumulation on the soil surface, the first step in organic matter decomposition is leaching of soluble organic material through the litter (and other plant biomass) layer and into the soil. Soluble fluxes of organic C from throughfall (leaching from live plant leaves and other aboveground biomass) and through the fallen litter layer may be 1–19% of the total litterfall C flux, and may represent 1–5% of NPP (References in Neff and Asner, 2001). The rate at which C solubilizes, leaches, and enters the soil is linked to precipitation driving fluxes; the direct movement of water through the vegetation and litter layers drives C fluxes. Experimental evidence suggests that DOC concentrations decrease through the soil horizon, and that the majority of C that enters the soil is biologically available and is utilized and respired by microorganisms (Cleveland *et al.*, 2004).

Abiotic Controls on Decomposition

The decomposition of nonleached plant material accumulated as soil organic matter is strongly linked to climate. For example, temperature affects decomposition directly through its effects on soil microbial activity. Over a broad range, increasing temperature elicits exponential increases in soil respiration (Figure 5). Temperature affects both the physicochemical characteristics of the soil environment as well as the physiological reaction rates of cells. Specifically, in a basic way, microbial decomposition of organic matter must follow simple reaction kinetics, with reaction rates increasing with temperature to a maximum, and decreasing at excessive temperatures that degrade enzymes. Freeze–thaw cycles can also contribute to decomposition, through the physical effects of freezing on the microorganisms decomposing dead plant material and soil organic matter.

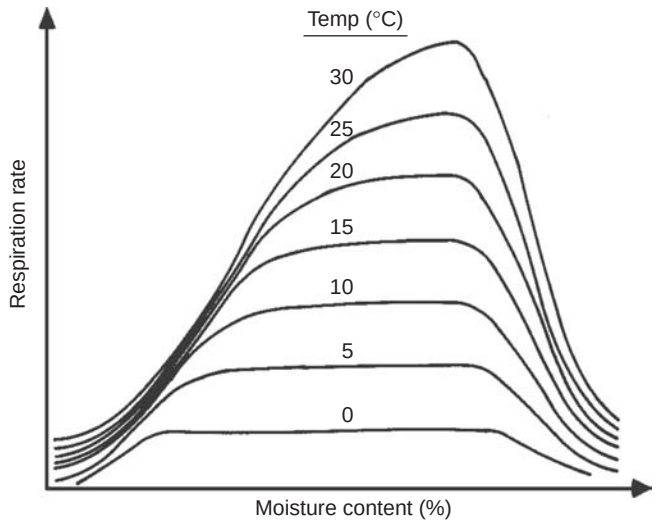

Figure 5 Semiperspective plot of computed soil respiration rate at different soil temperature and soil moisture levels (Reprinted from Paul and Clark, 1996, ©1996 with permission from Elsevier)

Soil moisture also strongly regulates decomposition. Like plants, decomposer organisms are most productive when water availability is high, provided sufficient oxygen is available in the soil (Paul and Clark, 1996). Microbial decomposition of organic matter is dependent upon diffusion processes in the soil environment. Excessive drying of soil prevents both enzymatic processes and physicochemical processes from allowing decomposition and nutrient mineralization to occur. Evidence suggests that decomposition declines at soil moisture values <30–50%, owing to the reduction in moisture necessary to allow rapid diffusion of necessary resources (Paul and Clark, 1996). Similarly, excess water in soils may also affect soil organic matter decomposition rates, but in the opposite direction. Excessive soil moisture can lead to soil anoxia, and decreased oxygen availability has been linked to decreased rates of decomposition (Schuur, 2003; Schuur *et al.*, 2001). The relationship between water availability and decomposition rate is another important link between the C and water cycles (Figure 3).

The decomposition rate of soil organic material is influenced by many factors. For example, soil temperature, soil moisture, organic matter quality, soil oxygen availability, and the activity of specific microorganisms all influence the rate of conversion of organic C to CO_2. However, as with NPP, an analysis of decomposition at the global scale is useful for determining the role of climate in regulating large-scale variations in decomposition. Meentemeyer (1978) demonstrated that while litter quality strongly correlates with decomposition rates, the slope of the relationship between litter quality and decomposition rate decreases coincidentally with ecosystem actual evapotranspiration (AET; Meentemeyer, 1978). While AET most appropriately represents water losses from a system, it is also a useful proxy for the amount of water (and energy) entering an ecosystem (Schimel *et al.*, 1997). Thus, the observed relationship between AET and decomposition integrates the effect of soil moisture and precipitation inputs on decomposition, and further demonstrates the linkage between precipitation and soil processes, including organic matter decomposition. *In situ* soil respiration, which includes plant root and soil microbial respiration, is also a useful proxy for heterotrophic decomposition. Like with NPP, at large scales, soil respiration is positively related to soil moisture availability (Raich and Schlesinger, 1992; Figure 5).

Precipitation exerts control on soil processes (including C decomposition) through AET and soil moisture, demonstrating another important linkage between the C cycle and water cycle. However, abundant precipitation not only affects soil processes, but also soil moisture availability, and this constitutes another feedback mechanism linking soil water availability, soil C cycling, and water losses to the atmosphere. Specifically, evaporative losses of water directly from soil are necessarily higher when soil moisture is higher (i.e. the difference between AET and potential evapotranspiration (PET) results from differences in soil moisture) (*see* **Chapter 42, Transpiration, Volume 1**). High precipitation in mesic ecosystems contributes to high soil moisture, and high soil moisture in ecosystems may perpetuate high precipitation through high rates of AET. Soil is a huge reservoir for water in terrestrial ecosystems, and evaporative processes from soil represent a significant portion of AET. Moreover, variable decomposition rates can affect the amount of organic matter accumulation in ecosystems. Because organic matter in soils often increases water-holding capacity, the linkage between water and C cycles in the atmosphere and soil is completed.

PLANT–SOIL INTERACTIONS

There are important linkages between water availability and both plant and soil processes, and factors affecting these interactions may lead to important feedbacks that further influence the fluxes of water and carbon into and out of ecosystems (Figure 3). However, there are also important interactions that occur between plants and soil, and these interactions affect and are affected by ecosystem C cycling and water status, and hence fluxes of water and C between terrestrial ecosystems and the atmosphere. For example, most inputs of organic matter into ecosystems are the result of primary production. While the fate of soil organic matter is strongly dependent on climatic (e.g. temperature and moisture) and edaphic (e.g. soil texture, soil chemistry) factors, ecosystems with high rates of NPP will have correspondingly high organic matter inputs to soil. Soil organic C decomposition, which is linked to the water cycle through its strong relationship to soil moisture, is also linked to NPP and inputs of organic carbon as the main source of carbon and energy for heterotrophic microorganisms. CO_2 flux from soil is highly correlated with NPP, which supplies organic molecules to decomposers. Across the world's major biomes, Raich and Schlesinger (1992) showed a direct relationship between soil respiration and NPP. Experimental manipulations of C also consistently reveal increases in soil respiration following C inputs (Schlesinger and Andrews, 2000). Thus, precipitation regulates NPP, NPP regulates decomposition and soil C, soil C regulates soil moisture, which in turn, may regulate precipitation *via* AET (Figure 3).

The interactions between NPP and soil processes also operate in reverse. Precipitation exerts control on soil organic matter decomposition, which in turn represents the major mechanism for nutrient mineralization and nutrient cycling in terrestrial ecosystems. On an annual basis, most of the nutrient demands by plants are met through the activity of soil microorganisms, which liberate important nutrients during soil organic matter (SOM) decomposition. Thus, soil moisture can indirectly affect NPP through decomposition and nutrient mineralization. High levels of NPP also provide increased C substrate and fuel higher levels of soil microbial biomass. In systems where nutrients are extremely rare, high levels of microbial biomass can positively affect nutrient cycling and plant growth (Paul and Clark, 1996).

Some interesting data suggest complexities of the interactions between C and water cycles, and provide evidence for the feedbacks depicted in Figure 3. For example, data from grasslands suggest fascinating interactions between NPP, soil processes, and water availability. First, when grassland sites spanning a precipitation gradient are compared, average NPP increases with precipitation (References in Chapin *et al.*, 2002). Moreover, in a single grassland site, NPP increases during wet years, and responds to experimental water addition, indicating that NPP in grasslands is water limited. However, the apparent water limitation is really nutrient limitation; increased soil moisture increases decomposition rates and nutrient mineralization rates, and hence nutrient supply (Chapin *et al.*, 2002). Arid grasslands are never as productive in wet years as grasslands that regularly receive high moisture inputs, suggesting that arid grasslands lack biomass, species, or soil fertility to exploit high moisture years (Laurenroth and Sala, 1992). Thus water controls NPP, but soil moisture determines NPP in three ways: direct stimulation of NPP, its effect on nutrient supply, and its constraints on species composition and the productive capacity of an ecosystem. This example illustrates the complexity of the interactions between C and water cycles in terrestrial ecosystems.

DEVIATIONS FROM ''THE MODEL'': BIOTIC REGULATION OF C AND WATER CYCLES

Abiotic factors, including climate and growing season length strongly regulate fluxes of water and carbon into and out of ecosystems. At least on the global scale, there are robust relationships between NPP, soil processes, and precipitation, and these processes link the C and water cycle in ecosystems. Water is a basic requirement for biological organisms. Thus, it is not surprising that water availability regulates biological processes such as NPP and decomposition. These relationships between climatic

variables and ecosystem processes are extremely useful, as they allow estimation of NPP without direct measurement (e.g. Schuur, 2003; Lieth, 1975). However, while climate drives much of the large-scale variability in C cycling, the variability of the data compiled to generate these relationships suggests that other factors influence processes at the plot- to ecosystem-levels (Figure 2). For example, precipitation inputs alone explain 56% of the variability in NPP at the global scale, while temperature alone explains only 47% (Schuur, 2003). Thus, while the relationships are fairly robust, the variability of the data highlights the inability of climate to accurately predict NPP values at small scales. The inability to capture variability at smaller scales suggests that other factors influence plant and soil processes and their effects on C and water cycling.

ECOLOGICAL CONSTRAINTS ON ECOSYSTEM PROCESSES

We refer to the factors other than temperature, moisture, and radiation that may affect plant and soil processes as ecological constraints. An understanding of the effects of ecological constraints on ecosystem processes is critical for predicting interactions between C and water on small scales. The ecological constraints on plant and soil processes can take many forms, and their effects are often complex. Ecological controls on ecosystem processes can vary both spatially and temporally, can have positive or negative consequences, and can have rapid and dramatic effects on ecosystem C cycling. As a result, ecological constraints on plant and soil processes can have profound implications for water cycling at many levels of organization, from the community to the ecosystem scale.

Most ecological constraints on soil and plant processes fall into three general categories: trophic interactions, or the activity of other organisms in an ecosystem that affect plants and soils directly or indirectly (top-down controls); biogeochemical interactions, or the effects of soil nutrient status and soil biogeochemistry on C cycling (and hence water cycling) of an ecosystem (bottom-up controls); and anthropogenic/environmental interactions, or the influence of the many facets of global environmental change (including those driven by human activity) on ecosystem processes. Although many of the consequences of global change on C and water cycling are largely speculative (due to the rate at which the changes are occurring and ecosystems are responding), it is useful to consider some of the major changes and to discuss the state of the science predicting how global change may affect the interactions between C and water cycling.

Trophic Interactions

Herbivory is the consumption of living plant tissue (primary producer) by an organism occupying another tropic level (consumer), and may influence ecosystem NPP. By the broadest definition, consumers include: parasitic and phytophagous microorganisms (e.g. fungi and algae); phytophagous invertebrates (e.g. stem and foliage feeding insects, root-feeding insects and nematodes and seed predators); and browsing and grazing vertebrates (Barbour *et al.*, 1999). Estimates suggest that on a global scale, ~10–20% of terrestrial NPP is consumed by herbivores, and that the percentage varies by ecosystem. Values of NPP reduction from herbivory in natural ecosystems range from 2–3% in deserts and alpine tundra, 4–7% for forests, 10–15% in lightly grazed grasslands, and 30–60% in heavily grazed grasslands (Barbour *et al.*, 1999). However, periodic outbreaks of herbivore pests such as pathogens or insects may consume up to 100% of NPP.

Grazing

Herbivory in managed ecosystems results in significantly greater reductions in NPP, and thus the associated feedbacks between NPP and the C and water cycles may be impacted to a greater degree than in natural ecosystems (*see* **Chapter 118, Land Use and Land Cover Effects on Runoff Processes: Agricultural Effects, Volume 3**). In particular, grazing may decrease productivity directly, through a decrease in the potential photosynthetic plant material capable of fixing atmospheric CO_2 into new biomass. An analysis of 276 cases of grazed–ungrazed comparisons over 236 sites, Milchunas and Lauenroth (1993) demonstrated the significance of grazing in heavily managed ecosystems. In general, grazing had predominantly negative impacts on NPP. Grazing decreased aboveground NPP (ANPP) by 44%, 55%, 51%, and 60% in grassland, shrubland, mountain (e.g. alpine), and forest ecosystems, respectively (Milchunas and Lauenroth, 1993).

However, predicting the net effects of decreasing NPP from grazing on C and water cycles are complex. For example, the removal of vegetation by grazing can lead to profound changes in soil properties that can affect water balance. Diminished NPP due to leaf herbivory may contribute to decreased losses of water *via* transpiration. However, leaf herbivory that removes canopy vegetation may alter the balance between light absorbed and reflected (i.e. changes in albedo) and increase the importance of evaporation from soils. Additionally, the effects of grazing and the associated feedbacks on the C and water cycles are not limited to the effects on NPP. Soil trampling and vegetation removal can decrease soil organic matter and soil water-holding capacity. Furthermore, soil compaction can increase soil bulk density and break up soil aggregates, reduce water infiltration, soil stability, soil food-web structure, and nutrient cycling rates (Warren *et al.*, 1986; Ingham *et al.*, 1989). Finally, vegetation removal can increase the amount of bare soil, and leads to soil erosion through both hydrological

and aeolian processes (*see* **Chapter 118, Land Use and Land Cover Effects on Runoff Processes: Agricultural Effects, Volume 3**; **Chapter 119, Land Use and Land-cover Effects on Runoff Processes: Forest Harvesting and Road Construction, Volume 3**). All of these potential interactions highlight the complexity of the relationship underpinning the linkage between C and water cycling, and the potential importance of trophic interactions in regulating the relationship.

Insect Herbivory

There are multiple lines of evidence suggesting that grazing of arid lands can have profound effects on ecosystem C cycling which, in turn, could dramatically affect water cycle in terrestrial ecosystems. However, grazing is not the only top-down regulator of ecosystem C cycling. Herbivorous insects and pathogens also play a key role in regulating vegetation growth and dynamics, and represent one of the most important and pervasive agents of disturbance in ecosystems worldwide (Logan *et al.*, 2003). Insects are important components of most ecosystems, and can have both positive and negative effects on ecosystem processes. However, insects have the capacity for extremely high population growth. Thus, when outbreaks of herbivorous insects occur, the effects can be profound. In North American forests, insects affect an area more than 50 times larger than fire on an annual basis, and with substantially greater economic repercussions (Dale *et al.*, 2001).

Insect outbreaks can alter the interactions between C and water cycling in several important ways. First, significant foliage removal or tree mortality resulting from insect herbivory may lead to declines in NPP. In extreme cases, insect defoliation can remove 100% of NPP. At the scale of the individual, decreases in leaf area may lead to declines in plant water uptake and transpiration. At larger scales, this effect can lead to changes in the ways water cycles through the affected ecosystem. For example, landscape-level insect denudation of plant biomass may favor increased water losses as runoff and, thus, lead to decreases in soil moisture across the landscape. Such declines in soil moisture may, in turn, lead to declines in evaporation, plant stand relative humidity and nutrient cycling. Insect outbreaks resulting in large-scale stand mortality may further influence C and water cycling *via* negative effects on nesting birds, mycorrhizal fungi (References in Dale *et al.*, 2001), and on climate (which may affect competitors and natural enemies regulating the abundance of pests and pathogens), creating another potential feedback on insect distribution and abundance (*see* **Chapter 103, Terrestrial Ecosystems, Volume 3**; **Chapter 120, Land Use and Land Cover Effects on Runoff Processes: Fire, Volume 3**). Large-scale stand mortality may also accelerate stand fire regimes, further affecting short-term C and water cycling processes.

Interactions between insect outbreaks and water availability are also complex, and are not unidirectional. Specifically, evidence suggests that the potential ecological effects of insect herbivory not only influence ecosystem water balance, but there is also mounting evidence that insect outbreaks in terrestrial ecosystems are related to climate fluctuations, and in particular, water availability (Speer *et al.*, 2001). For example, reductions in soil water potential from low precipitation and soil moisture (drought) have been linked to declines in tree production and health, and such environmental stresses often predispose plant species to attack by insects and other parasites (Hanks *et al.*, 1999). Decreases in tree health resulting from drought often reduce tree resistance to colonization by insects. Thus, in many cases, drought weakens trees, making them more vulnerable to insect infestations. In contrast, using a tree-ring reconstruction, Ryerson *et al.* found evidence that outbreaks of spruce budworm, an insect affecting mixed conifer forests, correspond to increases in moisture. Grassland ecosystem insect susceptibility has also been demonstrated to correlate with changes in precipitation inputs.

A growing body of evidence also suggests that insect herbivory can directly alter nutrient cycling in terrestrial ecosystems, with profound consequences for NPP. Tree damage caused by insect herbivory leads to obvious C losses from trees. These C debits can, in turn, have negative effects on mycorrhizal fungi (Chapin *et al.*, 2002). Mycorrhizal fungi form symbioses with nearly all plants, and their function in the symbiosis is to absorb and translocate important nutrients to their plant host. Mycorrhizal fungi are capable of absorbing mineral nutrients, like phosphorus (P) at much lower concentrations than nonmycorrhizal plant roots. However, the advantages of mycorrhizal infection are reciprocated through a flow of photosynthetically produced C from the host plant to the fungus, providing the C substrates necessary for the fungus to meet much of its energy requirement to grow and sustain biomass. Declines in C available to sustain such symbioses as a result of insect defoliation have clear implications for nutrient acquisition, and thus may also affect ecosystem water fluxes.

Plant Pathogens

Insect infestations also can affect the interactions between C and water cycling *via* interactions with other organisms. For example, plant disease can have a major impact on terrestrial ecosystem dynamics. Chestnut blight in North America and jarrah dieback in Western Australia have severely impacted plant species populations, leading to a cascade of changes to many affected forest ecosystems (References in Rizzo and Garbelotto, 2003). *Phytophthora cinnamomi*, a plant pathogen affecting jarrah, has eliminated most tree species over hundreds and thousands of hectares of the eucalyptus forests of Western Australia, converting them to grassland or shrubland (Rizzo and Garbelotto, 2003).

The severity of such diseases is often related to insect outbreaks. Dutch elm disease, which decimated the population in North America, was spread through the population by elm beetles that carried fungal spores from individual to individual. The wholesale conversion of forest to grassland has profound implications for the water cycle in these affected ecosystems (*see* **Chapter 103, Terrestrial Ecosystems, Volume 3**). The effects of such feedbacks are likely to increase as introduced exotic diseases spread and impact native plant populations (Rizzo and Garbelotto, 2003).

Biogeochemical Constraints on Ecosystem Processes: NPP

The observed decreases in NPP in ecosystems with high precipitation (Figure 2) suggest that in mesic systems, either excess water inhibits NPP, or that in these ecosystems, other biotic or abiotic processes limit NPP. In many terrestrial ecosystems, nutrient availability strongly regulates NPP and decomposition, and thus the nutrient status of an ecosystem is necessary to understand ecosystem C and water balance. However, nutrient limitation to ecosystem processes is often complex and thus generalizations about nature of nutrient limitation in ecosystems are difficult to make. A substantial amount of data from temperate and high latitude ecosystems suggests that nitrogen (N) commonly limits plant growth (Aber *et al.*, 1991; Vitousek and Howarth, 1991). While nitrogen gas (N_2) comprises ~80% of the atmosphere, N_2 gas must be fixed into reactive forms to be utilized by plants. In the absence of human influence, two major processes convert N_2 into biologically available forms: lightning and biological nitrogen fixation (BNF) by microorganisms (both free-living and in symbiotic associations with plants). However, N_2 fixation by terrestrial BNF is roughly an order of magnitude greater than that by lightning (Galloway *et al.*, 1995) and is therefore the dominant source of newly fixed N to the landscape.

The N status of ecosystems is largely dependent on the presence and activity of the organisms that can convert N_2 into usable forms. In temperate ecosystems, relatively frequent glaciations effectively remove accumulated N by removing soils and vegetation. The succession of plant and microbial species (and hence soil N accumulation) following deglaciation is relatively slow (10^3–10^4 years), and this phenomenon results in relatively N-poor ecosystems where NPP is N limited. Evidence for N limitation of NPP comes from a wide variety of data, including manipulations of nutrient availability (Figure 6). The pervasiveness of N limitation, and the positive effect of N fertilization on primary production are also clearly illustrated by the magnitude of N applied as fertilizer to the world's agricultural systems. Thus, in temperate ecosystems, an understanding of the factors regulating NPP and the associated feedbacks on water cycling in terrestrial ecosystems requires an understanding of the effects of nutrient status, particularly N status, on primary productivity.

In contrast to temperate and high latitude ecosystems, many tropical forests lie on extremely weathered soils (Vitousek and Sanford, 1986). Many tropical ecosystems have not been influenced by large-scale natural phenomena (e.g. glaciations), and as a result, many tropical ecosystems are rich with free-living N fixers and symbiotic N-fixing species. In these ecosystems, NPP is commonly limited by rock-derived elements (Vitousek and Sanford, 1986). Over millions of years, high rates of precipitation result in rapid chemical and physical weathering of soil, and lead to losses of important, relatively "non-renewable" elements like calcium (Ca), phosphorus (P), magnesium (Mg), or potassium (K). Low levels of these

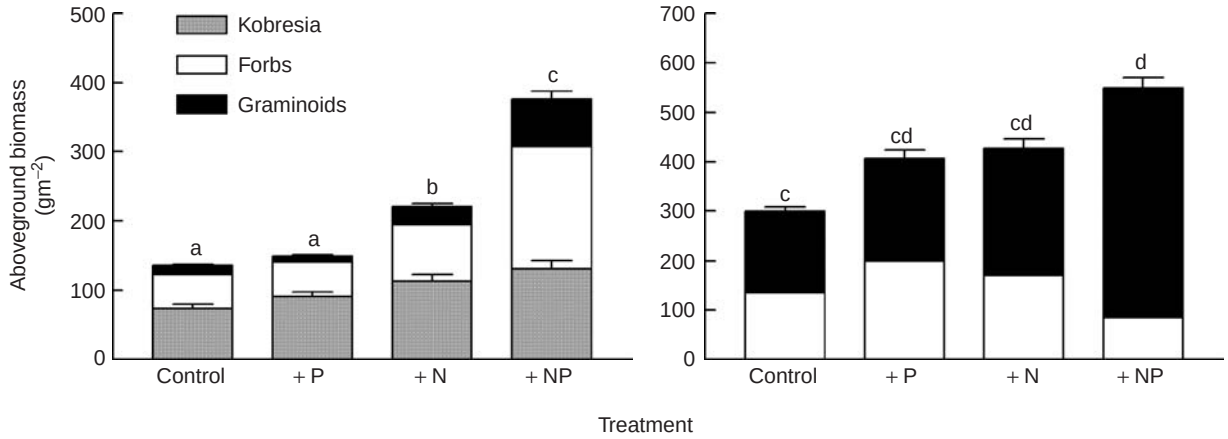

Figure 6 Aboveground biomass production for two alpine tundra communities, dry and wet meadows, under four treatments: control (C), phosphorus (P), nitrogen (N), and N + P treatments. Letters above bars indicate homogeneous means as determined by a Tukey's multiple range test (Reproduced from Bowman *et al.* (1993), by permission of Ecological Society of America)

nutrients may contribute to declines in NPP in tropical ecosystems with high precipitation. Phosphorus is generally believed to be the most limiting element in the majority of tropical forests on older soils (Vitousek, 1984). Indirect attempts to assess nutrient limitation, such as foliar element ratios, strongly suggest P constraints on NPP in many tropical forests on such soils (*see* **Chapter 96, Nutrient Cycling, Volume 3**). Long-term fertilizations in Hawaiian rainforests have also shown that NPP on older soils is clearly limited by phosphorus (Vitousek and Farrington, 1997), and root in-growth studies under different fertilizer applications suggested phosphorus (and possibly calcium) limitation on one oxisol in the Venezuelan portion of Amazonia (Cuevas and Medina, 1988). In contrast, fertilizer additions to a younger soil in the mountains of western Venezuela showed N to be the primary limiting nutrient (Tanner *et al.*, 1998). Similar results were found on younger soils in Hawaii (Vitousek and Farrington, 1997). The latter data suggest the complexity of nutrient controls on NPP, but clearly illustrate the potential for nutrient constraints of NPP.

Biogeochemical Constraints on Ecosystem Processes: Decomposition

The strong relationship between organic matter decomposition and AET (Meentemeyer, 1978) suggests the importance of ecosystem water availability on nutrient cycling and hence NPP. However, in some cases, microbial decomposition of plant material may also be strongly nutrient limited, and in such cases, may exacerbate plant nutrient limitation. For example, in many nutrient poor ecosystems, the pool of actively cycling nutrients is insufficient to allow rapid microbial decomposition. Hobbie and Vitousek (2000) showed that in a phosphorus limited tropical forest in Hawaii, decomposition was also limited by phosphorus (*see* **Chapter 96, Nutrient Cycling, Volume 3**). While microbial nutrient immobilization may prevent important nutrient losses in the long-term, in the short-term, the superior ability of soil microorganisms to compete for available soil nutrients may exacerbate plant nutrient limitation, thus impacting NPP.

C AND WATER CYCLES: THE ROLE OF ENVIRONMENTAL CHANGE

The carbon budget of terrestrial ecosystems is tightly coupled to the water cycle, and changes in C cycling in ecosystems can have potentially profound impacts on the water cycle. Moreover, while climate exerts strong control on C cycling at coarse scales, finer scale variations in C cycling (and hence water cycling) are greatly influenced by ecological processes and interactions. Thus, an understanding of these interactions is critical in assessing the future water balance of terrestrial ecosystems.

Water is a fundamentally important natural resource vital for ecosystem functioning and human well-being. Human use of fresh water, which is expected to triple in the next two decades, and contamination are stressing this important resource, and perturbations to the hydrologic cycle may have profound consequences for people and the environment (Graedel *et al.*, 2001). Consequently, the Natural Research Council of the National Academies of the United States recently suggested that accurate prediction of "changes in fresh water resources and the environment caused by floods, droughts, sedimentation, and contamination in a context of growing demand on water resources" was one of the "Grand Challenges in Environmental Science" (Graedel *et al.*, 2001). Success in this endeavor depends on an appreciation for the tight coupling of the C and water cycles, and an understanding of the complexity of these interactions in a world that is experiencing unprecedented, rapid environmental change.

The global environment is undergoing rapid modification. As the human population and the magnitude of global change continue to grow, an understanding of the structure and functioning of ecosystems will not be possible without an understanding of the strong influence of human activity (Vitousek, 1994). Human activities, including agriculture, industry, fishing, and international commerce have changed the land surface, perturbed global biogeochemical cycles, and altered species dynamics in most of earth's ecosystems. While some of the direct effects are well documented, many of the indirect effects of global change on ecosystem structure and functioning are much more tenuous. However, some of these interactions will undoubtedly result in alterations to global C and water cycles. Specifically, three major categories of global change will play important roles regulating C and water cycling in ecosystems: land transformations, alterations of global biogeochemical cycles, and biotic changes (Vitousek, 1994).

Land Transformations

Humans have caused dramatic changes to the earth's land surface, and this trend is likely to increase well into the future. At present, it is estimated that ~35% of the earth's continental surface (55 million km^2) has been cleared and converted to cropland, pasture, and urban settlements (Figure 7; Foley *et al.*, 2003). To date, the majority of human-induced land conversion has occurred in temperate terrestrial ecosystems; the only three significant remaining areas to be exploited are tropical rain forests (in South America, Asia, and Africa), boreal forests (in Canada and Russia), and deserts (Foley *et al.*, 2003). These ecosystems face increasing development pressure as the rising human population demands more forest and agricultural

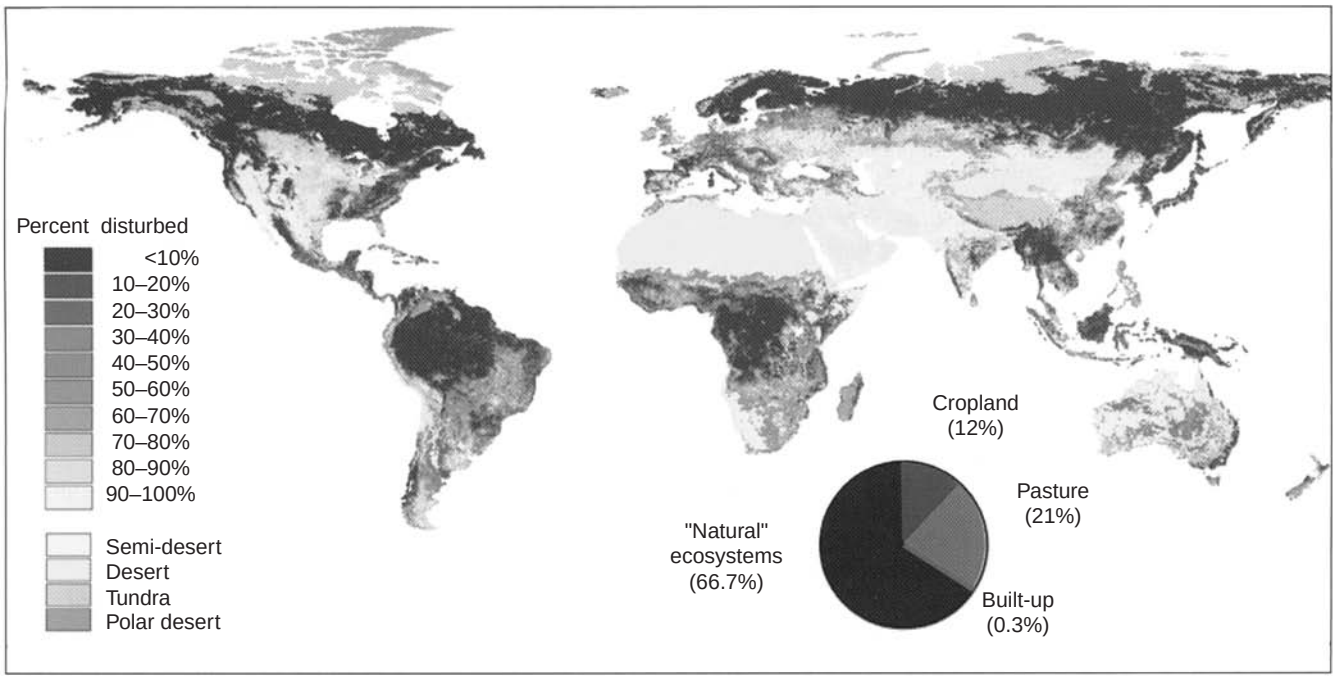

Figure 7 The global extent of human land use, including croplands, pastures, and urban areas across the world (Reproduced from Foley *et al.,* 2003 by permission of Ecological Society of America). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

products. Activities such as wood extraction, forest conversion to pasture, burning, irrigation, and livestock and poultry management will all affect the biogeochemical cycling of elements, including C and water (*see* **Chapter 103, Terrestrial Ecosystems, Volume 3**).

Rates of human-induced land conversion are reaching rates unprecedented in history, and the ecological consequences of land conversion and land use change are numerous (*see* **Chapter 57, Land-cover Classification and Change Detection, Volume 2**). Land conversion leads to losses of indigenous species, introductions of exotic species, rerouting of hydrological flows, and industrial contamination of water, air, and land (Graedel *et al.*, 2001). In addition, land conversion often leads to wholesale changes in the biogeochemical cycling of important elements, including C and water (Vitousek, 1994). However, the specific effects of land use change on C and water cycling are often ecosystem-dependent. For example, in North America, changes in C fluxes following land conversion are related to the fate of converted lands, or the proportion of irrigated to nonirrigated croplands (*see* **Chapter 118, Land Use and Land Cover Effects on Runoff Processes: Agricultural Effects, Volume 3**) or grazed lands (Ojima *et al.*, 1994). These differences, in turn, affect regional climatic patterns, including precipitation inputs to the landscape (Pielke *et al.*, 1997).

Recent evidence suggests that land conversion and the accompanying ecological changes in tropical rain forests may lead to profound feedback that alter water cycling in these ecosystems (*see* **Chapter 103, Terrestrial Ecosystems, Volume 3**). Moist tropical forests comprise one of the world's largest and most diverse biomes, and exchange more carbon, water, and energy with the atmosphere than any other ecosystem. In recent decades, tropical forests have also become one of the world's most threatened biomes, subjected to exceptionally high rates of deforestation and land degradation (e.g. Nepstad, 1999). The effects of land conversion and land use change in tropical rain forests have been thoroughly investigated in recent years (References in Foley *et al.*, 2003). The climatic impacts of such changes are typically evaluated using linked general circulation and biophysical land surface models (Shukla *et al.*, 1990). Most of these analyses suggest that large-scale deforestation and conversion of tropical rain forest will result in a significant temperature increase and decreases in annual evapotranspiration and rainfall (Shukla *et al.*, 1990). Climatic changes are driven largely by shifts in surface energy, water, and momentum balance that accompany deforestation (Figure 8). Lower surface roughness, leaf area, and root depth in pastures relative to forests reduce evapotranspiration, resulting in a decrease in evaporative cooling and surface temperature increases (*see* **Chapter 45, Actual Evaporation, Volume 1**).

Modeled reductions in precipitation following large-scale tropical deforestation also result from changes in ecosystem water and energy balance. For example, reduced APAR

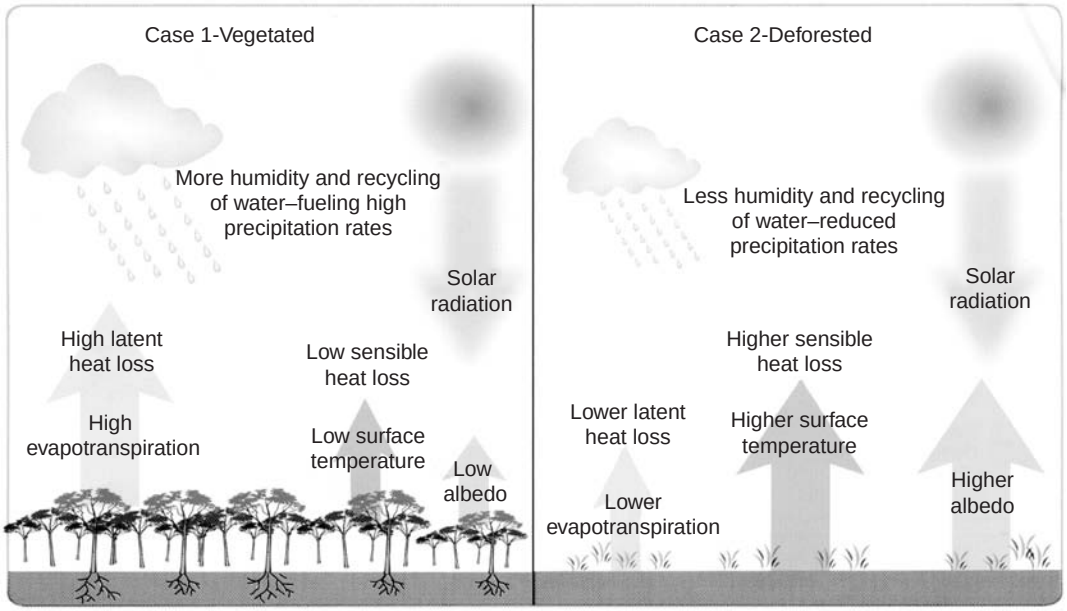

Figure 8 Climatic effects of tropical deforestation on water balance, boundary-layer fluxes, and climate. In vegetation-covered areas (a), the low albedo of the forest canopy provides ample energy for the plants to photosynthesize and transpire, leading to a high latent heat loss that cools the surface. In deforested areas (b), bare soil's higher albedo reduces the amount of energy absorbed at the surface. Latent heat loss is severely reduced and the surface warms, as it has no means of removing the excess energy through transpiration (Reproduced from Foley *et al.*, 2003 by permission of Ecological Society of America). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

and elevated surface temperatures contribute to a decrease in the net radiative heating of the land, or a decrease in the energy available to fuel atmospheric circulation and convective precipitation (e.g. Wang and Eltahir, 2000a). By reducing AET, land conversion of forests to pastures results in lower atmospheric water availability, contributing to a decrease in rainfall, and may set into motion the feedbacks (Figure 8). For example, water deficits in the Brazilian Amazon are also linked to increased fire susceptibility, another disturbance mechanism that can affect C and water cycling in these areas (Figure 8).

The potentially profound effects of land conversion and land use change on C and water cycling are also observed in analyses of desert ecosystems. For example, the pronounced and persistent drought conditions present in the Sahel region of West Africa for the past three decades have drawn considerable attention. While there are two theories on the physical mechanism behind this drought, the most widely accepted is that intense human activity in the region have significantly altered land cover at the regional scale and caused the prolonged drought conditions (Wang and Eltahir, 2000b). In particular, it is suggested that ecosystem dynamics play an important role in regulating the climate of the region.

Using a coupled biosphere-atmosphere model that incorporated ecosystem dynamics and feedback between the biosphere and atmosphere, Wang and Eltahir (2000b) explored the relationship between land use change and drought in the Sahel. As discussed previously, vegetation plays a prominent role in the exchange of carbon, water, and energy between the land surface and the atmosphere. Vegetation removal can modify the local carbon, water, and energy balance. Specifically, in the Sahel region, overgrazing, overcultivation of marginal land, slash-and-burn agricultural practices, logging, and poor irrigation techniques have led to widespread land degradation and desertification. Following desertification, ET (and hence surface latent heat flux) significantly decreases, as does precipitation. In simulations, drought conditions are the result of feedbacks involving the response of the natural ecosystem to imposed changes in land cover (Wang and Eltahir, 2000b). Further, when damage to an ecosystem reaches a threshold, climate changes significantly and leads to deterioration of other "healthy" natural ecosystems (Wang and Eltahir, 2000b; Figure 9). Research also suggests that sea surface temperature (SST) is also critical in regulating Sahel climate, but that ecosystem dynamics may dampen the response of the climate system to recover following changes in SST that would promote a return to wetter conditions (Wang and Eltahir, 2000b). Thus, similar to tropical rain forests, land conversion in arid and semiarid ecosystems may lead to changes in regional climate that continue to have feedbacks on C and water cycling.

Alterations to Global Biogeochemical Cycles

Human activities are leading to profound alterations to the earth's major biogeochemical cycles. For example, fertilizer use, legume crop production and fossil fuel combustion have doubled the amount of N entering ecosystems *via* all natural pathways combined (Galloway *et al.*, 1995). Next, it is estimated that humans use 10 to 55% of annual terrestrial NPP for food and fiber or to support grazing animals (Rojstaczer *et al.*, 2001). Perhaps, the most well-documented aspect of global environmental change is the recent increase in atmospheric CO_2 (Schlesinger, 1997), and rising CO_2 could have profound implications for ecosystem water balance. Rising CO_2 has been postulated to affect plant growth, ecosystem structure, and ecosystem function in many ways. In both laboratory and field experiments, plant photosynthesis often increases under elevated CO_2, and this can lead to changes in C cycling at the ecosystem scale (References in Hungate *et al.*, 1997). Increased CO_2 can lead to decreases in plant stomatal conductance, and corresponding decreases in plant transpiration and evapotranspiration. Changes in stomatal conductance can, in turn, have profound consequences for ecosystem water cycling. Studies conducted in both herbaceous and woody ecosystems have demonstrated reductions in evapotranspiration leading to increases in soil water content and increased plant water-use efficiency (Figure 10). Increased CO_2 effects on plant water use and transpiration could have feedbacks ranging from changes in soil processes, increased water yield in watersheds, or to altered precipitation regimes. In systems like the Amazon Basin where evapotranspiration provides moisture for convective storms, increased water use efficiency with increased CO_2 may feed back to lower regional precipitation (Shukla *et al.*, 1990; Nobre *et al.*, 1991).

Increasing CO_2 concentrations in the atmosphere has two potential effects on climate. First, the radiative effect of increased CO_2 leads to tropospheric warming (the greenhouse effect). Next, the radiative effect of increased CO_2 warming the troposphere may also increase atmospheric water content (*see* **Chapter 195, Acceleration of the Global Hydrologic Cycle, Volume 5**) (through more evaporation) and intensify the global water cycle. Such changes would be beneficial to vegetation in regions where water availability or low temperatures limit plant NPP. However, there is also direct impact of changes in atmospheric CO_2 concentration on vegetation through the physiological effects, or through decreases in evapotranspiration. In arid regions, where climate is often driven by vegetation dynamics, relatively small changes in plant physiology resulting from increased atmospheric CO_2 could have profound implications on climate and particularly on precipitation regime in these systems. Thus, changes to the overall water balance of an ecosystem represent the net effects of the biotic and abiotic responses to elevated CO_2 concentrations. Using a coupled biosphere-atmosphere model to simulate the effects of increased atmospheric CO_2 on climate in the Sahel region of Africa, Wang and Eltahir (2002) found that elevated CO_2 did result in significant declines in plant transpiration due to increased plant water-use efficiency. However, the radiative effects of CO_2, which enhance precipitation, overshadowed the physiological effects, and led to more rainfall to the Sahel (Wang and Eltahir, 2002). Under this simulation, precipitation increased and led to increased NPP. In this specific ecosystem, increased water

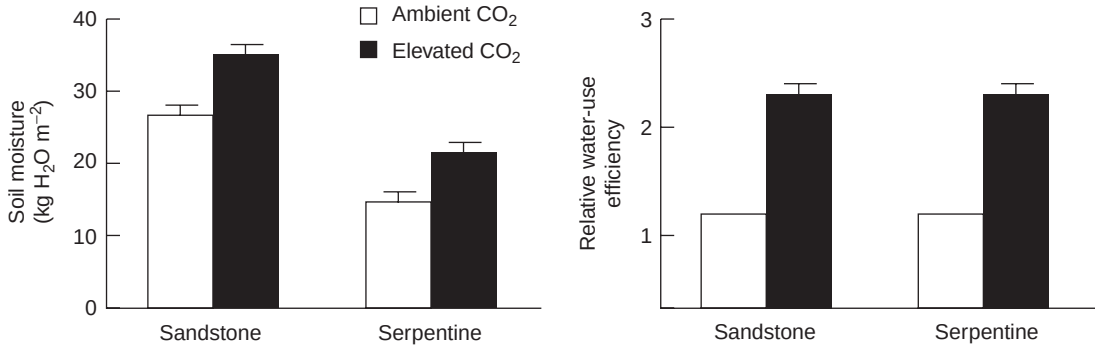

Figure 10 Soil moisture (a) and relative water-use efficiency (b) in untreated and elevated CO_2-treated plots. Values are means ± S.E. (Reproduced from Hungate *et al.*, 1997 by permission of Springer)

availability led to denser vegetation growth at higher CO_2 concentrations, causing subsequent increases in evapotranspiration (i.e. as a result of an increase in transpiring leaf surface area) and reinforced higher levels of precipitation. This simulated feedback again illustrates the close interaction between C and water cycles, and provides clear evidence of the potential effects of a biogeochemical perturbation (increased CO_2) on regional hydrologic cycles.

Biotic Changes

Human activity has greatly modified the earth's biological resources, and changes to its species and genetically distinct populations are on the rise (Vitousek, 1994). While extinction is a natural phenomenon, current rates of species loss are much higher than "background" levels, and this accelerated extinction rate results in part from the activity of humans. However, human enterprise is not only affecting species loss rates, but causing substantial species redistribution by transporting "exotic" species into areas where they do not occur naturally. In some terrestrial ecosystems, plant invasions have led to complete shifts in species composition, and caused dramatic changes in the structure and functioning of ecosystems. In freshwater ecosystems, accidental species introductions have led to widespread invasions, and often lead to wholesale changes in the hydrologic cycle. In many arid regions in North America and Africa, exotic species have established extensively along watercourses. While harsh growing conditions in arid lands generally limit the extent of exotic plant invasions, riparian areas provide suitable habitat for some exotic species, and their establishment can have profound ecological and hydrological consequences.

For example, saltcedar (*Tamarix*) was first introduced into the western United States, and now dominates many waterways throughout the southwest (Sala *et al.*, 1996). Saltcedar invasion has profound consequences for water cycling in arid ecosystems. Saltcedar traps and stabilizes alluvial sediments, and can greatly decrease river channel width (Graf, 1978). An increase in stabilized deposits along stream channels can decrease the ability of the channel to adjust during high flow events, leading to increased flooding. Saltcedar invasion can also directly affect water cycling in invaded areas. Recent research suggests that saltceder uses water much more inefficiently than native vegetation, and the increased water losses as a result of saltcedar invasion are profound. In riparian areas where water availability is high, dense saltcedar stands are characterized by extremely high rates of evapotranspiration, and AET in these areas can exceed potential evapotranspiration by a factor of 2 in nonriparian sites within the ecosystem (Sala *et al.*, 1996). Increased riverine water losses due to saltcedar invasion could be extremely important in arid regions that depend on annual reservoir replenishment *via* riverine inputs to meet the water demand of their growing populations. In this case, saltcedar invasion decreases water that would otherwise be available to meet the growing agricultural and urban water demands in arid regions.

The science of ecohydrology centers on understanding the linkages and feedbacks between terrestrial ecosystems and the hydrologic cycle. Within the disciplines of hydrology, ecosystem ecology, and community ecology, a wide range of conceptual, mathematical, and field-based approaches have evolved to address specific ecohydrologic research questions. In this article, we discuss key elements of these ecohydrologic approaches. We begin by focusing on conceptual frameworks that are organized at the patch level, which define spatially homogeneous units. We compare a set of models in terms of the specific hydrologic and ecologic processes considered and the degree of coupling between them. We then address issues of landscape heterogeneity and compare approaches to the resolution of spatial patterns of soil, topography, vegetation, and atmospheric conditions and the representation of the interactions and feedbacks between neighboring patches. The hierarchical structure and function of terrestrial ecohydrologic systems involve processes varying over very different time and space scales. Finally, we discuss challenges and next steps in developing an integrated framework that can address the range of spatial and temporal scales implied by hydrologic feedbacks on both shorter-term ecosystem material and energy cycling and longer-term ecosystem structure and evolution.

INTRODUCTION

Ecohydrology is an interdisciplinary area of research concerned with the interactions between the hydrologic cycle and ecological processes. Water as a resource, media, reactant, and geomorphic agent is central to many ecosystem functions. These include the influence of water availability on ecosystem material cycling, solute and sediment transport, productivity, trophic systems, ecological community patterns and dynamics, as well as direct and indirect controls of disturbance (e.g. floods, mass wasting, drought, fire). In turn, ecological systems influence water cycling through their control of processes including canopy interception, evapotranspiration, infiltration, and flow resistance. This area has evolved over a period of decades from a set of research themes including forest hydrology and ecology, agricultural water management, acid rain impacts on watersheds, ecosystem budgets of small catchments, biogeography, and aquatic ecology (Bonell, 2002). A set of recent reports has cited the importance of understanding how the mutually regulating cycles of water, carbon, and nutrients (WCN) evolve under different climates and geomorphic conditions as well as disturbance regimes (e.g. NRC, 1998, 1999a; Gupta *et al.*, 2000; WCSG, 2001). Coupling ecological to hydrologic systems through their integration with biogeochemical cycling is a key interdisciplinary area required to address a series of important scientific and societal issues including nonpoint source pollution, freshwater availability, impacts of increased nitrogen deposition and the response of terrestrial and aquatic ecosystems to land use and climate change (WCSG, 2001). Differences in disciplinary conceptual representation of hydrologic and ecological states and processes have been a barrier to effective integration (Benda *et al.*, 2002), which needs to be addressed as part of a new research paradigm.

In this article, we address multiple approaches to understand the geophysical and biological processes of interest to predominantly physical science disciplines (hydrology, geomorphology), community-landscape ecology, and ecosystem science. Our emphasis is on the interactions between hydrologic processes with terrestrial ecological patterns of vegetation and soil disturbance. In particular, we compare how conceptual and operational models in each discipline

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

typically represent interaction between physical and biological processes, and spatial relationships within networks of patches in the landscape. Patches are generally defined as the fundamental spatial unit of study. Patches may be grid cells or irregular shapes. The scale and rules used to define patches vary across disciplines and for specific applications in each discipline. We discuss current integrated approaches that consider feedbacks between WCN cycling and ecosystem structure and function at the patch to landscape and watershed scales, and then explore potential "next steps". While this area necessarily explores coupling and feedback with carbon and nutrient cycling, we do not discuss the details of biogeochemical transformations, transport, or export, which are covered in **Chapter 96, Nutrient Cycling, Volume 3**. Additional, detailed treatment of various aspects of ecohydrology can be found in the recent texts by Baird and Wilby (1999), Tenhunen and Kabat (1999), and Eagleson (2002).

CONCEPTUAL OVERVIEW OF ECOHYDROLOGIC SYSTEMS

Conceptual frameworks in the disciplines of hydrologic and ecosystem science use a systems approach to define stores, fluxes, and transformations of water in the case of hydrology, and WCN in the case of ecosystem cycling, within specific control volumes. The control volumes are defined as a soil body, a canopy, a patch (combining soil and canopy), hillslope, water body, or watershed. Material stores are the amount of a given substance within a control volume (ML^{-3}, where M are units of mass, and L are units of length), while fluxes are the rate of transfer of materials across an interface into, out of, and between control volumes ($ML^{-2}T^{-1}$). Transformations are considered as *in situ* processes occurring within a control volume ($ML^{-3}T^{-1}$). Each of these terms is linked and constrained by mass balance.

In community and disturbance ecology, the concept of stores and fluxes translates into representation of patterns of organisms (e.g. population counts, density, diversity, composition) and the processes that alter those patterns. Ecological patch dynamics (Pickett and White, 1985) incorporates the spatial and temporal evolution of patch patterns by the slow processes of recruitment, growth, aggradation, and succession, as well as disturbance processes involving a rapid change of patch conditions or creation of new patch patterns. The patch dynamics processes of recruitment, mortality, and growth of individual organisms and populations are linked as components in carbon and nutrient budgets. In human dominated ecosystems, these processes are augmented by import, export, and management of carbon and nutrient stocks.

Table 1 shows a set of key state and process variables frequently of interest in each of the three disciplines of hydrology, ecosystem ecology and community/landscape ecology. The control volume is implicitly taken to be at the scale of an ecological patch with a vertical extent from the top of the canopy to some datum below the surface, often the maximum root depth. The hydrologic flux processes in Table 1 include the major input/output components contributing to the canopy and soil water balance of a patch. The three sets of state and process variables either have direct overlap or indirect overlap by mutual regulation and mass conservation. Biogeochemical cycling or ecosystem ecology focuses on short to long-term fluxes and transformation of water and nutrients. Each of the carbon and nitrogen cycling processes interacts, either directly or indirectly, with the storage and flux of water within the patch. In this sense, ecohydrologic coupling emphasizes soil moisture as a major control of ecosystem processes including the role of water as

1. a limiting resource influencing moisture stress
2. a transport mechanism controlling the supply of other limiting resources such as dissolved nutrients
3. an influence on rates of biogeochemical transformations through regulation of soil chemical conditions and microbial populations

Short-term (e.g. daily or subdaily) flux and transformation processes redistribute mass between atmosphere, canopy, litter, and soil. The carbon stores fixed by canopy photosynthesis at the patch scale form the base of the trophic hierarchy, providing feedback through primary productivity to ecological state variables and processes in the right-hand column such as herbivory, predation, decomposition, and mineralization by terrestrial and soil organisms. Long-term aggradation and change of canopy structure and composition, litter decomposition, and soil development in turn feed back to short-term WCN cycling. Water storage and flux at the patch level also influence disturbance processes with effects on fire ignition and spread, erosion, and mass wasting. Therefore, interactions between hydrologic processes, biogeochemical cycling (ecosystem ecology), and community structure and function involve feedbacks across a range of timescales.

Beyond the scale of individual patches, networks of patches exchange water, nutrients, carbon, genetic material (e.g. seeds, pollen), microbial communities, and are in turn grazed by mobile fauna. Some of the exchange is concentrated along hydrologic flowpaths (Figure 1) including engineered flowpaths for water supply, drainage, and transportation infrastructure. Lateral transport along these flowpaths has a significant impact on space/time soil moisture, nutrient concentrations, and seed dispersal, providing a significant influence on ecological patch dynamics. However, a substantial amount of patch dynamics exchange is independent of hydrologic flowpaths, and includes atmospheric transport, and transport by fauna

Table 1 State and process variables commonly used within the three disciplines of hydrology, ecosystem ecology, and community/disturbance ecology

	Hydrology	Ecosystem ecology	Community and landscape ecology
Stores/Patterns	***Above Ground*** Surface water storage in canopy, litter, detention stores (e.g. rooftop, soil surface, impervious surface)	***Above Ground*** Physiologic WCN in foliar and stem biomass, litter water, carbon, and nitrogen content	***Above Ground*** Patch community characteristics – species composition, abundance, diversity, age and size class, fine fuel load and flammability
	Subsurface Unsaturated zone soil moisture, rooting zone soil moisture, groundwater depth, and storage	***Subsurface*** Fine and coarse root carbon and nitrogen, soil organic matter (SOM), microbial C and N pools	***Subsurface*** Soil organism abundance, diversity, taxonomic composition, functional types, soil shear strength
Fluxes/Dynamics	***Vertical***	***Vertical***	***Vertical***
	Precipitation, interception, evaporation, transpiration, infiltration, exfiltration, throughfall, stemflow, runoff, unsat-sat drainage, capillary rise	Photosynthesis, respiration, allocation (above ground and below ground), exudate production, solute leaching, litterfall, mortality, root turnover, decomposition, mineralization, other *in situ* BGC transformations	Reproduction, seed production, recruitment, growth[a], competition, mortality, disturbance (e.g. fire, windstorm)
	Lateral Hortonian, and saturation excess overland flow, through flow, groundwater flow	***Lateral*** Transport and export of particulate and dissolved C and N constituents	***Lateral*** Seed dispersal, organism movement/migration, disturbance propagation (e.g. fire, pathogen, and insect spread), flood, mass wasting

[a]maturation, change in age structure.

and human populations, with each providing detectable feedbacks to both hydrologic and ecosystem processes. This provides multiple, overlapping patterns and space and timescales of patch dynamics, leading to a hierarchical structuring of ecosystem form and change (Wu and Loucks, 1995).

ECOHYDROLOGIC INTERACTIONS AT THE PATCH SCALE

The concept of the ecological patch, delimited by the top of canopy, a defined depth into the soil (often the rooting zone) and bounded by the extent of a vegetation stand (or other land cover), has been used as a basic unit and control volume (or linked set of control volumes) to study the vertical exchange of mass, energy, and momentum and forest species dynamics. Most often, the patch as control volume is accepted as a conceptual framework at a range of spatial scales, without consideration of internal heterogeneity of soils, canopy or atmospheric conditions, or the lateral exchange of water, carbon, and nutrients. The patch paradigm has been applied to a wide range of features and scales ranging from research plots and small catchments, to grid cells used to represent land-atmosphere interaction in regional or global atmospheric circulation models. At all these scales, soil moisture availability is an important regulator of canopy water and carbon exchange with the atmosphere, with water shortage resulting in stomatal closure and in more significant stress events by a drop in leaf display. The actual mechanisms by which soil water conditions influence leaf stomata may not be fully understood (Roberts, 2000), but explicit or implicit representation of this control is one of the most fundamental mechanistic links between hydrologic and ecosystem processes. A set of soil vegetation atmosphere transfer (SVAT) models (discussed below) has been developed in the hydrologic, atmospheric, and ecological disciplines that incorporate some level of soil moisture control on canopy carbon and water cycling, commonly simulating vertical exchange of energy and mass, and neglecting lateral flux. Many field investigations have been patterned on this conceptual model. Trade-offs in detail of soil and canopy representation in terms of number and arrangement of stores, flux, and transformation processes and the simplicity of use, analysis, and measurement distinguish many of these investigations.

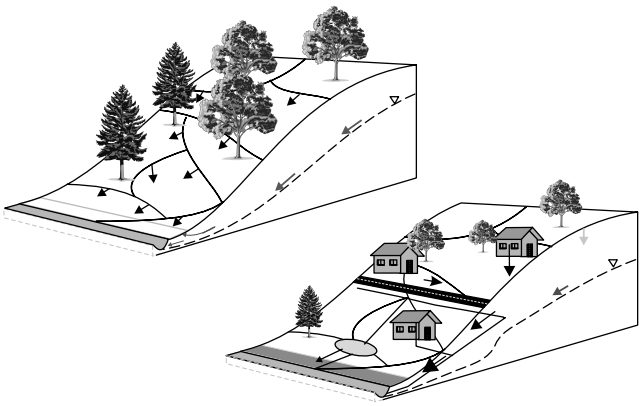

Figure 1 Hillslope ecohydrologic system showing a network of ecosystem patches connected through natural and engineered flowpaths. Note the riparian patches (base of hill) that are maintained by recharge from above. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

A simple method of illustrating first-order links between hydrologic and ecological systems can be presented by inspecting the Penman–Monteith combination equation (Monteith, 1965) for transpiration:

$$LE = \frac{\Delta R_{\mathrm{n}} + \gamma C_{\mathrm{p}} \rho_{\mathrm{a}} g_{\mathrm{a}} VPD}{\rho_{\mathrm{a}} \lambda (\Delta + \gamma (1 + g_{\mathrm{a}}/g_{\mathrm{c}}))} \quad (1)$$

where LE is the latent heat-flux of transpiration, Δ is the slope of the temperature-saturation humidity curve, R_{n} is canopy net radiation, γ is the psychrometric constant, C_{p} is the heat capacity of the air, g_{a} is the canopy aerodynamic conductance, ρ_{a} is the air density, VPD is the atmospheric vapor pressure deficit, λ is the latent heat of vaporization and g_{c} is the canopy conductance. Canopy radiation transmission and absorption are influenced by leaf form, albedo, canopy leaf area index (LAI), and canopy clumping. The canopy conductance term is the leaf conductance integrated over the LAI, and is influenced directly or indirectly by a set of environmental factors of VPD, soil water availability, absorbed photosynthetically active radiation (PAR), and temperature. Both of the conductance terms and the net radiation in the Penman–Monteith equation are dependent on patch level canopy structure, species composition, stand age, and soil conditions as discussed below. The stomatal conductance is regulated by photosynthetic assimilation rates, which are subject to leaf temperature, absorbed PAR, the atmosphere to leaf CO_2 gradient, and enzymatic limitations due to nitrogen availability (Farquhar *et al.*, 1989). Consequently, transpiration rates and photosynthetic assimilation are tightly linked, with both a function of similar biotic and abiotic patch conditions. Therefore, a set of simplified approaches to ecohydrologic linkages have used reductions in canopy and species specific evapotranspiration rates compared to potential evapotranspiration as a surrogate for limitations on productivity. Further discussion of hydrologic controls on transpiration can be found in **Chapter 42, Transpiration, Volume 1**.

Stochastic Water Budget Approaches

Eagleson (1978a,b,c; 1982a,b) introduced an approach based on the coupling of transpiration and productivity assuming soil moisture stress as a rate-limiting factor. In a classic set of papers, Eagleson developed stochastic models of a relatively simple, one-dimensional soil water balance operating at the daily time step with a two-zone soil moisture store characterized by the unsaturated zone and a deep groundwater table. This approach was designed to derive the temporal distribution function of root zone soil moisture conditional on prevailing climate, soil, and plant characteristics. Climate conditions were characterized by probability density functions of interstorm periods and daily precipitation, with prescribed interstorm potential bare soil evaporation and canopy evapotranspiration rates that are modified by available soil moisture. These models allowed the optimization of vegetation type, density, and canopy properties (including root depth) to minimize water stress, and thus maximize productivity, for different vegetation life forms under prevailing climate and soil conditions.

The approach of deriving stochastic models of soil water balance to investigate impacts on water-limited ecosystems has been further developed by Rodriguez-Iturbe and others (e.g. Rodriguez-Iturbe, 2000; Porporato *et al.*, 2002). With an emphasis on water-limited ecosystems, a series of articles extended the approach of using probabilistic one-dimensional water balance conditional on climate, soil, and vegetation characteristics to investigate a range of ecosystem dynamics. The probabilistic approach allows the derivation of both seasonal mean root zone soil moisture conditions, as well as the frequency of water-stress events. Multispecies systems are incorporated by specifying different rooting depths, maximum rates of evapotranspiration, and different thresholds for the onset of water-stress limitations to evapotranspiration. By necessity, these approaches emphasize simplified process representation of water balance in order to develop analytical solutions to the water balance stochastic differential equations incorporating observed frequency distributions of storm and interstorm characteristics as driving functions of ecosystem water stress. Following Eagleson's original work, in most applications ecological response is assumed to be based on an optimization of species type and cover to minimize soil moisture stress, and do not directly address carbon budgets or nutrient availability. However, recently D'Odorico *et al.* (2003) and Porporato *et al.* (2003) have extended the stochastic framework with carbon and nitrogen cycling expressions conditional on soil moisture levels to incorporate the development of soil organic matter (SOM). These models emphasize optimal states of the canopy (assuming

the water-stress optimization principle) to soil conditions and stationary growing season precipitation statistics. As such, the approach does not address transient response to climate or disturbance perturbations, although interesting research addressing the effects of interannual variability in precipitation regime has been used to investigate multimodal soil moisture regimes and resulting shifts in optimal vegetation conditions (D'Odorico *et al.*, 2000).

These stochastic methods offer a data and computationally efficient approach, based on physical principles, for analysis of the influence of daily to interannual variability in climate conditions on ecosystem optimal structure and behavior. By assuming an optimal ecosystem state, as canopy cover or carbon and nitrogen cycling stores, however, these approaches do not extend to investigate long-term growth and aggradation that treat system transience due to disturbance. The stochastic optimization approaches do not incorporate patch dynamical evolution by growth, succession, or mortality. To address long-term feedback to local moisture conditions, as a patch or population of patches develop, representation of transient response rather than optimal state would need to be included.

Canopy Vegetation Atmosphere Transfer Models

In contrast to this approach that emphasizes simplicity in canopy and soil representation, and time-averaged optimal response to precipitation regime, Deardroff (1978) and others developed more complex one-dimensional models of SVAT of energy and water including plant canopy impacts on radiative transfer and multilayer canopy and soil representation. These models are forced by meteorological time series and are operated as land surface process (LSP) models coupled to an atmospheric model (typically at the resolution of the atmospheric model grid), or off line using prescribed meteorological data. The level of process detail incorporated into these models precludes analytical solutions, but allows the representation of more complete coupling of water and energy carbon cycling. In addition to representation of energy, water, and momentum exchange, ecosystem photosynthetic and respiration processes have been incorporated into the biological components and controls of surface exchange (e.g. Dickinson, 1986; Sellars *et al.*, 1986). Resolution of stomatal physiology and stand structural effects on radiation and turbulent exchange (e.g. height, leaf and plant area, leaf form, foliar and soil albedo) produce a greater dependency on both physiological and aerodynamic characteristics of the vegetation. These models typically emphasize short-term (sub-diurnal to seasonal) coupling of atmosphere with the surface, typically with a prescribed vegetation layer. While incorporating assimilation and respiration fluxes of carbon between atmosphere, canopy, and soil, these models do not generally operate over a long enough period to simulate ecosystem aggradation and structural or compositional change. Exceptions include those LSP models that incorporate crop growth models with explicit phenology (e.g. Tsvetsinskaya *et al.*, 2001). For additional discussion, *see* **Chapter 104, Satellite-Based Analysis of Ecological Controls for Land-Surface Evaporation Resistance, Volume 3**.

Ecosystem Carbon Budget and Ecological Community (Gap) Models

An additional set of one-dimensional models of patch level processes were developed in the ecosystem community that incorporate integrated water, carbon, and nutrient cycling at the plot to watershed scale (e.g. Aber and Federer, 1992; Parton *et al.*, 1987; Running and Coughlan, 1988; Running and Hunt, 1993). These models were designed to operate with comprehensive climate data from meteorological stations or climate models, and to resolve diurnal to seasonal patterns, but with the ability and emphasis on long-term ecosystem growth ranging to decadal or centennial timescales. Consequently, time steps typically range from daily to monthly and capture soil moisture dynamic effects on a more complete cycling of carbon and nutrients subject to soil, vegetation type, and climate conditions. In this case, the atmosphere has typically been prescribed, so that there is no feedback from the surface physiological and hydrologic conditions to the atmosphere. These models follow an ecosystem, rather than population or community ecology approach, with an emphasis on water, carbon, and nutrient pools within a stand, instead of representation of individual organisms. While they do track ecosystem aggradation of biomass, as well as allocation of carbon to above ground and below ground pools, there is typically a simple, prescribed mortality loss rate, and only rudimentary treatment of competition and compositional change. However, by solving a full carbon budget with explicit treatment of transient evolution of organic matter pools, some aspects of dynamic changes in one or more patches are incorporated. This includes aggradation of litter over long time periods, as well as daily scale adjustments of litter moisture, with potential use for computing fire ignition and spread probabilities, discussed below.

Patch models arising from the ecological, rather than hydrologic community, include models based on populations of individual trees (stems) growing under a set of water, temperature, nutrient, and light constraints and simulate size class and species dynamics of the stand, but without the detailed representation of WCN flux and transformation processes (e.g. Botkin *et al.*, 1972; Shugart, 1984; Pastor and Post, 1986). These gap models concentrate on stem recruitment, germination, mortality, and growth as influenced by simple water (and other resource) availability reduction factors that are typically set as patch characteristics, although more detailed treatment of patch soil

moisture conditions and other constraints have improved the ability of these models to replicate biogeographic and temporal variability in stand dynamics (e.g. Pacala *et al.*, 1996; Bonan, 1989).

Hybridization of the different model approaches discussed above has been carried out in the last decade. Several researchers have sought to directly link the strengths of the ecophysiological and gap succession models (e.g. Friend *et al.*, 1993; Huston, 1991; Keane *et al.*, 1996), directly linking short-term water and carbon cycling processes with the long-term growth, aggradation, and succession of vegetation (typically forest) patches. Mesoscale and global atmospheric circulation models have been coupled with both ecophysiological and community ecology models (e.g. Foley *et al.*, 1998; Pielke *et al.* 1998) to address land use and climate change effects on land–atmosphere coupling, including shifts in water availability.

All of the above patch models emphasize vertical exchange of water, carbon, and nitrogen. Eagleson (2002) and others recognized that the one-dimensional approach fails to adequately represent hydrologic behavior for a set of conditions in which significant lateral flux of water is a critical element of system behavior, such as in riparian areas. A number of researchers have criticized the assumptions of the one-dimensional approach, stating that both modeling and measurement of lateral divergence of water, nutrients, carbon, and energy are critical components of many ecosystems (e.g. Band *et al.*, 1993; Wood, 1999). While the magnitude of vertical flux of moisture may substantially exceed lateral flux at and below the surface, persistent gradients in moisture conditions developed by lateral flux produces repeated patterns and variance in ecohydrologic behavior over the landscape. In scaling from patch models to watersheds and landscapes, techniques for including this spatial heterogeneity become an important part of ecohydrology studies.

SMALL CATCHMENT RESEARCH

Much of our knowledge base on ecosystem and hydrologic process interactions has been developed from monitoring and experimentation at the scale of a small research plot or below. A major challenge to the community is to learn how system behavior at this level can be linked to landscape or regional level systems. Small catchment research presents an empirical approach to scaling up to regions by investigating the behavior of these units as basic elements. As first-order catchments typically comprise more than half the area of a watershed and a substantial amount of the total stream length, an important question is whether understanding the dynamics of the population of headwater catchments provides sufficient information to understand the behavior of large watersheds. Certainly, downstream processes in higher order streams as well as alluvial floodplain sites that have unique ecohydrologic interactions are not incorporated in this research approach.

Small watershed monitoring and experiments originated with the assumptions of the plot paradigm implicit in their design, simply substituting the full catchment as a metapatch. This approach parallels the lumped hydrology paradigm common in many hydrologic models and allows a conceptualization of the catchment with uniform or dominant soil and vegetation attributes, and the assumption of uniform (measured) precipitation and atmospheric deposition inputs, as well as measured streamflow outputs. This allows for estimation of catchment evapotranspiration rates and nutrient sinks and sources through mass balance. Most small catchment experiments were designed assuming that the net groundwater exchange was minimal, although in many cases it has been found that groundwater may be a significant and unmeasured output. In the United States, the Department of Agriculture and the National Science Foundation have set up a series of experimental watersheds over the last several decades to investigate the interactions between forest management and catchment hydrology. These include a set of the current Long-Term Ecological Research (LTER) sites, including the Coweeta Hydrologic Laboratory, HJ Andrews Experimental Forest, Hubbard Brook as well as the Agricultural Research Service (ARS), US Geological Survey (USGS) and other agency catchments. Similar experimental watersheds have been operated in other countries and used to investigate effects of vegetation management on water yield and quality.

A set of planned and inadvertent experiments in vegetation manipulation and disturbance effects on water yield have been carried out focusing on water use of different species and life forms, as well as ecophysiological conditions of the canopy. Emphasis has been placed on the effects of forest management (timber rotation, species conversion, age class distributions) and disturbance (e.g. wildfire) on water yield and quality. Langford (1976) documented long-term reductions in catchment water yield when old growth Mountain Ash Eucalypt stands were replaced by young stands following wildfire in the Melbourne water supply catchments. Reduction in stand transpiration and photosynthetic rates in old growth Douglas Fir has also been documented in the Pacific Northwest (Yoder *et al.*, 1994), with important implications for regional water supply as old growth is harvested. These reductions have been attributed to a set of factors, including reduced hydraulic conductance in stem tissue, reduced leaf area, and changes in stand structure. Forest conversion to grass cover in the Coweeta Hydrologic Laboratory was shown to increase water yield over the long term, although transpiration rates and water yield were sensitive to nutrient availability, with fertilized grass cover water yields returning close to those of the original forest cover (Hibbert, 1969), linking photosynthetic to transpiration rates. Conversion of mature broadleaf cover

to white pine in a paired catchment experiment at Coweeta has shown persistent declines in annual water yield over a period of decades (Swank *et al.*, 2001). Experiments in the San Dimas Experimental Forest in Southern California converted chaparral to grass cover, to increase water yield. While water yield did increase substantially with the conversion to the more shallow rooted grass cover, reduction in soil strength by decay of the chaparral roots coupled with increased soil moisture led to massive increases in mass wasting and sedimentation from these catchments (Rice *et al.*, 1969). Similar increases in both water yield and mass wasting have been documented following timber harvest, with reduction in soil strength due to loss of root cohesion cited as a key factor (Ziemer, 1981; Roering *et al.*, 2003).

There is also a substantive history of small catchment experiments linking hillslope hydrologic processes and ecosystem biogeochemical cycling (reviewed in **Chapter 96, Nutrient Cycling, Volume 3**)

Valuable compendiums of the long-term research linking hydrologic and ecosystem processes in small catchments in the Coweeta and Hubbard Brook LTER sites can be found in Swank and Crossley (1988) and Likens and Bormann (1995).

APPROACHES TO SCALING ECOHYDROLOGIC INTERACTIONS TO THE LANDSCAPE

Scaling from homogeneous patches to heterogeneous landscapes raises two issues. First, the distribution of patch characteristics within the landscape as a control on aggregate response must be considered, as a set of carbon and nutrient cycling processes have a nonlinear response to soil moisture and canopy conditions. Second, the potential for interactions resulting from gradient driven fluxes of water, nutrients, and organic matter between heterogeneous patches must be explored. The former source of heterogeneity includes local edaphic factors such as soil properties, topography, and microclimate, while the latter source is dependent on the drainage sequence of patches arrayed over the landscape. More general discussion of techniques for representing heterogeneity in hydrology can be found in **Chapter 3, Hydrologic Concepts of Variability and Scale, Volume 1**.

Grid-based Mosaic Approaches

A first-order approach to incorporate landscape heterogeneity in many terrestrial ecosystem process models has been the implementation of ecosystem process models for a cellular grid of patches. Running *et al.* (1989) developed a grid-based implementation of FOREST-BGC (Running and Coughlan, 1988) to simulate carbon and water cycling over a 1200 km^2 area of western Montana over which there are strong gradients in topographically modulated temperature, precipitation and insolation. Similar applications have been implemented for other ecosystem models (e.g. PNET Aber *et al.*, 1995). Similarly, in atmospheric LSP models, characterizing heterogeneity in surface processes by distributed parameterization of spatial grid cells has been termed the *mosaic approach* (Avissar and Pielke, 1989). In these implementations, there is no transfer of water and nutrients from one location to another such that persistent recharge and discharge zones, and patterns of relative soil moisture, are not maintained. Therefore, these approaches capture spatial variation in ecosystem function due to local patch conditions, but do not necessarily capture variation in ecohydrologic dynamics due to position within hydrologic flowpaths. In this respect, the distribution of patches within the landscape could be reshuffled with no impact on aggregate behavior.

Incorporating Hillslope Hydrology to Ecosystem Models

Hillslope scale catenary patterns between soil, water, and vegetation form and process are evident in many ecosystems and critical to the behavior of the full catchment. The partial or variable source area concept in catchment research (Hewlett and Hibbert, 1967; Dunne and Black, 1970) was developed from small catchment research by recognition of distinct and repeatable patterns of soil moisture, maintained by the lateral (and vertical) redistribution of water within hillslopes. Landscape scale spatial patterns of soil moisture produce complex interactions between soil water content, canopy physiology, and ecologically limiting processes of water stress, root aeration, and nutrient availability. As soil water patterns are forced by combinations of climate, soil, and substrate hydraulic properties and topography, a dynamic zonation of ecological limiting conditions develops, which is strongly tied to site geomorphology. Recognition of this zonation is often implicit in ecosystem process studies that focus on particular features such as riparian areas in terrestrial systems.

To extend patterns of terrestrial ecosystem patterns and process to the landscape level necessitates coupling with hydrologic models (conceptual and quantitative) of spatial patterns of moisture conditions. These approaches have ranged from the use of simple soil water indices such as the TOPMODEL topographic/soil wetness index (Beven and Kirkby, 1979) and TOPOG (O'Loughlin, 1981, 1986), to progressively more detailed representation of vertical and lateral unsaturated and saturated zone moisture exchange along hillslope flowpaths including the Distributed Hydrology Soil Vegetation Model – DHSVM (Wigmosta *et al.*, 1994), the Regional HydroEcological Simulation System – RHESSys (Band *et al.*, 1993; Nemani *et al.*, 1993), Dynamic TOPMODEL (Beven *et al.*, 2001),

and MIKE-SHE (Refsgaard and Storm, 1995). For more extended treatment, *see* **Chapter 14, Hydroinformatics and its Contributions to Hydrology: From Computation to Communication, Volume 1**.

Additional coupling of carbon and nutrient balances, as well as long-term growth and aggradation of canopy and soil conditions have been implemented in RHESSys (Mackay and Band, 1997; Tague and Band, 2004; Band *et al.*, 1993, 2001) and TOPOG (Vertessy *et al.*, 1996), as well as Macaque (Watson *et al.*, 1999) and Stieglitz *et al.* (2003). These systems were designed to operate over years to decades to reflect the longer timescales involved in organic matter cycling and ecosystem aggradation. Therefore, these approaches allow for the development of persistent spatial patterns in carbon and nutrient dynamics following hydrologic flowpaths, as well as recovery from disturbance events such as logging, fire, and road construction (e.g. Watson *et al.*, 1999; Tague and Band, 2001).

Linking Hillslope Hydrology with Community Ecology

Community ecology studies seek to understand the dynamics of ecosystem structure and function from a species perspective rather than that of biogeochemical cycling. Studies of the distribution of species assemblages and community characteristics along resource gradients, including soil moisture, have been pursued for decades (Whittaker, 1973). Biogeographic and community studies commonly use hydroclimatologic indices as an environmental variable in multivariate analysis of community species patterns or analysis of species-environment relationships (Franklin, 1995; Guisan and Zimmerman, 2000; Wilson and Gallant, 2000). The models assume equilibrium between biotic distributions and environment, and the hydrologic variables are typically static, and are used to summarize geomorphic (topographic wetness) and climate controls (radiation and temperature indices) on soil moisture variation. As with coupled hydrologic ecosystem process approaches, the use of hillslope hydrologic models can be used to extend these models by adding a dynamic hydrologic component. Spatially distributed hydrologic model predictions of average soil moisture conditions can then be related to species and community patterns, for example, TOPMODEL (Ostendorf and Reynolds, 1998) and DYNWET (Wilson and Gallant, 2000) for soil moisture, as can models of topographically distributed solar insolation related to evaporative demand (Dubayah and Rich, 1995).

Meentenmeyer and Moody (2002) used dynamic simulations of water balance around complex watersheds in Southern California to compute both average and extreme stress conditions as controls on chaparral species distribution. Using RHESSys with a prescribed crop (uniform, low height, and LAI) to remove local effects of variable canopy conditions, they mapped the frequency of extreme stress events defined as predawn leaf water potentials below 5 MPa. (Figure 2). Sampled chaparral community composition showed that species were well arrayed along this stress gradient according to physiological thresholds for embolism (Figure 3). In addition, disturbance-dependent species frequency increases along this gradient, likely reflecting increased fire frequency or intensity.

In landscape ecology, a more dynamic approach has been taken to modeling communities. Spatially explicit models focus on disturbance regimes and community dynamics. In many cases, time steps of these models preclude temporally dynamic hydrology (Mladenoff and Baker, 1999). Landscape models of community dynamics that are not primarily driven by hydrology nonetheless usually characterize the landscape in terms of gradients of moisture availability and nutrients, for example, Mladenoff and He (1999), and other references in Mladenoff and Baker (1999). This characterization of site conditions, whether it is spatially continuous or discrete, is used to determine potential species response (probability of establishment, growth rate, competitiveness), and acts as a template for community dynamics.

Incorporating Disturbance and Management

A major goal of ecohydrologic research is to link community-based ecological concepts such as trophic level, biodiversity, succession, and disturbance with a storage-flux framework that represents the distribution of significant sources, sinks, and transformations of water, carbon, and nutrients within hydrologic flowpaths. This goal has implications for

1. the selection of specific ecohydrologic processes and feedbacks to consider in the development of models and field experiments,
2. resolution of mixed time and space scales of interest,
3. landscape representation, from both a conceptual and operational model standpoint. The models discussed above have typically emerged from the individual disciplines of hydrology, ecosystem process ecology, or community ecology. While interactions between ecology and hydrology are included, none of these models have been designed to integrate a storage-flux WCN framework with community-based ecologic concepts nor do they fully explore the integration of hydrologic flowpaths as both a driver of ecological gradients and as a response to long-term ecosystem evolution.

Representation of disturbance is limited in most ecohydrologic approaches. While community-based ecologic models (e.g. Lake, 2000; Poff *et al.*, 1997) rely on disturbance frequencies, the use of hydrologic models to predict flood and to a lesser extent fire frequencies has primarily been done off-line (where each model is run

Figure 2 Topographic distribution of extreme water-stress frequency in the mission canyon watershed. Disturbance-free species dominate mesic shaded slopes (a), ephemeral drainages (b), and moderately sheltered, high elevation slopes (c). Disturbance-dependent species dominate exposed slopes at low to midelevations (d) and ridges (e). Mixed stands form on exposed high elevation slopes (f) (Reproduced from Meentenmeyer and Moody (2002), by permission of Opulus Press AB)

separately) and do not include feedbacks between vegetation structure and dynamics and hydrologic control of disturbance extent and frequency (*see also* **Chapter 119, Land Use and Landcover Effects on Runoff Processes: Forest Harvesting and Road Construction, Volume 3** and **Chapter 120, Land Use and Land Cover Effects on Runoff Processes: Fire, Volume 3**).

For example, Keane *et al.* (1996) used the ecosystem carbon and water cycling of FOREST-BGC to develop fuel loads, and linked carbon budget information to a growth and succession model. However, given the timescales of the succession model, fuel load component moisture conditions were prescribed. Additional linkage of the litter layer moisture balance to the fire ignition and spread model would provide spatial dynamics based on forest canopy, soil, and topographic modulation of the litter. Similarly, applications of models of fire–vegetation species interactions such as LANDIS (Landscape Disturbance Simulator) have incorporated static predictions of soil moisture spatial characteristics (Franklin, 2003). These approaches could be

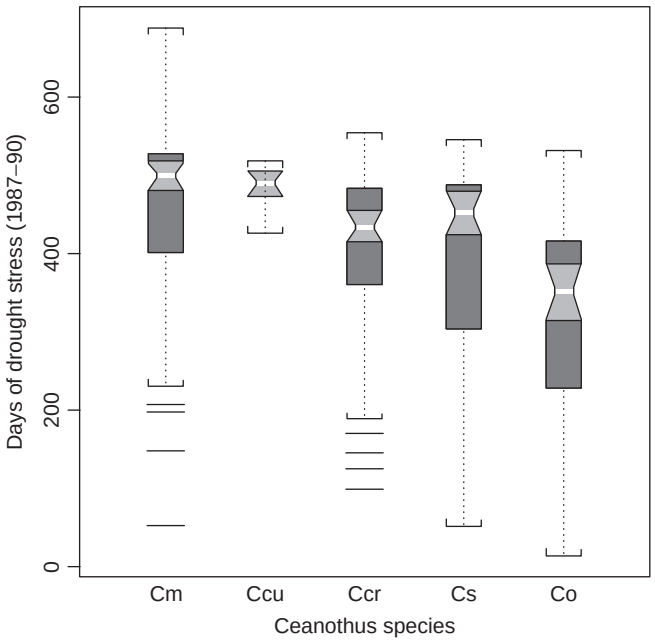

Figure 3 Plot of ceonothus species arranged by their lab-measured susceptibility to soil water tension against ''days of drought stress'' gradient. *Ceanothus megacarpus* (Cm) has 100% xylem embolism at a soil water tension of −13.8 MPa; *C. cuneatus* (Ccu) at −12.9 MPa; *C. crassifolius* (Ccr) at −11.6 MPa; *C. spinosus* (Csp) at −9.2 MPa; and *C. oliganthus* (Co) at 08.2 MPa (Reproduced from Meentenmeyer and Moody (2002), by permission of Opulus Press AB)

extended by coupling with dynamic models of soil and litter moisture patterns that include feedbacks from vegetation, disturbance, and hydrology.

NEXT STEPS: INTEGRATION WITH SOCIETAL PROCESSES AND APPLICATIONS TO ECOSYSTEM MANAGEMENT

Our ability to understand and effectively address critical societal issues ranging from nonpoint source pollution, the maintenance of freshwater supplies, storm water, soil erosion, and sedimentation, and resulting impacts on habitat and biodiversity is dependent on developing a framework to integrate hydrologic science with the structure and function of terrestrial ecosystems at the watershed scale. The development of solutions to these problems also requires that we understand their generation as societal issues, and the interaction of human society as part of the watershed ecosystem. In extending to more fully integrated ecohydrologic frameworks at the landscape level, the selection of appropriate scales of process and coupling representation needs to address the range of scales over which different controlling variables and human regulatory instruments and management techniques are organized. For example, recent literature on terrestrial ecosystem nutrient cycling emphasize fine scale (m) nexus of WCN cycling or "hot spots" and "hot moments" within riparian zones linked to microbiologic response to wetting and drying cycles (McClain *et al.*, 2003). The dynamics of these patches cannot be explained in isolation. At the landscape level, these "hotspots" are a response to space/time variation of hillslope flowpath and stream flow dynamics, which in turn respond to a combination of hydrogeomorphic changes that impact biogeochemical cycling and community structure/function in these zones. Further incorporation of community dynamics to reflect species composition within the riparian zone may necessitate consideration of disturbance regimes such as flooding, fire, insect infestation, or policy and regulation (e.g. riparian buffers) that occur at scales well beyond that of the patch or hillslope. Groffman *et al.* (2002, 2003) have investigated current riparian zone nitrogen retention in urban areas as a function of larger scale development processes, including historical catchment scale land cover and channel change, and the evolution of drainage infrastructure (*see also* **Chapter 117, Land Use and Land Cover Effects on Runoff Processes: Urban and Suburban Development, Volume 3**).

The example of regulatory and infrastructure effects on riparian zones highlights the significance of building in explicit consideration of human individual and institutional activity as an integral part of the ecohydrologic system. Just as ecological communities respond and provide feedback to hydrologic systems, so do human communities by water supply, drainage, fertilization, vegetation management, and the development of various types of best management practices and ecological restoration efforts.

A set of models has begun to integrate patch dynamic processes at overlapping patterns and scales of hydrologic ecosystem and community ecology, with human community and regulatory regimes. The RHESSys model represents landscape elements and processes by progressively nesting watersheds, climate zones, hillslopes, patches, and vegetation strata as a containment hierarchy, with different hydrologic, ecological, climatic, and social/regulatory processes and features defined for specific levels (Band *et al.*, 2000; Tague and Band, 2001). This framework incorporates human management activity as well as disturbance events that can reset ecohydrologic system state differentially within different levels and elements of the landscape hierarchy. DeAngelis *et al.* (1998) linked a spatially explicit ecosystem process model with a multilayer trophic model including herbivores and predators for an area of the Florida Everglades with water management options. Costanza and Voinov (2004) have presented a set of spatially explicit grid-based ecosystem models linked to land use change models for human dominated ecosystems. These models attempt to integrate land value derived from spatial econometric models as a driver of land use change. A general unit ecosystem

model is then parameterized for each grid cell by local land use, and embedded within a grid-based hydrologic routing scheme to estimate watershed scale integration of water, nutrient, and carbon dynamics.

While these issues of heterogeneity and process complexity present challenges for the ecohydrologic community, they also present opportunities for advancement in understanding how ecohydrologic systems evolve and respond to change. Within the developing framework of "hydrological patch dynamics", treating the patch mosaic as a structured set of ecosystem units arranged along flowpaths, a set of questions with both important theoretical and practical implications can be posed:

1. How do ecohydrologic systems coevolve in response to specific disturbance, regulatory and management regimes?
2. How do the spatial arrangements of patch type and conditions impact on ecosystem behavior at the watershed scale, and are there specific arrangements that are more resilient to expected disturbances?
3. Do specific spatial patterns of patch conditions optimize ecohydrologic functions, such as landscape level water yield or retention, ecosystem productivity, or nutrient retention?

Resolution of these issues would address landscape scales at which environmental management is focused (e.g. subdivision, planning district) and promote ecohydrologically based restoration design and implementation.

Acknowledgments

Development of concepts presented in this chapter was partially supported by funding from the National Science Foundation, DEB-97-14835, and BCS-0095796. We are grateful to Aaron Moody for discussion of his research and contribution of figures, and to Peter Groffman for a careful reading and critique, which significantly improved the manuscript.

104: Satellite-Based Analysis of Ecological Controls for Land-Surface Evaporation Resistance

STEVEN W RUNNING AND JOHN S KIMBALL

Department of Ecosystem and Conservation Sciences, NTSG University of Montana, Missoula, MT, US

Lack of available water constrains ecological processes for two-thirds of the earth's biosphere. These water limitations are manifested as either physical water deficiency or as a chemical unavailability of water as a result of being frozen. This article summarizes global principles of water limitations on the biosphere, and physiological limitations on plants. It presents hydrometeorological principles of evapotranspiration and organizing logic of the soil–vegetation–atmosphere transfer models commonly used to compute evapotranspiration. We then introduce remote sensing from both optical/thermal and active/passive microwave sensors for calculating landscape scale evapotranspiration. Finally, we offer a multisensor-based integrated surface resistance to define landscape water availability under all conditions.

GLOBAL EXTENT OF WATER LIMITATIONS ON THE BIOSPHERE

Water in an available physical–chemical state is a fundamental property of the land surface in Earth systems science. Presence of liquid water is a requirement for life, so the activity of the biosphere is intimately related to the ever-changing conditions of water on the landscape. Water availability is the primary limiting factor for vegetation growth over roughly two-thirds of the Earth (Nemani *et al.*, 2003). At the most general, global scale, the role of water in the biosphere has two dimensions. First, is the abundance of water, or most commonly the limitations of seasonally suboptimal water supply on vegetation physiology. A second consideration is the physical state, or seasonal duration of liquid water on the landscape. Vast areas of the high latitudes have an abundance of water, but that water is in a frozen state for much of the year and largely unavailable for most biological activity.

Two other localized water limitations must be acknowledged before proceeding. Water inundation from flooding or poor topographic drainage exerts a different control on ecosystems, producing anaerobic soil conditions that cause many plants literally to drown from lack of root aeration. Also, water with high salt concentrations occasionally found in desert systems can have osmotic potentials too low for plant tolerance, producing a different kind of chemical water limitation. This article will not deal with these conditions that can be locally severe, but are limited in global scope.

The purpose of this article is to develop a more integrated analysis of primary water limitations on biospheric activity. We can define vegetation by its relative abundance (a forest) or absence (a desert), and by its biological activity, the growing season when the ecosystem biogeochemical cycles are active, as contrasted with the dormant season, when water, carbon, and nutrient fluxes are minimal to zero. In like manner, we can define water also by its activity. The severe absence of water, a drought condition, limits ecosystem activity to a near dormant state until rainfall returns. Water in a frozen state is rather equivalent to vegetation in its dormant state, and in fact freezing of water is a primary cause for vegetation to enter dormancy.

So this more comprehensive measure of water availability to the biosphere requires measuring both the presence of water and its physical frozen or liquid state. The history of remote sensing for these land surface properties

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

is concentrated on optical/thermal and passive microwave sensors for defining water abundance, and active–passive microwave measures for surface freeze–thaw condition. This article will attempt an analysis combining aspects of all these sensors toward a single measure of water mobility on the landscape. We will recommend a multisensor satellite-based algorithm that can provide an integrated global, year-round evaluation of water availability for the biosphere.

Global Biospheric Patterns and Hydrologic Limits

Biogeographers have for decades related global vegetation distribution to broad indices of temperature and water (Walter, 1979). At global scales, the most obvious explanation for the difference in vegetation between deserts and forests was persistence of available water for plant growth. Water availability was most simply described by supply of annual precipitation, but it was quickly apparent that a more refined approach had to include evaporative demand, or a water balance, precipitation minus potential evapotranspiration (PET). Although the logic for use of these water balances as an environmental index is sound, there are many different formulations and temporal domains. PET can be computed in many different ways using radiation, temperature, humidity, wind speed, and other variables for formulations of varying complexity, and computed for time spans from subhourly to annually (Vorosmarty *et al.*, 1998).

Grier and Running (1977) quantified a more explicit functional relationship between climate and vegetation, observing that leaf area indices (LAI) of forests in Northwest America were directly correlated to an annual water balance. LAI is a more useful definition of vegetation than biomass or height because the functional leaf surface area for evapotranspiration, and canopy interception of radiation and precipitation is quantified directly. Nemani and Running (1989b) further developed the soil–vegetation–atmosphere systems logic relating soil water holding capacity and vegetation LAI to meteorological water balances. Similar ideas have also been pursued by Stephenson (1990) and Eagleson (2002).

Woodward (1987) expanded this analysis to global scales, computing a more sophisticated index of vegetation water balance, and using global climate data to predict both biome distributions and LAI. Prentice *et al.* (1992) and Nielson (1995) use similar water balance computations to predict global vegetation distribution patterns, in what are now known as *Dynamic Global Vegetation Models* (DGVMs). Kergoat (1998) introduced remote sensing to calculating global hydrologic equilibriums for predicting LAI, using biweekly NDVI data to follow the vegetation growing season, or phenology. Most recently, Nemani *et al.* (2003) evaluated climatic controls on global vegetation productivity, and determined that over 40% of the Earth's vegetated surface is limited by low water availability, while approximately 33% is limited by cold temperatures and water in it's frozen state, also limiting water availability for plant growth (Figure 1).

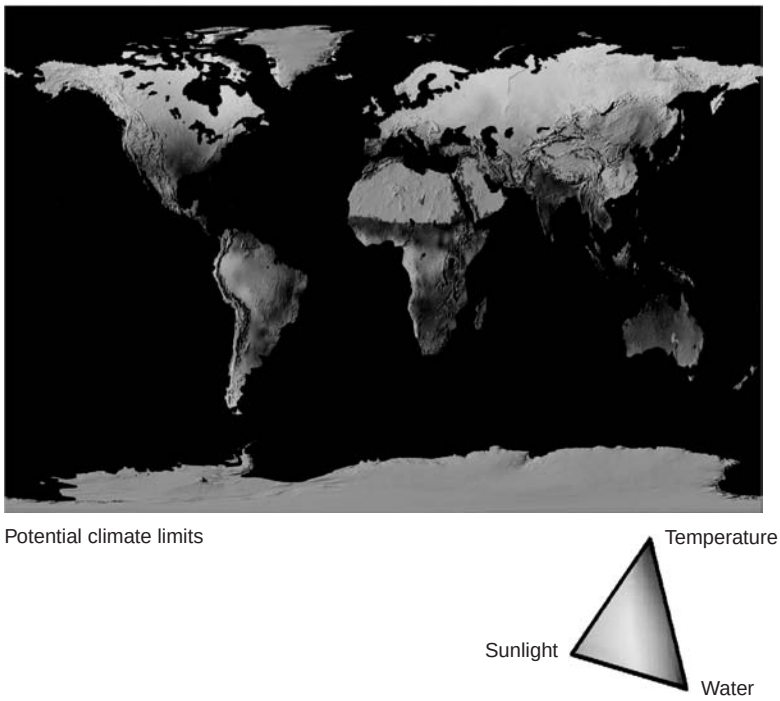

Figure 1 Global analysis of the relative balance of climatic controls on evapotranspiration of vegetation. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

All of these studies relate water limitations to vegetation structural development over relatively long time scales (i.e. decades). We next evaluate how water controls vegetation biophysics and physiology over more immediate daily to seasonal time domains.

Ecological Principles of Water Limits on Plants

Vegetation responds to water deficits in many ways (Waring and Running, 1998). Even mild soil water deficits begin to inhibit cellular expansion, xylem water flow from roots to leaves and phloem sugar transfer in stems of growing plants. Plant water deficits induce progressive leaf stomatal closure, which reduces plant water loss while bringing photosynthesis, transpiration, and canopy-atmosphere gas exchange nearly to a halt. Sustained drought will produce early leaf senescence and shedding, and may impact ecosystem leaf area for a number of years. Additionally, dry soils reduce soil litter decomposition rates, and related nutrient mobilization. Subzero temperatures and frozen water induce the same ecosystem responses, although the biological mechanics are somewhat different; plant cellular growth is inhibited; stomata are closed, limiting photosynthesis, gas exchange, and transpiration; water movement across root membranes, xylem sap flow, soil decomposition, and plant nutrient uptake are severely restricted. When plants are in a fully frost tolerant state, water molecules are hydroscopically bound to cell walls, minimizing ice crystal formation and cellular rupture. It is the lack of these cold tolerant mechanisms that restricts tropical plants to climates that never experience freezing temperatures. Consequently, lack of mobile water, either from the absence of liquid water or from freezing, has similar impacts on reducing plant leaf area, transpiration, growth, and related ecosystem activity.

Hydrometeorological Principles of Vegetation Limits on Evapotranspiration

For meteorological processes, land surface water status and frozen or thawed state determine whether the incident radiant energy is dissipated by heating the air and soil, or by evaporating or sublimating water. From energy balance theory it is clear that:

$$R_n = H + LE + G \tag{1}$$

Net radiation, R_n, being absorbed by the land surface is predominantly partitioned into H, sensible heat, or LE, latent energy evaporating water ($W\,m^{-2}$), while energy loss through soil conductance and photosynthesis, G, are relatively minor components of the energy budget (<5%) over vegetation so are often ignored. Thus, the summary Bowen ratio:

$$B = \frac{H}{LE} \tag{2}$$

can quantify the wide range of energy partitions found from completely dry surfaces where B approaches infinity, that is, all net radiation is translated into heat, to $B = 0$, an open water surface where nearly all net radiation is used to evaporate water. Quantifying the available water at the land surface and the resistance to surface evaporation from soil and vegetation is key to computing LE.

For hydrologic processes, evaporation is quantified as a component of the land surface water budget,

$$PPT = ET + Q + \Delta S \tag{3}$$

where PPT, ET, Q, and ΔS represent precipitation, evapotranspiration, outflow, and a change in water storage ($kg\,m^{-2}$) per unit time, respectively. The storage term, ΔS, includes both surface and subsurface water storage, including water in the subsurface soil profile that ultimately drains to streamflow or groundwater recharge.

For ecological processes, soil moisture is important for determining litter decomposition rates and soil CO_2 evolution, and for providing available liquid water to plants for transpiration demands. Ultimately, therefore, the availability of water for land surface evaporation is a fundamental constraint and integrator of meteorological, hydrological, and ecological processes.

The most widely accepted formula for computing land surface evaporation is the Penman–Monteith (P–M) equation, which combines the key meteorological drivers for evaporation, net radiation, humidity, and windspeed, with the key surface attributes that control evaporation rates. The surface attributes are defined as resistances, one biologically mediated by leaf area and leaf stomatal dynamics, the other physically related quantifying canopy roughness and aerodynamic exchanges. The P–M equation computes latent energy, or λE

$$\lambda E = \frac{\Delta \cdot r_e \cdot (R_n - G_0) + \rho C_p \cdot (e_{sat} - e)}{r_e \cdot (\gamma + \Delta) + \gamma \cdot r_i} \tag{4}$$

where e and e_{sat} are actual and saturation vapor pressure respectively; γ is the psychrometric constant, and Δ is the rate of change of saturation vapor pressure with temperature (i.e. $\partial e_{sat}(T)/\partial T$); r_i is the bulk surface internal resistance and r_e is the external or aerodynamic resistance. In the above equation, it is assumed that the turbulent exchange characteristics for heat and vapor transfer are the same. The Penman–Monteith equation is strictly valid only for a closed vegetation canopy; however, the formula can be adapted for sparse vegetation or even a bare soil surface with properly defined bulk internal diffusion and turbulent transfer resistances.

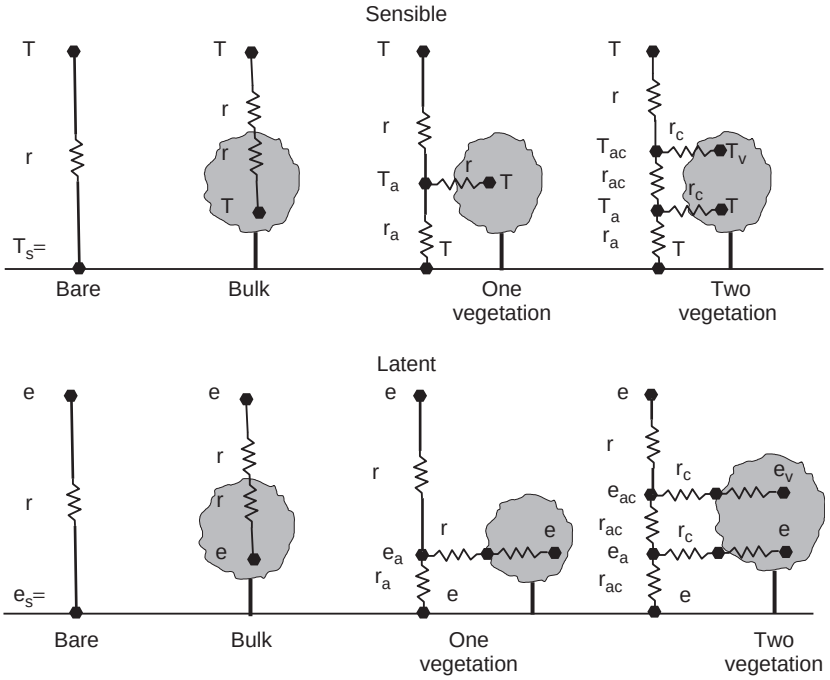

Figure 2 Electrical analog theory used to depict components of meteorology and resistance in transfer of sensible and latent heat from vegetation to the atmosphere. ($T_{a,s,v,g}$ = temperature of air, soil, vegetation, ground; $e_{a,v,g}$ = vapor pressure at atmosphere, vegetation, ground; $r_{a,c,s}$ = resistances at aerodynamic, canopy, surface) (Reproduced from Bonan, 2002 by permission of Cambridge University Press)

Systems Analysis of Soil–Vegetation–Atmosphere Transfer

Critical to computing accurate surface-atmosphere energy transfer and evaporation rates is the representation of various constraints in the soil–vegetation–atmosphere system. These constraints have classically been defined as resistances using electrical analogue theory (Figure 2). Surface resistance includes a variety of surface properties that impede the evaporation of water from the surface, and can incorporate both physical and biological impediments. For example, vegetation height exerts an aerodynamic roughness that decreases resistance, soil litter exerts a bulk diffusion resistance and vegetation physiological stomatal control increases surface resistance as stomata close in reaction to water deficits. Although the P–M equations were derived from electrical analogue theory incorporating resistances, we can simply transform these resistances to their reciprocal, surface conductance, with the advantage that surface conductances are then directly, rather than inversely proportional to the final evaporation rates.

Beginning in the 1970s these concepts were organized into a variety of SVAT (Soil–Vegetation–Atmosphere Transfer) models (Waring and Running, 1998). Some of these SVAT models were incorporated within atmospheric General Circulation Models, GCMs, like the BATS Biosphere Atmosphere Transfer Scheme of Dickinson (1996) and SiB Simple Biosphere model (Sellers *et al.*, 1986). The Project for Intercomparison of Land Surface Models analyzed the various logics and structures for these models (Pitman, 2003). Other SVAT models were designed to work in ecological biogeochemistry modeling such as FOREST-BGC (Running and Coughlan, 1988) or in hydroecological modeling (Band *et al.*, 1993).

A simple SVAT model flowchart is shown in Figure 3 (Bonan, 2002). Critical hydrologic components include precipitation, snowpack, and soil water storage, surface, and subsurface runoff. These topics are covered in detail elsewhere and in other articles. For this article, we now focus on evaporation and transpiration processes, and the control of these rates by the surface resistance. The total, or bulk surface resistance, integrates aerodynamic, soil, and canopy resistances to evaporation, and the physiological control of stomatal dynamics to vegetation transpiration. These resistance components are often dealt with separately, but landscape evapotranspiration rates are constrained by this total surface resistance.

REMOTE SENSING PRINCIPLES FOR EVAPOTRANSPIRATION

Remote sensing provides a particularly valuable methodology for evaluating total surface resistance, because the satellite sensor inherently views the entire land surface, not separating vegetation from soil. The reflectance, emission,

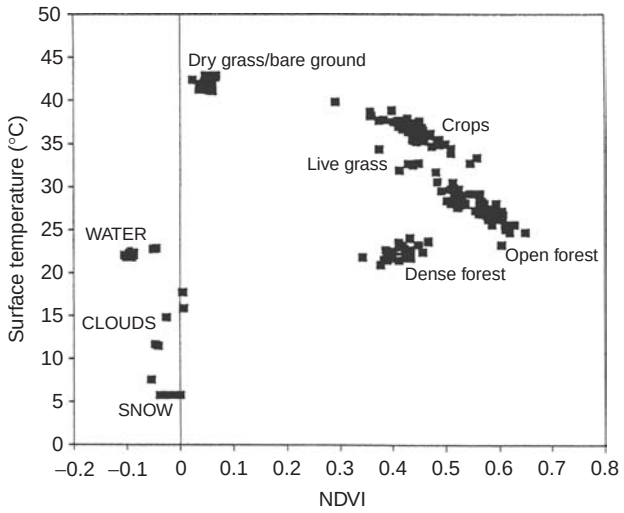

Figure 4 Ranges of radiometric surface temperature LST, and NDVI observed for a 106 000 km^2 landscape of western Montana on 14 July 1987 from AVHRR. Water clouds and snow all have low NDVI and very cool radiometric temperatures compared to the vegetated landscape, with dry bare ground the warmest (Reproduced from Nemani and Running, 1989a by permission of American Meteorological Society)

or backscatter of electromagnetic energy as observed from a satellite sensor provides an integrated view of the landscape dependant on the spatial resolution of the dataset. With any sensor of spatial resolution larger than approximately 5 m, individual plants are not resolved, and a combined view of multiple plants and the surrounding soil or litter surfaces are always included. Rather than attempting to laboriously separate vegetation from soil, or limiting analysis only to completely vegetated or bare soil surfaces, satellite remote sensing lends itself well to evaluating the total landscape resistance to surface-atmosphere energy and mass exchange.

The evaporation theory summarized above is very well developed, and measurement of land surface evaporation and conductance constraints is rather routine for plot scales. The challenge now is to represent regional and continental scales with this theory. The meteorological drivers in the P–M equation are regularly available from mesoscale to global-gridded meteorological models. Representing the extreme spatial and temporal heterogeneity of surface resistances is the biggest limitation for accurate measures of evaporation at landscape to continental scales. At these scales, remote sensing data are readily available, and consequently a variety of sensors have been explored for both direct and indirect assessment of evaporation and associated surface resistances to water and energy movement.

Optical/Thermal Sensors

Optical and thermal sensors provide two key attributes for quantifying land surface evaporation. First, these sensors are sensitive to photosynthetic biomass and surface temperature, and are useful for quantifying vegetation cover and canopy leaf area index. Structural, phenological, and other morphological differences among major vegetation types (e.g. forests, grasslands, croplands) are defined by land cover classes distinguished using optical/thermal sensors like MODIS (Figure 4). Evaluating seasonal trajectories of vegetation indices such as NDVI and land surface temperature (LST) provides an additional dimension of biome discrimination, as more open and arid vegetation types show dramatically higher LST (Figure 5). Global 1 km resolution datasets of general land cover classes that include simple vegetation biome discrimination are now regularly available and are updated annually to reflect land cover changes (Friedl *et al.*, 2002). Higher resolution land cover data are also available based on 30-m resolution Landsat data, allowing more precise vegetation cover discrimination (Vogelmann *et al.*, 2001). Newer generation land cover mapping methods avoid logical classification errors by computing continuous fields of fractional vegetation cover that are then directly interpretable for defining surface roughness, albedo, and LAI for evaporation calculations (Hansen *et al.*, 2002).

NIR/red spectral band ratios such as the NDVI are widely used to estimate vegetation LAI over large areas (Myneni *et al.*, 2002). Increasing LAI provides greater cumulative surface area for canopy water interception and evaporation, and for transpiration by vegetation canopies. Higher LAI also infers more robust vegetation with deeper

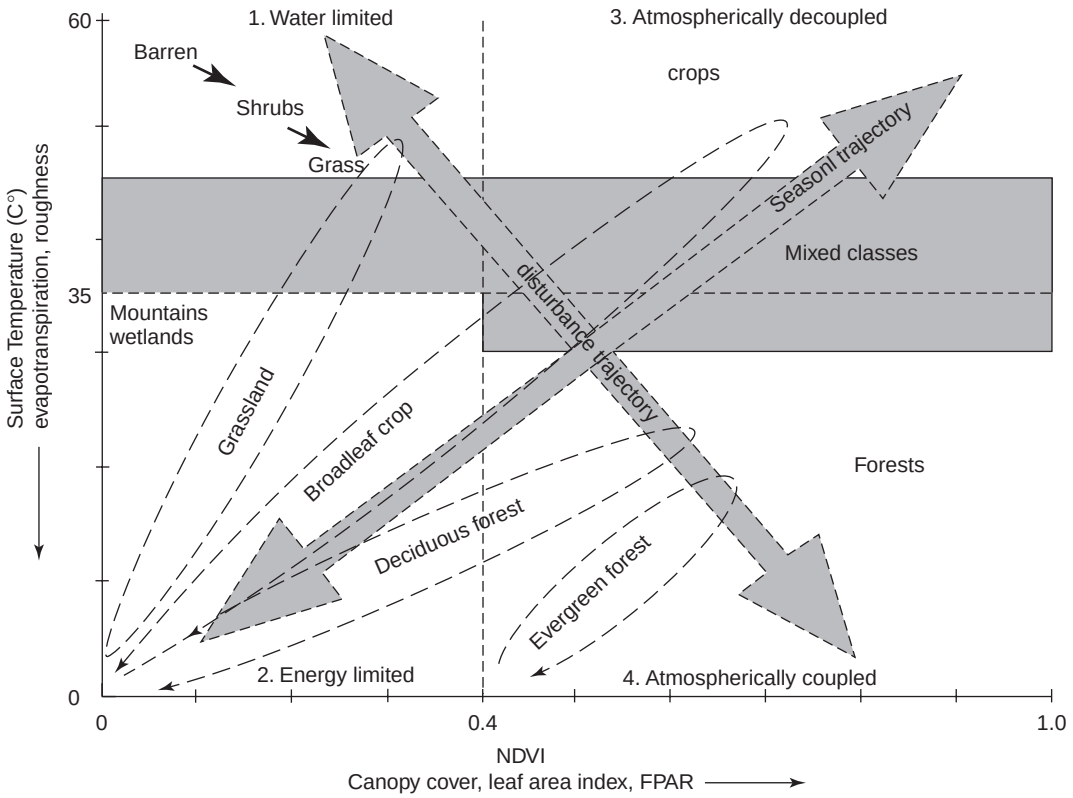

Figure 5 Separation of biome types possible by following the seasonal time series of radiometric surface temperature LST and NDVI. As vegetation grows in the spring NDVI and LST rise, but at different rates depending on the surface energy exchange characteristics of the vegetation. As vegetation desiccates in late summer, or with disturbances, NDVI falls and LST rises (Reproduced from Nemani and Running, 1997 by permission of Ecological Society of America)

rooting zones that are able to tap water deeper in the soil profile, thus allowing an indirect measure of deeper soil water availability than surface observations alone can directly provide.

Thermal remote sensing of radiometric land surface temperature, LST, most directly measures the sensible heat component of the energy balance, and is thus inversely proportional to latent energy and evaporation rates (Wan *et al.*, 2002). As previously discussed, the Bowen ratio (H/LE) is a relatively simple parameter summarizing the relationship between sensible and latent heat flux from a surface. Land surfaces can vary from a very high Bowen ratio when completely dry, often more than 10, to as low as 0.1 when wet. These changes in land surface energy partitioning can occur slowly as a vegetated landscape dries out over many weeks during summer, and then abruptly as the Bowen ratio drops following a substantial rainfall event. Thermal remote sensing can provide an integrated look at land surface evaporation, although overpass timing is critical, as midafternoon radiant heating of the land surface provides the most useful signal. Historically, the NOAA AVHRR sensor with 1430 local overpass time has been most valuable, and now the MODIS sensor on the 1330 Aqua platform is providing high-quality LST data. For some purposes, geostationary satellite data from GOES also can be used to derive LST and surface ET every hour under cloud-free conditions (Norman *et al.*, 2003; Diak *et al.*, 2004).

Many studies have combined both spectral vegetation index and LST information from satellite optical/infrared sensors to infer land surface evaporation rates, typically as a ratio of LST/NDVI (Gillies *et al.*, 1997; Sandholt *et al.*, 2002; Moran *et al.*, 1994; Goward *et al.*, 2002). The denominator, NDVI or equivalent, quantifies potential *increases* in evaporation due to more evaporating surface of LAI, while the numerator, LST infers *decreases* in evaporative conductance from increases in sensible heat. If we examine a single scene of a complex natural landscape in midsummer, a logical pattern of NDVI and LST is discernible (Figure 4, Nemani and Running, 1989a). In this Montana mountainous landscape, clouds and snow are shown with low NDVI and low LST, mesic forests have a high NDVI but rather cool LST, and dry grasses or bare land show low NDVI but high LST. This surface discrimination is strongest during midsummer conditions under relatively high surface solar energy loading with

spatially heterogeneous energy partitioning and associated LSTs. As a surface dries, the LST pattern becomes progressively higher and can easily exceed 60 °C, even with screen-height air temperatures below 40 °C (Figure 6a). By quantifying temporal changes in the slope of the maximum LST/NDVI curve, an inference of surface resistance can be made (Figure 6b; Nemani *et al.*, 1993; Nishida *et al.*, 2003a, 2003b).

However, when we attempt to monitor a region regularly through the vegetation growing season, the most fundamental constraint is the regular interruption by cloudiness and atmospheric aerosols that limit clear imaging of the land surface. In humid tropical areas, cloud cover limits optical/infrared remote sensing more than 80% of the year, and latitudes above 50 degrees also have extended periods of summer cloudiness (Figure 7). For these situations of extended cloudiness and/or inadequate seasonal solar illumination, microwave sensors provide the potential

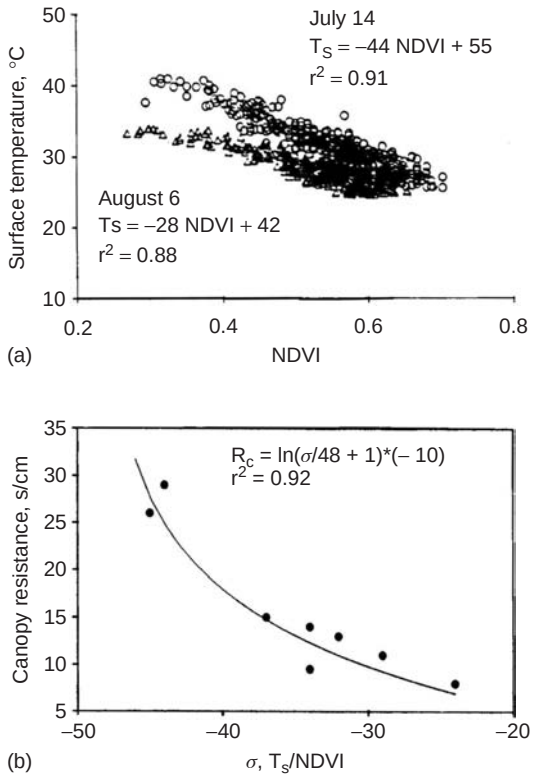

Figure 6 (a) Change in the slope of the LST/NDVI relationship from 14 July, after extended drought, and 6 August, after 3.2 cm of rain, for a natural landscape in western Montana, as observed by AVHRR. A reduction in Bowen ratio is evident in the reduced LST after substantial rainfall. (b) A canopy resistance, simulated by the SVAT model, FOREST-BGC, was highly correlated with seasonal changes in slope of the LST/NDVI relationship, suggesting a way to infer surface resistances by satellite over large regions. Figure 7 The fraction of annual MODIS land surface optical reflectance data degraded by cloud cover for 2003. Data from Zhao *et al.* (2005). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

for all-weather imaging of the land surface. Remote sensing at microwave wavelengths is largely independent of solar illumination, cloud cover, and other atmospheric attenuation impacts that can significantly degrade remote sensing capabilities at optical and infrared wavelengths. However, microwave wavelengths also provide different information than optical/infrared wavelengths and must be evaluated in a different way.

Active/Passive Microwave Sensors

Microwave remote sensing occurs over much longer spectral wavelengths (0.1 to 30 cm) than optical/NIR remote sensing (0.4 to 10 μm). The signal detected by an active or passive microwave sensor is a function of the emission, absorption, transmission, scattering, and reflectivity of electromagnetic (EM) energy by the landscape and intervening atmosphere at a given spectral wavelength (Ulaby *et al.*, 1986). These properties, in turn, are sensitive to changes in the physical characteristics of the landscape including, surface structure, roughness, orientation, and dielectric properties. At the microwave wavelengths most commonly used for Earth remote sensing, the atmosphere is largely transparent with minimal attenuation of EM energy.

The dielectric constant characterizes the electrical properties and propagation of EM energy in the landscape (El-Rayes and Ulaby, 1987). The interaction of EM energy with a dielectric material has its origin in the response of charged particles to the applied field. The displacement of these particles from their equilibrium positions gives rise to induced dipoles that respond to the applied field. In addition, polar materials contain permanent dipoles caused by the asymmetric charge distribution within the molecules themselves. Water is relatively unique in that it has strong molecular (positive, H^{+2}, and negative, O^{-2}) polarity, exhibiting a dielectric constant that dominates the microwave response of natural landscapes (Kraszewski, 1996). Water molecules

in a liquid state align themselves with an applied EM field, while water molecules in ice are bound in a crystalline lattice and cannot freely rotate, resulting in a substantially lower dielectric constant.

Most natural materials have a dielectric constant ranging from 3 to 8 when dry, while liquid water has a dielectric constant of approximately 80 (Ulaby *et al.*, 1986). Thus, short-term variability in landscape radar backscatter and microwave emissions is to a large extent, a function of changes in the moisture status of vegetation, surface, and soil media. Variations in the predominant frozen or thawed state of the landscape also have a major impact on microwave emissions and reflectivity because frozen water has a very low dielectric constant of approximately 2, which is similar to very dry soil.

In seasonally frozen environments, the most dynamic temporal changes in microwave emissions and reflectivity occur in response to seasonal freeze–thaw transitions

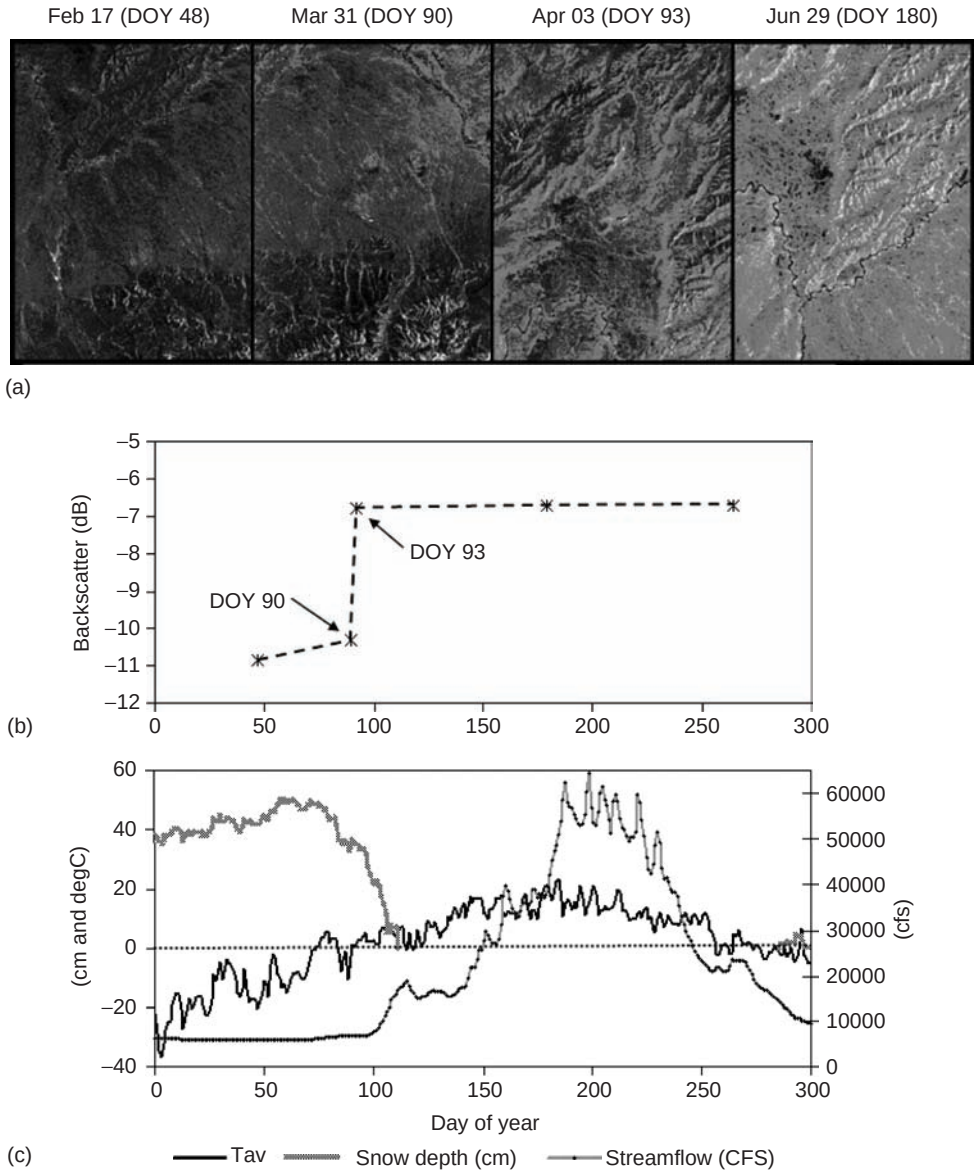

Figure 8 (a)Temporal series of JERS-1 SAR images acquired over interior Alaska boreal forest. The image series shows the landscape radar backscatter transition from predominantly frozen to thawed conditions during spring, 1998. The middle plot (b) shows the radar backscatter temporal response averaged over four sites within the domain. (c) Freeze–thaw transitions dominate the 3–5 dB seasonal variation in radar backscatter. A pronounced backscatter increase between days (DOY) 90 and 93 coincides with thawing air temperatures (T_{av}), seasonal snowmelt and the new release of water on the landscape indicated by local weather station data and USGS streamflow records (redrawn from Entekhabi *et al.*, 2004). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

(Way *et al.*, 1997; Zhang *et al.*, 2003). Spring thaw and the disappearance of seasonal snow cover in these environments is often rapid due to moderate air temperatures and increasing solar radiation, resulting in large decreases in surface albedo of up to 80% between snow covered and snow free conditions (Zhang *et al.*, 2003). The images in Figure 8 show a temporal sequence of JERS-1 satellite L-Band Synthetic Aperture Radar (SAR) images that capture a seasonal freeze–thaw transition event in the boreal forest region of Alaska (Entekhabi *et al.*, 2004). The pronounced increase in radar backscatter between days 90 and 93 occurs in response to seasonal thawing, snowmelt, and the new release of water on the landscape as indicated by seasonal increases in regional stream flow. This event and other freeze–thaw transitions dominate the 5–6 dB seasonal variation in radar backscatter. The surface resistance to evaporation under frozen conditions is similar in magnitude to that of arid, desert environments, while resistance is minimal following snowmelt, with evaporation approaching potential rates. These changes are most dramatic at high latitudes where seasonal increases in surface energy and liquid water available for evaporation have important consequences for regional weather patterns, hydrological, and biospheric processes (Bonan *et al.*, 1995; Chapin *et al.*, 2000; Kimball *et al.*, 2001, 2004).

Active and passive microwave remote sensing techniques have proven sensitive to vegetation phenology, water stress, and other changes in vegetation structure and water content, snow cover, and soil moisture (Waring *et al.*, 1995; Kane *et al.*, 1996; Kimball *et al.*, 2004). The ability of microwave remote sensing to detect changes in the moisture status of these various landscape components is strongly dependent on sensor wavelength, polarization, and spatial resolution. Landscape topography, vegetation structure, soil type, the presence/absence and structure of snow cover also influence retrieval accuracies. Longer wavelengths (e.g. L-band) are generally sensitive to a greater volume of surface vegetation and soil media, relative to shorter (Ku-, C-bands) wavelengths under similar conditions. Longer microwave wavelengths are also directly related to soil moisture as long as the overlying vegetation water content is low (i.e. $<5–6\,kg\,m^{-2}$). Soil moisture sensitivity is also generally limited to the top 5–10 cm of the surface soil layer even in bare soil environments. At biomass levels roughly above that of a fully developed corn crop, however, the ability of microwave remote sensing to detect soil moisture decreases, while sensitivity to vegetation increases.

Vegetation cover is a major impediment limiting direct microwave remote sensing detection of soil moisture over much of the globe. The relatively coarse spatial scales, band widths, and orbital geometries of all current and planned satellite microwave remote sensing platforms also limit capabilities for resolving subgrid scale differences in the moisture content of individual landscape components. However, these scales are generally optimal for regional assessment and monitoring of bulk, landscape surface resistances to evaporation and a fundamental limitation to latent energy and water exchange with the atmosphere.

INTEGRATED REMOTE SENSING OF LANDSCAPE WATER MOBILITY

Regional to Global Scaling

The regional patterns and temporal dynamics of water mobility and surface resistances of the landscape have important consequences for troposphere boundary layer development, weather and global climate. For example, the seasonal transition between frozen (high surface resistance) and nonfrozen (low surface resistance) conditions in the spring is relatively abrupt and coincident with seasonal snowmelt and runoff, large decreases in surface albedo and the initiation of the growing season at high latitudes and upper elevations. The timing and spatial extent of this seasonal shift is of critical importance to the establishment and location of the polar front and regional to global scale weather patterns (Bonan *et al.*, 1995; Chapin *et al.*, 2000). The timing of this frozen/thawed transition is also a major control on vegetation productivity and regional source-sink strength for atmospheric CO_2 (Kimball *et al.*, 2004; McDonald *et al.*, 2004).

At continental scales, satellite-based approaches have been developed to monitor changes in plant available moisture on the landscape (Nemani *et al.*, 1993; Nishida *et al.*,

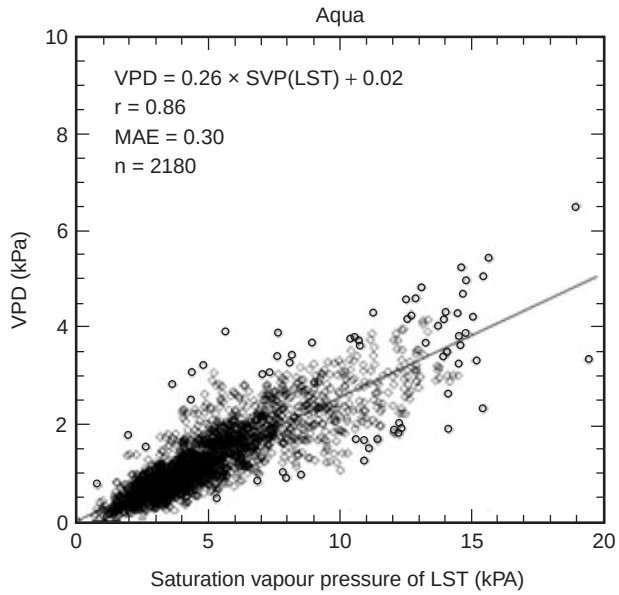

Figure 9 Relationship between a composited maximum 8-day LST from MODIS Aqua at 1330 overpass time and global land surface VPD measured at 2180 surface weather stations for August 2003. (From H. Hashimoto unpublished data) A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

2003a, 2003b). These advancements offer the potential for finer temporal sampling and mitigation of atmospheric interference. For example, improved MODIS radiometric calibration and cloud-screening algorithms allow the assessment of daily LST temporal dynamics for individual sensor footprints. The scatterplot in Figure 9 shows the relationship between Aqua MODIS LST and the atmospheric vapor pressure deficit (VPD), which is the primary driver of land-atmosphere latent energy and water fluxes. An 8-day time composite of the MODIS Aqua maximum LST for the period provides a metric of changing land surface evaporation resistance that can be mapped at 1 km resolution over regional, continental, and global extents (Figure 10). These technological advances offer potentially simpler techniques for monitoring surface resistances to water mobility compared to earlier methods developed from NOAA AVHRR data using the LST/NDVI ratio technique (e.g. Nemani *et al.*, 1993).

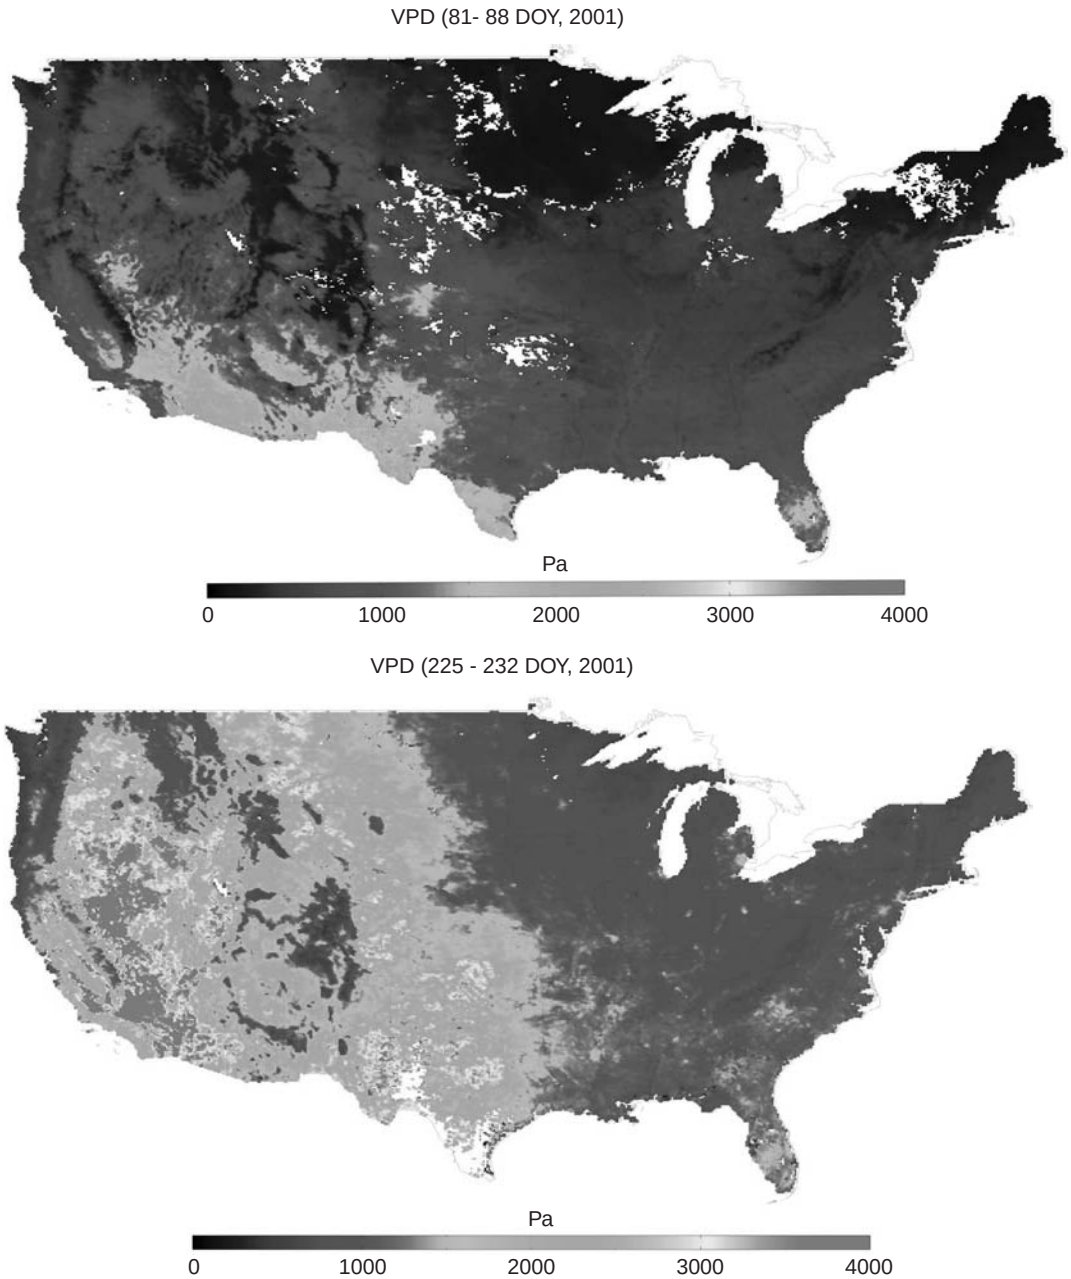

Figure 10 Mapping of maximum weekly VPD during spring and midsummer at 1 km across the continental United States using MODIS Aqua and the relationship in Figure 9. (Hashimoto, unpublished data). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Global satellite remote sensing of landscape water mobility at continental scales requires relatively high (e.g. daily) temporal repeat and moderate spatial scales consistent with the development and dynamic nature of regional weather patterns (Schmugge *et al.*, 2002). Evolving weather systems are influenced by land surface characteristics through surface coupling of energy and water fluxes to the atmospheric boundary layer (ABL). The ABL integrates and responds to surface fluxes on the order of 10 km or less (Albertson and Parlange, 2000). The major limitation on the use of satellite optical/infrared methods to monitor landscape water mobility lie primarily with the coarse temporal compositing required to mitigate the effects of clouds, smoke, and other atmospheric aerosols.

The maps in Figure 11 show seasonal extremes of global plant soil water availability for representative early spring and midsummer conditions estimated using an ecosystem process model (Biome-BGC) driven by daily meteorological inputs from an Atmospheric GCM. Areas of low and high soil water availability represent respective surrogates for high and low resistances to surface latent energy, water, and gas exchange with the atmosphere. In winter and early spring, high latitude and upper elevation landscapes are predominantly frozen and have both low water mobility and high resistance to surface-atmosphere exchanges that are of the same order of magnitude as arid desert regions. Areas of low water mobility (high surface resistances) such as arid deserts and frozen regions are dominated by sensible

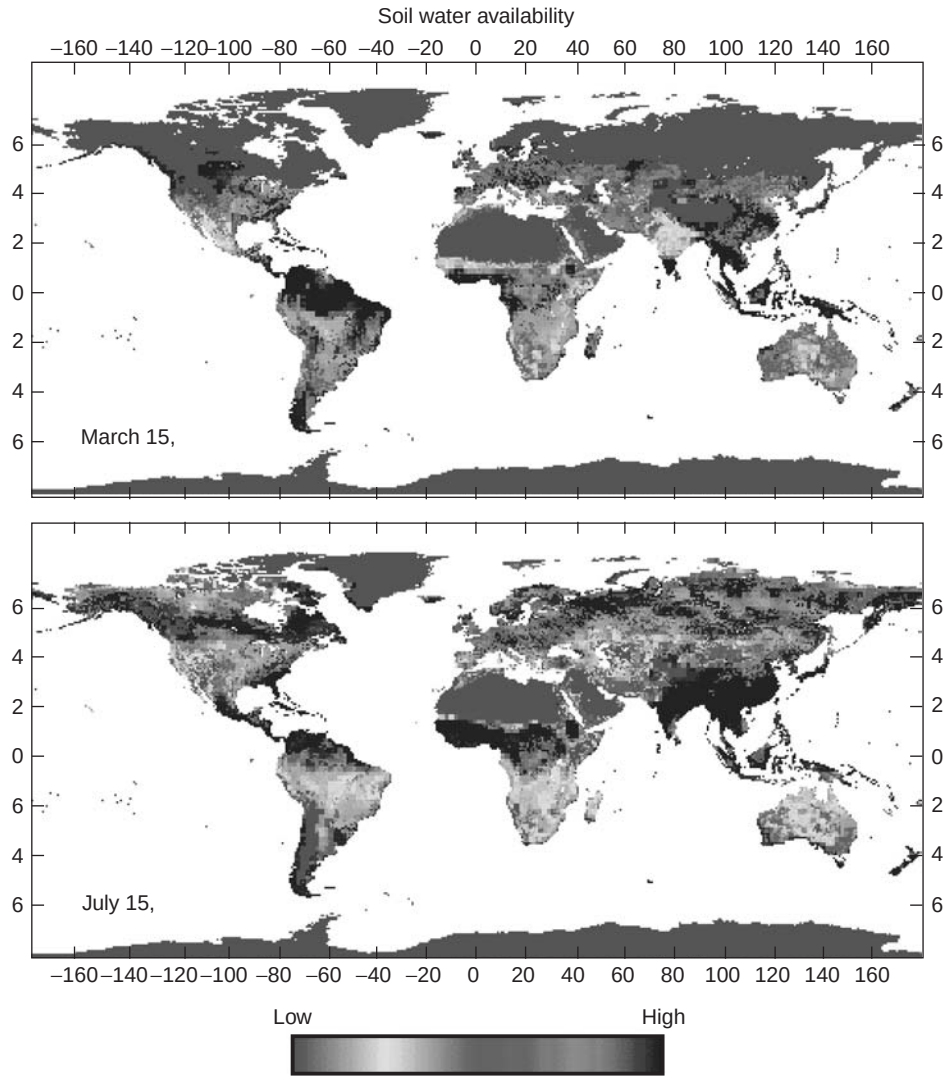

Figure 11 Simulation of a relative integrated soil water availability using NCEP reanalysis daily surface meteorology and the SVAT model Biome-BGC model for 1999. In late winter, 15 March, surface resistance for ET is very high in high latitudes because of freezing temperatures, and in dry deserts. In midsummer, surface resistance is not temperature limited, so high surface resistances are primarily a result of soil water deficits. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

energy exchange, surface temperature extremes and relatively stable atmospheric conditions. In contrast, areas of high water mobility (low surface resistance) are dominated by latent energy exchange and moderate surface air temperatures. Boreal and arctic regions have relatively high seasonal variability in surface resistances to water mobility, while arid deserts and regions of permanent ice and snow maintain relatively persistent low water mobility, high surface resistance conditions.

Future Sensors

A number of recent and planned satellite sensors potentially satisfy the spatial and temporal demands for global monitoring of terrestrial water mobility. The NASA EOS MODIS sensors onboard Terra and Aqua satellites provide both LST and spectral vegetation index information twice daily on a global basis useful for derivation of surface resistances (Nishida *et al.*, 2003a, 2003b). These data are strongly degraded by the presence of clouds and other atmospheric aerosols as well as low solar illumination, shadowing, and the presence of snow cover that often occur at high latitudes and upper elevations. However, the two MODIS sensors operating in tandem onboard Terra and Aqua offer potential for twice daily global observations at relatively high (1 km) spatial resolution (Justice *et al.*, 1998). MODIS also has improved spectral and radiometric resolution compared to older NOAA AVHRR series data. Operational continuity of MODIS capabilities will be provided by the NPOESS (National Polar Orbiting Environmental Satellite System) designed for global daily coverage in the 1330 h overpass time, and scheduled for first launch in 2010 (Townshend and Justice, 2002). NPOESS will have a sensor, VIIRS (Visible Infrared Imager/Radiometer Suite) that will have equivalent spectral capabilities of MODIS in visible, infrared, and thermal infrared wavelengths.

Satellite microwave remote sensing also offers the potential for continuous monitoring of the land surface, with direct sensitivity to landscape moisture, freeze–thaw state and aerodynamic roughness for monitoring landscape water mobility. The NOAA SSM/I sensor series has been providing global daily observations since 1988 at coarse (~25 km) spatial scales (Armstrong and Brodzik, 1995). The AMSR-E sensor recently launched onboard the NASA Aqua satellite also provides global daily observations at similar spatial scales (Kawanishi *et al.*, 2003). Active microwave sensors such as SeaWinds, ERS, and Radarsat are also available and offer the potential for global mapping of freeze–thaw state and surface aerodynamic roughness at spatial resolutions on the order of 25 km or less (McDonald *et al.*, 2004; Way *et al.*, 1997; Le Toan *et al.*, 1992).

The National Aeronautics and Space Administration (NASA) is scheduled to launch the Hydrosphere States Mission (HYDROS) in 2010. This combined active–passive microwave remote sensing satellite is specifically designed to study the state of the global terrestrial hydrosphere including soil moisture and freeze–thaw state (Entekhabi *et al.*, 2004). The HYDROS L-band sensors will provide global mapping of landscape freeze–thaw state at spatial and temporal scales of 3 km and 1 to 3 days. Surface (<5 cm) soil moisture will also be distinguished to within 4% volumetric accuracy, allowing discrimination between dry and saturated conditions over the sparsely vegetated areas of the global land surface at spatial and temporal scales of 10 km and 3 days or less. More importantly, the HYDROS sensor will provide an integrated surface resistance measure that will give full global coverage under all conditions of cloud cover, solar illumination, and vegetation cover through integration of optical/thermal and microwave-based algorithms as discussed here.

The sensitivity of these data to different and complementary landscape biophysical variables such as surface temperature, soil moisture, photosynthetic leaf area and vegetation stress provide a potentially effective means for monitoring ecological controls to surface resistance and water mobility for regional hydro-meteorological research and future water management.

We review the processes involved in the transport of bacteria in the saturated subsurface. Our goal is to communicate priority topics in the basic science of bacterial transport processes, and this leads to a focus on the nanometer to micron scales of observation. The scope of this review is the set of physical, chemical, and biological processes involved in the transport of individual cells, and the constitutive theory underlying conceptual depiction of these processes.

INTRODUCTION

Concern about pathogen contamination of groundwater and the use of bacterial agents in the cleanup of groundwater has highlighted the need for an improved understanding of the fate and transport of microbes in the subsurface. In particular, *in situ* bioremediation of contaminated groundwater may involve microbial transport promoted by intrinsic bioremediation (as part of natural attenuation, e.g. Chapelle and Lovley, 1990; Semprini *et al.*, 1992; Wiedemeier *et al.*, 1995; Clement *et al.*, 2002)), biostimulation (by the addition of substrates or electron donors, e.g. Semprini and McCarty, 1992; Huesemann and Truex, 1996), or bioaugmentation (by the introduction of microbial cells with specific function to the subsurface; e.g. Mayotte *et al.*, 1996; Duba *et al.*, 1996a,b). Bioaugmentation in this context includes both injection of bacterial suspensions in the saturated zone near a contaminant plume and emplacement of solid media with attached bacteria as a "biobarrier" through which mobile contaminant is expected to pass and be degraded (Kao and Yang, 2000; Dybas *et al.*, 2002). Both biostimulation and bioaugmentation approaches have been widely applied to *in situ* remediation of chlorinated solvents, and the science of underlying processes is well within the topical public news (e.g. Bowman, 2002). The relative effectiveness of biostimulation versus bioaugmentation approaches was recently debated in Nyer *et al.* (2003) and in Major *et al.* (2003).

In this article, we focus on the physical, chemical, and biological processes involved in the transport of bacteria in the saturated subsurface. Since our main focus is on the basic scientific understanding of bacterial transport processes, we do not treat in great detail either conventional mathematical models of bacterial attachment/detachment kinetics (recently reviewed in Clement *et al.*, 1999, and in Murphy and Ginn, 2000; here treated briefly in the Section on "Conventional models of bacterial attachment/detachment kinetics"), or continuum-scale (e.g. laboratory column) experiments elucidating apparent effects of aqueous or mineralogical physicochemical conditions (such as grain size distribution, presence of mineral oxides or organics, aqueous ionic strength, pH, and velocity; recently reviewed in Ginn *et al.*, 2002, and in Harvey and Harms, 2001). Thus, the scope of this review is limited to physical, chemical, and biological processes involved in bacterial transport, and the constitutive theory underlying their conceptual depiction. Transport of other microorganisms (e.g. viruses) is often treated by considering approaches similar to those used for bacteria, but will

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

not be considered in detail in this work (the interested reader is referred to Schijven and Hassanizadeh, 2000). Also in our attempts at concision we focus on the references most generally applicable to subsurface fate and transport sometimes at the cost of identifying the first references.

In Figure 1, we have presented a schematic illustration of a sequence of length scales that might apply to microbial transport in the subsurface. At the most fundamental scale (Level I of Figure 1; hereafter referred to as the "cell scale" or "cytoscale"), transport is influenced by the interactions between the complex heterogeneous cell surface and the solid phase (which is itself a complex, heterogeneous material). These interactions, although manifest at the scale of nanometers, is nevertheless one of the controlling features of microbial transport at the largest scale of interest (the "field scale", Level IV in Figure 1), which might represent the scale associated with an aquifer remediation zone or the depth of a bioreactor such as a tricking filter. In between these two length scales, one may further identify several other scales of interest: the "pore scale" (Level II) where cell transport is governed by the conservation of mass and momentum within the porous matrix, and where groups of cells may become evident as biofilms within the porous media; and the "Darcy scale" where the details of individual cells are not apparent, and the cell mass is treated as a homogeneous chemical phase.

We will first review conceptual models of bacterial phases in the subsurface, and then the processes controlling fate and transport on short (e.g. bioremediation) timescales. Finally, we briefly review field-scale bacterial transport experiments and discuss a number of issues that impact the application of current process descriptions and models at the field scale.

CONCEPTUAL AND MATHEMATICAL REPRESENTATION OF SUBSURFACE BIOMASS

The transport and fate of microbes in the subsurface is naturally dependent on the distribution of biomass in the aqueous and solid phases. Thus, the mathematical description of the kinetics of biomass transformation resulting from processes such as growth and cellular attachment to surfaces first requires a conceptual model of the biotic phases. Aqueous-phase biomass is commonly treated as a dilute suspension of "free-living" (i.e. aqueous or planktonic) cells, and is typically mathematically represented as a dilute reactive solution (e.g. Murphy *et al.*, 1997). The assumption of a dilute solution neglects interactions between aqueous cells, and this assumption will not be valid when there are significant cell interactions such as those encountered in cell clumping and quorum sensing (Ward *et al.*, 2001). Approaches that invoke the interactions among cells have not yet been developed; however, such effects have been rigorously incorporated in the description of the transport of simple colloids (e.g. Peters, 1990; Peters and Ying, 1991). A similar analysis for representing the interactions among microorganisms represents a significant challenge, and is an open area for continuing research.

Biomass associated with the solid phase can be modeled using three conceptual approaches representing major schools of thought, as discussed originally by Molz (1987). Later, Baveye and Valocchi (1989) formalized these concepts into (1) unstructured macroscopic and (2) structured microscopic models, where the biofilm geometry was accounted for, at least conceptually. The structured models specify the geometrical aspects of the attached biophase in particular, for example, as "pointwise" colonies, or as a biofilm described with a thickness and porosity, and so on. These models allow quantification of momentum and mass transfer at the cytoscale.

Momentum transfer between the solution and structured biophase is important for evaluating forces involved in biomass growth that lowers permeability, that is, bioclogging. Unstructured models treat biomass as another mixture component (like a solute and/or sorbate) without specification of physical structure. Clement *et al.* (1996b) showed that permeability reduction can also be modeled using unstructured macroscopic approaches and pointed out some of the similarities and differences between macroscopic- and biofilm-based bioclogging models. MacDonald *et al.* (1999a,b) examine the role of growth in a structured subsurface biofilm in the clogging of porespaces during bioremediation. Dupin *et al.* (2001a,b) combine pore-scale biodegradation and bacterial growth, using a structured approach, with quantitative treatment of the mechanics of biofilm deformation. Biomass is modeled as a continuous uniform isotropic hyperelastic material, using both structure colony ("aggregate") and biofilm conceptual models, whose expansion and deformation are governed by material mechanics stress-strain relations. Results in the context of a 2-D lattice porous medium suggest that aggregates have a much greater potential impact on clogging than biofilms, so the geometry of the attached biophase (and its representation in models) matters to the simulation and prediction of clogging.

In the unstructured biophase approach, no structural presumption is imposed on the biophase (MacQuarrie *et al.*, 1990; Sudicky *et al.*, 1990; Semprini and McCarthy, 1992; Widdowson *et al.*, 1988; Clement *et al.*, 1999) and the biomass is treated as a suspended, but kinetically sorbing/desorbing species (Zysset *et al.*, 1994; Murphy *et al.*, 1997). In this case, the biomass is viewed as a mixture component that is not a separate phase, occupies no volume, and is fully mixed with other aqueous species. It is also assumed that a linear relation between mass of substrate consumed and biomass produced, and that no diffusion limitations affect the transfer of substrate mass from solution into the biomass. This approach has been taken in model construction (Corapcioglu and Haridas, 1984; Borden and Bedient, 1987; MacQuarrie *et al.*, 1990), in column studies that focus on bacterial transport (Lindqvist *et al.*, 1994; Tan *et al.*, 1994) and in intermediate-scale flow cell studies of growth and coupled transport (Wood *et al.*, 1994; Murphy *et al.*, 1997). Challenges in validating the conceptual model are associated with the difficulty in gathering data at the proper (pore) scale, with nonlinearities in models associated with biofilm growth, and with the tremendous spatial and temporal variability of biofilm properties. Peyton and Characklis (1995) report that published biofilm for density values range from 10 to 130 $\mathrm{kg\,m^{-3}}$ of bulk porous media. These values typically vary even more under conditions of active biodegradation (Murphy and Ginn, 2000). However, a quantitative foundation for understanding microbial processes in porous media may best be achieved through structured models explored at the pore scale and below (e.g., Wood and Whitaker, 1998; 2000a; 2000b).

Within the context of mass-transfer processes, the definition of how to best model biological phases in porous media has been the topic of much discussion and debate (see, e.g. the original research articles by Moltz *et al.* (1986), Baveye and Valocchi (1989), Taylor and Jaffé (1990), and subsequent comments on these articles by Widdowson (1991), Baveye and Valocchi (1991), Baveye *et al.* (1992), Jaffé and Taylor (1992)). Although initially much of the focus of these debates was related to the geometry and distribution of microorganisms associated with the solid phase (and, subsequently, the kinds of conceptual models that were relevant to these various geometries), it was pointed out by Rittmann (1993) that in practice the actual geometry may make little difference in the determination of the effective reaction rate for mass transfer associated with biodegradation. What

does matter is whether the biotic phase itself limits diffusive mass transfer of degradable compounds and reactants; when there is no diffusion limitation between extra-biofilm fluid and intra-biofilm fluid, the biofilm is said to be in local mass equilibrium (LME) with the fluid phase. This assumption implies the absence of significant concentration gradients within the biofilm itself, and when valid leads to a single conservation equation for reactive solutes in the aqueous phase. When mass transfer between the extra-biofilm fluid and the biofilm fluid is diffusion-limited, a two-region nonequilibrium model (leading to two coupled conservation equations for reactive solutes, one for the fluid phase and one for the biological phase) is indicated.

The first model is consistent with what has also been called the *strictly macroscopic model* (Baveye and Valocchi, 1989). This model has been used extensively in the literature (e.g. MacQuarrie *et al.*, 1990; Sudicky *et al.*, 1990; Zysset *et al.*, 1994; Wood *et al.*, 1994, 1995; Clement *et al.*, 1996a,b; Zysset *et al.*, 1994; Murphy *et al.*, 1997), and has recently been derived by upscaling the physical and biological processes at the microscale via volume averaging (Wood *et al.*, 2002, Wood, 2004). For the second model, the situation is slightly more complex. If it is assumed that the characteristic time for changes in the biofilm phase is much smaller than those for the fluid phase, then the biofilm can be treated as being quasi-steady. This approach has been adopted widely, with minor differences in the conceptual picture of the biomass distribution, by a large number of researchers (e.g. Molz *et al.*, 1986; Widdowson *et al.*, 1988; Baveye and Valocchi, 1989; Dykaar and Kitanidis, 1996; Chen *et al.*, 1992). If it is further assumed that the concentration profile in the biofilm is quasi-steady but not necessarily fully penetrating, then the reaction rate can be developed in terms of an "effectiveness factor" that corrects the fully penetrating model to account for a nonuniform substrate distribution in the biofilm. Such approaches have been presented by fewer researchers (e.g. Taylor and Jaffé, 1990; Kim *et al.*, 2004). Finally, for the case of relatively thick biofilms where the mass-transfer effects within the microbial phase itself may be important (e.g. near an injection well in which a pulsing scheme is used for adding substrates; within a bioreactor), it may be necessary to use a fully transient two-region nonequilibrium model. This model would be similar to the "mobile–immobile" modes that are often used for describing solute transport and reactions in highly heterogeneous media (e.g. van Genuchten *et al.*, 1976). However, other than the very general models just mentioned, no two-region models particular to biodegradation in the subsurface have yet been proposed.

Although the structure and geometry of biofilms at the pore scale may not be of paramount importance for predicting reaction rates under the fully penetrated biofilm assumption, it may be important for systems that are not fully penetrated or where the two-equation model applies. Additionally, even for the fully penetrated model, the biofilm geometry and structure within the pore space does affect the effective dispersion tensor that is observed (Wood, 2004). Experimental work has been conducted to expose the structure of biofilms within experimental systems. Observations have ranged from distributions of cell aggregates or "microcolonies" (Vandevivere and Baveye, 1992; Dupin and McCarty, 2000) to relatively thick and continuous films (e.g. Paulsen *et al.*, 1997; Sharp *et al.*, 1999; Dupin and McCarty, 2000; Vayenas, 2002). These studies have focused primarily on two-dimensional structure observed either in etched micromodels or on select surfaces of porous materials. More recently, the three-dimensional structure of thick biofilms has been observed using nuclear magnetic resonance, as reported by Seymour *et al.* (2004) and Wood (2004). Studies of this type should help to elucidate ultimately the conditions under which the LME and nonequilibrium models must be adopted, and representations that allow one to predict the change in the effective parameters of these models (e.g. reaction rates, effective dispersion tensors, effectiveness factor) for these two conditions.

PHYSICAL PROCESSES

Microbial transport in the subsurface involves a host of complex and interacting processes. It is thus not surprising that the literature contains many inconsistencies regarding the effects of bacterial variables such as size, shape, hydrophobicity, and electrostatic charge (Lawrence and Hendry, 1996). As such, it is not currently possible to state definitive correlations between bacterial properties and transport. Because microbes are living organisms, their transport in the subsurface is more complex than is the case for abiotic colloids. Not only are they subject to the same physicochemical phenomena as are colloids, but there are also a number of strictly biological processes that affect their transport (e.g. temporal changes in surface properties due to changes in metabolic state; predation by other subsurface organisms). Because of the complexity of the combined physicochemical and biological processes, these processes are described in separate sections in the material following.

In comparison to the biological processes, physical processes affecting microbial transport such as advection, dispersion, straining, and physical filtration have been the focus of numerous experimental and numerical modeling studies. These important processes provide the framework of bacterial transport and reaction in porous media. In addition to the following, readers are referred to reviews by Harvey and Garabedian (1991) and McDowell-Boyer *et al.* (1986) for more thorough discussions of these processes.

Transport

Microbes undergo convective transport as a particulate suspension moving with the pore water whose velocity is governed by the hydraulic pressure gradient, porosity, and permeability distribution. The occurrence of nutrient and/or electron acceptor as a solute undergoing transport may be coupled to the transport process through the effects of these constituents on the fluid properties of density and viscosity. Convective transport in porous media is also associated with hydrodynamic dispersion, the mixing process arising from the variations in velocity along the tortuous convective paths compounded by diffusional displacements of cells across streamlines of convective transport.

Straining and Filtration

Straining and physical filtration represent the removal of microbes from solution by physical (geometric and intermolecular/surface) forces. Straining is the trapping of microbes in pore throats that are too small to allow passage and is exclusively a result of pore geometry (Corapcioglu and Haridas, 1984). Estimates based on purely geometric relations between the effective diameter of biocolloids and the diameter and packing (coordination number) of grains suggest that mass removal by straining is not significant where the colloid diameter is less than 5% of the porous media grain diameter (Corapcioglu and Haridas, 1984; Harvey and Garabedian, 1991; McDowell-Boyer *et al.*, 1986). It should be noted that in natural heterogeneous porous media, a fraction of the pore diameters might be small enough to cause straining of colloidal particles even though the average grain diameter passes this rule of thumb for nonsignificance of straining.

Physical filtration is the removal of particle mass from solution via transport to and deposition on the porous media surface (note that in this context, "transport" means the conveyance of a microbe from the aqueous phase to the solid phase of the porous medium); here the term includes both attachment and sedimentation. Attachment of bacteria in the natural subsurface via filtration is often treated using colloid filtration theory (CFT; e.g. Yao *et al.*, 1971; Rajagopalan and Tien, 1976), which posits the kinetic rate of attachment as

$$\text{kinetic attachment rate} = \frac{3}{2}\,\frac{1-\varepsilon}{d}\alpha\eta\|v\|C_{A\gamma} \qquad (1)$$

Here, $C_{A\gamma}$ is the bulk aqueous concentration of mobile microbes, ε is porosity, d is average diameter of the porous media grains, η is the collection efficiency (defined as the fraction of microbes approaching an idealized porous media grain that collides with the grain) and α is the collision (or "sticking") efficiency (defined as the fraction of microbes colliding with the idealized porous media grain that attaches to its surface). Generally, η is calculated *a priori* based on bacterial and porous media properties, and then α is calibrated with the use of data from column experiments. The literature contains a helpful clarification on the use of the analytical expressions for η (Logan *et al.*, 1995), as well as a summary of CFT's major assumptions and the implications for modeling bacterial transport in natural porous media (Nelson and Ginn, 2001).

The most commonly used equation for η (the RT equation) was developed by Rajagopalan and Tien (1976). The RT equation describes transport to the porous media surface due to interception, sedimentation, diffusion, and Derjaguin Landau Verwey Overbeek (DLVO) surface interaction forces. Interception is filtration due to convection and the finite size of the colloidal particle. In other words, if a particle is riding exactly on a fluid streamline, then it will make contact with the grain if the streamline comes within one particle radius of the grain.

Sedimentation is enhanced filtration due to gravity (Corapcioglu and Haridas, 1984; McDowell-Boyer *et al.*, 1986) and depends on particle buoyancy (Wan *et al.*, 1995). Many natural bacteria and viruses are neutrally buoyant, in which case sedimentation is negligible. However, cultured microorganisms are typically larger and sometimes more dense than their native counterparts (Harvey *et al.*, 1995) and may involve sizable buoyancy-driven filtration. Sedimentation has been approximately quantified in Harvey *et al.* (1995) by augmenting the advective pore-water velocity with an additional downward component whose magnitude is given by the classical Stokesian velocity of a dense sphere falling through a fluid; $v_s = (\rho_s - \rho)gd_s/18\,\mu$, where v_s is the sedimentation velocity (acting vertically downward), ρ_s is the cell density, ρ is the solution density, g is the gravitational acceleration, μ is the dynamic viscosity, and d_s is the cell diameter (treated as a sphere). It should be pointed out that if CFT is employed and the RT equation for η is used with a microbial cell density greater than that of water, then the CFT kinetic rate of attachment (equation 1) will contribute an *additional* velocity magnitude; however, this CFT sedimentation velocity necessarily acts in the same direction as the principal flow direction, which is inconsistent with general application of the advective-dispersion equation. This is due to the orientation of the Happel sphere-in-cell model (Happel, 1958) that was used in the RT equation's derivation.

Diffusion is filtration due to the Brownian motion of the suspended particles. Since smaller particles will be moved farther by the random molecular bombardments of surrounding water molecules, the effect of diffusion becomes more important as particle size decreases. Indeed, diffusion is the dominant filtration mechanism for submicron passive particles. The RT equation assumes that the effect of diffusion (as described by the Smoluchowski-Levich assumptions that neglect interception and external forces)

can be considered separately from the effects of the other mechanisms. Recent studies (Tufenkji and Elimelech, 2004; Nelson and Ginn, 2005) have indicated that this assumption can result in significant errors for Brownian particles. For its representation of DLVO forces, the RT equation neglects the effect of the electrostatic double layer force, resulting in a surface interaction potential that consists of the attractive London-van der Waals force.

Another important aspect of the CFT is that it is based on an analysis of particle transport within an idealized pore space, and therefore this analysis must be upscaled for application in a macroscopic transport equation such as the advective-dispersion equation. Equation (1) represents the formula that has typically been employed for upscaling the CFT analysis. Recent work (Nelson and Ginn, 2005) has shown that this conventional methodology for upscaling the microscopic CFT analysis contains two inconsistencies. These issues and a proposed alternative methodology are presented in the Section on "Upscaling the Smoluchowski equation to the Darcy scale".

Size Exclusion

Size exclusion is a phenomenon where transported particles move faster than the mean pore-water velocity due to the size or charge of the material conveyed. When the phenomenon is observed in one-dimensional macroscopic scale, it appears as an earlier breakthrough of excluded particles. As a change in speed without change in macroscopic direction this is also termed "speedup" (Ginn, 2002). Size exclusion effects have been observed in laboratory columns (Engfield and Bengtsson, 1988; Pyle, 1979; Shonnard *et al.*, 1994; Hornberger *et al.*, 1992; Mayotte *et al.*, 1996) and in field experiments (Harvey *et al.*, 1989; Pyle and Thorpe, 1981; Wood and Ehrlich, 1978). Identification of exclusion from observations of tracer and particle breakthrough is not straightforward and has led to some confusion in the literature. The most reliable indicators of exclusion are (i) a significant difference in fitted advective velocities in a model parameter estimation exercise, or (ii) significantly higher normalized concentrations (C/C0) of suspended microbes during the rising limb of the breakthrough curve. These issues are discussed further by Zhang *et al.* (2001a) and DeBorde *et al.* (1999). With regard to processes causing exclusion, one may distinguish anionic and size effects, and further divide size effects into classical chromatographic and "pore exclusion" processes. Anion exclusion involves velocity enhancement by channeling of anionic molecular-scale solute particles in finer-grained porous media away from pore walls due to electrochemically repulsive forces that act on nanometer scales, and as such are not generally significant for bacterial transport. In size exclusion, microbes and large colloids, by virtue of their size characteristics alone, preferentially experience the higher velocities near pore centerlines, yielding an average convective velocity that is higher than that of a dissolved tracer. The occurrence of exclusion typically requires the effective bacterial diameter to be less than 1% of the characteristic pore throat length scale (e.g. mean grain diameter) that is common for transport in sandy aquifers (de Marsily, 1986; Dodds, 1982). When the colloidal particle is of the same scale as a significant fraction of pore channels, not all pores are accessible. The presumed rerouting of particles to alternate pore throats (or alternate porous materials at the macroscopic scale) in this case occurs on a relatively larger detour scale than does chromatographic or ionic exclusion. Termed *pore exclusion* (Woessner *et al.*, 2001), for virus transport), this has been suggested as a velocity enhancement of the excluded material in natural aquifers. Recent research based on visualization of microsphere transport within pore-scale micromodels (Sirivithayapakorn and Keller, 2003) indicates that size exclusion processes (which focus colloids near pore throat centers) also cause colloids to move along a different set of flowpaths than solute molecules, which provides a potential mechanism for preferential transport of colloids along selected flowpaths (i.e. pore exclusion) such that the two processes are in fact closely related. Note that pore exclusion has also been called *size exclusion* by some authors (Rehmann *et al.*, 2000), as well as various other terms such as *volume exclusion* (Bales *et al.*, 1989), *pore-size exclusion* (Sinton *et al.*, 2000), or *size exclusion chromatography* (Harvey *et al.*, 1989). The term *differential advection* has also been introduced (Zhang *et al.*, 2001a,b) to generally describe the phenomenon of earlier breakthrough of colloids relative to a solute tracer without specific regard to the mechanism.

The mechanics and modeling of pore exclusion have been recently debated (Ginn, 2000b; Rehmann *et al.*, 2000). One approach, also used in anion exclusion, involves reducing the kinematic porosity (that associated with aqueous phase moving in response to hydraulic gradient) by an "excluded" fraction that is unavailable to the anion. The remaining porosity is then divided into mobile and immobile fractions (Gvirtzman and Gorelick, 1991). However, the simple porosity reduction approach is unsatisfactory because unrealistically large porosity reductions would be required in cases where a high degree of speedup is observed (e.g. Dong *et al.*, 2002). Ginn (2002) developed a mathematical approach to incorporating exclusion effects in a lagrangian context, relating the distribution of excluded particle travel times to that of nonexcluded, or "ideal" particles, such as reflected by a dye tracer test. The analysis involves a constitutive speedup function that tells how travel times of nonexcluded particles map to those of excluded particles. This approach was used to analyze *Cryptosporidium* breakthrough data in saturated columns (Harter *et al.*, 2000). Scheibe and Wood (2003) modeled exclusion phenomena observed in sand column experiments using a modified

particle-tracking approach. In the latter approach, the distribution of local dispersive displacements (corresponding to the value of dispersivity estimated from conservative tracer breakthrough observations) was truncated at the lower end to represent the exclusion of bacteria from regions of the pore space with very small local velocity (i.e. very near pore walls). This approach was demonstrated to be effective at simulating observed large exclusion effects (bacterial velocities nearly double that of conservative tracers) with minimal truncation (on the order of 5%) of the dispersive displacement distribution. They also found a decrease in apparent dispersion of the bacteria relative to conservative tracers, consistent with theoretical considerations and observations (Sinton *et al.*, 2000). James and Chrysikopoulos (2003) derived similar relationships using a particle-tracking model of colloidal transport in a uniform fracture, and also determined that exclusion leads to decreased effective dispersion.

SURFACE INTERACTIONS INFLUENCING MICROBIAL TRANSPORT

Although the physical processes described above are well understood by most hydrologists, the influence of electrochemical interactions between microorganisms and solid surfaces are not as familiar. These forces may act over characteristic lengths that are only fractions of nanometers to microns, but ultimately they determine how microorganisms adsorb and desorb from the solid surface, and thus can dramatically affect microbial transport at even the largest scales. In this section, we review some of the current research and perspectives on these processes.

Understanding the Interaction Potential: is the DLVO Appropriate for Microbes?

CFT, introduced above, assumes that attachment is a two-step process. First, the bacterium must be transported to the porous media grain (the "collector"). Second, the physicochemical and microbiological interactions that occur upon contact of the two surfaces determine if the bacterium attaches to the surface of the collector. Traditionally, the collection efficiency parameter, η, which represents the transport step, is calculated *a priori* from characteristics of the bacterium, the porous media, and the flow field. The sticking efficiency (α, representing the attachment step in filtration theory) is then treated as a fitting parameter in conjunction with experimental data. This conceptual model may be erroneous in that the transport and attachment steps may in fact be coupled (McClaine, 2001; Nelson and Ginn, 2001).

Once a bacterium is transported to within a separation distance on the order of fractions of its own radius away from a collector, a complex set of interactions occurs. The DLVO theory of colloid stability has been widely employed as a model for describing the interaction forces between a microbe and a solid surface. The DLVO force potential is the sum of the London-van der Waals force and the electrostatic force (i.e. the "double layer" force which may be repulsive or attractive depending on the charges of the two interacting surfaces).

Although the DLVO theory is a useful conceptual model of the interactions between microorganisms and solid surfaces, Ninham (1999) and Boström *et al.* (2001) have pointed out that it is not generally applicable for microbial cells whose surfaces are not molecularly smooth, solid, and inert. Atomic force microscopy (AFM) measurements of the forces between bacteria and solid surfaces often show substantial disagreement with the predictions of DLVO theory both in magnitude and decay distance (Camesano and Logan, 2000a). Similar conclusions have been reached by the observation of *Escherichia coli* taxis along a glass surface; the bacteria-surface interactions could not be explained by DLVO theory (Viegeant and Ford, 1997). Further, bacterial adhesion data often deviates from the predictions of the extended DLVO model, which allow for electron donor–acceptor interactions to be accounted (van Oss, 1994; Jucker *et al.*, 1998a).

In addition, recent work has suggested that DLVO theory is not appropriate for microbes because their soft surfaces allow for the exchange of ions through the membrane. This has led to the development of "soft-particle" DLVO theory (Ohshima, 1989), in which the colloid is assumed to consist of an ion-penetrable, charged polyelectrolyte layer around a rigid core (Hayashi *et al.*, 2001). Energy barriers calculated on the basis of classical and soft-particle DLVO theory can be significantly different for some microbes. For example, the critical height of the energy barrier below which spontaneous adhesion of *E. coli* JM-109 could adhere to sand was $49\,k_B T$ (where k_B is the Boltzmann constant and T is absolute temperature) based on soft-particle theory, or $72\,k_B T$ based on conventional, or rigid-particle DLVO analysis (Abu-Lail and Camesano, 2003a). Despite the improved applicability in the application of soft-particle DLVO theory to bacteria, there are still large discrepancies between DLVO predictions and measurements of bacterial adhesion. There are also some microorganisms that cannot be well described by the soft-particle DLVO theory, such as the fungus *Candida parapsilosis* (Emerson and Camesano, 2004). The latter probably has a more rigid cell wall than many bacterial cells, and therefore it may not be as ion-penetrable.

It has been suggested that the failures of DLVO, soft-particle DLVO, and extended DLVO theory are most likely caused by the presence of polymers, other macromolecules, and structures such as pili and flagella on the bacterial surface (Jucker *et al.*, 1998a; Otto *et al.*, 1999; Camesano and Logan, 2000b; Ginn *et al.*, 2002). Thus, an understanding

of polymer-mediated interactions is a priority for the successful prediction of bacterial attachment rates in porous media. Observation of polymer interactions with surfaces and related attachment of bacteria have been under way for over 30 years (e.g. Fletcher and Floodgate, 1973). Bacterial polymer layers can cause a steric repulsive force (van Loosdrecht *et al.*, 1990; Rijnaarts *et al.*, 1999; Simoni *et al.*, 1998; Jucker *et al.*, 1998a) as well as an attractive bridging phenomena (Rijnaarts *et al.*, 1995a; Williams and Fletcher, 1996; Jucker *et al.*, 1998a,b). The occurrence of attraction or repulsion depends on the coverage degree, polymer characteristics, and the type of solvent (Rijnaarts *et al.*, 1995a). Of critical importance to the interplay of attractive and repulsive tendencies is the relative affinity of the polymers for the solid surface and for water. Both types of steric interaction may operate for a given polymer, and since the attraction and repulsion potentials will depend differently on the separation distance, the net result is likely to change signs as separation varies (Rijnaarts *et al.*, 1995a). Heterogeneity in the physical and chemical properties of the polymers on a bacterium would yield a force potential that is distributed over the cell surface. For example, the presence of a small number of long polymer chains, extending far beyond the reach of the bulk polymer layer would not encounter the same energy barrier as the rest of the polymer layer. If only a few of these long chains form hydrogen bonds, the binding force could be sufficient for irreversible attachment. This scenario has been proposed as an explanation for the observed adhesion of *Stenotrophomonas maltophilia* (Jucker *et al.*, 1998b), and a similar argument was made for *Pseudomonas fluorescens* (Williams and Fletcher, 1996; Smets *et al.*, 1999). Larger cell-surface structures such as flagella may also behave in a similar manner (e.g. Otto *et al.*, 1999).

In the last decade, atomic force microscopy (AFM) has surfaced as a viable technology for making the interaction force measurements required for the development of a predictive theory of polymer-mediated interactions (see overview in Ginn *et al.*, 2002). In addition to force measurements, AFM can be used to characterize cell-surface properties such as polymer conformations (e.g. Abu-Lail *et al.*, 2002; Camesano *et al.*, 2002). For a review of AFM cell-surface characterization in general, see Dufrêne, 2001. The basic setup involves a probe, attached to a cantilever; this unit is moved toward the microbial sample (or vice versa) until contact is made, and then retracted. The force is calculated from the deflection of the cantilever via Hooke's Law (or more complicated analyses that incorporate cantilever geometry). The conceptual model for biopolymer interactions with surfaces and associated AFM approach/retraction data is illustrated in Figure 2.

In general, data from the approach can provide information on the transport step, and data from the retraction can provide information on the attachment step or on the physicochemical properties of the biopolymers (Abu-Lail and Camesano, 2002; Camesano and Abu-Lail, 2002). In data collected to date, the approach curve represents almost exclusively repulsive forces for a wide variety of microbes that have been studied, such as *Burkholderia cepacia* (Camesano and Logan, 2000b; Ginn *et al.*, 2002), *Pseudomonas spp*(Camesano and Abu-Lail, 2002), *E. coli* (Ong *et al.*, 1999; Abu-Lail and Camesano, 2003b; Burks *et al.*, 2003), and *Streptococcus mitis* (Vadillo-Rodriguez *et al.*, 2003). The force curve is also commonly hysteretic; that is, the retraction curve is substantially different from the approach curve (in fact, the retraction curve often shows the presence of *attractive* forces). Such curves have been observed for purified biopolymers (Frank and Belfort,

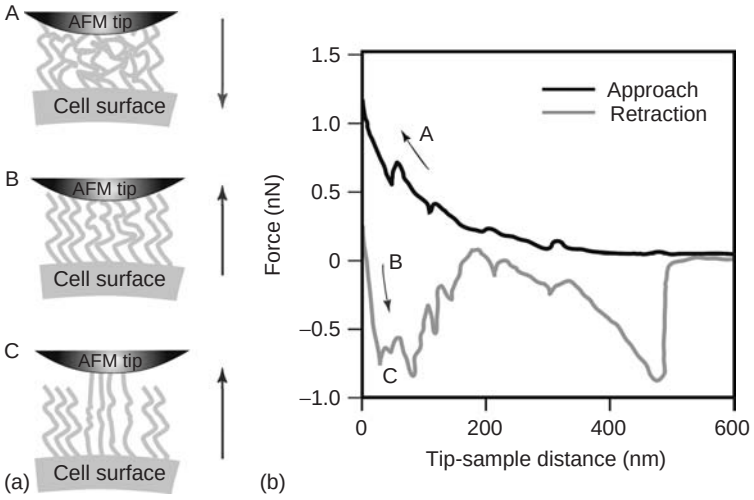

Figure 2 (a) Schematic of biopolymer/surface interactions as measured by atomic force microscopy After (Ginn *et al.*, 2002). (b) An example of the associated force curve showing hysteresis (Adapted from Abu-Lail and Camesano, 2002)

1997), and it is likely that macromolecules on the cell surface are responsible for this attraction between the probe and the microbe. The presence of such macromolecules has been confirmed in some cases by SEM and TEM micrographs. For example, micrographs of *B. cepacia* show a 30–50 nm thick polymer layer in its dehydrated state (e.g. Ginn *et al.*, 2002). Several researchers (e.g. Camesano and Abu-Lail, 2002; Ginn *et al.*, 2002, Section 2.2) have hypothesized that the repulsive force on approach is due to rearrangement of the macromolecules as the tip approaches the surface. Although attractive forces may exist between the tips of individual macromolecules and the probe tip surface, they are overwhelmed by the net repulsive force caused by such steric interactions. On retraction, the force gradually decreases (although not necessarily along the same trajectory as the approach curve). At some point, the net force will reach zero and then begin to become attractive, due to adhesion of the macromolecules to the probe tip. This description is supported by the shape of the retraction curve, which shows some distinctive peaks in the interaction force as individual or clusters of macromolecules break away from the probe surface (Butt *et al.*, 1999).

The complex nature of bacterial surface biomacromolecules has led to much of the difficulty in using simple potential functions to describe the tendency of microorganisms to adsorb to surfaces. In many instances, the length of the surface macromolecules (or surface structures) is greater than the characteristic distance of interaction forces predicted by conventional theories such as the DLVO model. In these instances, the microbial adsorption process is dominated by the interactions between the macromolecules and the solid surface; the bulk of the cell itself may not play a significant role in terms of the interaction forces. Similarly, conventional theories do not predict potential functions that are hysteretic, and this may be a crucial step in understanding microbial adsorption and adhesion. Hysteresis in microbial interactions with solid surfaces is probably due to the interaction of a variety of complex phenomena, including (i) formation of polymer bridges, (ii) biopolymer surface heterogeneity (both in the physical and chemical characteristics of the polymers), and (iii) the dynamic elastic properties of the cell. Hence, the development of a hysteretic interaction potential function will require an understanding of the biomechanics of bacterial cells from a variety of perspectives.

Recent Progress on Modeling and Understanding Microbial Adsorption and Adhesion

Some initial progress in representing the role of exopolymeric substances (EPS) on adsorption and adhesion has been made. Ortiz and Hadziioannou (1999) directly measured the entropic elasticity of individual polymer chains *via* AFM. These data were fitted to two different models of polymer elasticity, the "freely jointed chain" (FJC) model and the "wormlike chain" (WLC) model. Camesano and Abu-Lail (2002) and Abu-Lail and Camesano (2002) performed similar experiments on individual surface polymers of *Pseudomonas putida* KT2442. Their retraction curve data was fitted to the FJC model, and the results indicated that biopolymer heterogeneity on a single cell cannot be explained by differences in molecular weights alone but may be influenced by chemical differences as well. They hypothesized that the presence of multiple polymers with different properties on a cell surface may be the chief cause for the difficulty in predicting bacterial adhesion.

While, some bacterial polymers are well described by the freely jointed chain model (Abu-Lail and Camesano, 2003a), which accounts for the entropic stretching of the polymer chain, other bacterial polymers are better described by the extensible freely jointed chain model, in which entropic and enthalpic effects are considered (Van der Aa *et al.*, 2001). Electrostatic interactions appear to have an indirect effect on bacterial interaction forces, by altering the conformation of the biopolymers (Abu-Lail and Camesano, 2003a). Many bacterial polysaccharides have a negative charge and tend to coil in high salt solutions and extend in lower salt solutions. This type of electrostatic interaction cannot be accounted for with any of the existing DLVO-type models. The ability to measure and quantify conformational changes in bacterial polymers has brought forth a new perspective on cytoscale interaction forces: the standing challenge is to upscale these cytoscale forces, that is, quantify their net macroscopic-scale force, to understand larger scale behavior.

Some inroads on this problem have been made. A number of researchers have investigated the relationship between bacterial polymer properties and attachment likelihood via adhesion experiments on smooth surfaces. The isoelectric point (IEP) of a bacterium was found to be correlated with adhesion to Teflon and glass (Rijnaarts *et al.*, 1995b). An IEP $\leq$ 2.8 indicated the significant presence of cell-surface polysaccharides containing negatively charged phosphate and/or carboxyl groups, which may inhibit adhesion. An IEP $\geq$ 3.2 indicated the absence of polymers that inhibit adhesion. In a detailed study of bacterial surface polysaccharides, lipopolysaccharides (LPS) were extracted from five gram-negative bacterial strains and the adhesion of the isolated LPS to SiO_2, TiO_2, and Al_2O_3 was studied (Jucker *et al.*, 1998b). However, even with detailed information on the physicochemical structure of the LPS molecules, their adhesion could not be predicted.

In summary, the experimental results and theoretical observations of several researchers suggest that the DLVO theory of colloid stability does not adequately describe such interactions when the colloids in question are microbes, and that macromolecules on the cell surface may play an important role in the interactions governing the adhesion of microbes to porous media surfaces. Elucidating the ways in

which cell-surface macromolecules influence the adhesion process is a topic of current research.

Combining Physical and Electrochemical Phenomena Through the Smoluchowski Equation

The transport of microorganisms within a fluid can be described by a convection-dispersion type equation when the suspension is dilute and the particles are far from phase interfaces. However, in porous media the transport microorganisms may be significantly influenced by the presence of solid–fluid interfaces as described above. Under these conditions, the microbial transport phenomena at the subpore scale must be explicitly accounted. Here we introduce a basic approach to combining some of the forces described in the previous section under some simplifying assumptions, the first of which is the absence of hysteresis in the cell-surface force model.

For systems with physically realistic interaction force functions and that do not exhibit hysteresis, it is possible to develop a continuum transport equation that accounts for the particle-surface interactions. From a statistical-mechanical analysis (e.g. Peters, 1990; Peters and Ying, 1991), one can show that for incompressible flows the relevant transport equation for particles takes the form:

Smoluchowski Equation

$$\frac{\partial C_A}{\partial t} + \nabla\cdot(C_A\mathbf{v_o}) = \nabla\cdot(\mathbf{D_o}\cdot\nabla C_A) + \nabla\cdot\left[\left(\frac{1}{kT}\mathbf{D_o}\cdot\nabla\Phi_A\right)C_A\right] \quad \text{in the fluid phase} \quad (2)$$

with the boundary condition

$$\mathbf{n}_{\gamma\kappa}\cdot\left[\mathbf{D}_o\cdot\nabla C_A + \left(\frac{1}{kT}\mathbf{D}_o\cdot\nabla\Phi_A\right)C_A\right] = 0, \quad \text{at the solid–fluid interface} \quad (3)$$

where C_A is the volumetric aqueous particle concentration, $\mathbf{v}_o$ is the velocity field for the particles due only to fluid motion, $\mathbf{D}_o$ is the (position dependent) diffusion tensor for the particles, k is the Boltzmann constant, T is the temperature (in K), and Φ_A is the (position dependent) potential function for the particle-solid surface interactions. In principle, Φ_A can also be a function of the local aqueous and surface concentrations of particles and of time. Such time dependence (if it were known) would allow one to account for changes in the microbe-surface interactions as cell physiology changes in time. The terms of equation (2) correspond to change in local mass (or number) cell concentration, advection, dispersion, and surface interaction, respectively. Note that this equation applies at the interfacial length scale associated with Level I in Figure 1, as well as at the pore scale associated with Level II in Figure 1. As such, the application of equations (2) and (3) in porous media systems is an inherently multiscale exercise. At the subpore scale, equation (2) provides the complete description of the evolution of a dilute suspension of particles. There are two main difficulties in applying equation (2) to applications of microbial transport in porous media: (i) it is a microscale equation, and therefore applies at the pore scale rather than at the Darcy scale; (ii) the length scale associated with the potential function may be much smaller than the length scales associated with convection in the pore space, and this makes the problem difficult to solve.

Upscaling the Smoluchowski Equation to the Darcy Scale

Ideally, the complex physicochemical and biological interactions that are manifest at the molecular, cell, and pore scale would be formally included in a description of cell transport at the Darcy Representative Elementary Volume (REV) scale and above. This connection can in principle be made using various upscaling methods that link subpore-scale (and below) processes to their effective representation at the Darcy scale (and above). However, because of the complexity of the processes there is still substantial research to be done for describing microbial transport in the subsurface. Recent work has been initiated (e.g. Wood *et al.*, 2001, Wood, 2004), and there has been some success in upscaling the Smoluchowski equation (equation 2) to provide a conventional form of a convection-dispersion equation with an effective reaction at the fluid–solid boundary. The essential motivation behind the upscaling is to replace the conservation equations specified by equations (2) and (3), by a simple conservation equation with a reaction boundary condition. In other words, one seeks to replace equations (2) and (3) by the effective representation

$$\frac{\partial C_{A\gamma}}{\partial t} + \nabla\cdot(C_{A\gamma}\mathbf{v}_\gamma) = \nabla\cdot(\mathscr{D}_\gamma\nabla C_{A\gamma}) \quad \text{in the fluid phase} \quad (4)$$

$$-\mathbf{n}_{\gamma\kappa}\cdot(\mathscr{D}_\gamma\cdot\nabla C_{A\gamma}) = k_f C_{A\gamma} - k_r C_{As} \quad \text{at the fluid–solid boundary} \quad (5)$$

$$\frac{\partial C_{As}}{\partial t} = k_f C_{A\gamma} - k_r C_{As} \quad \text{at the fluid–solid boundary} \quad (6)$$

Here, $C_{A\gamma}$ is the concentration of particles in the fluid phase, C_{As} is the surface concentration of particles, $\mathbf{v}_\gamma$ is the average particle velocity in the pore space (note that this is in general different from the fluid velocity that would be observed in the absence of the particles), $\mathscr{D}_{A\gamma}$ is the particle diffusion coefficient, $\mathbf{n}_{\gamma\kappa}$ is the unit normal vector pointing outward from the fluid phase toward the solid phase, k_f is the forward (adhesion) kinetic constant, and k_r is the reverse (detachment) kinetic coefficient.

The transition from equations (2) and (3) to equations (4) to (6) is accomplished by upscaling. Various approaches have been used to determine the forward effective reaction rate parameter (k_f) from the Smoluchowski equation and a variety of boundary conditions; some of the classical works on this topic include studies by Kramers (1940), Brinkman (1956), Ruckenstein and Prieve (1973), Spielman and Friedlander (1974), Rajagopalan and Tien (1976), Shapiro *et al.* (1990), and Song and Elimelech (1993). It should be noted that the classical studies have focused on nonliving colloids, but one recent study (Wood, 2004) has presented an approach for the determination of k_f for cells.

Of special relevance is the upscaling by idealized Happel sphere-in-cell conceptual model (Yao *et al.*, 1971; Rajagopalan and Tien, 1976; Tufenkji and Elimelech, 2004; Nelson and Ginn, 2005), because it underlies CFT that is often used as a conceptual (at least) starting point for bacterial transport in porous media. The latter two recent studies provide a return to the Smoluchowski basis of the Rajagopalan and Tien (1976) approximated analysis, and resolve the equation in the context of the Happel model, in eulerian (Tufenkji and Elimelech, 2004) and lagrangian (Nelson and Ginn, 2005) coordinates respectively. Both find significant but moderate departures in the predicted attachment rate factor (the collision efficiency) in different ways. Thus, the current numerical solutions of the Smoluchowski equation in the simplified and idealized Happel sphere conceptual model exhibit some disparities, although the general trends in the dependence of the attachment rate on pore-water velocity and cell-to-grain size ratio are consistently captured in all three approaches.

As noted in the Section on "Straining and filtration", recent work (Nelson and Ginn, 2005) has shown that the conventional methodology (i.e. equation 1) for upscaling the CFT microscale results contains inconsistencies. The primary difficulty is that it has been common to calculate the rate of particle deposition based on the Happel sphere-in-cell model, while the total rate of particle flux through the idealized pore space is computed based on the isolated sphere model. The different geometries of these models result in a definition of k_f that may yield physically impossible rates of deposition such that more microbes are being deposited on the surface than the number flowing through the pore space. Therefore, it is proposed that the CFT upscaling equation be always expressed so that both the deposition rate and the total flux rate are defined based on the Happel model (which provides a better representation of porous media than the isolated sphere model). A secondary flaw is that the conventional CFT upscaling equation is an approximation of the exact solution. In virtually all cases of practical application, the approximation will be indistinguishable from the exact solution. However, it is conceivable that the approximation may incur significant errors for some experimental systems. Therefore, it is recommended that the exact solution be used. Incorporating both the consistent Happel model definition of fluxes and the exact solution yields the following CFT upscaling equation for the forward effective reaction rate parameter (Nelson and Ginn, 2005),

$$k_f = -\left[\frac{3}{2}\,\frac{(1-\varepsilon)^{1/3}\|v\|}{d}\ln(1-\alpha\eta)\right] \tag{7}$$

Equation (7) multiplied by $C_{A\gamma}$ should replace the right-hand side of equation (1). It is important to note that this definition of k_f requires that the formula for η is also based on the consistent Happel definition of fluxes. This corresponds to the definition given by equation (14) of Rajagopalan and Tien (1976) and equation (16) of Logan *et al.* (1995).

Now we turn to upscaling in the more realistic setting of arbitrarily complex solid surfaces. Although equations (4) to (6) eliminate the interfacial length scale associated with the interaction potential function, it is still a pore-scale representation of microbial transport. In general, a Darcy scale description of microbial transport (at the scale of the large circle in Level III of Figure 1) is the form that would be useful in applications. If one assumes that equations (4) to (6) provide a reasonable representation of the subpore-scale processes affecting microbial transport at the pore scale, it can be shown that in general the Darcy scale representation takes a form that is classically used to describe microbial transport in porous media. Again, neglecting the details we present only the result that has been reported elsewhere (Wood *et al.*, 1999; Ginn *et al.*, 2002).

Darcy Scale Transport Equation

$$\frac{\partial\langle C_{A\gamma}\rangle^{\gamma}}{\partial t} + \langle\mathbf{v}_{\gamma}\rangle^{\gamma}\cdot\nabla\left(\langle C_{A\gamma}\rangle^{\gamma}\right) = \nabla\cdot\left(\mathbf{D}_{eff}\cdot\nabla\langle C_{A\gamma}\rangle^{\gamma}\right) - \frac{a_{\gamma}}{\varepsilon_{\gamma}}\left(k_f\langle C_{A\gamma}\rangle^{\gamma} - k_r\langle C_{A\gamma}\rangle_{\gamma\kappa}\right) \tag{8}$$

Here $\langle C_{A\gamma}\rangle^{\gamma}$ represents the volume averaged intrinsic (pore-water) concentration, $\langle C_{A\gamma}\rangle_{\gamma\kappa}$ is the surface-averaged surface concentration, $\langle\mathbf{v}_{\gamma}\rangle^{\gamma}$ represents the volume averaged intrinsic (pore-water) velocity of the microorganisms, $\mathbf{D}_{eff}$ is the effective dispersion tensor, a_{γ} is the area per unit volume of the fluid–solid interface, ε_{γ} is the porosity, k_f is the adsorption kinetic parameter, and k_r is the desorption kinetic parameter (in the context of linear reversible kinetics for attachment/detachment). Although the averaging that leads to equation (6) as it applies to the Darcy scale has been established, the determination of the effective dispersion tensor for this problem has not yet been studied in detail.

BIOLOGICAL PROCESSES

Biological processes affecting microbial transport are expressed through the growth/decay process and include active adhesion/detachment, chemotaxis, and predation. The biological nature of these processes presents a challenge for transport modeling in that one biological mechanism is often dependent on or influenced by another biological mechanism. Thus, it may be necessary to consider the interdependency among the various biological processes.

Active Adhesion/Detachment

Active adhesion/detachment is treated here as a biologically driven process. Several studies have reported that microorganisms exhibit active adhesion/detachment processes that may be responses to local nutrient availability (Dawson *et al.*, 1981; Kjelleberg and Hermansson, 1984; van Loosdrecht *et al.*, 1989, 1990), survival mechanisms (Dawson *et al.*, 1981; Kjelleberg and Hermansson, 1984; Gilbert and Brown, 1995; Wrangstadh *et al.*, 1990), and/or growth (Jenneman *et al.*, 1985; Reynolds *et al.*, 1989; Sharma *et al.*, 1993). No generally accepted quantitative treatment of dynamic biologically mediated adhesion/detachment processes exists. It is possible that the evidently dynamic attachment/detachment processes are in fact ramifications of EPS mechanics or other cell-driven factors under transient metabolic states. Smets *et al.* (1999) reported experimental results indicating the adhesion of a pseudomonad to glass was significantly more favorable in the exponential growth phase than in the stationary or decay phase, which they hypothesized was due to differences in the cell-surface structure, the cell physicochemistry, or the hydrodynamic behavior of the cells. Thus, the distinction between a microorganism's response to nutrient availability, survival stress, and growth are not necessarily separable or independent processes.

Chemotaxis

Microorganisms that have the capability to move in response to a chemical gradient are termed *chemotactic*. Both random motility (taxis in the absence of a chemical gradient) and chemotaxis have been cited as potential means of transport for subsurface organisms (Barton and Ford, 1995; Corapcioglu and Haridas, 1984; Jenneman *et al.*, 1985; Mercer *et al.*, 1993; Reynolds *et al.*, 1989). Quantitatively, random motility is an effective diffusive flux for microorganisms that depend on the local spatial gradient in aqueous microorganism concentration, whereas chemotaxis is a flux of microorganisms associated with the gradient in nutrient supply. Chemotaxis requires energy and therefore is closely linked to growth processes in porous media. In oligotrophic environments nutrient gradients will be quite small and will likely be associated with either preferential flow paths (if the nutrients arise from recharge) or solid-phase chemical heterogeneity. Chemotaxis may be a very important transport mechanism in these low-nutrient environments. Mercer *et al.* (1993) found that bacteria subjected to oligotrophic conditions displayed enhanced chemotactic response. A contaminant plume will result in large chemical gradients that may also contribute to microbial transport via chemotaxis. Like virtually all microbial characteristics, tactic capability varies widely among organisms. In addition, the chemotactic capability of a given organism can vary depending on the nutrient to which it is being attracted. However, only a small fraction of the many organism-nutrient systems found in natural subsurface conditions and bioremediation schemes has been studied (see Lewis and Ford, 2001 for a compilation of random motility and chemotactic sensitivity coefficients that have been reported for a few different organisms and nutrients). Consequently, these organism-specific and nutrient-specific transport characteristics have not been incorporated into predictive models of microbial transport applicable for field-scale hydrogeological applications.

Much work has been done on developing basic models of chemotactic transport of cell populations in response to gradients in aqueous-phase nutrients. The interested reader is referred to Ford and Cummings (1992), which delineates the relationships between the various models and derives a reduced form of the rigorous three-dimensional cell balance equations of Alt (1980), as well as the review of Ford and Cummings (1998), which includes a comparison of model predictions with experimental results. How to apply our understanding of chemotaxis in a bulk aqueous medium to the modeling of chemotaxis within a porous medium is an open question. However, Barton and Ford (1995, 1997) derived expressions that relate the standard random motility and chemotactic sensitivity coefficients for bulk water to effective values that reflect the impact of the porous medium on an individual cell's swimming behavior. The application of their model to experimental data of bacterial migration through sand cores was consistent with the observed reduction in random motility and provided an explanation (the chemoattractant gradient was too small) for the observed lack of a chemotactic response. The Barton and Ford model modifies the advection-dispersion transport operator of equation (6) to represent random motility and chemotaxis as microbial transport fluxes driven by the random motility coefficient (d_μ) and the chemotactic velocity (v_χ), respectively. This modeling approach is an adaptation for porous media of the classical chemotaxis models reviewed in Ford and Cummings (1992) and Ford and Cummings (1998).

Predation

Tracer studies at field sites have both demonstrated that predation by native protozoan populations on injected

bacteria can have a significant impact on transport distances and concentrations. At South Oyster (described below), a dramatic increase in protozoan populations was observed in response to the injection of bacteria (Choi *et al.*, 2000). Although the total effect is difficult to quantify because of limited observations of attached protozoan populations, it was shown that an increase in apparent attachment (or removal) rate coincided with the timing of the protozoan bloom at a time when a decrease in apparent attachment (or removal) rate would have been expected based on other factors (Zhang *et al.*, 2001b).

Metabolic Effects on Microbial Transport

Some macroscopic-scale evidence suggests that bacterial attachment/detachment kinetics are metabolically mediated, in ways distinct from EPS-associated mechanisms described above. In an experiment conducted in an intermediate-scale flow cell ($100 \times 20 \times 10$ cm dimensions), a substrate pulse resulted in an increase in aqueous-phase bacteria (Murphy *et al.*, 1997, Figure 1), similar to observations in field bioremediation efforts (DOE, 1993; Balkwill *et al.*, 2001). Column experiments have suggested that the response observed in Murphy *et al.* (1997) may be cell-division-mediated transport, a mechanism long recognized in the microbiology literature (cf. references cited in the Section on "Active adhesion/detachment"). Cell-division-mediated transport has also been referred to as *mother–daughter* or *shedding cells* and occurs when the "mother" cell, attached perpendicular to the mineral surface, grows, divides, and the "daughter" cell is released into the aqueous phase (Marshall, 1996). The mother cell remains attached.

Many investigators have noted that starvation or nutrient availability can stimulate a change in the partitioning of a microbial community between the solid and aqueous phases (e.g. Kjelleberg and Hermansson, 1984; Kjelleberg, 1993). A contaminant plume creates a dynamic nutrient environment, but it is not clear whether the corresponding response in partitioning of the microbial community will have any effect at all on the actual contaminant degradation. Therefore, Ginn *et al.* (1998) investigated the relative importance of dynamic partitioning of the bacterial phase on contaminant degradation by numerically modeling the response of a consortium of anaerobic bacteria involved in the degradation of chlorinated hydrocarbons. This example concerns the stimulation of a natural subsurface microbial community that would be initially associated with the solid phase. When substrate is present, as in a contaminant plume, the propionate degrader displays dynamic partitioning (e.g. the forward attachment rate, k_f, changes with the level of metabolic activity). The simulation results showed enhanced degradation under dynamic conditions due to the aqueous partitioning of one member of the consortium that resulted in an increasing population moving with the plume, and hence increasing degradation. This simulation illustrates the importance of the potential partitioning of bacteria under dynamic growth conditions during *in situ* biodegradation.

OVERVIEW OF MICROBIAL TRANSPORT FIELD EXPERIMENTS

Microbial transport processes as described above are conceptualized and defined at the pore to local continuum scale. Most of the experimental work on which these definitions are based has been performed in the laboratory on small porous columns (commonly homogeneously repacked) under one-dimensional flow conditions. Translation of these representations to field-scale transport of bacteria in natural aquifers involves additional factors for consideration, such as the effects of three-dimensional flow fields, multiple scales of heterogeneity in aquifer and groundwater properties, interactions with native microbial communities, and temporal variations due to natural transient fluctuations. These factors confound the straightforward extension of laboratory results to field-scale predictions.

Microorganisms were first used as environmental tracers to delineate subsurface flow pathways, particularly in fractured or karst environments. A number of field studies have also been performed to determine the potential for transport of pathogenic organisms from sources such as septic systems or artificial recharge areas to drinking water supply wells. More recently, local-scale controlled injection and recovery experiments have been conducted at a number of sites to directly study the mechanisms of microbial transport at the field scale in porous aquifers. Harvey and Harms (2001) review the historical use of microbial agents as tracers, and describe several methods used for field-scale bacterial transport injection and recovery tests. Schijven and Hassanizadeh (2000) present a detailed review of viral transport models, processes, and parameters derived from field experiments.

Detailed, local field-scale bacterial transport experiments were pioneered at the United States Geological Survey's Cape Cod Toxic Substances Hydrology Research Site. Several forced- and natural-gradient tests were conducted in saturated glacial outwash sediments using bacteria, viruses, protozoa, inorganic colloids, and solute tracers. Harvey *et al.* (1989) provide an initial overview of transport results using bacteria-sized fluorescent microspheres, native bacteria, and a conservative tracer. A forced-gradient experiment was conducted using a divergent flow design, with multilevel samplers (MLS) 1.7 and 3.2 m from the injection well. A natural-gradient experiment was conducted in a contaminated zone of the aquifer using microspheres only; samples were collected in a row of MLS 6.9 m down-gradient of the injection well. Transported bacteria and microspheres of varying diameter were observed at both sample collection

points in the forced-gradient test, although relative breakthrough was less than 1% at the closest sampling point. Breakthrough of bacteria prior to a conservative bromide tracer was observed, particularly at the distant MLS. Peak abundance of microspheres increased with increasing diameter, qualitatively consistent with filtration theory. Behavior of bacteria and similar-sized microspheres was observed to be significantly different. Harvey and Garabedian (1991) applied filtration theory to quantitatively model transport of bacteria in a subsequent natural-gradient experiment at the same site, and estimated a collision efficiency of 5×10^{-3} to 1×10^{-2} at a travel distance of 6.9 m. Harvey *et al.* (1993) demonstrated the importance of physical heterogeneity in controlling field-scale bacterial transport. Observations of microsphere, bromide, and bacterial transport 6 m down-gradient of the injection point varied significantly in three sampling ports separated by a total vertical distance of 0.7 m. Bales *et al.* (1995) coinjected bromide tracer, viruses (bacteriophage), bacteria, and latex microspheres under natural gradient and observed breakthrough at several multilevel sampling points. The three colloidal materials behaved in a significantly different fashion, with bacteriophage most strongly attenuated by attachment (five orders of magnitude reduction in 6 m travel distance) under ambient pH conditions (5.7). They found that the attached phage could be remobilized by subsequently injecting a high-pH (8.3) pulse of water, consistent with similar laboratory results. Harvey *et al.* (1995) studied the transport of groundwater protozoa at the Cape Cod site, and found that the protozoa were attenuated more rapidly than bacteria although the protozoa were of the optimal size for transport based on experiments with microspheres of various diameters. Pieper *et al.* (1997) performed injections of bacteriophage at the site, and found that attenuation was significantly lower in zones of the aquifer containing high concentration of sewage-derived organic matter. They attributed this observation to the blocking of attachment sites in the organic-rich zone. Similar findings are reported in Harvey *et al.* (1989) and Powelson *et al.* (1991) (for virus tracers), and explored experimentally in Johnson and Logan (1996).

Several subsequent experiments at other sites have further explored field-scale phenomena associated with microbial transport in a variety of geologic settings. DeFlaun *et al.* (1997) report preliminary results of forced-gradient bacterial injection and recovery experiments conducted in a sandy aquifer (marine shoreface sediments) near Oyster, Virginia. Although bacterial breakthrough was observed at the furthest sampling point (4 m from the injection), the large majority of bacteria (greater than 99%) were retained between the injection well and the first sampler only 50 cm away. A dual subpopulation model was proposed as a possible explanation for the observed behavior.

Three forced-gradient bacterial injection and recovery experiments were conducted from 1999 to 2001 at two locations near the town of Oyster, referred to generally as the South Oyster site. These locations are near that of the preliminary experiments reported by DeFlaun *et al.* (1997). Two separate flow cells with different groundwater chemistry were utilized to evaluate the transport of aerobic and facultative iron-reducing bacteria under both oxic and suboxic (reducing) groundwater conditions. Balkwill *et al.* (2001) give an overview of the site characteristics, experiments conducted, and results. Under oxic conditions, bacteria were observed to closely follow high-permeability flow paths, as identified using high-resolution geophysical methods, in a similar manner as a conservative tracer but attenuated by attachment (Hubbard *et al.*, 2001). However, under suboxic conditions, a simple relationship between physical heterogeneity and bacterial transport pathways was not observed. Predictions of the extent of bacterial transport based on laboratory column experiments using intact sediment cores from the site were overly conservative; observed transport at the field scale was much greater than predicted (Scheibe *et al.*, 2001). Estimates of bacterial collision efficiencies based on field-scale modeling decreased as a function of distance traveled (Mailloux *et al.*, 2003).

Schijven *et al.* (2000) injected viruses and bacteria into a deep sandy aquifer in the Netherlands and observed breakthrough at four monitoring wells ranging from 8 to 38 m distant from the injection. Although one bacterium (*E. coli*) was observed only at the closest well, the second (spores of *Clostridium bifermentans*) was observed at all four wells. The attenuation of two bacteriophages was intermediate between that of *E. coli* and *Clostridium* spores. A systematic decrease in attachment rate coefficients with distance was inferred using one-dimensional models of the experiment, with much higher rates of attachment occurring in the first 8 m of transport (attributed to different geochemical conditions near the injection well). Sinton *et al.* (1997) introduced bacteria, bacteriophage, and rhodamine WT dye into an alluvial gravel aquifer near Christchurch, New Zealand and observed transport to wells as far as 400 m down-gradient. Groundwater flow rates in this aquifer are rapid, as high as 86 m day^{-1}. Transport from the ground surface through the vadose zone to the groundwater table was also observed in an irrigation experiment. They represented bacterial attenuation by an apparent decay constant (incorporating attachment losses as well as true bacterial decay), and estimated values on the order of 1.0/day for coliform bacteria in groundwater. Pang *et al.* (1998) describe results of a second experiment in which rhodamine WT, Cl^-, and a bacterium were injected below the water table. They observed faster velocities of the bacteria relative to inert tracers, and estimated total removal rates of 2.4–9.4/day. Sinton *et al.* (2000) further examined the apparent velocities of microbial (bacteria and virus) and inert tracers, and

found that apparent velocity increased, and apparent dispersion decreased, with increasing particle size.

McKay *et al.* (2000) conducted a natural-gradient transport experiment with microspheres, viruses, and bacteria in a fractured shale saprolite aquifer. All of the colloids were detected 13.5 m from the injection well, and the bacteria and microspheres were detected as far as 35 m from the injection well. In this fractured system, microbes exhibited early arrival (at velocities as much as 500 times greater than solute tracers) and variable rates of attenuation corresponding to highly heterogeneous aquifer properties. Becker *et al.* (2003) conducted forced-gradient transport experiments in saturated fractured crystalline bedrock using several bacterial strains and microspheres. They found that relatively small differences in physical characteristics of bacteria (e.g. cell size, Gram type, and motility) corresponded to large differences in field-scale transport behavior.

Conventional Models of Bacterial Attachment/Detachment Kinetics

Modeling of attachment/detachment kinetics is extensively reviewed in Clement *et al.* (1999), Murphy and Ginn (2000), and Harvey and Harms (2001). A brief summary is given here. The linear attachment/detachment kinetic model appearing (as the last two terms on the right-hand side) in equation (8) is perhaps the most basic approach, and reflects the essentially universal treatment of bacterial attachment/detachment as a kinetically controlled process. This model may be viewed as a modification of the CFT approach noted above, wherein a linear detachment process is included (no such detachment occurs in original CFT), and wherein dependence of the rate coefficient for attachment on pore-water velocity is ignored. Murphy *et al.* (1997) extend the linear reversible model to include nonlinear dependence of the rate coefficients on ionic strength of solution, manifest in intermediate-scale experiments. Tan *et al.* (1994), Lindqvist *et al.* (1994), and Saiers and Hornberger (1994) all introduce the classical site-saturation limiting factor on the attachment rate coefficient, in order to account for potential depletion of available surface sites as attached microbe densities increase, which may occur when aqueous microbes cannot attach to attached microbes. Clement *et al.* (1997) performed soil column experiments to evaluate the classical first-order detachment rates of a denitrifying consortium under various growth conditions. The data presented in this work supported the hypothesis that the bacterial detachment rates in porous media systems will increase with increase in the value of specific growth rates. Johnson *et al.* (1995) provide an accounting of the effects of residence time on detachment by zeroing the detachment rate for microbes whose residence time exceeds a particular threshold in a finite difference model of the fate and transport. Ginn (2000a) modeled such non-Markovian (e.g. residence-time-dependent) attachment/detachment kinetics apparent in experiments of McCaulou *et al.* (1994) using the exposure-time approach of Ginn (1999).

Impact of Physical and/or Chemical Heterogeneity

Physical heterogeneity (spatial variations in grain size, permeability, and porosity of the porous medium) clearly plays a significant role in controlling patterns of field-scale transport. Harvey *et al.* (1993) reported a dramatically different character of bacterial breakthrough at three adjacent elevations in a single multilevel sampler, separated by only tens of centimeters. In controlled experiments in two dimensions, Murphy *et al.* (1997) demonstrated how bimodal heterogeneity induced spatial variability in microbial growth through mixing of limiting nutrients and consequently induced significant variations in microbial transport. At the field scale at the South Oyster site, significant effort was invested in characterization of the spatial structure of physical aquifer properties using geological, hydrologic, and geophysical techniques (Chen *et al.*, 2001; Hubbard *et al.*, 1999, 2001). It was demonstrated that transport patterns of both bacteria and bromide were closely related to patterns of permeability and that apparent dispersivities were consistent with correlation lengths inferred from tomographic observations (Hubbard *et al.*, 2001).

Many sandy aquifers contain variable amounts of iron and other metal oxide minerals, commonly in the form of amorphous coatings on quartz grain surfaces. Under pH conditions commonly observed, quartz surfaces are negatively charged while iron oxides are positively charged. This leads to an enhancement of bacterial attachment to surfaces with iron oxide coatings, which has been demonstrated in laboratory experiments (Knapp *et al.*, 1998; Mills *et al.*, 1994; Scholl and Harvey, 1992). However, these effects can be modified at the field scale by variable flow paths caused by physical heterogeneity or by other factors such as blocking of iron oxide sites by attached organic carbon (Johnson and Logan, 1996). Identification of the relative importance of physical and chemical heterogeneity is confounded by cross correlation between the two; iron-rich minerals and coatings tend to be concentrated in finer-grained zones that also have lower permeability and higher collector efficiency.

Apparent Decrease in Attachment with Distance

The apparent rate of attachment (as usually quantified by fitting a collision efficiency parameter or attachment rate coefficient to breakthrough observations) has been observed to decrease with distance traveled in almost all field studies of microbial transport (e.g. Harvey and Garabedian, 1991; Harvey *et al.*, 1995; DeFlaun *et al.*, 1997; Schijven *et al.*, 2000; Woessner *et al.*, 2001). This appears to be the key factor limiting the direct application of laboratory core experiments to predict the extent of field-scale

transport. The phenomenon has occasionally been interpreted as reflecting *in situ* growth (Harvey and Garabedian, 1991) or heterogeneity in aquifer properties (Schijven *et al.*, 2000; Schijven and Hassanizadeh, 2000). Most often, however, it is interpreted as reflecting variability in the cell-surface properties within a monoclonal bacterial population (Albinger *et al.*, 1994; DeFlaun *et al.*, 1997; Bolster *et al.*, 2000; Schijven and Hassanizadeh, 2000), which would cause the more "sticky" bacteria to attach rapidly at short travel distances while a smaller subpopulation with less propensity for attachment transports much farther. Baygents *et al.* (1998) and Glynn *et al.* (1998) observed a bimodal distribution of surface-charge density in selected bacterial strains, providing experimental support for this hypothesis. Redman *et al.* (2001a,b) proposed a multiscale (fractal) distribution of filtration length scales arising from heterogeneity in surface properties of microbes and collectors, and provided experimental support for the model based on column experiments of virus transport. Mailloux *et al.* (2003) estimated a field-scale distribution of apparent collision efficiencies for the oxic flow cell at the South Oyster site. The estimated values clearly decreased with distance, and the distribution inferred from small-scale core experiments was shown to be a subset of the field-scale distribution with the highest values. However, subsequent experiments at the suboxic flow cell conducted by (Dong *et al.*, 2005) (submitted) indicated that intrapopulation variability in collision efficiency is not responsible for the observed decrease in apparent collision efficiency with transport distance at the field scale. Models of bacterial transport in heterogeneous aquifer systems suggest that local-scale heterogeneity in physical and geochemical aquifer properties can lead to apparent enhancement of microbial transport over larger scales, particularly if there exists an inverse correlation between hydraulic conductivity and attachment parameters (Rehmann *et al.*, 1999; Bhattacharjee *et al.*, 2002; Scheibe, 2002). If cell-to-cell surface interactions are more favorable than cell–grain surface interactions, initial attachment of cells near the injection point could increase subsequent attachment of more cells, thereby causing an apparent "ripening" effect that would lead to increased attachment rates nearer the point of injection. However, because attachment parameters for viable cells are not yet in general predictable from basic property measurements, it is also possible that the apparent systematic trend reflects some fundamental shortcoming with the assumed attachment model (generally treated as first-order kinetic). This is especially true when the bacterial population changes from oligotrophic to eutrophic conditions (Murphy *et al.*, 1997). At any rate, it is clear that field-scale transport of microbes will usually be underestimated if predictions are based directly on attenuation rates estimated from laboratory column experiments (Schijven and Hassanizadeh, 2000).

Extended Tailing/Detachment

Typically, rates of detachment of attached cells are low and do not contribute significantly to observed bacterial concentrations during the main breakthrough pulse. However, slow release of attached bacteria at low concentrations over long periods of time may contribute significantly to transport over longer distances. At the South Oyster site, inferred detachment rate coefficients were similar in magnitude to attachment rate coefficients (Zhang *et al.*, 2001b). This contrasts with laboratory experimental results reported in the literature, in which estimated detachment rate coefficients are one to three orders of magnitude smaller than attachment rate coefficients (Zhang *et al.*, 2001b, Table 2). Nevertheless, the inferred detachment rate coefficients were similar to those reported in the literature, so the investigators attribute the observed ratio to unusually low attachment rates of the organism, which had been selected for adhesion deficiency. Numerical simulations using the derived rate coefficients demonstrated that bacterial detachment could have a significant impact on long-term distribution of attached bacteria in the subsurface. Model fits to experimental data also support the hypothesis that there exist both reversible and irreversible attachment events (corresponding to heterogeneity in grain or bacterial cell-surface properties). Zhang *et al.* (2001b) estimated that 70% of the attachment events were irreversible under forced-gradient conditions, increasing to nearly full irreversibility under low-velocity natural-gradient conditions. Other factors that may impact microbial detachment include changes in aquifer geochemistry (Bales *et al.*, 1995), growth of attached bacteria (Murphy *et al.*, 1997), and cell division associated with the edge of an injected groundwater plume (Johnson and McIntosh, 2003).

SUMMARY AND CONCLUSIONS

This paper has reviewed the progress that has been made toward understanding and predicting microbial transport in natural porous media at a variety of characteristic length scales. This review has also revealed the many gaps that still exist in our understanding of the many interrelated processes affecting transport and how these processes fit together. Some of the findings to date and needs for future research are as follows:

1. Aqueous-phase biomass is generally treated as a dilute suspension of cells with no cell-to-cell interactions, an assumption that may sometimes be violated. Attached phase biomass has been treated by different models, and the importance of biofilm spatial structure in porous media is also an area in need of additional research.

2. The physicochemical processes affecting transport have been studied extensively and are reasonably well understood. Although conventional CFT does incorporate many important physical and chemical processes, it also neglects some important ones such as the complex electrochemical phenomena associated with bacterial cells and particle detachment. Attempts to remedy this deficiency have not yielded a definitive approach. Thus, the study of microbial processes as they relate to filtration theory merits further attention.
3. The use of volume averaging to upscale mass transport and reaction processes for both biofilm formation and for microbial transport may be useful in refining our understanding of the macroscopic-scale manifestations of microbial transport and the role of biophase structure in the subsurface. Such formulations will have to be coupled to an improved understanding of the electrochemical processes that affect microbial adhesion at the nanoscale.
4. The effects of multiscale physicochemical aquifer heterogeneity on microbial transport can lead to interesting and complex behavior. The interplay between subsurface heterogeneity and macroscopic-scale transport of microorganisms is an area that is in need of additional research.

The biological processes affecting transport are less well understood. Needs for future work include the following:

1. Development of a transport theory that can account for the space- and time-nonlocal dependence a population of microorganism, particularly as it relates to phenotypical variations caused environmental changes (e.g. nutrient status, quorum sensing).
2. Incorporation of the methods of molecular biology into research pertaining to microbial transport and adhesion. Such methods could help elucidate exactly which mechanisms are responsible for changes in cell-surface properties as environment conditions change.
3. Studies on the possibly coupled nature of the effects of nutrient availability, survival stress, and growth on active adhesion/detachment.
4. Continued cell-scale, pore-scale, and column-scale studies on chemotaxis for relevant bacteria-nutrient systems.
5. Studies on the interactions between bacterial surface polymers and solid surfaces, and methods to reliably quantify cell-surface properties for bacterial species.
6. Increased research on the partitioning of bacteria under dynamic growth conditions and the transient movement of bacteria under changing chemical conditions. Ideally such work would focus on more realistic conditions involving subsurface materials, groundwater analog solutions, and natural consortia of bacterial populations.

Microbial communities in aquifers consist of diverse interactive individuals which break down complex organic matter for metabolic energy. Microbes are adapted to function over environmental conditions ranging from freezing to boiling, acidic to alkaline. They can use oxygen as a reducible metabolite during organic carbon oxidation, but, since oxygen is rapidly depleted in subsurface environments, different groups of organisms may also rely upon other compounds such as reducible metals or upon fermentation. Community members are interdependent, but compete for resources, and communities often have predominant groups that rely on recognizable chemical pathways such as sulfate reduction. The predominant group varies spatially and temporally, as the available nutrients change or are depleted.

INTRODUCTION

We will address the classification of microbial communities in groundwater, their relation to aquifer geochemistry, and some approaches to investigating microbial effects on groundwater chemistry. Other sections discuss microbial activity with respect to water quality (*see* **Chapter 91, Water Quality, Volume 3**), nutrient cycling (*see* **Chapter 96, Nutrient Cycling, Volume 3**), water quality remediation, and the degradation of contaminants. Microbes catalyze oxidation-reduction reactions to gain energy for metabolism. The different forms of microbial life are widely distributed, and the local abundance of the individual forms is determined by their environment (Stevens, 2002). In aquifers, the substrates for metabolism may be organic or inorganic compounds, but most communities rely ultimately on the oxidation of complex organic compounds deposited along with the solid components of the aquifer. Individual microbes occupy relatively narrow niches in the trophic web that transforms complex organic matter to carbon dioxide, and in natural groundwater systems the community of individuals will be in some sort of equilibrium with its surroundings. Characterization of the environment according to relevant chemical and physical parameters should therefore provide an understanding of the microbial community. Because the microbial community is diverse and adaptive and the environment is heterogeneous and complex, studies of microbial communities usually include microbial and geochemical components.

In an undisturbed environment, the equilibrium community will contain a stable, disparate population that can efficiently exploit and utilize the nutrients available to it. When a disturbance occurs, the population will change to exploit changes in environmental conditions and will evolve to regain an equilibrium condition. Also, the interplay between the microbial community and its environment affects the environment itself, so that each is driven eventually to a condition that is relatively stable. This can occur after abrupt disturbances such as contamination events, or during longer-term changes such as the exhaustion of a particular natural nutrient.

The microbial community is composed of individuals living within the limitations of their metabolic capability, competing with other individuals to most efficiently utilize the available nutritional resources in an aquifer, and also cooperating with other microbes to the mutual benefit of various community elements. Because of the qualitative interdependence of microbes and environment, microbes can be classified according to the environments that harbor them and the chemical transformations they effect.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

MICROBIAL CLASSIFICATION

Microbial taxonomy may be based on properties such as cell morphology, staining characteristics, biochemical transformations, or molecular biology (Chapelle, 1993). Molecular methods have recently become powerful and accessible tools for characterizing microbes at structural and functional levels. Using these methods, changes in nucleotide sequences in ribosomal RNA (16S rRNA) have been used to measure the evolutionary relationships among cells, defining three distinct cellular lineages in nature, the *Bacteria, Archaea*, and *Eukarya* (Woese, 2002). Organisms within these groups may be further associated into subgroups. Bacteria, for example, have been resolved into 12 major lineages by ribosomal RNA sequencing (Madigan *et al.*, 1997). In applications to microbial ecology, the molecular methods liberate the investigator from cultivation-based characterization and provide the means to determine the microbial composition of any environmental niche. The use of these genetic associations is limited, however, by the limited ability to predict physiology based on phylogeny; identifying which microorganisms are present does not say what they are doing (Embley and Stackebrandt, 1996).

Among the three evolutionary branches, *Bacteria* comprise most of the commonly encountered microbes and can have profound effects on the aquifer environment. They inhabit oxic and anoxic aquifer sediments and rely on organic chemicals or inorganic chemicals for energy. Most *Archaea* are anaerobes, and may thrive under unusual conditions such as hot springs. They also can transform the subsurface environment and introduce chemical components through metabolism. The *Bacteria* and *Archaea* usually coexist in aquifer systems and may be indistinguishable in their environmental effects. Microbes within the *Eukarya* are the least significant with respect to aquifers and aquifer chemistry. They include algae, fungi, and protozoa. Algae are photosynthetic and do not function in the subsurface, although they may be present there (Sinclair and Ghiorse, 1989). Fungi are not abundant in subsurface ecosystems (Madsen and Ghiorse, 1993). Protozoa are motile and feed on other organisms or organic particles and have a limited effect on the aquifer environment (Kinner *et al.*, 2002).

Descriptive, practical classification systems are based on microbial attributes that can be observed in the field or laboratory. These include metabolic processes, favored physical conditions, tolerance to oxygen, and the inorganic chemical transformations they make in the environment.

METABOLISM

Metabolically, microbes acquire energy through an electron donor, such as organic carbon, that can provide electrons and become oxidized. They also require an electron acceptor, a substance that can accept electrons and become reduced. The net energy gained in an oxidation-reduction reaction is used for metabolic function and growth. Microbes are classified metabolically according to their limitations in obtaining organic carbon for cell mass during this process. For example, microbes that require organic compounds as a carbon source are termed *heterotrophs. Autotrophs* can utilize CO_2 as the sole carbon source, while catalyzing inorganic reactions for energy. *Mixotrophs* utilize inorganic substances as energy sources and organic carbon as a source of cellular carbon. *Chemolithotrophs* obtain energy by oxidizing reduced inorganic chemicals, and *photolithotrophs* obtain energy from light. *Fermenters* use organic compounds as donors and acceptors.

PHYSICAL ENVIRONMENT

The range of conditions in the subsurface places limits on the existence of microbial life, and in general, the subsurface seems unsuited to microbes. Photosynthesis is impossible, organic carbon and other nutrients are usually scarce, the temperature may be extreme, and interpore space may be cramped. Nonetheless, microbial life has been observed in environments where pore spaces exceed 0.5 μm in diameter (Fredrickson *et al.*, 1997). Microbes have adapted to live not only where conditions are moderate and nutrients abundant, but also where temperatures, pressure, acidity, and energy sources/sinks are extreme, in all lithologic environments (Colwell, 2001; Stevens, 2002). The preferred environment may thus be used to describe microbes. Examples include microbes observed at temperatures as high as 113 °C (Stetter *et al.*, 1993): they are *thermophilic*; to grow at pH below 2 (Reysenbach *et al.*, 2002; Tyson *et al.*, 2004): they are *acidophilic*; above pH 10 (Grant and Tindall, 1986): they are *alkaliphilic*; and are found in deep-sea environments at pressures up to >100 MPa (Yayanos, 1995): they are *barophilic*. The deep-sea environment at mid-ocean ridges harbors bacteria in an environment that is at high pressure and ranges in temperature from below freezing (i.e. the bacteria are *psychrophilic*) to above boiling (Horikoshi and Tsujii, 1999).

OXYGEN TOLERANCE

Dissolved oxygen, coupled to an electron donor as an oxidant in an oxidation-reduction reaction, provides the highest yield of metabolic energy. Because oxygen is only sparingly soluble in water (saturation occurs at approximately 9 mg of O_2 per liter), it is rapidly depleted in most aquifer environments. Many microbes have evolved to function in environments where oxygen has been removed and may not tolerate the presence of dissolved oxygen. Microbes may therefore be described according to their oxygen tolerance. Those that use oxygen are *aerobic* and those that use

alternative compounds as oxidants are *anaerobic*. In addition, aerobes may be *obligate*, requiring oxygen; *facultative*, preferring but not requiring oxygen; or *microaerophilic*, requiring oxygen at levels lower than saturated. Anaerobes also may be *aerotolerant*, not requiring oxygen and growing no better when oxygen is present; or *obligate*, requiring an absence of oxygen to avoid damage or death (Madigan *et al.*, 1997).

CHEMICAL FUNCTION

A fourth useful classification system is based on the chemical transformations that microbes carry out. The study of microbial ecology began with investigations of chemical transformation by unidentified natural organisms. As early as 1839, the ability of microbes entrained in soil to oxidize hydrogen gas was established, although hydrogen-oxidizing bacteria were isolated much later. Toward the end of the nineteenth century, individual organisms were isolated from natural materials and identified by their ability to accomplish inorganic chemical transformations. The subsurface microbes were thus usually described not by their shape or genetics or other taxonomic features, but by their relative chemical function. In addition, since numerous species can effect the same inorganic transformation, the microbes were organized for descriptive purposes according to the observable chemical transformations with which they are associated in natural environments, regardless of how closely they were related genetically (which was unknown). These groupings are called *functional groups* or *guilds* such as "sulfate reducers" or "methanogens". Functional groups provide a convenient and useful means of describing and investigating microbial communities in groundwater because they are directly dependent on the chemical environment and make many chemical transformations that can be observed in groundwater.

MICROBIAL COMMUNITIES

Within the community ecosystem, there are numerous chemical pathways and chemical resources that can be exploited for energy, and multiple individual species may use the same chemical resources for metabolic energy. The population grouped into guilds comprise the community's guild structure (Atlas and Bartha, 1993), where, for example, a guild may consist of all species that utilize sulfate reduction as a metabolic pathway. Thus, while diversity is necessary for community stability, the loss of a single species will not disrupt the overall community structure because multiple species may serve the same function.

The microorganisms within the community compete for resources, and they have a number of survival strategies that allow them to compete and maintain themselves. They may, for example, rely upon high reproduction rates (Andrews and Hall, 1986). An organism with a rapid reproduction rate would dominate when resources were temporarily abundant, where the benefits of reproduction outweigh other competitive adaptations. This could be important in ecosystems with a seasonal or other temporal fluctuation in nutrient availability, and growth-adapted organisms might be expected to flourish in remediation scenarios where the disturbance of the local environment causes an influx of nutrients. In subsurface environments where the supply of resources is relatively constant, organisms compete by having adaptations that allow them to efficiently utilize specific nutrients. In resource-limited environments especially, these organisms would be expected to be successful.

Microbial communities are structured and function according to their composition, dominant species, and population dynamics (Atlas and Bartha, 1993). Different microbial communities occupy different environments, members of a community compete and are interdependent, and the community members respond to environmental changes. In the application of microbial ecology to hydrology, we are perhaps most interested in the function of subsurface microbial communities; that is, the effect the microbial community has on the hydrologic system. Chemical properties and variations are readily obtainable and are often understandable directly in terms of the microbial community's effect on the aquifer environment.

TERMINAL ELECTRON-ACCEPTING PROCESSES

We can compare organisms and their relative dominance in subsurface systems according to the chemical reactions they mediate and the amount of energy they derive from these reactions. To do this, we must establish a uniform basis for comparison.

In groundwater environments, microbes derive metabolic energy from remnant clastic organic carbon or from electron-donating inorganic compounds. The vastly predominant energy source is photosynthesized remnant organic carbon deposited during sedimentation. Photosynthesis proceeds by the disproportionation of energy into localized centers of highly negative $p\varepsilon$ and a reservoir of O_2 (Stumm and Morgan, 1996), where $p\varepsilon$ is the relative tendency of a solution to accept or transfer electrons. Photosynthesis thus imposes a state of disequilibrium on the chemical components that comprise the microbial ecosystem. Non-photosynthetic organisms exploit this disequilibrium, and act to restore it, by using enzymes to decompose the unstable organic products of photosynthesis. They may do this by respiration, using an external acceptor (e.g. oxygen or sulfate) for electrons liberated from electron donors, or by fermentation, in which an organic compound is oxidized

(electron removed) inside a cell and the liberated electron is transferred to another, partially oxidized compound to reduce it (Ehrlich, 1990); that is, a complex organic molecule is split into relatively oxidized and reduced parts. In either case, the microbes facilitate thermodynamically feasible chemical reactions, realizing a fraction of the available free energy for metabolic purposes.

The rapid depletion of oxygen forces anaerobic metabolism to prevail within most groundwater systems, and the geochemically significant reactions are those that involve inorganic terminal electron acceptors such as sulfate. Measurements with respect to microbial community function are therefore based on chemical species that incorporate the products or reactants within microbially catalyzed chemical reactions. For example, in the examination of a subsurface environment where sulfate-reducing bacteria are active, the overall reaction can be represented by

$$2CH_2O + SO_4^{2-} + H^+ + 2H_2O = HS^- + 2CO_2 + 4H_2O \quad (1)$$

Of the reactants and products, the obvious target for the determination that sulfate is reduced is dissolved sulfide, since sulfide is not a common abiotic component of groundwaters. Sulfate reduction will not occur in the absence of sulfate, of course, and the abundance of the electron acceptor could be an indicator of the potential for sulfate reduction (Stevens and McKinley, 1995; Stevens *et al.*, 1993).

The composition of subsurface microbial communities is strongly linked to the chemical environment, which controls the relative abundance of potential electron acceptors and donors (Berner, 1981; Chapelle, 1993; Chapelle *et al.*, 1995). The carbon flow in subsurface environments is regulated by microbial food chains. No individual microbe has the capability to degrade all organic compounds present in groundwater environment, so individual microbes are specialized to perform particular metabolic processes (Chapelle, 1993). In most environments, organic matter degradation of such materials as lignin is begun by fermentation, yielding simpler compounds that can be broken down by other organisms, and the community of microorganisms accomplishes complete degradation to CO_2, with the final degradation step represented by terminal electron-accepting processes (TEAPs). Degradation is accomplished by microbial consortia (Chapelle *et al.*, 1987). The most common TEAPs in groundwater systems, constructed from constituent half-reactions (Champ *et al.*, 1979; Stumm and Morgan, 1996), are listed in Table 1 in order of net energy yield. (The derivation of free energies for comparison is summarized in the Appendix.) In environments where the microbial community has reached an equilibrium or steady state with respect to the supply of electron donors, competition for the available donors controls the predominance of community members through the relative free-energy relationships. For example, in a natural environment where ferric iron and sulfate were degrading organic matter, the iron-reducing bacteria would gain more net energy ($-116\,kJ\,mol^{-1}$) than would sulfate-reducing bacteria ($-105\,kJ\,mol^{-1}$), and the predominant geochemical process would be iron reduction (Chapelle and Lovley, 1992). If ferric iron were not present, sulfate reduction would predominate. The diverse microbial community may quickly transition to predominance by members using alternative TEAPs as geochemical conditions change.

In most groundwaters, the supply of organic compounds and other nutrients is severely limited, and these environments are termed *oligotrophic*. Spatial zonation in community composition may develop as organisms characterized by a particular TEAP locally outcompete other organisms. The study of zonation in natural aquifers may be difficult and require extensive analysis of sediments and groundwaters over extensive geographical areas (Chapelle *et al.*, 1987; Chapelle and Knobel, 1983), although a systematic approach has been developed and demonstrated (Chapelle *et al.*, 1995). Zonation is more commonly investigated in disturbed (contaminated) environments, where the introduction of nutrients causes variation over relatively short distances (Bjerg *et al.*, 1995; Chapelle *et al.*, 1996). Even in contaminant plumes, there is often general agreement with the expected TEAP succession (Baedeker *et al.*, 1993; Chapelle *et al.*, 1996; Vroblesky and Chapelle, 1994).

Table 1 Redox processes in closed systems (modified after Champ *et al.*, 1979)

Reaction	Equation	$\Delta G^\circ(W)$, kJ mol^{-1} e^{-1}
Aerobic respiration	$CH_2O + O_2 = CO_2 + H_2O$	−502
Denitrification	$5CH_2O + 4NO_3^- + 4H^+ = 2N_2 + 5CO_2 + 7H_2O$	−476
Nitrate reduction	$2CH_2O + NO_3^- + 2H^+ = NH_4^+ + 2CO_2 + 3H_2O$	−343
Manganese reduction	$CH_2O + 2MnO_2 + 4H^+ = 2Mn^{2+} + CO_2 + 3H_2O$	−340
Iron reduction	$CH_2O + 8H^+ + 4Fe(OH)_3 = 4Fe^{2+} + 11H_2O + CO_2$	−116
Fermentation	$3CH_2O + H_2O = 2CH_3OH + CO_2$	−113
Sulfate reduction	$2CH_2O + SO_4^{2-} + H^+ + 2H_2O = HS^- + 2CO_2 + 4H_2O$	−105
CO_2 reduction	$4H_2 + CO_2 = CH_4 + 2H_2O$	−104
Methane fermentation	$2CH_2O = CH_4 + CO_2$	−93

An interesting application of groundwater investigations of microbial communities uses the relationship of fermenting bacteria (which use no external electron acceptor) at the base of the microbial food chain, to the predominant TEAP, controlled by free energy and the availability of the relevant electron acceptor. Because the supply of electron donors is controlled by fermentation, the predominant organism will be the one degrading the electron donor most efficiently. Along with simple organic substrates, fermentation produces H_2, which can be used by many organisms also as an electron donor. Those organisms that can gain the most energy from H_2 oxidation – in the presence of their favored electron acceptor – will predominate by driving the equilibrium H_2 concentration to the lowest utilizable level, and to a level that is not easily utilized by less efficient competitors. The dissolved concentration of H_2 may therefore be used as an indicator of the dominant environmental TEAP (Chapelle *et al.*, 1996; Lovley and Goodwin, 1988), or may be used in conjunction with measurements of other substrates (Chapelle *et al.*, 1996).

Although the succession of TEAPs may be hypothetically and conceptually straightforward, exceptions to the free-energy ordering of TEAPs have been observed. In contaminated environments, in particular, the free-energy succession may not be followed, or two TEAPs may significantly occur simultaneously. The variations in observed TEAPs and in the TEAP succession may be explained by partial thermodynamic equilibrium (Postma and Jakobsen, 1996). According to this approach to evaluating subsurface processes, the fermentation of sedimentary organic matter is considered to be rate limiting, and the TEAPs are all considered to be close to thermodynamic equilibrium. In evaluating which TEAPs are operating in a given environment, all geochemical variables are accounted for in calculating permissible organic matter oxidation pathways, and multiple processes are simultaneously allowed if they are thermodynamically permissible (have a negative free energy). By explicitly including thermodynamic evaluations, the partial equilibrium model thus explains systems in which sulfate reduction and iron reduction occur simultaneously, and where the theoretical succession of TEAPS is not observed. This approach was used to explain simultaneous sulfate and iron reduction (i.e. the simultaneous appearance in the sediment column of Fe(II) and S^-) in lake-bottom pore waters (Postma and Jakobsen, 1996).

ENVIRONMENTAL INVESTIGATIONS OF GROUNDWATER COMMUNITIES

The investigation of microbial communities has often focused on community function, revealed by chemical transformations in groundwater or its enclosing sediment, along with microbial investigations through culturing or molecular methods. As noted previously, the direct investigation of microbiological communities is complicated by the biases inherent in the investigation methods: traditional culturing may not describe all members of the community, and molecular methods do not determine the relative significance of the community's members. Following are examples of some biogeochemical investigations.

REGIONAL AQUIFERS

A number of research efforts have focused on the evolution of aqueous geochemistry along a groundwater flow path (Chapelle *et al.*, 1987; Chapelle *et al.*, 1988; McMahon and Chapelle, 1991; Murphy *et al.*, 1992). Those studies confirmed the generality that the microbial community was dependent on geochemical variables and that the geochemical environment was simultaneously modified by bacteria contained within it. Redox zonation, the segregation of different TEAPs during the degradation of sedimentary organic matter, was shown along groundwater flowpaths or between distinct sedimentary environments.

An analysis of the Middendorf aquifer in South Carolina (Murphy and Schramke, 1998; Murphy *et al.*, 1992) using chemical analysis of groundwater, sediments, and microbial culturing methods showed the regional effects of microbial metabolism. The combination of regional and detailed local chemistry and microbiology was required to understand the microbial succession and its effects on aquifer geochemistry. The geochemistry was shown to be controlled by a complex interplay of chemical and microbial factors, as illustrated and summarized in Figure 1 (Murphy and Schramke, 1998). High-lignite zones were noted, along with organic carbon-stained sands, and inorganic carbon increased along the flowpath because of the oxidation of organic carbon. From the point of recharge, aerobes were most numerous, overall, in zones without lignite, and *vice versa*, suggesting that lignite oxidation was coupled to oxygen depletion. Along the flowpath, oxygen was eventually depleted and organic acids were produced by fermenters, and the sulfate-reducing and iron-reducing bacteria were in turn supported by these fermentation-produced electron donors. A modified system of redox zonation was observed: the aquifer underwent transition from aerobic waters to anaerobic waters containing Fe^{2+} and Mn^{2+}, and then to waters with increasing SO_4^{2-} and decreasing Mn^{2+} and Fe^{2+}. Zonation was not completely predicted by the principle of TEAP succession or by the nature of iron-reducing microbes, however. Ferrous iron (Fe^{2+}) increased along the flowpath in an oxygenated portion of the aquifer (Figure 1); this should not occur because iron reduction is an obligately anaerobic process, where oxygen should reach undetectable levels before Fe^{2+} is observed. Sediment analysis showed that the occurrence of Fe^{2+} was

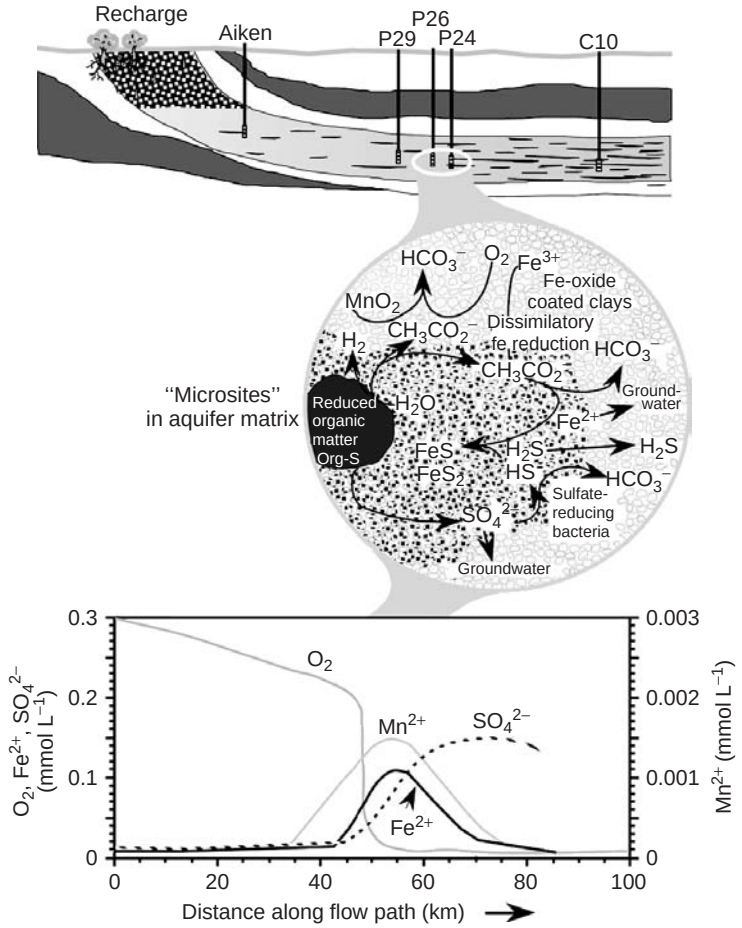

Figure 1 Groundwater evolution and the significance of microbial microsites in the Middendorf aquifer, South Carolina (Murphy *et al.*, 1992). Redox zonation occurred along the aquifer flowpath, and microbial microsites were inferred by the occurrence together of dissolved oxygen and reduced metal species (By courtesy of E. Murphy). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

coupled to the occurrence of high-lignite zones in the aerobic portion of the aquifer. Careful observation, modeling, and deduction indicated the existence, as illustrated in the figure, of a complex fine-scale relationship between anaerobic microsites, where dissimilatory iron-reducing bacteria (DIRB) could use fermentation-produced organic acids and contribute ferrous iron as a solute observable in oxygenated groundwaters. The macroscopic transitions between TEAPs were thus obscured by processes acting at fine scale over a broad area to produce an overlap of the products of microbial metabolism.

Microbial microsites, physically separate, small-scale, chemically distinct sedimentary domains harboring distinct microbial communities and producing anomalous chemical signatures in groundwater, may be important components of an overall microbial community. For example, in a natural system containing the fermentation products H_2, propionate, and butyrate, the concentrations of H_2 were calculated, on thermodynamic grounds, to be too high to permit the syntrophic degradation of propionate and butyrate (Conrad *et al.*, 1986). These compounds were known to be degraded. The conclusion was drawn that an environmental niche – resulting from fine-scale heterogeneity – must have existed where the processes were favored. Specifically, the anaerobic oxidation of butyrate and propionate must have taken place where zones of active methanogenesis (drawing down H_2 concentration) drove the pertinent oxidation reactions through mass action on the overall system. The hyporheic zone of the Columbia River, Washington, a microbially active subsurface interface between groundwater and surface water, was similarly deduced to harbor anaerobic microsites (Moser *et al.*, 2003). The sediment at the river bottom, overlying an aerobic aquifer, was sampled by freezing and intact removal. Relatively high numbers of heterotrophic aerobes were present, along with significant numbers of anaerobic nitrate, sulfate, and iron-reducing microbes. The presence of acid-volatile sulfide indicated that the sulfate-reducing microbes, at least, were

metabolically active. The presence of anaerobic microsites in the otherwise aerobic sedimentary environment was required for the production of sulfide.

In each of the cases cited, the use of the term *microsite* was used without reference to an absolute scale, and it is often used to describe heterogeneity below the scale of observation. In the studies of the Middendorf aquifer (Murphy and Schramke, 1998; Murphy *et al.*, 1992), for example, inferences were made from the information that was available, including compositions derived from groundwater sampling wells that tapped significant vertical intervals in the aquifer and from smaller scale core studies. Under favorable circumstances at other locations, the scales of microbial heterogeneity have been related to aquifer properties measured at the same scale; for example, at the centimeter to decimeter level (Bekins *et al.*, 2001; Smith *et al.*, 1991). As sampling technology progresses, aquifer measurements at or below the scale of community heterogeneity may become more acheivable. With access to information at the scale of heterogeneity distinctions could be made between mixed redox conditions due to permissible free energies for multiple reaction, redox conditions varying over centimeter to decimeter scale controlled by aquifer properties such as sediment texture or compositions, and μm-scale regions or sites controlled by chemical diffusion.

SEDIMENTARY TRANSITIONS

Sedimentary interfaces represent an abrupt transition in depositional environments. Because natural communities are in equilibrium with their environments, it follows logically that they are limited by the supply of some nutrient or by some physical condition. Where the texture and composition of adjacent lithologies contrasts sharply, particularly where a carbon-rich lithology is juxtaposed with a carbon-poor lithology, the microbial environments may favor communities with markedly different structures, and relatively fine-scale investigations of these systems can reveal the interdependence of geochemistry and microbial function. A microbiological study of aquifer and aquitard sediments in the Atlantic Coastal Plain (McMahon and Chapelle, 1991), for example, indicated that fermentation reactions in aquitard sediments produced simple organic compounds and H_2. In the aquitard, the production of organic acids outpaced respiration, and in the aquifer, respiration outpaced fermentation. The diffusive transport of organic acids from the aquitard was calculated to be sufficient to support the observed rates of microbial respiration within the aquifer. Similar studies of a deeply buried, anaerobic, organic-rich paleosol in an otherwise aerobic aquifer indicated that the environment within the paleosol was electron-acceptor limited, and that the diffusion of electron acceptors into the anaerobic stratum drove the metabolism of fermentation-derived organic acids (Fredrickson *et al.*, 1995; Kieft *et al.*, 1995; McKinley *et al.*, 1997).

Deeper, more indurated, and older aquifer systems show the same interformational interaction. A detailed study of a deep aquifer consisting of a transgressive-regressive sequence of sandstones and shales in New Mexico showed that the aquifer was anaerobic, and was fed by regional infiltration of meteoric water from areas at higher elevation (Walvoord *et al.*, 1999). The sediments were sampled by argon-rotary core drilling, and found to include shales that were relatively rich in organic carbon, interbedded with organic carbon-poor sandstones (Figure 2). The microbial environment across the lithologic boundary changed dramatically at the centimeter scale. The shale pore sizes in particular limited the viability of microbes within them (Fredrickson *et al.*, 1997). Chemical measurements of the two lithologies included aqueous compositions and dissolved gases, using a passive multilevel sampler (McKinley, 2001; Ronen *et al.*, 1987), and of sulfate reduction directly within the cores using a silver foil technique (Krumholz *et al.*, 1997). Sulfate reducers, detected by the production of sulfide directly from core samples (Figure 2), were most active at the shale-sandstone interfaces, where fermentation-produced organic carbon from the organic-rich shales diffused into the more transmissive, sulfate-rich sandstone aquifers. The concentration of methanogen methane was lowest in the transmissive sandstones, and highest in the less-transmissive shales where sulfate reduction was apparently limited by the diffusive transport of sulfate. A later study of the same sequence using sediments incubated within a passive multilevel sampler showed that the abundances major archael guilds shifted dramatically over centimeter distances (Takai *et al.*, 2003).

DISTURBED ENVIRONMENTS

Much interest in microbial communities is related to the potential for those communities to remediate contamination, either through natural processes or after stimulation by the addition of the necessary nutrients. *Bioremediation* may degrade organic contaminants and lower the valence of reducible metals. The remediation of contaminated sites by *in situ* organisms without amendment has been termed *intrinsic bioremediation* and has been of particular interest in sites contaminated with organic compounds (Madsen, 2001). There are a number of well-studied sites contaminated with organic compounds, including the landfill at Vejen, Denmark, and a site at Cape Cod, Massachusetts.

At the Vejen site, the distribution of inorganic and organic compounds was determined and a series of investigations tracked the movement and degradation of the contaminant plume associated with the landfill (Baun *et al.*, 2003). An analysis of microbial community structure before and after

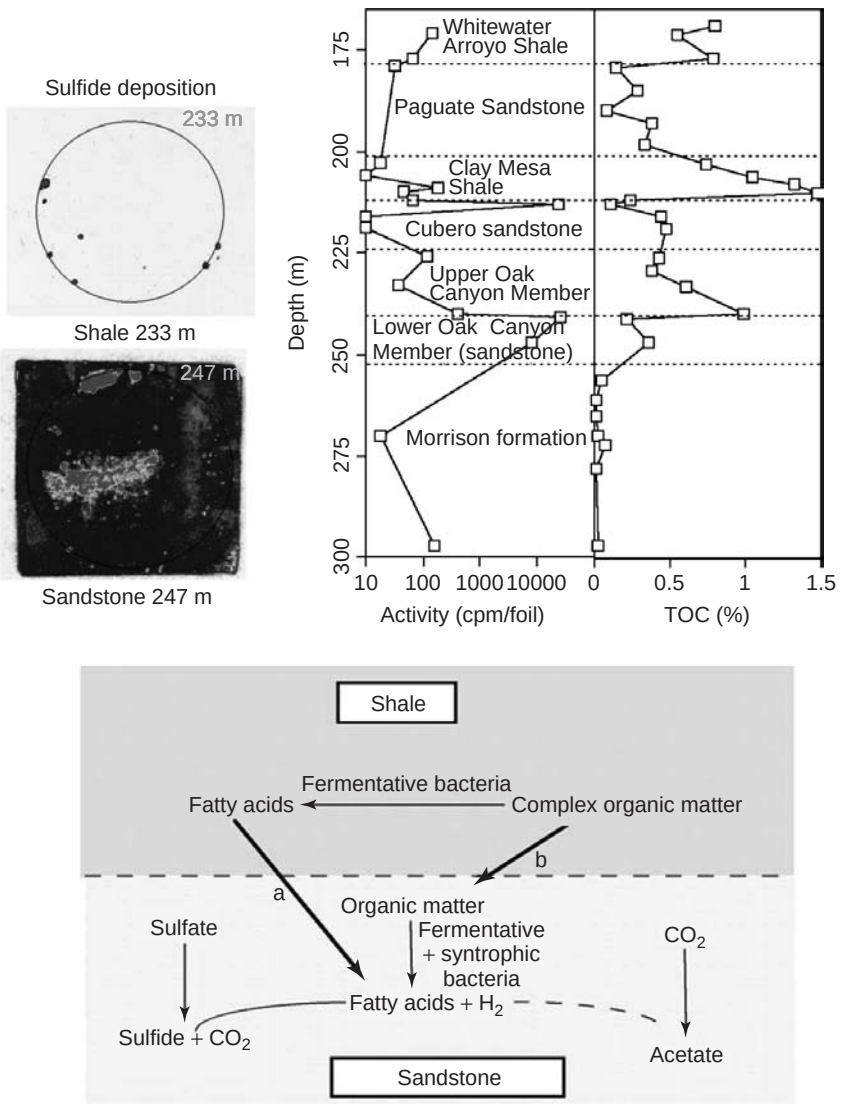

Figure 2 Sulfate-reducing activity as part of a complex interaction across lithologic boundaries in a deep sandstone-shale aquifer near Seboyeta in New Mexico (Krumholz *et al.*, 1997). Silver foils (left), inserted into broken sediment cores, were used to map sulfate reduction. The transgressive-regressive sequences of sandstones and shales harbored interdependent communities (By courtesy of L. Krumholz). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

prolonged exposure to contaminant herbicides indicated that the overall structure of the community was altered, but the community diversity was not (de Lipthay *et al.*, 2004). Related review articles of the biogeochemistry of landfills (Christensen *et al.*, 2001) and of the characterization of redox conditions within landfill plumes (Christensen *et al.*, 2000) contain useful additional information. The long-term and detailed investigation of the Cape Cod site (USGS, 2005) evaluated the fate of organic and inorganic contaminants. The site included a large plume of contaminated groundwater due to secondary treatment and disposal of domestic sewage to a shallow unconfined aquifer. Biodegradation of labile organic compounds was observed, but many trace organics such as trichloroethene persisted for more than 30 years (Barber *et al.*, 1988).

The bioreduction of metals and other inorganic compounds may also be important as a bioremediation approach. The metal-reducing microbes have been extensively studied (Lovley, 1991; Lovley, 1993), and have been shown to reductively immobilize contaminant species such as pertechnetate and uranium. Because uranium is a widespread contaminant at the former weapons production facilities in the United States (Riley and Zachara, 1992), its bioreduction to insoluble and immobile U(IV) has been extensively investigated. The microbial reduction of U(VI) to U(IV) has been demonstrated at mill tailings sites and in

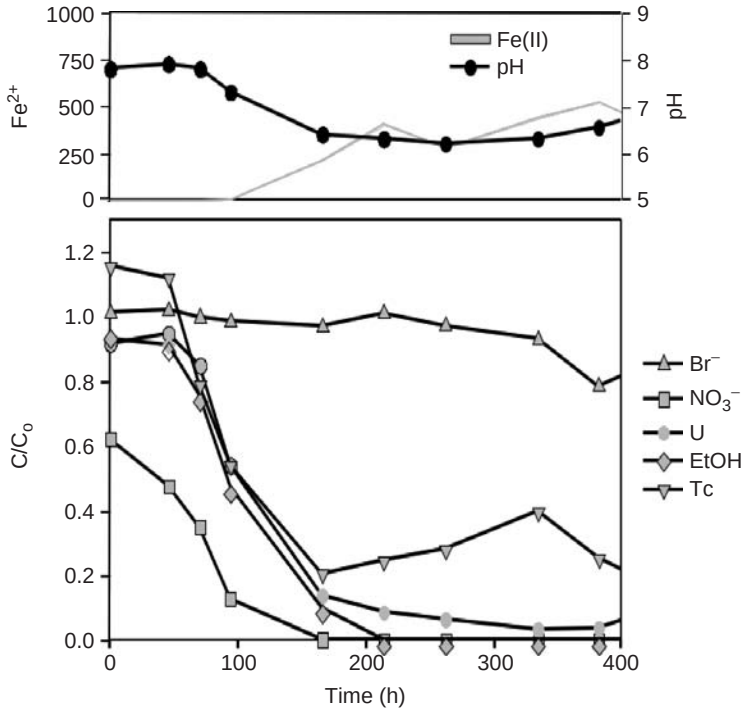

Figure 3 Results of a push-pull test at Oak Ridge, Tennessee, demonstrating the ethanol-stimulated reduction of nitrate, technetium, uranium, and ferric iron. The injected solution was withdrawn over a long period; the results normalized to initial concentrations indicate the stimulation of *in situ* microbial activity (Reprinted from Istok 2005. © 2005 with permission of American Chemical Society)

related laboratory studies (Anderson *et al.*, 2003; Finneran *et al.*, 2002; Senko *et al.*, 2002), particularly where the zone of contamination was stimulated by the addition of an electron donor (Anderson *et al.*, 2003). Uranyl (UO_2^{2+}), the predominant soluble U(VI) ion, was found to be reduced by several metal-reducing microbes, but the presence of nitrate (NO_3^-) and the production of nitrite (NO_2^-) during nitrate reduction was observed to cause U(IV) reoxidation (Senko *et al.*, 2002).

Uranyl reduction can be rapidly stimulated *in situ*, as demonstrated in numerous field studies, including the following example using a hydrologic method. A novel method that can stimulate and determine the direct bioalteration of contaminants has been extensively demonstrated by researchers at Oregon State University (Istok, 2005). The method, a *push-pull test*, uses a single monitoring well, into which is injected an aqueous tracer along with an electron donor and other amendments as necessary. After injection of a significant test volume, ground water is withdrawn and sampled over time and the tracer concentration is used to correct for mixing and to monitor the relative abundance of other dissolved components, including the electron donor. An application of the method is illustrated in Figure 3, for an aquifer contaminated with uranium and technetium at the US Oak Ridge site, Tennessee. Details of the series of injections and their interpretation are presented elsewhere (Istok *et al.*, 2004). The concentration of the electron donor (ethanol) and of nitrate, technetium, uranium, ferrous iron, nitrite, and pH were monitored over the time of water withdrawal (up to 800 h), along with that of the bromide tracer (Figure 3). Nitrate was rapidly reduced as ethanol was oxidized (note their positions below the mixing-normalized tracer concentration), and technetium and uranium were rapidly reduced and removed from solution, while ferrous iron was introduced to solution through sedimentary iron reduction. Nitrate thermodynamically inhibited uranium reduction, indicated by the substantial removal of nitrate prior to the decrease in uranium. The experiments were bounded by injections without donor, and, along with companion injections (not shown), demonstrate directly the biostimulation of an *in situ* microbial community to reductively immobilize technetium and uranium.

Appendix

Microbial organisms act as redox catalysts, mediating the electron transfer between an electron-donating (oxidation) half-reaction and a coupled electron-accepting (reduction) half-reaction. It is convenient to combine the ideas of $p\varepsilon$ and half-reactions into a simple thermodynamic method for evaluating the feasibility of hypothetical reactions for driving microbial metabolism (Stumm and Morgan, 1996).

The quantity $p\varepsilon$ can be defined in a way that is analogous to pH,

$$p\varepsilon = -\log\{e^-\} \tag{2}$$

giving the hypothetical electron activity, and indicating the tendency of a solution to accept or transfer electrons. In a highly reducing solution the electron activity is relatively high, and in an oxidizing solution the electron activity is relatively low. The $p\varepsilon$ can be related to the standard electrode potential and free energy of reaction by the relations

$$E_H^\circ = -\Delta G^\circ/nF = (RT/nF)\ln\ K = (2.3\ RT/nF)$$
$$\log\ K = (2.3\ RT/F)\,p\varepsilon^\circ \tag{3}$$

where ΔG° is the standard Gibbs free-energy change in the reduction reaction, K is the thermodynamic equilibrium constant, n is the number of electrons in the reaction as written, R is the gas constant, and F is the Faraday constant. The energetics of half-reactions may be characterized by the value of K for the reaction, by the standard potential (E_H°), or by the $p\varepsilon^\circ$. By summing appropriate half-reactions, the net potential for any given oxidation-reduction reaction can be readily derived.

A convenient modification of $p\varepsilon$ as a tool for understanding energy-yielding reactions in natural waters is to define a subsidiary constant, $p\varepsilon^\circ(W)$. This quantity is analogous to $p\varepsilon^\circ$, except that $\{H^+\}$ is assigned its activity in neutral water to unambiguously negate the effects of variable pH on comparisons based on $p\varepsilon^\circ$. Standard conditions for $p\varepsilon^\circ(W)$ are thus defined at 25 °C, unit activities of oxidant and reductant, and pH = 7.00. $p\varepsilon^\circ(W)$ is defined by

$$p\varepsilon^\circ(W) = p\varepsilon^\circ + \log[H^+]^n \tag{4}$$

where n is the number of moles of protons exchanged per mole of electrons, and $[H^+]$ equals 1×10^{-7} mol L^{-1}. Using this convention, half-reactions can be evaluated according to $p\varepsilon^\circ(W)$, so that a ranked list will contain reactions ordered in such a way that any higher (more positive) system will oxidize any lower (more negative) system. For example, given a table of half-reactions with values for $p\varepsilon^o(W)$, one can readily establish that NO_3^- can oxidize HS^- to SO_4^{2-}. Details of this approach along with tables and examples may be found elsewhere (Champ *et al.*, 1979; Stumm and Morgan, 1996). The construction of ranked lists of half-reactions has become widespread, and has proved useful in understanding redox reactions that support life, the competition and interplay between microbial metabolic processes, and in exploring the possibilities of life elsewhere (e.g. Gaidos *et al.*, 1999; Klass, 1984; Lovley and Goodwin, 1988; Madigan *et al.*, 1997; Stumm and Morgan, 1996).

107: Natural and Constructed Wetlands

CHRISTOPHER B CRAFT

School of Public and Environmental Affairs, Indiana University, Bloomington, IN, US

Wetlands are characterized by periodic to continuous inundation or saturation with water (wetland hydrology), soils that are periodically deficient in oxygen (hydric soils), and vegetation that is adapted to periods of anaerobic or anoxic soil conditions (hydrophytic vegetation). Wetlands include herbaceous marshes and fens, forested swamps, and Sphagnum-dominated peat bogs. Wetland plants possess morphological adaptations (aerenchyma, buttressed trunks, pneumatophores, hypertrophied lenticels) to facilitate transport of oxygen to the roots and metabolic pathways to respire anaerobically without toxic effects. Duration, depth, and frequency of inundation, water source (precipitation, surface flow, groundwater), and water quality (fresh, saline, oligotrophic, eutrophic) determine the distribution, productivity, and nutrient cycling characteristics of wetland vegetation. Floodplain swamp forests and estuarine marshes and mangroves receive large quantities of water and nutrients during overbank flooding and tidal inundation that enhances plant productivity and sediment, nutrient, and pollutant retention as compared to wetlands that receive most of their water from precipitation. The ability of natural wetlands to filter pollutants has led to construction of artificial wetlands to treat wastewater, stormwater, acid mine drainage, nonpoint runoff and other sources of pollutants. Wetlands also are constructed to replace important ecological functions (water storage, biological productivity, biodiversity) that are lost when natural wetlands are damaged or destroyed by human activities.

INTRODUCTION

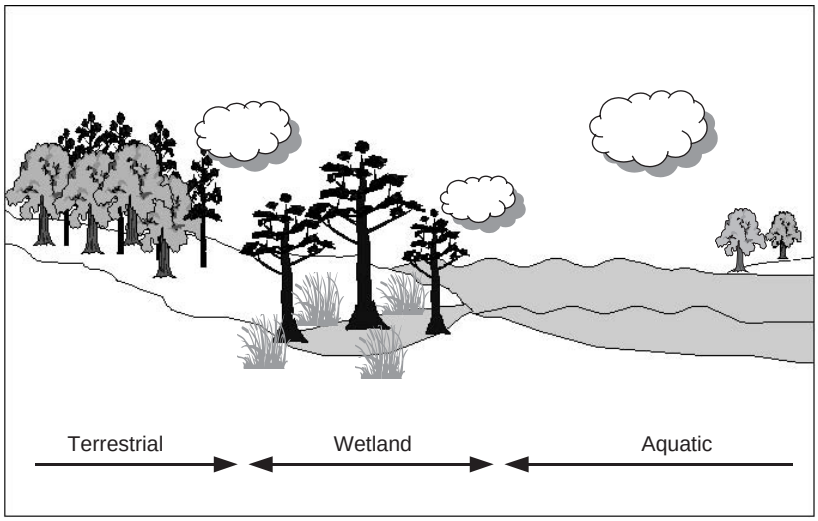
Wetlands are transitional between terrestrial and aquatic ecosystems and are periodically to continuously inundated or saturated with water, producing anaerobic soil conditions and favoring the growth of vegetation adapted to periods of low or no soil oxygen. Wetlands require inundation or soil saturation long enough during the growing season, usually 7 to 21 consecutive days, to produce anoxic (anaerobic) soil conditions. When soils become reduced, heterotrophic microorganisms use nitrate (NO_3^-), ferric iron (Fe^{3+}), sulfate (SO_4^{2-}) and other terminal electron acceptors to support growth and metabolism. In wetlands, extended periods of soil anoxia stresses and kills terrestrial plant species, favoring species adapted to low oxygen. By definition, a wetland must have the three following characteristics: periodic to continuous inundation or saturation with fresh or saline water (*wetland hydrology*), soils that are periodically anoxic (*hydric soils*), and rooted emergent vegetation adapted to periods of low or no oxygen (*hydrophytic vegetation*) (USACE, 1987). Thus, wetlands differ from terrestrial ecosystems by the presence of wetland hydrology, hydric soils, and hydrophytic vegetation. They differ from aquatic ecosystems by the presence of emergent vegetation that is rooted in soil (Figure 1).

Wetlands receive water of varying proportion from precipitation, groundwater, and surface water. The source of water as well as hydroperiod – the duration, depth, and frequency of inundation – interact to determine the plant species that will grow there. Hydrophytic vegetation ranges from herbaceous emergent plants such as the ubiquitous cattail (*Typha*) to woody trees such as bald cypress (*Taxodium distichum*). Hydrophytic species possess morphological and metabolic adaptations that enable them to survive and thrive in anaerobic soils.

CLASSIFICATION OF WETLANDS BASED ON VEGETATION

At the broadest level, wetlands are classified based on inundation with freshwater (freshwater wetlands) or partially diluted seawater (estuarine wetlands). Below this level,

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.



Hydrology:		
Dry	Intermittently to permanently inundated or saturated	Permanently inundated
Redox status:		
Oxidized	Intermittently to permanently reduced	Permanently reduced
Biogeochemistry:		
Source of materials	Source, sink, or transformer	Sink
Plant productivity:		
Low to medium	Generally high but sometimes low	Generally low

Figure 1 Hydrologic, biogeochemical, and biological functions of wetlands relative to terrestrial and aquatic ecosystems. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

wetlands often are separated on the basis of the dominant vegetation because it is a conspicuous feature of the landscape that reflects underlying environmental gradients. Freshwater wetlands include bogs, fens, marshes, and swamps. They are found in a variety of locations, often on regional topographic low spots near rivers, streams, and lakes and on higher parts of the landscape, on broad flats and depressions that do not readily drain. Estuarine wetlands occur in coastal regions and include salt, brackish, and tidal freshwater marshes and, tropical and subtropical regions, mangrove forests.

Freshwater Wetlands

Bogs and fens are the most common wetlands across large areas of the northern hemisphere, above 45° north (Matthews and Fung, 1987; Aselmann and Crutzen, 1989). Bogs are dominated by peat forming vegetation, notably peat mosses of the genus *Sphagnum* (Clymo, 1978; Crum, 1995). Over time, peat accumulation of several meters or more elevates the bog surface above that of the surrounding land such that precipitation is the major source of water and nutrients to these wetlands (Figure 2). Bogs are acidic, nutrient poor (Clymo, 1978) and dominated by acidophilic vegetation such as *Sphagnum*, ericaceous shrubs, and conifers like black spruce (*Picea mariana*) (Table 1, Crum, 1995). In Canada, black spruce-*Sphagnum*-dominated bogs are known as *muskegs*. Fens are often found in association with bogs but at lower elevations on the landscape where groundwater is a more important source of water (Figure 2). Because groundwater often contains greater concentrations of dissolved minerals such as calcium, the pH of fens is higher than in bogs, usually near circumneutral (Bridgham *et al.*, 1996). Fens are dominated by graminoid (grass-like) vegetation, grasses, sedges, and rushes (Table 1).

Like fens, marshes also are dominated by herbaceous emergent vegetation (Mitsch and Gosselink, 2000). However, marsh vegetation is found in almost any geomorphic

Table 1 Common freshwater and estuarine wetlands based on vegetation type. Primary water source, hydroperiod, and dominant vegetation also are presented

Wetland Type	Primary Water Source	Hydroperiod	Dominant Vegetation
Freshwater:			
Bog	precipitation	near-continuous saturation	peat mosses (*Sphagnum* spp.)
Fen	groundwater	near continuous inundation or saturation	grasses (Poaceae), sedges (Cyperaceae)
Swamp	surface water	periodic inundation	bald cypress (*Taxodium distichum*) and other trees
Marsh	precipitation, surface water, groundwater	periodic to continuous inundation or saturation	grasses (Poaceae), sedges (Cyperaceae), rushes (Juncaceae), reeds (*Phragmites, australis, Phalaris* sp.), cattail (*Typha* spp.)
Estuarine:			
Salt marsh	surface water	regular (2x daily) tidal inundation	cordgrass (*Spartina alterniflora*)
Brackish marsh	surface water	regular to irregular tidal inundation	needlerush (*Juncus roemerianus*), *Spartina* spp., salt grass (*Distichlis spicata*)
Tidal freshwater Marsh	surface water	regular tidal inundation	cattail (*Typha* spp.), *Panicum* spp., pickerelweed (*Pontedaria cordata*), *Sagittaria* spp.
Mangrove	tidal inundation	regular to irregular tidal inundation	trees (*Rhizophora* sp., *Avicennia* sp.)

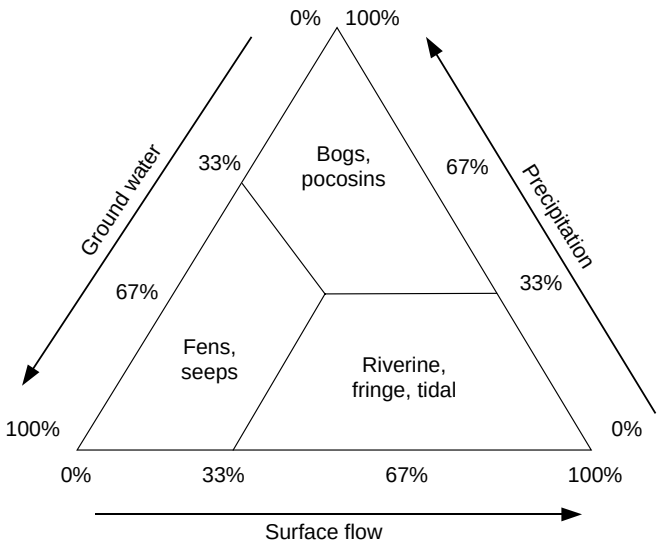


Figure 2 Relationship between water source and wetland vegetation. Modified from Brinson (1993)

setting, including shorelines of ponds, lakes, and rivers as well as seepage slopes and depressions. Common marsh species include the sedges, *Carex* and *Cyperus* spp., rushes, *Juncus* spp., and other species like cattail (*Typha* spp.).

Swamps are forested wetlands that exist along floodplains of varying size and on low-lying or flat geomorphic settings. Along river corridors, swamp forests are classified as bottomland, alluvial, or riparian forest on the basis of duration and frequency of river flooding. Bottomland forests are located in old river channels and oxbows of large river floodplains where inundation is of long duration (Figure 3). Bald cypress (*Taxodium distichum*) and Tupelo gum (*Nyssa aquatica*) are common tree species of bottomland floodplain swamps of the southern US (Wharton *et al.*, 1982). Alluvial forests are found on higher elevations of the floodplain, older terraces of large rivers, and floodplains of smaller rivers where the flood pulse is of shorter duration (Figure 3), several weeks to several months annually. Plant species diversity is greater in alluvial versus bottomland hardwood swamp forests because of the shorter duration of flooding and soil anoxia (Wharton *et al.*, 1982). Riparian forests form narrow corridors along perennial and intermittent streams (Brinson *et al.*, 1981b). These wetlands are inundated for short duration, hours to several days at a time. Riparian forests are important because they maintain stream water quality by shading and by intercepting sediment and pollutants that are transported from the surrounding terrestrial landscape (Naiman and Decamps, 1997).

Estuarine Wetlands

Estuarine wetlands are found in coastal regions where freshwater discharged from rivers interacts with and is diluted by seawater. Estuarine wetlands exist along a gradient of salinity and are characterized by frequent, cyclic flooding from astronomical tides (Figure 4). In estuarine wetlands, salinity and sulfides impose additional stresses on the wetland vegetation in addition to stress imposed by soil anoxia. Most estuarine wetlands are dominated by herbaceous emergent vegetation although forest vegetation replaces herbaceous emergent species in tropical and subtropical estuaries where mangroves dominate.

Salt marshes are found near the estuarine-ocean interface where seawater salinity is diluted from 35 ppt down to 20–30 ppt (Wiegert and Freeman, 1990). Salt marshes are flooded twice daily by the astronomical tides. Predictable tidal pulsing of water, sediment, and nutrients

Plant species	
Freshwater marsh	Cattail (*Typha* spp.), maidencane (*Panicum hemitomon*), wild rice (*Zizania aquatica*), pickerelweed *(Pontedaria cordata*), arrow arum (*Peltandra virginica*), duck potato (*Sagittaria* spp.)
Brackish marsh	Needlerush (*Juncus* spp.), saltmeadow cordgrass (*S. patens*), giant cordgrass (*S. cynosuroides*), spikegrass (*Distichlis spicata*) marsh elder (*Iva frutescens*)
Salt marsh	Smooth cordgrass (*Spartina alterniflora*), glasswort (*Salicornia* spp.)
Mangrove (not shown)	Red (*Rhizophora mangle*), black (*Avicennia germinans*) and white (*Laguncularia racemosa*) mangrove

Figure 4 Relationship between wetland plant communities and salinity along the estuarine continuum. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

makes these wetlands among the most productive in the world. Salt marshes are dominated by nearly monotypic stands of cordgrass *Spartina alterniflora* in the eastern US, *S. foliosa* on the pacific coast, and *S. anglica* in Europe. Other salt-tolerant species such as saltwort (*Salicornia* spp.) are also present.

Brackish marshes exist in areas upstream and landward of salt marshes where salinity is lower, 0.5 ppt to 20 ppt (Figure 4) (Eluterius, 1984). Brackish marshes often are the dominant wetlands in areas of reduced astronomical tides such as the Gulf Coast region and the Albemarle–Pamlico estuaries of North Carolina. Plant species

diversity of brackish-water marshes is greater than in salt marshes because salinity stress is less. Vegetation of brackish marshes includes needlerush (*Juncus roemerianus, J. gerardi*) spp., saltmeadow cordgrass (*Spartina patens*), giant cordgrass (*Spartina cynosuroides*), spikegrass (*Distichlis spicata*), and salt-tolerant woody shrubs (*Iva frutescens*) (Stout, 1984, 1988).

Tidal freshwater marshes occur at the landward (most upstream) end of the estuary where seawater rarely penetrates (salinity <0.5 ppt) but where tidal inundation still occurs (Figure 4). Tidal freshwater marshes are common in large river estuaries such as the Hudson River, Delaware River, Chesapeake Bay, and Mississippi delta of Louisiana (Odum, 1988). Tidal freshwater marshes often have much higher-plant species diversity than either brackish marshes or salt marshes (Simpson *et al.*, 1983; Odum, 1988). Common species include emergents like cattail (*Typha* spp.), giant cutgrass (*Zizaniopsis milaceae*), wild rice (*Zizania aquatica*), maidencane (*Panicum hemitomon*), saw grass (*Cladium jamaicense*), bulrushes (*Schoenoplectus* spp.), and others as well as soft-stemmed species like pickerelweed (*Pontedaria cordata*), arrow arum (*Peltandra virginica*), and duck potato (*Sagittaria* spp.) (Odum *et al.*, 1984; Odum, 1988).

Mangrove forests are the dominant wetlands of estuaries in tropical and subtropical regions (Lugo and Snedaker, 1974; Odum *et al.*, 1982). In the intertidal zone, mangrove forests are dominated by red mangrove, *Rhizophora mangle*. Inland from the red mangrove zone, where tidal inundation is less frequent and less tidal flushing occurs, black mangrove (*Avicennia germinans*) and white mangrove (*Laguncularia racemosa*) are found (Odum *et al.*, 1982). Because mangroves are intolerant of below freezing temperatures, they are restricted to latitudes between about 25° north and 25° south (Mitsch and Gosselink, 2000).

PLANT ADAPTATIONS TO WATERLOGGING AND ANOXIA

In order to grow and reproduce in anaerobic soil environments, wetland plants must possess adaptations that maintain aerobic respiration to support cell growth, maintenance, and reproduction. In the absence of oxygen, vegetation must respire via anaerobic biochemical pathways that produce less energy to support cell maintenance and growth and that also produce metabolites (e.g. ethanol) that are toxic unless eliminated from the system. Because most respiration occurs in the roots of plants (Nobel, 1999), many adaptations to anoxic conditions involve morphological changes in stem or leaf structure that are designed to facilitate oxygen transport to the roots. Other adaptations to anoxia involve alteration of metabolic processes and pathways that reduce or eliminate toxic metabolites produced during anaerobic respiration.

Morphological Adaptations

Morphological adaptations involve physical changes in plant structure to facilitate oxygen transport to the roots. These adaptations include aerenchyma, hypertrophy leading to buttressed (swollen) trunks, pneumatophores, adventitious roots, shallow root systems, root aeration, pressurized ventilation, radial oxygen loss from roots and storage of carbohydrate reserves.

Aerenchyma is spongy tissue containing large hollow conduits in roots, stems, and leaves that transport oxygen-rich air to the roots (Armstrong, 1978). Most herbaceous wetland species, including cattail (*Typha* spp.) and many woody species, possess aerenchyma tissue (Crawford, 1993). ***Hypertrophy*** is swelling of the stem base in woody and herbaceous plants that occurs when aerenchyma is formed. In woody plants such as bald cypress and Tupelo gum (*Nyssa aquatica*), it leads to the formation of buttressed or swollen trunks (Figure 5). ***Pneumatophores*** and prop roots are erect roots that extend aboveground in mangrove species such as black mangrove (*Avicennia* spp.) and red mangrove (*Rhizophora mangle*) (Figure 6). The freshwater tree, bald cypress, possesses knees that vaguely resemble pneumatophores but whose function is less well understood. Buttressed trunks and pneumatophores increase the surface area and number of lenticels (pores in the stems of woody plants through which gases are exchanged) that facilitate oxygen to diffuse into the plant. They also stabilize wetland trees in waterlogged and soft soils.

Wetland plants also produce ***shallow root systems*** and ***adventitious roots*** to enhance oxygen uptake in anaerobic soils. In the case of hydrophytic vegetation, roots are concentrated at or near the soil surface in order to maximize oxygen diffusion from the air or overlying water column.

Figure 6 Mangrove forest in Jervis Bay, South New Wales, Australia. Note the pneumatophores of black mangrove, *Avicennia* sp. Photo by Jim Lynch

When wetlands are flooded, some species produce adventitious roots that grow above ground into the water column or along the soil surface to assimilate oxygen directly from the water column or air (Crawford, 1993).

Morphological adaptations that enhance ***root aeration*** are important for sustaining growth in deep waters. The roots of cattail (*Typha*), spikerush (*Eleocharis* spp.) and other species contain porous cortices and thin steles that favor increased gas diffusion, deeper rooting and fine lateral root development relative to other species, adaptations that enable it to dominate in areas of deep water and long hydroperiod (Sorrell *et al.*, 2000). In the Florida Everglades, enhanced root aeration is thought to contribute to invasion by cattail into areas previously dominated by saw grass (*Cladium jamaicense*), whose roots contain less porous cortices, thicker steles and, thus, reduced gas transport (Sorrell *et al.*, 2000).

Some wetland plants augment diffusion of O_2 to the roots by means of ***pressurized ventilation*** (Dacey, 1981) or convective diffusion (Brix, 1993a). Pressurized ventilation occurs when gradients of temperature and pressure between the atmosphere and roots drive oxygen-rich air through the stomata of young leaves, down the shoots to the roots. Air containing respired compounds such as CO_2 is forced up more porous older stems and leaves where it is expelled back into the atmosphere. Pressurized ventilation requires aerenchyma tissue and it occurs in many wetland species, including yellow waterlily (*Nuphar luteum*) (Dacey, 1981), common reed (*Phragmites australis*), *Typha* spp., *Juncus* sp. *Eleocharis*, and other emergents with cylindrical stems and linear leaves (Armstrong and Armstrong, 1991; Brix, 1992).

Radial oxygen loss (ROL) is another adaptation to anoxic conditions driven by diffusion. Radial oxygen loss involves leakage of oxygen from the roots, oxidizing the area of soil around the roots and increasing the soil's oxidation-reduction potential (Armstrong, 1978; Ernst, 1990). Radial oxygen loss benefits the plant by oxidizing reduced metals (Fe^{2+}, Mn^{2+}) and sulfides that, otherwise, may be toxic. Evidence for ROL is observed in the rust colored (Fe^{3+}-rich) zones in the immediate vicinity of live roots. Radial oxygen loss has been observed in a variety of wetland plants, including woody, herbaceous emergent, and floating leaved species (Michaud and Richardson, 1989; Cronk and Fennessy, 2001).

One mechanism to combat short-term anoxia involves production of ***large carbohydrate reserves*** that are stored in roots. These reserves can be used to support anaerobic metabolism when soils are flooded or saturated for short periods of time. Plants with large rhizomes and carbohydrate reserves such as *Typha* and *Phragmites* can survive longer in flooded soils than species with small reserves (e.g. *Juncus, Carex*) (Barclay and Crawford, 1982).

Metabolic Adaptations

When soils are flooded and become anoxic, plants respond by shifting from aerobic metabolism, where CO_2 is the primary end product, to anaerobic metabolism, where ethanol, lactic acid, and other compounds are produced (Crawford, 1993; Summers *et al.*, 2000). Anaerobic respiration produces only 2 mol of ATP for every mole of glucose oxidized whereas aerobic respiration produces 38 mol of ATP (Atlas and Bartha, 1981). Thus, anaerobic respiration does not provide the high levels of energy (ATP) needed to maintain growth and metabolism that aerobic respiration does. One anaerobic pathway, ethanol fermentation, enables wetland plants to maintain high energy levels at least temporarily (Mendelssohn and Burdick, 1988). But, because ethanol is toxic to plants, wetland vegetation must be able to remove excess ethanol or convert it to a nontoxic compound such as malate. While some studies suggest malate production as an alternative metabolic end product (McManmon and Crawford, 1971), other researchers have observed that malate levels do not always increase during anaerobic metabolism (Saglio *et al.*, 1980; Menegus *et al.*, 1989). Also, ethanol may not be as toxic to plants as previously believed (Cronk and Fennessy, 2001) because when flooded, ethanol diffuses out of the roots and into the rooting medium where its toxicity is diluted (Summers *et al.*, 2000).

Davies (1980) suggested that short-term tolerance to anaerobic condition involves regulation of cellular pH to prevent cytoplasmic acidosis rather than accumulation of nontoxic compounds such as malate produced during anaerobic respiration. In plants, cytoplasmic acidosis occurs within minutes of the onset of anoxia as anaerobic metabolism kicks in and pyruvate is converted to lactic acid, leading to a decrease in cellular pH. In flood tolerant and intolerant plants, lactic acid is shunted to the vacuole, where it is isolated from the cytoplasm. In flood intolerant

plants such as maize, after a short period of time (10 h), acid leaks from the vacuole and acidifies the cytoplasm (Roberts, 1988). In flood tolerant species, lactic acid and other anaerobic respiration products are stored in vacuoles. Some data suggests that isolation of lactic acid in vacuoles may not be that important because, for some species, compounds such as succinate accumulate rather than lactic acid (Menegus *et al.*, 1989; Summers *et al.*, 2000).

HYDROLOGIC CONTROL OF PLANT DISTRIBUTION, PRODUCTIVITY, AND NUTRIENT CYCLING

Hydrology not only determines which plant species will survive and thrive in wetlands, it also determines their distribution within the wetland as well as their productivity and nutrient uptake characteristics. Plants vary in their tolerance to flooding and anoxic soil conditions, leading to their classification as obligate (OBL), facultative wet (FACW), facultative (FAC), facultative upland (FACU), or upland (UPL) species based on their degree of tolerance (Reed, 1988). Obligate species are highly tolerant of anoxic soils and, thus, are found in areas of long to continuous inundation within the wetland (Table 2). Upland species, in contrast, are intolerant of flooding and are, seldom if ever, found growing in wetlands (Table 2).

Species Distribution and Zonation

Within wetlands, vegetation frequently exhibits strong patterns of zonation that correspond to depth, duration, and/or frequency of inundation. For example, freshwater marsh vegetation exhibits striking patterns of zonation related to depth and duration of inundation (Figure 7) (Zedler, 1987; Kantrud *et al.*, 1989; Schalles and Shure, 1989). In deeper water where inundation is continuous, floating aquatic plants dominate. In shallower water where inundation is frequent and of long duration, herbaceous emergents (*Typha*) dominate. Hydrophytes tolerant of short hydroperiod and shallow flooding dominate along the wetland:upland boundary. Terrestrial vegetation dominates in unsaturated, aerobic soils above the upper limit of flooding.

Similar patterns of zonation are observed in forested wetlands. In floodplain forests of the southern US, areas of permanent inundation such as oxbows and abandoned river channels are dominated by bald cypress (*Taxodium distichum*) and tupelo gum (*Nyssa aquatica*) (*see* Figure 3 for example, Wharton *et al.*, 1982). Areas inundated by periodic overbank flooding are dominated by hardwoods such as black gum (*Nyssa sylvatica*), green ash (*Fraxinus pennsylvanicus*), and red maple (*Acer rubrum*). The highest, driest areas in the floodplain are dominated by species such as sweet gum (*Liquidambar styraciflua*) and sycamore (*Platanus occidentalis*) (Wharton *et al.*, 1982).

Plant Productivity

Hydroperiod, along with other factors such as salinity, pH, and nutrients, also determines plant productivity – the quantity of new leaves, wood, and roots produced per unit area and time. Odum *et al.* (1979) and others (Brinson *et al.*, 1981a; Odum *et al.*, 1995) suggested that periodic flooding subsidizes plant productivity by supplying nutrients to the wetland and removing toxins from the soil. Continuous flooding, however, acts as a stressor on vegetation by producing anoxic soil conditions that inhibit plant growth. The effects of inundation on plant productivity are best described by the subsidy-stress model (Odum *et al.*, 1979), which states that periodic inundation enhances

Table 2 Classification of plant species based on their frequency of occurrence in wetlands. Developed by Reed (1988) for US Fish and Wildlife Service

Indicator Status	Definition	Examples
Obligate (OBL)	Found in wetlands 99 times out of 100. (In uplands under natural conditions, is found less than once in 100 times.)	*Typha latifolia* (cattail), *Taxodium distichum* (bald cypress), many sedges (*Carex* spp. *Cyperus* spp.), and rushes (*Juncus* spp.)
Facultative wet (FACW)	Found in wetlands 67–99% of the time	*Fraxinus pennsylvanica* (green ash), *Quercus palustris* (pin oak), *Impatiens capensis* (jewel weed)
Facultative (FAC)	Found in wetlands 33–67% of the time. (Equally likely to be found in uplands.)	*Acer rubrum* (red maple), *Festuca rubra* (red fescue), *Ambrosia trifida* (ragweed)
Facultative upland (FACU)	Found in wetlands 1–33% of the time	*Liriodendron tulipifera* (tulip tree), *Cornus florida* (dogwood), *Prunus serotina* (black cherry)
Upland (UPL)	Found in wetlands <1% of the time	*Quercus prinus* (chestnut oak), *Pinus ponderosa* (ponderosa pine), *Zea mays* (corn)

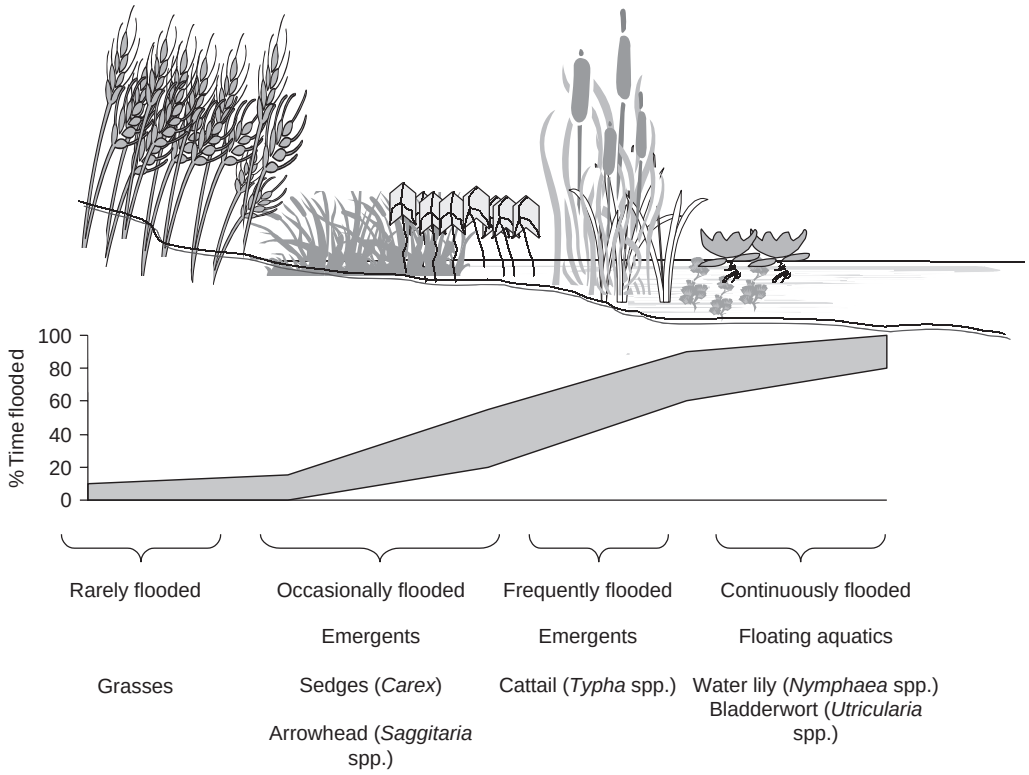

Figure 7 Relationship between zonation of plant species and hydroperiod in a freshwater marsh. (Reprinted with permissions from Brix, H (1993a). Macrophyte mediated oxygen transfer in wetlands: transport mechanisms and rates. plant growth, whereas continuous inundation or absence of inundation lead to reduced productivity (*see* Figure 8, for example). This hypothesis was developed to describe the high productivity frequently observed in tidal marshes and floodplain forests that are exposed to rhythmic inundation, ranging from twice daily inundation in salt mashes (Steever *et al.*, 1976) to annual inundation in floodplain forests (Broadfoot, 1967; Brinson *et al.*, 1981a). Mitsch and Rust (1984) refined the subsidy-stress model for alluvial floodplain forests by suggesting winter flooding is more beneficial to plant growth than summer flooding. According to this hypothesis, winter flooding provides a nutrient subsidy, but because the plants are dormant, anaerobic conditions caused by prolonged inundation do not stress the plant. Periodic flooding also may reduce stressors such as acidity by increasing soil pH through reduction of ferric (Fe^{3+}) iron to ferrous (Fe^{2+}) iron that consumes H^+ ions.

The subsidy-stress hypothesis of wetland plant production is supported by comparison of bald cypress (*Taxodium distichum*) productivity along a hydroperiod gradient from well drained to stagnant (standing water) hydrology. Cypress growth is greatest at intermediate (periodically inundated) hydroperiod as compared to well-drained or continuously flooded soils (Figure 8, Conner and Day, 1976, 1982; Mitsch and Ewel, 1979; Taylor *et al.*, 1990). A

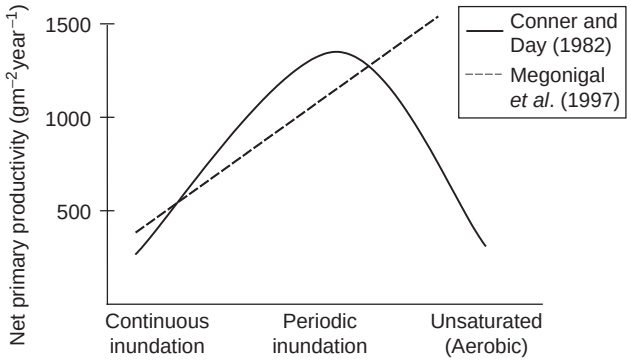

Figure 8 Relationship between aboveground net primary production and hydroperiod of floodplain swamp forest vegetation

recent study by Megonigal *et al.* (1997), however, found that growth was greatest in well-drained floodplain soils and decreased with increasing hydroperiod and anoxic conditions (Figure 8). Thus, the results of this study suggest that the stress caused by soil anoxia may be greater than the "subsidy" of nutrients provided by flooding.

Primary production also depends on hydrodynamics, especially water, and nutrient loads. Loading rate, the

quantity of nutrients that pass through the wetland, depends on the quantity of water and concentration of nutrients in water that flows across the wetland. Catchment size, land use in the watershed and connectivity to flowing aquatic ecosystems such as rivers and estuaries determine loading rates. Floodplain forests and tidal marshes have strong connectivity to aquatic ecosystems. The high productivity ascribed to tidal marshes, mangrove forests, and floodplain forests is attributed, in part, to greater water and nutrient inputs; that is, the subsidy part of the subsidy-stress hypothesis (Lugo and Snedaker, 1974; Gosselink and Turner, 1978; Mitsch *et al.*, 1979, 1991; Odum, 1980; Brinson *et al.*, 1981a,b; Hopkinson, 1992). Brown (1981), for example, observed a positive relationship between bald cypress production and phosphorus load in cypress swamps that varied from low precipitation-driven, low nutrient cypress domes to highly enriched cypress swamps receiving wastewater. Wetlands that lack connectivity include bogs and depressional wetlands, where precipitation is the primary water source. Plant productivity of these wetlands often is low relative to wetlands with strong connections (Moore and Bellamy, 1974; Craft, 2001).

Nutrient Cycling

Increased nutrient loadings associated with greater connectivity also accelerate nutrient cycling by vegetation. As nutrient loading increases, wetland vegetation assimilates more nutrients. However, the efficiency of assimilation decreases and the wetland becomes "leaky" with respect to nutrient retention. Comparison of phosphorus cycling between low connectivity cypress dome and high connectivity floodplain bald cypress swamps illustrates this point (Table 3). In the floodplain cypress swamp, greater connectivity from river flooding resulted in water and P loadings that were 32 and 140 times greater, respectively, than in than the low connectivity, precipitation-driven cypress dome.

Net primary production of the floodplain cypress swamp was 2.5 times greater than in the cypress dome and P uptake by vegetation was 3 times greater in the floodplain swamp ($1.22\,g\,m^{-2}\,yr^{-1}$) than in the cypress dome ($0.41\,g\,m^{-2}\,yr^{-1}$). The low connectivity cypress dome was highly efficient with respect to P cycling. Nearly half (44%) of the P taken up annually by vegetation was translocated belowground at the end of the growing season to be used the following growing season. In contrast, in the high connectivity floodplain swamp, only 25% of the P taken up each year was translocated belowground. The remaining 75% of P was lost to senescence and leaching, indicative of the "leakiness" of this highly connected, high nutrient (P) loaded system.

Hydrology-based Classification System for Wetlands

Recognition of the importance of hydrology to wetland nutrient and carbon cycles led to the development of a hydrology-based classification system for wetlands. The hydrogeomorphic (HGM) approach was developed by Brinson (1993) and others (Hauer and Smith, 1998) to assess hydrologic, biogeochemical, and habitat functions of wetlands. Using the HGM approach, wetlands are classified based on their geomorphic setting, dominant water source, and dominant hydrodynamics (Table 4). For example, an important function of wetlands is their ability to improve

Table 3 Carbon and phosphorus cycling characteristics of a low connectivity (Okefenokee GA) and a high connectivity (Cache River IL) cypress (*Taxodium distichum*) swamp forest (Data from Mitsch *et al.*, 1979 and Hopkinson *et al.*, 1992)

	Okefenokee GA (low connectivity)	Cache River IL (high connectivity)
Hydrology:		
Water source	Precipitation	River flooding
Hydrologic input	$170\,cm\,yr^{-1}$	$5500\,cm\,yr^{-1}$[a]
Nutrient input	Low ($0.57\,g\,P\,m^{-2}\,yr^{-1}$)	High ($80\,g\,P\,m^{-2}\,yr^{-1}$)[b]
Carbon Cycling:		
Aboveground biomass ($kg\,C\,m^{-2}$)	13.8	16.7
Net primary production ($g\,C\,m^{-2}\,yr^{-1}$)	311	801
Phosphorus Cycling:		
Uptake ($g\,P\,m^{-2}\,yr^{-1}$)	0.41	1.22
Aboveground storage ($g\,P\,m^{-2}$)	4.6	6.3
Translocation belowground (%)[c]	0.18 (44%)	0.31 (25%)
Senescence & Death (%)[c]	0.16 (39%)	0.77 (63%)
Loss to leaching (%)[c]	0.07 (17%)	0.14 (12%)
Retention in vegetation ($\%\,yr^{-1}$)[d]	72%	1.5%[e]

[a]Surface flooding accounts for $5300\,cm\,yr^{-1}$.
[b]$3.6\,g\,P\,m^{-2}\,yr^{-1}$ were retained in the wetland.
[c]Percent of annual uptake.
[d]Percent of nutrient input to wetland.
[e]34% of the P retained in the wetland ($3.6\,g\,m^{-2}\,yr^{-1}$) was retained in vegetation.

Table 4 Hydrogeomorphic (HGM) classification system for wetlands to assess ecological functions such as water storage, pollutant removal, and habitat (From Brinson, 1993). With respect to the ecological function *pollutant removal*, wetlands characterized by lateral surface flow have greater capacity to trap sediment than precipitation or groundwater fed wetlands

Geomorphic setting	Water Source	Hydrodynamics	Wetland type	Ecological function (sediment removal)
Depressional	precipitation	vertical	prairie potholes, vernal pools	low
Mineral soil flats	precipitation	vertical	wet pine flats	low
Organic soil flats	precipitation	vertical	peat bogs	low
Riverine	surface water	unidirectional, lateral	floodplain forests	high-very high
Estuarine fringe	surface water	bidirectional, lateral	salt marshes, mangroves	medium-high
Lacustrine fringe	surface water	bidirectional, lateral	Great lakes marshes	medium-high
Slope	groundwater	unidirectional lateral	fens, seepage wetlands	low

or maintain water quality by trapping sediment and pollutants. Highly connected wetlands such as floodplain forests have great potential for trapping sediment because of the high loadings of water and sediment during overbank flooding. Based on the HGM classification system, riverine, and fringe wetlands have greater potential to remove sediments than organic soil flats (peat bogs) or depressional wetlands that receive water mostly from precipitation (Table 4). Conversely, peat bogs have greater potential to sequester carbon through peat accretion, an important ecological function that absorbs atmospheric carbon dioxide, as compared to wetlands in other hydrogeomorphic settings.

CONSTRUCTED WETLANDS

Constructed wetlands are designed and built for water quality remediation and to replace wetland dependent functions lost when natural wetlands are destroyed. The ability of natural wetlands to filter or purify water has led to the construction of wetlands to treat wastewater, stormwater, mine drainage, animal waste, nonpoint runoff from agricultural lands and other sources (Hammer, 1989; Moshiri, 1993; Dubowy and Reaves, 1994; Kadlec and Knight, 1996; Pries, 2002). "Treatment" wetlands have been constructed throughout Europe, the United States and elsewhere to treat wastewater by removing suspended solids, coliform bacteria, BOD, and nutrients (N, P) (Vymazal *et al.*, 1998; Vymazal, 2001; Pries, 2002). In some instances, constructed wetlands are used to "polish" secondarily treated wastewater by removing nutrients (Kadlec and Knight, 1996; Vymazal *et al.*, 1998).

In the past 20 years, wetlands have been created and restored to mitigate for ecological functions (i.e. hydrologic, biological productivity, biogeochemical cycling, habitat) lost when natural wetlands are degraded or destroyed by human activities such as drainage and placement of fill in wetlands (Zelazny and Feierabend, 1988; NRC, 1992). Although laws have been implemented to protect wetlands from these activities, wetlands continue to be lost as a result of numerous small-scale actions that frequently are exempt from regulations designed to protect them (NRC (2001)).

Treatment Wetlands

Treatment wetlands consist of cells containing various planting substrates (pea gravel, sand, muck) planted with fast-growing hydrophytic vegetation. The type of planting substrate depends on whether the system is constructed for surface flow or subsurface flow (Figure 9). Hydrophytic vegetation is planted to provide oxygen to the rooting zone to enhance decomposition (Wolverton *et al.*, 1983; Brix, 1993a) and nitrification (Reddy *et al.*, 1989) and to stabilize the hydraulic conductivity of the soil (Brix, 1993b). Vegetation with high growth rates and that oxygenate the rooting zone are most often employed in treatment wetlands. Construction of treatment wetlands requires precise knowledge of water and nutrient loadings in order to size them appropriately. Water depths need to be shallow enough so that emergent vegetation is not submerged and drowned, but hydrologic retention times need to be long enough to filter and remove incoming pollutants.

Treatment wetlands utilize a variety of hydrophytic vegetation, including free floating, floating leaved, submersed, and emergent plants. Free-floating vegetation systems employ water hyacinth (*Eichhornia crassipes*), duckweed (*Lemna* spp), water lettuce (*Pistia stratiotes*), or pennywort (*Hydrocotyle umbellata*) (Figure 9a). These plants have very high rates of growth and nutrient uptake (Reddy,

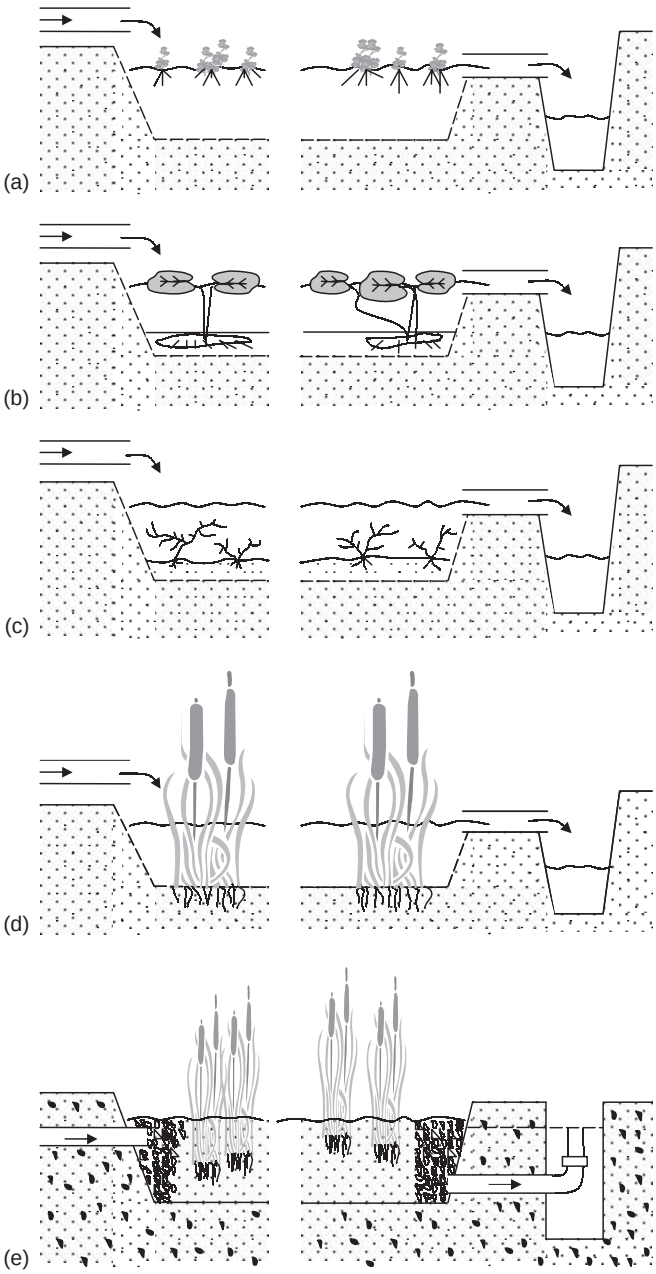

Figure 9 Design of (a) free floating, (b) floating leaved, (c) submersed, (d) surface flow and (e) subsurface flow treatment wetlands. Modified from Brix (1993b) (Reprinted with permissions from Brix, H (1993b). Wastewater treatment in constructed wetlands: system design, removal processes and treatment performance. In *Constructed Wetlands for Water Quality Improvement*, Moshiri G.A. (Ed.), Lewis Publishers: Boca Raton, pp. 9–22. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

1983) and, with periodic harvesting of plant biomass, N and P removal rates are high. Free-floating treatment systems vegetated with water hyacinth are limited to tropical and subtropical regions because of frost damage and reduced plant growth at temperatures below 10 °C (Vymazal, 1998). Systems vegetated with duckweed, which is more tolerant of cold temperatures, have been constructed in temperate regions (Brix, 1993b).

Floating leaved treatment wetlands rely on plants such as water lily (*Nymphaea* spp.), cow lily (*Nuphar lutea*), and lotus (*Nelumbo nucifera*) that are rooted in the substrate and whose leaves float on the surface (Figure 9b). These systems are not widely used because plant growth is less vigorous as compared to other hydrophytes. Treatment wetlands that rely on submersed vegetation also have been constructed (Figure 9c) but, like floating leaved wetlands, are not widely employed. These wetland systems are planted with waterweed (*Elodea* spp.), coontail (*Ceratophyllum* spp.), pondweed (*Potamogeton* spp.), hydrilla (*Hydrilla verticillata*), milfoil (*Myriophyllum heterophyllum*). Submersed vegetation needs high clarity, well-oxygenated water, so these systems are used to "polish" wastewater following primary (physical settling) and secondary treatment (microbial breakdown of organic matter) (Brix, 1993b).

Wetlands planted with emergent vegetation are the most common treatment wetlands. Fast-growing cosmopolitan species such as *Phragmites communis, Typha* spp., *Scirpus* spp., and *Juncus* spp. are usually planted in them. These species are widely distributed, possess high growth rates and are proficient at oxygenating the root zone (Gersberg *et al.*, 1986). Two types of emergent-based treatment wetlands are employed; surface flow or "free water" systems and subsurface flow systems (Figures 9d and e). In surface flow wetlands, water flows across the vegetated surface. Suspended solids settle out the under the low flow, quiescent conditions. Biochemical oxygen demand (BOD) is reduced by aerobic and anaerobic microbial decomposition. Nitrogen is removed by nitrification in aerobic surface waters followed by denitrification in the anaerobic soils (Wolverton *et al.*, 1983; Brix, 1993b; Hunt *et al.*, 2003). Removal of phosphorus in treatment wetlands is low relative to N and is controlled by sorption and precipitation with Al in acid soils and Ca in circumneutral soils (Reddy, 1983; Richardson and Craft, 1993). Uptake and storage of nutrients in plants represents a temporary sink for N and P because when vegetation senesces and dies, N and P are released back into the water column. Permanent storage of N and P occurs by accumulation of organic matter in soil, sorption, and precipitation with minerals (P) and removal from the system by denitrification (N).

In subsurface flow wetlands, wastewater moves either laterally (Figure 9e) or vertically through the soil or planting substrate. The substrate of subsurface flow wetlands is composed of gravel or crushed stone to maintain high hydraulic conductivity and reduce clogging with suspended solids. Subsurface flow treatment wetlands are widely used throughout Europe. These treatment wetlands are

Table 5 Mean removal efficiencies of surface flow and subsurface flow constructed data are from the North America database of constructed wetlands in Table 26–4 of Kadlec and Knight (1996)

	Concentration ($mg\,L^{-1}$)			Mass ($kg\,ha^{-1}\,day^{-1}$)

also referred to as "reed bed treatment systems" because common reed (*Phragmites communis*) frequently is planted. Advantages of subsurface flow systems over surface flow wetlands include even distribution and rate of flow through the system, reduced breeding opportunities for mosquitoes and less nuisance odor problems (Kadlec and Knight, 1996). However, subsurface flow systems are more susceptible to clogging than surface flow wetlands (Kadlec and Knight, 1996) and also are less effective at N removal because of insufficient oxygen supplied by the roots to support nitrification (Brix, 1993b).

Comparison of nutrient removal efficiencies for North American surface flow and subsurface flow treatment wetlands are shown in Table 5. Generally, removal efficiencies for most wastewater constituents are similar for both types of wetlands. However, NH_4–N removal is greater for surface flow wetlands owing to greater nitrification in surface waters. Phosphorus removal is low (<50%) in both surface flow and subsurface flow wetlands primarily because of limited sorption in the sand or gravel planting substrate.

Hybrid systems employing subsurface horizontal and vertical flow wetlands in a series of cells have been developed to achieve higher treatment efficiency (Brix, 1993b). In these hybrid systems, wastewater first enters a subsurface vertical flow wetland where suspended solids and BOD are removed. It then flows into a subsurface vertical flow wetland cell where ammonium is nitrified to nitrate. The terminal cell consists of a subsurface horizontal flow wetland where nitrate is denitrified. Some systems are designed such that if nitrogen removal is incomplete, wastewater is recycled back to the first cell and treated again.

Mitigation Wetlands

In recent years, wetlands have been created and restored to replace ecological functions such as hydrologic storage and recharge, biological productivity, biodiversity, carbon sequestration, and water quality remediation that are lost when natural wetlands are degraded or destroyed by human activities. Mitigation for wetland loss is required under US Federal law as set forth in Section 404 of the Clean Water Act (NRC, 1992, 2001) and mitigation wetlands must be of the same type as the natural wetlands that they replace. For example, if a bottomland hardwood forest is drained and converted to upland habitat, then the law requires that the mitigation wetland is of similar habitat, for example, bottomland hardwood forest. Because mitigation wetlands frequently provide a lower level of function than natural wetlands, the amount of wetland acreage created or restored often is greater than the acreage lost (NRC, 2001). A ratio of up to 5:1 of mitigation to natural wetland is used for impacts to endangered species habitat (NRC, 2001).

Studies of mitigation wetlands revealed that development of ecological functions does not occur instantaneously. Wetlands with predictable hydroperiod or emergent vegetation develop faster than those with less predictable hydroperiod or woody vegetation. For example, development of wetland dependent functions proceeds faster on constructed salt marshes where tidal inundation is predictable and frequent

Table 6 Plant biomass, soil properties, microbial processes, and benthic infauna community composition of constructed *Spartina alterniflora* salt marshes versus natural salt marshes. Values separated by the same letter (**in bold**) are not significantly different ($p = 0.05$) based on pair-wise *t*-tests Data are from Craft *et al.* (2003) and unpublished data (methane production, denitrification)

than on isolated wetlands where hydroperiod is less predictable (Campbell *et al.*, 2002; Craft *et al.*, 2002; NRC, 2001). Similarly, wetlands dominated by emergent vegetation develop faster than forested wetlands because it takes a long time to grow a mature forest (Niswander and Mitsch, 1995; NRC, 2001). Even in mitigation salt marshes, some components of the ecosystem, such as soil organic matter and heterotrophic food webs, may take 25 years or more to develop (Craft and Sacco, 2003; Craft *et al.*, 2003).

Biomass of emergent vegetation in young (1–3-year-old) constructed salt marshes is less than in older (24–28-year-old) constructed marshes and natural marshes (Table 6). Microbial processes are reduced in young constructed marshes and, density and diversity of benthic infauna (invertebrates) is lower than in older constructed marshes and natural marshes. Even after 28 years, standing stocks of soil organic C and N are significantly less in constructed marshes as compared to natural marshes (Table 6). In constructed salt marshes, development of heterotrophic activity (microbial processes, benthic infauna) depends on accumulation of soil organic matter that is driven, by inputs of organic matter from the developing plant community and by anaerobic soil conditions brought on by frequent tidal inundation that slows or inhibits decomposition of organic matter (Craft *et al.*, 2002)

In some cases, mitigation wetlands never achieve functional equivalence to natural wetlands, because of inadequate hydrologic restoration (Galatowitsch and van der Valk, 1996; Magee *et al.*, 1999; Cole and Brooks, 2000; Brown and Veneman, 2001), initial soil characteristics such as low organic matter or nutrients (N) (Langis *et al.*, 1991; Shaffer and Ernst, 1999) or land use changes in the watershed that alter water, sediment, and contaminant loadings and facilitate invasion by exotic species (NRC, 1992; Zedler and Callaway, 1999).

Successful replacement of wetland dependent functions using mitigation wetlands requires that, in addition to recreating hydrologic conditions, soil characteristics, and plant communities of the natural wetland, one also must reestablish energy flows and nutrient cycles that link wetlands with aquatic and terrestrial ecosystems, a goal that is increasingly difficult to achieve in a world increasingly altered by human activities.

108: Lake Ecosystems (Stratification and Seasonal Mixing Processes, Pelagic and Benthic Coupling)

DARREN L BADE

Center for Limnology, University of Wisconsin, Madison, WI, US

Seasonal stratification in lakes is caused by the differential heating of surface waters, causing them to become less dense and buoyant above colder, denser water. Other forces oppose stratification, including wind energy and loss of heat from the surface. Wind imparts many types of motions to lake waters, each having distinct patterns, energy, and scales of mixing. Theoretical considerations are presented in detail on the expected response of lakes to physical forcing. In addition, empirical equations are given for diverse regions of the world to predict epilimnetic and thermocline depth and timing of stratification. Lake morphometry along with climatic conditions determines the depth of epilimnetic mixing. The seasonal patterns of mixing and stratification are observed in a northern temperate lake (Sparkling Lake, Wisconsin, USA). The influence of stratification and mixing on the coupling of benthic and pelagic zones through processes of sedimentation, resuspension, eddy diffusivity, and hypolimnetic entrainment are discussed. Through these mechanisms, the hydrodynamics of lakes directly and indirectly influence the chemical and biological environment of lake ecosystems.

INTRODUCTION

Lake ecosystems are highly controlled by external physical forcing. Forces such as wind can cause mixing of water within lakes. Opposing the forces of mixing are the buoyant forces created by vertical density differences in the water column. Temperature and salinity both influence the density of water. If the buoyant force of the water exceeds the antagonistic forces causing mixing, a lake becomes stratified. Both mixing and stratification affect the distribution of nutrients, particulates, and biota within the water column of lakes.

Under conditions of stratification, the bottom waters can be in effect "sealed off" from surface water as vertical transport of dissolved substances is greatly reduced. Thus, oxygen diffuses only slowly into bottom waters, and only a small portion of nutrients released in the bottom waters diffuse into surface waters. These are just two examples where stratification limits the coupling between the benthic and pelagic areas of lakes. Mixing processes tend to increase this coupling by resupplying materials that may have been lost during stratification. Lake mixing patterns determine the strength of coupling between benthic and pelagic materials and processes. This strength of coupling may lead to differences in the levels of metabolism and secondary productivity. Most of these functional differences are manifest in the cycling of nutrients, but they also lead to variations in aquatic biota (Carpenter, 2003) (*see* **Chapter 96, Nutrient Cycling, Volume 3**; **Chapter 102, Trophic Dynamics, Volume 3**). In an extreme case, lakes that do not experience seasonal patterns of stratification cycle phosphorus in ways that are fundamentally different from those of lakes that do experience stratification.

Because physical forces are usually exerted at the lake surface, lake morphology (e.g. fetch, depth, etc.) constrains many of the mixing and stratification patterns of a lake. Another factor, regional climate, determines wind and heat fluxes, and is perhaps more interesting because of temporal dynamics. Therefore, understanding physical processes and their impact on chemical and biotic factors has timely relevance to the concern over the impact of global climate

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

change on lakes (McKnight *et al.*, 1996; Magnuson *et al.*, 2000). Changes in physical forcing of climate may impact lake ecosystem productivity (O'Reilly *et al.*, 2003) and viability of aquatic species (Shuter and Lester, 2004).

This chapter will review the conditions and properties of (i) **stratification** and (ii) **mixing**, and then consider (iii) **mixing patterns** and (iv) their influence on **benthic and pelagic coupling.** The goal is to provide a basic understanding of how physical processes within lakes affect chemical and biological processes. Understanding the physics of stratification and mixing and its relationship to pelagic-benthic coupling is needed for the conceptualization of how lake ecosystems function and respond to change.

STRATIFICATION

Vertical stratification of a lake develops because of the density differences between surface and bottom waters. These density differences can be caused by physical, chemical, or biological processes. The warming of surface waters that become buoyant above colder, deeper water represents the most common form of stratification. The introduction of water with salinities different from those of the lake can also impart stratification. Finally, the production of salts by the biological processes of decomposition can also create density differences, thereby stratifying lakes (Wetzel, 1973).

The density of water is related to temperature in a nonlinear fashion (Figure 1). The density of water is maximum at approximately 3.98 °C. Between the freezing point and 3.98 °C, density increases slightly, and above 3.98 °C density decreases. Therefore, it is possible for stratification to exist with warm water overlying cold water (for water >3.98 °C), or cold water above warmer water (for water <3.98 °C).

The density of water ρ^P(g cm^{-3}) for an applied pressure P(bar) is a function of temperature T (°C) and salinity S (grams of salt per kg of water), and has the form (Chen and Millero, 1986):

$$\rho^P = \rho^0 \left(\frac{1-P}{K}\right)^{-1} \tag{1}$$

where ρ^0 is the density at sea level

$$\begin{aligned}\rho^0 = {} & 0.9998395 + 6.7914 \times 10^{-5} T \\ & - 9.0894 \times 10^{-6} T^2 + 1.0171 \times 10^{-7} T^3 \\ & - 1.2846 \times 10^{-9} T^4 + 1.1592 \times 10^{-11} T^5 \\ & - 5.0125 \times 10^{-14} T^6 \\ & + (8.181 \times 10^{-4} - 3.85 \times 10^{-6} T + 4.96 \times 10^{-8} T^2) S\end{aligned} \tag{2}$$

and K (bar) is

$$\begin{aligned}K = {} & 19652.17 + 148.113T \\ & - 2.293T^2 + 1.256 \times 10^{-2} T^3 \\ & - 4.18 \times 10^{-5} T^4 \\ & + (3.2726 - 2.147 \times 10^{-4} T + 1.128 \times 10^{-4} T^2) P \\ & + (53.238 - 0.313T + 5.728 \times 10^{-3} P) S\end{aligned} \tag{3}$$

Because of the nonlinear relationship, a 1 °C difference in water temperature creates a larger difference in density in warmer water than in colder water, for $T > 4$ °C. This has important implications for the development of stratification. Though the buoyant forces could potentially cause stratification in either case, stratification would be more stable in the case of the warmer water. In addition, the amount of kinetic energy needed to disrupt stratification increases as the temperature gradient increases between water layers.

The largest flux of heat in lakes is through the surface, except for lakes with large volumes of inflowing or outflowing water. The heat flux is the balance of net radiation, latent heat of evaporation, and sensible heat exchange (Ragotzkie, 1978). The flux of heat H^* (W m^{-2}) creates a buoyancy flux B (m^2 s^{-3}),

$$B = \frac{\alpha g H^*}{C_p \rho_w} \tag{4}$$

where α is the coefficient of thermal expansion (°C^{-1}), g is the gravitational acceleration (m s^{-2}), C_p is the specific heat of water (J kg^{-1} °C^{-1}), and ρ_w is the density of water (kg m^{-3}). When heat is gained at the surface of a lake, potential energy is gained. Loss of heat from the surface causes potential energy to be converted to kinetic

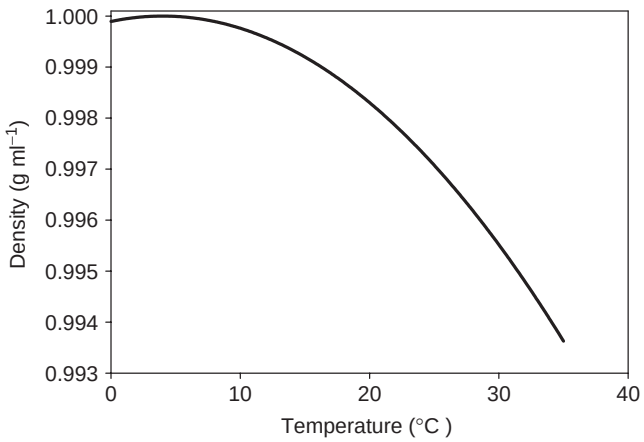

Figure 1 An example of the density change of water as a function of temperature

energy, creating convection (discussed further in section on Mixing).

The amount of work required to mix the entire water column of a stratified lake without the addition or removal of heat is the thermal stability (S).

$$S_t = \frac{g}{A_o} \int_{z_o}^{z_{max}} (\rho_z - \rho_m)(z - z_g) A_z \, dz \qquad (5)$$

where S_t = thermal stability ($J\,m^{-2}$), g = gravitational acceleration ($m\,s^{-2}$), A_o = surface area of the lake (m^{-2}), z = depth (m), z_o = surface of the lake, z_{max} = maximum depth, A_z = area at depth z, z_g = depth of the center of gravity if the water column was fully mixed, ρ_z = density ($kg\,m^{-3}$) at depth z, and ρ_m = mean density or the value of ρ at z_g (Idso, 1973). From equation (2), the importance of lake morphometry for thermal stratification becomes obvious. In order for a lake to thermally stratify, the environmental conditions must add heat to create stability. If the lake is shallow, only a small amount of energy is needed to mix the entire water column and stratification will be transient or nonexistent. The fetch of a lake (length of the lake in the direction of the wind) determines the amount of wind energy that is available for turbulent mixing. Therefore seasonal stratification in large lakes generally requires the lake to be relatively deep.

The interdependence of lake size and depth on thermal stratification was described empirically by Lathrop and Lillie (1980) and further explained by Gorham and Boyce (1989). The latter study determined theoretically a threshold depth which the lake's maximum depth z_{max} (m) must exceed for seasonal stratification to exist at the time of maximum heat content. This threshold,

$$z_{max} > 3.4 \left(\frac{\tau}{g \Delta\rho} \right)^{0.5} F^{0.5} \qquad (6)$$

shows a similar dependence with fetch F (m) as was found empirically ($z_{max} > 0.34 F^{0.5}$) for northern temperate lakes of Minnesota, Poland, and Ontario. In the above equation, the value in parentheses is related to the depth scale (m) of turbulent forces into buoyant fluid, where τ represents wind shear stress (described below), g, the acceleration due to gravity and $\Delta\rho$ the density jump between layers.

The timing of the onset of stratification in lakes is not only a function of lake morphometric characteristics, but is also dependent on local temperature. For 70 temperate and subtropical lakes of the Northern Hemisphere, Demers and Kalff (1993) empirically derived two equations to determine the onset of stratification using mean annual air temperature and the surface area to mean depth ratio (R). The first, for lakes that experience a period of ice cover, is

$$\text{Day of year} = 160 - 5.14 \times T + 5.74 \times \log(R) \qquad (7)$$

and the second, for lakes without ice cover, is

$$\text{Day of year} = 123 - 3.429 \times T + 20.636 \times \log(R) \qquad (8)$$

Some outliners from these models include lakes located in wind-protected valleys (e.g. Lake Zurich and Lake Ikeda) that attain stratification much earlier than predicted by equations (7) and (8) (Figure 2). Extremely large lakes (e.g. Lake Michigan and Lake Baikal) that experience extreme cooling before ice cover require larger inputs of heat to reach the point of thermal stratification. Finally, coastal lakes (e.g. Lake Washington) may experience greater wind stresses and less variation about the mean temperature and therefore stratify later than expected from these regressions.

The classic view of lake stratification often depicts three distinct vertical zones (Figure 3). The upper mixed layer, known as the *epilimnion*, is marked by temperatures that vary little over depth ($\delta T/\delta z \cong 0$). Below the epilimnion is a zone of transition known as the *metalimnion*. Here temperatures rapidly decrease from the warm epilimnion to the cooler bottom waters of the hypolimnion. This zone can be defined as the area where $\delta^2 T/\delta z^2$ varies from maximum to minimum. The thermocline is marked as a plane at the depth of maximum temperature change ($\delta T/\delta z \cong \min$; $\delta^2 T/\delta z^2 = 0$) (Hutchinson, 1957). Below the metalimnion lies the hypolimnion, which also shows little change in temperature with depth ($\delta T/\delta z \cong 0$). More comprehensive views of lake stratification illustrate additional complexity. First, the epilimnion is not always a well-mixed layer, as secondary stratification may develop

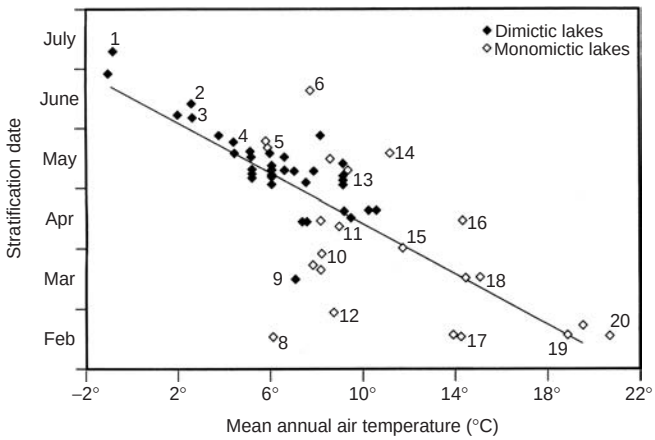

Figure 2 Relationship between mean annual air temperature and date of onset of stratification for 70 north temperate zone lakes. Identified lakes referenced in the text: 1)Baikal, Russia; 6) Michigan, USA; 8)Ikeda, Japan; 12)Zurich, Switzerland; 14) Washington, USA. (Kalff, J. Limnology, 1st Edition, ©2002. Reprinted by permission of Pearson Education, Inc., Upper Saddle River, NJ)

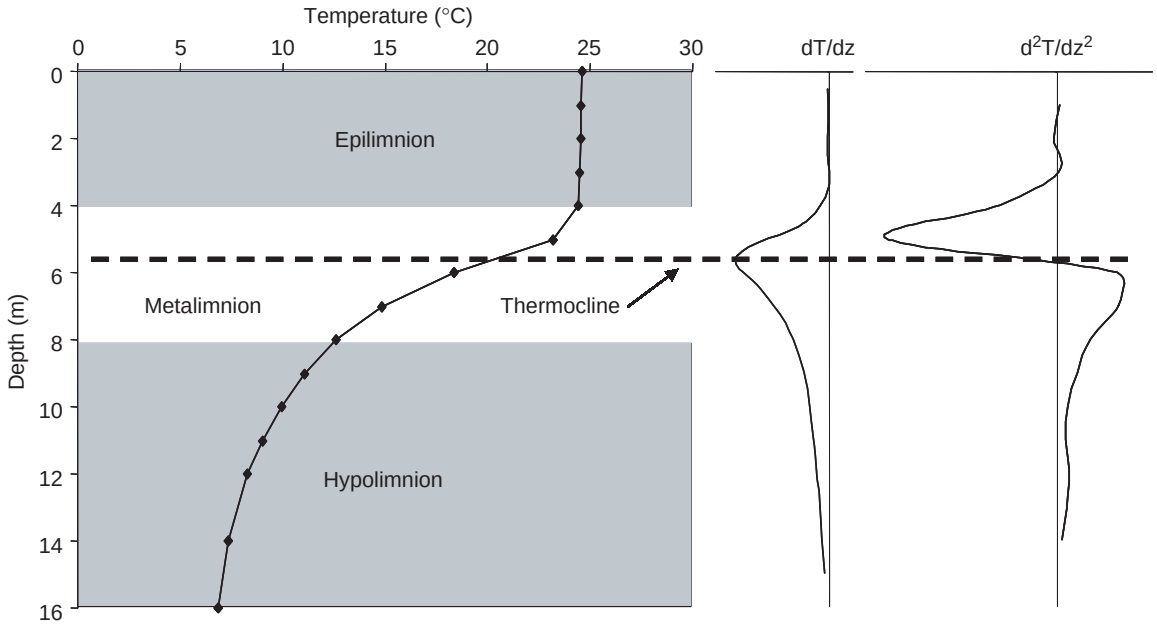

Figure 3 Typical midsummer temperature profile of Sparkling Lake, Wisconsin. Profiles of dT/dz and d^2T/dz^2 are used to determine the thermocline and extent of the metalimnion

in this zone. Diurnal thermoclines may develop with daytime heating and be broken down during evening cooling. Several thermoclines may exist above the deeper seasonal thermocline (Imberger, 1985). The hypolimnion, often thought of as quiescent, contains areas of mixing near the lake bottom. The turbulence in the benthic boundary layer creates important sites for flux of materials (Eckert *et al.*, 2002).

Not all lakes develop these three distinct zonations. Some lakes, where the ratio of epilimnion depth to maximum depth is between 0.5 and 1, may only have an epilimnion and metalimnion. Few lakes with stable stratification have been observed with thermocline depths greater than 70% of the maximum depth (Patalas, 1984; Gorham and Boyce, 1989). Turbulence caused in the benthic boundary layers inhibits the formation of a stable hypolimnion when the mixed layers become this deep.

Because the physical separation of water masses, which occurs when lakes stratify, is important to lake ecosystem function, numerous studies have been conducted to determine the depth of the epilimnion or the thermocline. Hanna (1990) presents an evaluation of many empirical models created for lakes from various temperate parts of the world. Most of these models follow some form of power law relating fetch or area to epilimnion or thermocline depth. In general, they explain a reasonable amount of variation in the response variable. Although these models yield a good first approximation to the mixing depth of many lakes, they should be used with caution, preferably within the limits of the geographical and morphological constraints of the source data. One notable exception to the general relationships is the relatively shallow mixing depths of the Laurentian Great Lakes, given their large surface area. As the Coriolis effect has greater relative influence on water movements in large lakes (see next section on Mixing), mixing by internal seiches may be dampened (Gorham and Boyce, 1989). The large lakes of Africa follow more closely a power law relationship between fetch and mixing depth (Kling, 1988). These lakes are less affected by Coriolis because of their proximity to the equator.

Much attention in limnological research is focused on temperate lakes of the Northern Hemisphere. Lakes in subtropical and tropical regions, however, do not fit the general patterns of temperate lakes. In addition, temperate lakes of the Southern Hemisphere are more influenced by coastal patterns because large landmasses that contribute to the continental climate in the Northern Hemisphere are far larger than in the Southern Hemisphere. Table 1 presents models predicting thermocline depth from diverse regions of the world.

Since thermal stratification is dependent upon heat absorption, differences in the vertical attenuation coefficient of solar radiant energy K_E (Kirk, 1983) should influence thermocline depths (Hocking and Straškraba, 1999). Turbidity, biological particulates, and dissolved colored material (e.g. colored dissolved organic carbon) increase K_E and therefore significantly influence the mixed layer depth (Mazumder and Taylor, 1994; Fee *et al.*, 1996; Xenopoulos and Schindler, 2001). Increased water clarity results in increased thermocline depth, after the effect of area

Table 1 Models predicting thermocline depth or mixed layer/epilimnion depth (meters) for lakes in different regions. Thermocline depth (Z_t), epilimnion depth (E_d), fetch (F), area (A), maximum effective length (MEL), maximum effective width (MEW), effective length (EL), maximum depth (Z_{max}), volume (V), maximum length (ML), maximum width (MW). Expanded from Hanna (1990)

has been accounted for by regression (Figure 4). Although variable, the pattern of decreasing mixed layer depth with increasing K_E is most prevalent in smaller lakes where wind mixing is less important (Fee *et al.*, 1996). Similar responses in thermocline depth have been noted in individual lakes that experienced changes in water clarity due to experimental or management manipulations (Edmundson and Lehman, 1981; Yan, 1983; Fee *et al.*, 1996).

Variables that represent geography, morphometry, and water clarity can predict thermocline depths in lakes. Generally, however, 20–30% of variance is unexplained in these models, likely attributable to local climatic conditions. The variation due to climate does not affect all lakes equally. For example, the thermal structure of clear lakes during abnormally warm years changed, while colored lakes tended to be more stable (Snucins and Gunn, 2000).

Apart from empirically based models, process-based models are often used to simulate the lake thermal structure. These models require the input of extensive meteorological data, but in turn can simulate vertical zonations of temperatures quite accurately with little or no parameterization. DYRESM (Dynamic Reservoir Simulation Model; **`http://www2.cwr.uwa.edu.au/~ttfadmin/model/dyresm1d/`**) is one example of this type of model (Imberger *et al.*, 1978; Spigel and Imberger, 1980). DYRESM is a one-dimensional numerical model that accounts for the budget of turbulent kinetic energy in the surface mixed layer to determine the depth of mixing that is countered

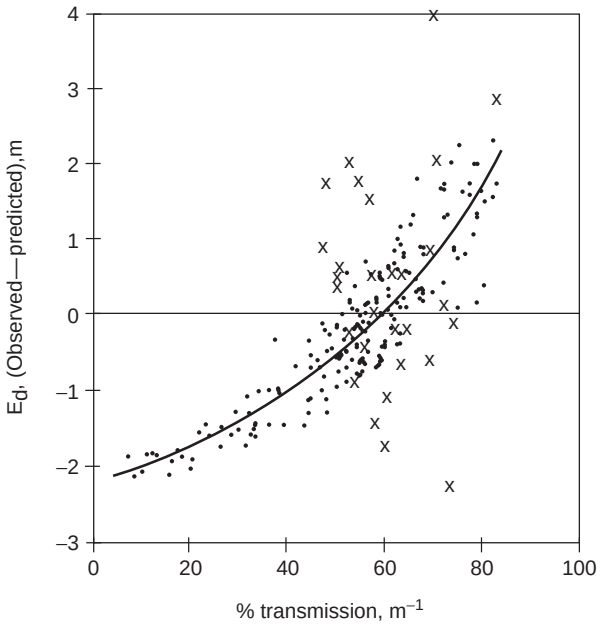

Figure 4 The residuals of a linear regression of lake size on mixing depth versus percent transmission of light within the lake. Lakes <500 ha – •; larger lakes – x. The curve is a least squares fit for lakes <500 ha [$-3 + 0.80$ * $\exp(0.022 T_{\%})$, $r^2 = 0.87$, $n = 186$ (Reproduced from Fee *et al.*. 1996; © 1996 by the American Society of Limnology and Oceanography, Inc.)

by buoyant forces. A recent update has created a pseudo two-dimensional model that accounts for internal and benthic boundary-layer mixing and has been tested on lakes ranging in size from 3.6 to 4800 ha (Yeates and Imberger, 2003). DYRESM often forms the basis for other water quality models (Hamilton and Schladow, 1997). The model is applicable to small to medium size lakes and reservoirs because these systems are more amenable to the assumptions necessary for one-dimensional modeling.

MIXING

The two main forces that contribute to the physical mixing of lakes are wind and the loss of heat from the surface. These forces impart kinetic energy and create several types of organized water movements. Over time, length scales of these water movements cascade into smaller and smaller eddies until they become turbulent kinetic energy (TKE) and dissipate into heat due to viscous forces. Whereas advective forces may transport materials over great distances in lakes, TKE is responsible for the mixing that creates spatial homogeneity. A large body of literature exists on the theory of movements and mixing of stratified lake waters. Some key reviews on this topic are given by Hutchinson (1957), Mortimer (1974), Csanady (1975), Hutter (1983), Imberger and Patterson (1990), Imberger (1994), Imboden and Wüest (1995), Imberger (1998), and Imboden (2004).

The flow of water, for example, in a pipe or in the mixed layer of a lake, ranges from laminar to turbulent. When flow is laminar, parcels of water move past one another in an orderly, smooth fashion, held together by the viscous property of the fluid. When flow becomes turbulent, the viscous forces are overcome, vortices form, and flow becomes chaotic or random. The nondimensional Reynolds number, *Re*, defines the interaction of the inertial forces of flowing water and the viscous property of water as

$$Re = \frac{UL}{\eta} \tag{9}$$

where U is the mean current velocity ($m\,s^{-1}$), L is the depth or thickness of the layer (m), and η is the kinematic viscosity of water ($m^2\ s^{-1}$). Flow is laminar at $Re < 500$ and turbulent at $Re > 2000$. Although flow is rarely laminar in aquatic systems, during calm conditions the scale of the turbulent vortices is small.

Two fluids of differing density moving across one another with differing velocities have the potential to create shear stress. The force associated with shear stress is perpendicular to the direction of flow of the fluid and creates turbulent vortices. When a lake is stratified either thermally or chemically, the potential energy of the stratification counters the kinetic energy that creates shear. The ratio of these two forces, the Richardson number (Ri), can be used to indicate when flow becomes unstable between the two layers, causing mixing to occur. For the mixed layer, the Richardson number is defined as

$$Ri = \frac{g(\mathrm{d}\rho/\mathrm{d}z)}{\overline{\rho}(\mathrm{d}u/\mathrm{d}z)^2} \tag{10}$$

In equation (10), buoyancy is represented by the buoyancy frequency, $N(s^{-1})$, the timescale for a displaced particle of differing density to return to its original position due to the force of gravity:

$$N^2 = \frac{g(\mathrm{d}\rho/\mathrm{d}z)}{\overline{\rho}} \tag{11}$$

where g is the acceleration due to gravity ($cm\,s^{-2}$), $\bar{\rho}$ is the mean density ($kg\,m^{-3}$) and ($d\rho/dz$) is the density change across the fluid of depth z (m). The other terms represents the shear forces created by flow, where u is the horizontal current velocity ($m\,s^{-1}$). For $Ri < 0.25$, flow becomes unstable and mixing occurs between the two layers. For $Ri > 0.25$, flow remains stable and the two layers of water flow past each other without the formation of vortices or mixing.

Wind-induced turbulence is generally the dominant force that creates mixing in larger lakes, except perhaps during

periods of low wind speeds, when convectively induced motion may be important. Wind causes two types of motions in lakes, those with periodicity such as waves, and those lacking periodicity such as currents. Wind associated with storm events imparts the most energy to lakes and is responsible for a large amount of mixing that occurs in lakes. Storm related winds cause surface waves and currents, as well as internal waves in stratified lakes.

The movement of wind across the surface of a lake conveys energy to the underlying water due to friction. The wind stress τ_w ($N\,m^{-2}$), which transfers energy from the wind to the water, is defined as:

$$\tau_w = \rho_a C_{10} (U_{10})^2 \tag{12}$$

where ρ_a is the density of air ($kg\,m^{-3}$), C_{10} is the drag coefficient, and U_{10} is the wind speed ($m\,s^{-1}$) at a height 10 m above the surface. The frictional velocity (u_* ($m\,s^{-1}$) of the water associated with this wind stress is

$$u_* = \left(\frac{\tau_w}{\rho_w}\right)^{0.5} \tag{13}$$

where ρ_w is the density of water ($kg\,m^{-3}$). Since the drag coefficient is a measure of the roughness of the water surface, the wind stress is not only a function of wind velocity but also of the wave field development. Therefore, the drag coefficient also varies with wind speed (Wüest and Lorke, 2003). Wind stress not only creates surface waves, but a small portion of the energy (1–4%) also goes into large-scale water motions (Smith, 1979)

Surface waves are the most conspicuous water motion observed on lakes during windy periods. However, surface waves transfer only moderate amounts of TKE, except when they break near the shore. Short surface waves are periodic and are characterized by wave height (H), amplitude (A), length (λ), period (T) and frequency (f) (Figure 5). Wave period is the time (s) for two consecutive wave crests (or troughs) to pass a fixed point. Wave frequency is the reciprocal of wave period. Waves of $\lambda < 1.8$ cm are generally considered ripples, since surface tension has greater influence on the wave than gravity

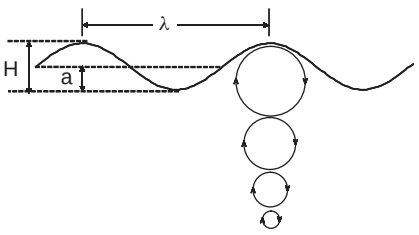

Figure 5 Diagram of short surface gravity waves. Symbols are wavelength (λ), wave height (H) and wave amplitude (a)

(Hutchinson, 1957). Waves of $\lambda > 1.8$ cm are referred to as *gravity* waves. Heights of gravity waves may be greater than 1 m during sustained winds over large lakes. The maximum wave height H_{max}, (cm) obtainable in lakes has been empirically related to the square root of the fetch F (cm) (Hutchinson, 1957):

$$H_{max} = 0.105\sqrt{F} \tag{14}$$

This relationship, however, gives no indication of the influence of bottom effects on wave height. In deep water, wavelengths are approximately 20 times the wave height. Movement caused by surface gravity waves in deep water is cycloidal. These movements decay with depth at approximately half the cycloid diameter for every increase in depth of $\lambda/9$ (Wetzel, 2001). Therefore, the motion induced by surface waves declines rapidly with depth, and the depth to which surface waters are mixed by surface wave movements is usually considered to be about 0.5 λ (Smith and Sinclair, 1972). Small distortion of the orbital particle motion of surface waves causes a small net movement of water in the direction of the wave.

In shallower waters the motion caused by surface waves begins to interact with the lake bottom. This causes the particle motions to become more elliptical as the vertical motion is suppressed and the horizontal motion is increased. In addition, the ratio of wave height to wavelength ($H{:}\lambda$) increases, causing waves to become less symmetrical, and they begin to break (Hutchinson, 1957).

Wind also imparts surface drift or large-scale currents to lake waters. The speed of water current is generally much reduced compared with the wind speed because of the difference in densities between air and water. The direction of water currents usually matches the wind direction until the currents encounter the lake boundaries or opposing topography within the lake. In large lakes, the earth's rotation (Coriolis force) causes currents to deflect to the right of the wind in the Northern Hemisphere and to the left in the Southern Hemisphere. The Coriolis force is strongest at the poles and zero at the equator.

The Eckman spiral (Figure 6) is created by the interaction of current Coriolis deflection and changing current speed over depth. The deflection due to Coriolis forces continues with depth, but currents decrease exponentially until the point of no net flow. Below this there is generally a return flow that is much slower than the surface flow. These surface currents have a large influence on the horizontal advective stirring in lakes.

Langmuir (1938) currents are another surface water movement that has a large impact on distributing materials. Langmuir cells are helical currents, parallel with the wind, which are created from an interaction between surface waves and surface currents (Plueddemann *et al.*, 1996)

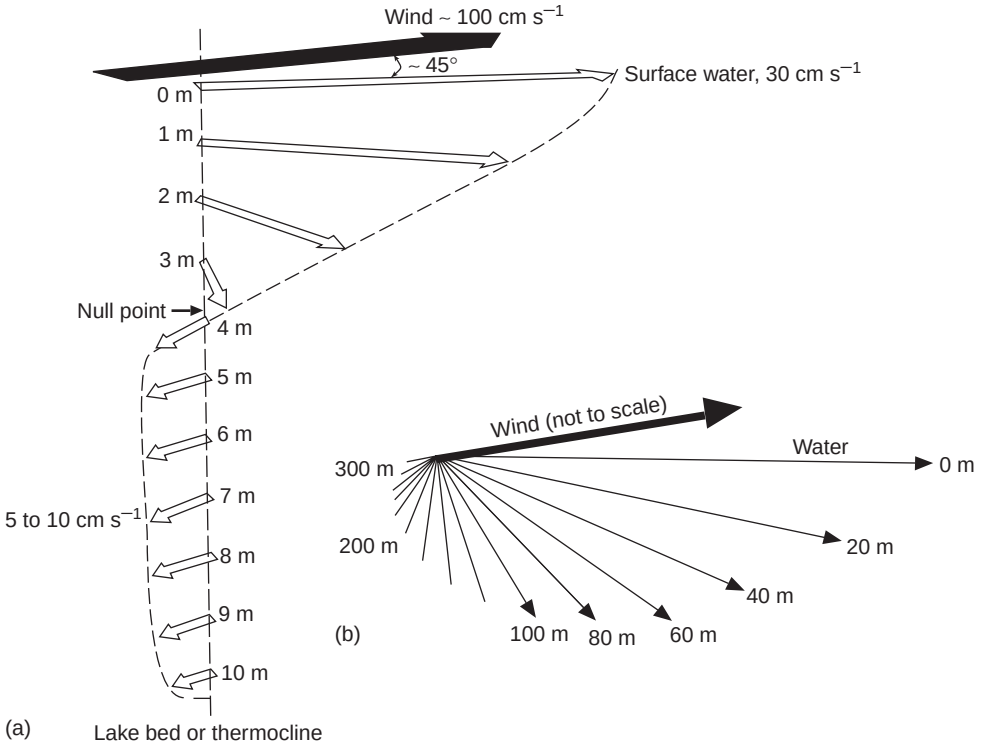

Figure 6 (a) Idealized and (b) measured diagrams of an Eckman spiral. The measured values are from the Pacific Ocean where depths are much deeper than what would be found in lakes (Reproduced from Horne and Goldman, 1994 by permission of McGraw Hill Education)

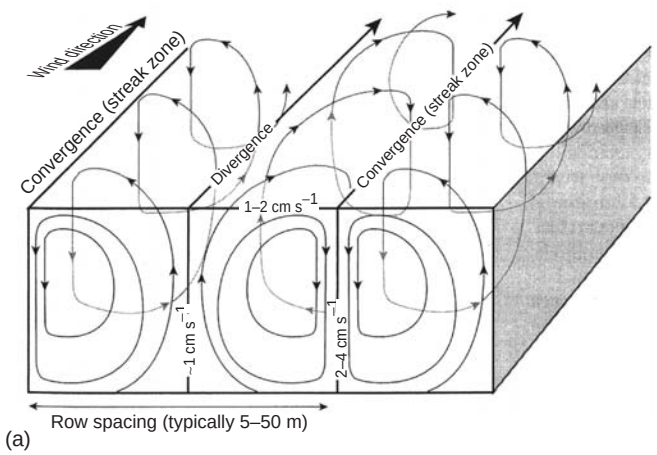
(Figure 7(a)). This pattern of Langmuir cells is observable (at wind speed greater than $3-4\,\mathrm{m\,s^{-1}}$) as bands or windrows of foam and other particulates that accumulate in areas of downwelling (Figure 7(b)). The vertical currents of Langmuir cells are strongest and most concentrated in the downwelling zone and weaker and more diffuse in the upwelling areas (Imboden and Wüest, 1995). Under conditions of strong winds, Langmuir currents may penetrate to the depth of the thermocline. These currents can have considerable influence on the distribution of detritus and planktonic organisms.

Another surface phenomenon is the formation of surface standing waves or surface seiches (barotropic waves). As with surface gravity waves, the turbulent kinetic energy in these waves also is low. These waves are usually set up, as sustained winds blow in a steady direction causing water to accumulate on the leeward side of the lake. At the same time, there is a decrease in water depth on the windward side. As this occurs, the water picks up momentum and overshoots the equilibrium tilt that can be sustained by the force of the wind. To regain equilibrium, the water level now increases on the windward side and decreases on the leeward edge. This rocking motion is usually centered on one or more nodes that move little in the vertical direction, but exhibit the greatest horizontal velocities. The antinodes experience little horizontal water movement but maximum vertical displacement. Length and mean depth influence the period of these waves (in lakes where length greatly exceeds mean depth) such that:

$$T_s = \frac{1}{n}\frac{2L}{\sqrt{g\bar{z}}} \tag{15}$$

where T_s is the period (s), L is the basin length (m), g is gravitational acceleration ($\mathrm{m\,s^{-2}}$) and $\bar{z}$ is the mean depth (m). Equation (15) is used for lake basins approximating a rectangular shape. The period can also be estimated for alternative basin shapes (Hutchinson, 1957).

Surface seiches are responsible for creating internal seiches (baroclinic waves). As surface waters accumulate on the leeward side of the lake, the metalimnetic waters are depressed to compensate for the increase in pressure. Similar to a surface seiche, the internal seiche is set into motion once the wind eases, and the water level oscillates towards its mean level. Internal seiches are much more important for mixing than surfaces seiches because they attain greater amplitudes than surface standing waves. Internal seiches may have amplitudes of several meters. Theoretically, the potential energy stored in the internal seiche exceeds the potential energy of the surface seiche



(a)

by $(\Delta\rho/\rho_0)^{-1}$, where $\Delta\rho$ is the change in density between the surface mixed layer and the base of the metalimnion (ρ_0) (Imboden, 2004). However, in natural conditions, internal seiches may not reach this theoretical bound, as morphometric characteristics tend to decrease the actual magnitude of the seiche. Like surface seiches, internal seiches are periodic and the period (T_i) can be calculated as

$$T_\mathrm{i} = 2L\left[\frac{g' z_\mathrm{e} z_\mathrm{h}}{(z_\mathrm{e} + z_\mathrm{h})}\right]^{-0.5} \tag{16}$$

where L is the length of the basin, z_e and z_h are the depth of the epilimnion and metalimnion. The reduced gravity, $g' = g\Delta\rho/\rho_0$, is the reduced gravitational acceleration due to the change in density (Spigel and Imberger, 1980).

In large lakes (minimum fetch >2–3 km), internal seiches are influenced by Coriolis forces (Mortimer, 1974). The earth's rotation should significantly influence the motion of the internal seiche if the period of the internal wave is less than the inertial period, ($T_\mathrm{i} < T_\Omega$) (Csanady, 1975), where

$$T_\Omega = \frac{2\pi}{f} \text{ and } f = 2\Omega\sin\phi \tag{17}$$

The angular frequency of earth's rotation Ω is 7.29×10^{-5} s^{-1}, and ϕ is the geographical latitude. The simplest modification created by Coriolis forces imparts a counterclockwise (in the N. Hemisphere) motion to the seiche. The seiche pivots about a single node and is termed a *Kelvin wave*. The amplitude of Kelvin waves decreases exponentially with distance from the shore. This motion creates coastal jets that run parallel to the shoreline and are important for distributing materials that enter near the coastline. In very large lakes where internal waves are influenced by Coriolis forces but not impacted significantly by coastal morphometry, *Poincaré waves* are generated. These waves can be visualized as alternating cells of hills and valleys that undulate and rotate clockwise (Mortimer, 1974). These waves do not decrease in amplitude with distance from the shore and therefore can impart large motions to metalimnetic waters.

All of the above phenomena contain kinetic energy that cascades into TKE. The cascade of energy into TKE may be different for the different motions. One mechanism for the formation of turbulent kinetic energy is shear created by currents of different densities flowing over one another. Shear can create billows that may become unstable and break. This process is referred to as *Kelvin–Helmholtz* instability and these billows are areas of increased turbulent mixing that incorporate denser water into the surface mixed layer (Mortimer, 1974).

Because internal seiches can have large amplitudes (and can contain a large amount of energy) they are extremely important for mixing and the entrainment of deeper waters into the epilimnion. To examine the response of the internal seiche to a wind event, the Richardson number (equation 10) can be modified to characterize the mixed layer as a whole, and include episodic, lake-specific mixing patterns. The modification is termed the *Wedderburn number* (W_e)(Imberger and Hamblin, 1982),

$$W_\mathrm{e} = \frac{g' h^2}{u_*^2 L} \tag{18}$$

where g' is the reduced gravitational acceleration, h is the depth of the mixed layer, u_* is the surface shear velocity (equation 13) and L is the fetch of the metalimnion in the direction of the wind. When W_e is small ($W_\mathrm{e} < 1$), the wind energy is large compared to the strength of stratification, and stratification may break down. When W_e is large,

stratification remains stable (Spigel and Imberger, 1980). A similar term that applies to the entire lake and may have a more mechanistic applicability is the lake number L_N. This dimensionless number incorporates the Schmidt stability index (equation 5) as well as forces other than wind that can disrupt stability (Imberger and Patterson, 1990).

There are a number of mechanisms caused by the movement of internal seiches that can contribute to turbulent mixing. Horn *et al.* (2001) put forth five possible regimes that might exist during the degeneration of internal seiches. These regimes are classified by W_e and the ratio of the mixed layer depth to the maximum depth. Two regimes were observed frequently in lakes. The most common regime observed involves the nonlinear steepening of the internal seiche, forming groups of solitary waves (solitons). The other observed regime was the dampening of the internal seiche before the formation of solitons could occur. Conditions of supercritical flow, Kelvin–Helmholtz billows, or the formation of bores and billows were not observed. The solitary waves transfer their energy to turbulence as they propagate and break on the sloping lake bottom (Imberger, 1998). Therefore, turbulent kinetic energy generated from internal seiches is most prevalent where the thermocline intersects the side of the lake. Combining the pathways by which TKE is produced shows that TKE is most prevalent in the surface mixed layer and at the sides and bottom of the lake, whereas turbulence is weak in the interior of stratified lakes (Wüest and Lorke, 2003).

Cooling, or in the case of saline waters, evaporation, causes surface water to become denser than underlying water (*see* **Chapter 44, Evaporation from Lakes, Volume 1**). This produces convection currents, as the denser water sinks. In small lakes, or large lakes that experience periods of low wind, penetrative convection may be the dominant source of kinetic energy and mixing. The buoyancy flux (B in equation 4) determines the penetrative convection velocity ($m\,s^{-1}$), $w_* = (Bh)^{1/3}$, where h is the depth of the mixed layer. The convection velocity can be compared to wind-generated shear velocity, by examining the ratio $(u_*/w_*)^3$. The depth at which convection and surface wind shear contribute equally is the *Monin–Obukhov length* L_M (m):

$$L_M = \frac{u_*^3}{B} \tag{19}$$

For a negative heat flux, the ratio of $L_M : h$ determines the dominant source of shear at the mixed layer. If $L_M : h > 1$, wind shear is dominant. If $L_M : h < 1$, the ratio is the relative depth of the mixed layer, influenced by u_*, and below L_M, convection dominates. For a positive heat flux, L_M describes the depth at which wind mixing is balanced by the generation of potential energy.

Whereas the onset of thermal stratification requires periods of calm and positive heat flux, the destruction of thermal stratification takes place during periods of cooling and episodes of high wind. As surface waters cool and turbulent forces cause the surface waters to mix into the metalimnion, a deeper thermal stratification will develop. When the density difference between the epilimnion and hypolimnion become small enough that buoyancy is overcome by turbulence, stratification breaks down completely. Empirically, the timing of autumnal mixis in stably stratified lakes depends upon several factors, such as hypolimnetic temperature, mean depth, and latitude adjusted for altitude (Nürnberg, 1988). Hypolimnetic temperature explains the largest portion of the variation in date of turnover for lakes located in similar regions; lakes with colder hypolimnetic temperatures turning over later than lakes with warm hypolimnia. Increasing mean depth also leads to later turnover, and finally, an increase in adjusted latitude causes lakes to mix earlier. These factors are likely related to the water column stability, the mass of water that must be cooled and mixed, and the local climatic conditions, respectively. Interannual variation in climate may be the cause of some of the unexplained variation in these empirical models (Nürnberg, 1988).

PATTERNS OF STRATIFICATION AND MIXING

Not all lakes may experience the same patterns of stratification and mixing due to geographic location or lake morphometry. Schemes for classifying lakes based on stratification patterns have been constructed since the early periods of limnology. A review of these early schemes is provided by Hutchinson (1957). There have been many modifications of these schemes. For example, Lewis (1983) suggests eight patterns of seasonal stratification and mixing that can be found in lakes throughout the world. These patterns are: amictic, cold monomictic, continuous warm and cold polymictic, discontinuous warm and cold polymictic, dimictic, and warm monomictic. Lakes that do not mix completely on a seasonal basis are meromictic lakes.

Amictic

Amictic lakes are perennially ice-covered and therefore are not subject to the direct effects of seasonal temperature variations or wind. Although the name implies that these lakes never mix, inflows from streams or melting ice can add heat or turbulence to the lake. If the ice cover is clear, solar radiation may penetrate to the water or sediments below and cause convective currents. Amictic lakes are found mainly in the Antarctic, although examples are also found in the Northern Hemisphere.

Cold Monomictic

Lakes with one period of circulation, and temperatures that do not reach much greater than 4 °C are termed

cold monomictic. These lakes are generally located at high latitude and are ice-covered for most of the year. Only during a brief period of no ice does complete mixing occur. Because there is little net gain of heat during this period, wind exposure generally does not allow periods of stratification during the ice-free season. However, regional climatic variation can create years when stratification during the ice-free season does occur, and two periods of circulation (dimictic; see below) are present.

Continuous Cold and Warm Polymictic

These lakes have relatively modest depth, or are wind exposed. Cold polymictic lakes rarely reach temperatures greater than 4 °C, but thermal inputs can be sufficient on calm, sunny days to create brief (up to several days) periods of stratification. Warm polymictic lakes reach temperatures greater than 4 °C, but because of excessive winds or large cooling events, stratify only intermittently.

Discontinuous Warm and Cold Polymictic

Lakes that grade from polymictic to dimictic because of increasing duration of stratified intervals are classified as discontinuous.

Dimictic

Many lakes in the temperate regions that have an ice-covered period fall under this category. There are two periods of mixing, one in the spring after the ice has thawed, and another in the fall after the summer thermal stratification has broken down.

Warm Monomictic

Lakes that do not experience ice cover but stratify stably only once annually are termed *warm monomictic*. Compared to their polymictic counterparts, these lakes are generally deeper and have a greater heat storage capacity, preventing intermittent mixing.

Meromictic Lakes

Lakes that experience mixing throughout the entire water column are termed *holomictic*. In certain lakes, the mixing patterns described above are interrupted by a chemocline that cannot be overcome by forces of wind mixing. These perennially stratified lakes are defined as *meromictic*. Meromictic lakes contain an unmixed bottom layer, the monimolimnion, and an upper layer, the mixolimnion, which may experience patterns of thermal stratification. There are generally two situations that result in meromixis. The first, ectogenic meromixis, is brought on by the intrusion of saltwater into a freshwater lake, or *vice versa*. Secondly, biogenic or endogenic meromixis is generally created when decomposition products in the monimolimnion create water of greater density. Many of the deep, highly productive equatorial lakes are meromictic (Wetzel 2001). Lakes may experience periods of intermittent meromixis if conditions prevent full mixing of salts accumulated in the hypolimnion over the stratified period. This allows continued increase in bottom water densities, requiring even greater mixing forces to disrupt the chemocline and mix the entire lake.

An Example of Stratification in a North Temperate Dimictic lake

Because a large number of lakes are in the temperate zone and fall under the category of dimictic, it is worth discussing the annual patterns of stratification and mixing experienced by these lakes. In addition, these lakes experience nearly the entire range of thermal conditions that exist in lakes. Therefore, the patterns of other lakes can quite easily be inferred from the behavior of dimictic lakes. Sparkling Lake is located in the Northern Highland Lake District of Wisconsin, USA. (Lenters *et al.*, 2005) (Figure 8). The lake has a surface area of 64 ha, a maximum depth of 20 m and a mean depth of 10.9 m. Ice covers Sparkling Lake for an average of 141 days each year. Daily average temperatures were recorded with a thermistor chain suspended from a buoy located centrally in the lake. Temperature was recorded at a depth of 0.1 m, then every meter from 1 to 12 m, and finally at 14 and 16 m.

At the time of spring ice melt, lake water is isothermal near the temperature of maximum density (~4 °C; the lake was ice free on 24 April 2002). After ice-off, the surface water is mainly heated by the absorption of solar energy. The thermal resistance to mixing at this time is insufficient to counteract the turbulent mixing created by the force of wind. This creates a period of gradual warming and mixing of the entire water body. Cooling at night creates convection currents that aid in creating an isothermal period of spring mixis. In Sparkling Lake, this period lasted until about 25 May 2002, at which point the bottom of the lake had warmed to a temperature of 6.5 °C.

As the temperature of the entire water body warms, further increases in the surface water temperature cause this water to become increasingly resistant to the forces of mixing with cooler water below. This is due to the nonlinear relationship between water density and temperature increases above 4 °C. In Sparkling Lake, intermittent stratification exists from 25 May until 6 June. After a relatively calm, warm period, the surface warms considerably, buoyancy forces resist further wind mixing of the entire water column, and stable summer stratification sets in. In deep lakes with small surface areas that experience ice cover late

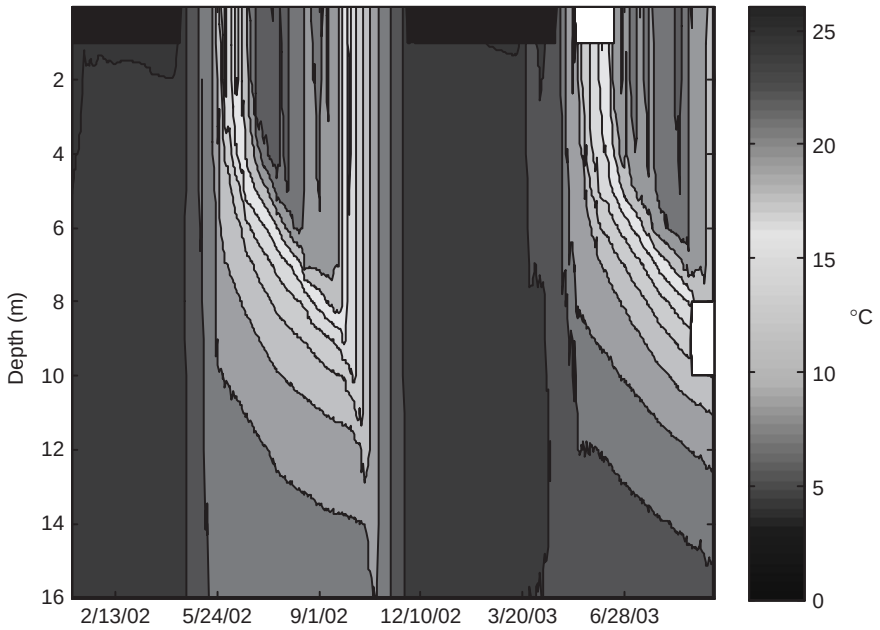

Figure 8 Depth-time diagram of isotherms in Sparkling Lake, Wisconsin. Each isotherm represents a 2 °C change in temperature. Black areas are ice cover (not to scale) and white areas are no data. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

into the spring, heat flux to the lake may be great enough that stratification develops before complete mixing occurs. In Sparkling Lake, the period of mixing is short enough that the deepest waters warm only a few degrees before stratification. In moderately deep lakes (>10 m), stratification is generally stable for the entire summer. Strong wind events and net loss of heat later in the summer season can deepen the thermocline, but stratification generally does not break down. Periods of calm may create secondary thermoclines nearer the surface, but buoyant forces are generally not strong enough for secondary thermoclines to persist.

A change to net negative heat flux in late summer and autumn gradually cools the mixed layer. This aids in eroding the thermocline due to a decrease in the buoyant forces. Generally the entire water body does not mix until the surface water has nearly reached the temperature of the hypolimnion. In Sparking Lake, the hypolimnion gradually warms throughout the entire summer reaching a maximum of about 8 °C (10 October 2002), at which point the epilimnion has cooled to a similar value and the lake is isothermal. The lake then experiences a period of autumnal mixis during which the water temperature continues to fall into the winter months.

Although water reaches its density peak at ~4 °C, cooling beyond this point does not create stable stratification of the less dense colder water above the 4 °C isotherm. This is because the density differences are small at low water temperatures and the resistance to mixing is also low. The temperature at which ice begins to form on water bodies is partly a function of the fetch (F) of the lake (for F (km) <9, $T(^{\circ}\mathrm{C}) = 1.36F^{-0.49}$; Kalff, 2002). Ice can form on small lakes, such as Sparkling, when the temperature of most of the water is between 3 and 4 °C. Large lakes continue to cool below this point and often do not freeze until the water temperature is below 1 °C. After ice formation, the lake is protected from the forces of the wind, and an inverse thermal stratification is set up due to a temperature gradient from ~0 °C very near the ice to higher temperatures of up to 4 °C near the bottom. Inputs of heat from sediments, surface, or groundwater, as well as solar radiation passing through the ice, can create currents and mixing during periods of ice cover (e.g. Likens and Hasler, 1962). As spring approaches again, a large amount of the lake's heat budget goes to melting the ice. This is an important distinction when comparing lakes that do not undergo a period of ice cover (e.g. warm monomictic lakes), because this heat would otherwise be used to establish the next thermal stratification event. In early spring (~14 April 2003), the ice on Sparkling Lake was abnormally clear and allowed for solar heating of the water beneath the ice. Interestingly, the temperature at 1 m reached a daily average high of nearly 6 °C on 15 April, and temperatures of greater than 5 °C extended several meters deep. The ice did not recede until 24 April.

BENTHIC AND PELAGIC COUPLING

Patterns of stratification and mixing have great importance for the dynamics of lake ecosystems. Most obvious is the

physical environment that is created at different times of the year, but this has large ramifications for chemical and biological conditions within lakes. For example, nonmotile algal cells that are negatively buoyant rely on turbulent forces in the mixed layer to maintain their position within the photic zone. If cells sink out of the mixed layer and beyond the photic zone, the cells can no longer grow and have no means to regain their position within the photic zone. On the other hand, the density difference found within a less turbulent metalimnion may allow some species of algae and bacteria to exist in discrete layers that satisfy their chemical and light environment needs. Movement of gases and nutrients must proceed by the slow process of diffusion when turbulent energy is not available. The slow movement of materials through the metalimnion compared to their production or consumption in the hypolimnion has the apparent effect of sealing the hypolimnion of lakes from receiving oxygen from the atmosphere, and traps the decomposition products in the deeper water. Consequently, cold-water fishes living in temperate zones rely on lakes that are stratified to provide cold hypolimnetic waters, but their distribution can be limited because of the oxygen limitation in these environments.

Perhaps the most striking feature of stratification is the chemical separation of the epilimnion from the hypolimnion, or the profundal benthic zone from the pelagic mixed layer. Although the littoral benthic zone is generally in contact with the mixed layer, the profundal benthic zone is physically separated from interactions with surface waters during stratified periods. While surface waters are in contact with the atmosphere and receive solar radiation for primary production, the profundal zone is dominated by heterotrophic activities. Nutrients are lost from surface water as particles sink, but remineralization taking place within the profundal can release nutrients back into the water column. Recycling of nutrients in this manner can be an important term in nutrient budget of some lakes (Poister *et al.*, 1994).

Several processes are of importance for understanding the influence of stratification on lake ecosystems. These processes, described in the following text, are sedimentation, resuspension, vertical and horizontal eddy diffusion, and hypolimnetic entrainment.

Sedimentation is of great importance to algal cells (Smayda, 1970; Reynolds, 1984). Although particles in the mixed layer of a lake continuously experience turbulent forces allowing them to remain suspended in the water, at times turbulent forces will be diminished. If the cell sinks into the metalimnion or hypolimnion, turbulent forces may be minimal and flow may be nearly laminar. Thus the probability of sedimentation is the product of the number of particles, the settling velocity, and the depth of the mixed layer. The settling velocity of particles is described by the Stoke's equation (Reynolds, 1984). Settling is dependent upon the particle density, radius, and viscosity and is defined as

$$\omega_s = \frac{2gr^2(\rho_s - \rho_w)}{9\mu\varphi} \tag{20}$$

where ω_s is the settling velocity ($m\,s^{-1}$), g is gravitational acceleration ($m\,s^{-2}$), r is the radius of a sphere with volume identical to that of the particle (m), ρ_s and ρ_w are the densities of the particle and water ($kg\,m^{-3}$), μ is the dynamic viscosity ($kg\,m^{-1}\ s^{-1}$), and ϕ is the coefficient of form resistance. Originally Stoke's equation described only spherical particles. Therefore, the coefficient of form resistance can be solved as the deviation of ω_s from that of a sphere with identical density and volume to the respective particle.

Once a particle has sedimented out of the mixed layer or photic zone, the nutrients contained in the particle can no longer be recycled for use by other photosynthetic organisms. This is especially important for nutrients that often limit productivity in lakes, such as P and N, and Si (for diatoms). The particle size distribution of algal communities, because of its impact on sedimentation rate, is an important factor in the rate of decline in P concentration in the mixed layer (Guy *et al.*, 1994). In addition, losses of nutrients from the photic zone are subject to seasonal trends associated with annual blooms of algae (Poister *et al.*, 1994).

Resuspension of sediments that have reached the benthic zone have further ecological importance. Resuspended sediments increase turbidity and may be a source of nutrients or contaminants, or they can act to "scrub" certain chemicals from the water column as they are adsorbed to the particles (Gunatilaka, 1982). Resuspended material can constitute a large proportion of particulate matter in lakes (Evans, 1994). Lake morphometry may dictate some of the properties of sediment resuspension (Carpenter, 1983; Håkanson and Jansson, 1983). For example, resuspended sediments are often considered most important in shallow lakes. However, some amount of sediment resuspension takes place in all lake settings. For sediments to become resuspended, current velocities must create enough shear stress to overcome gravity and the cohesiveness of the sediments (Bloesch, 1995). The shear stress τ ($N\,m^{-2}$) can be quantified directly as

$$\tau_s = \rho_w C_1 u_1^2 \tag{21}$$

where ρ_w is water density ($kg\,m^{-3}$), C_1 is the drag coefficient 1 m above the bottom and u_1 is the current velocity ($m\,s^{-1}$) 1 m above the bottom. The shear stress is often presented, however, as a shear velocity $u_* = (\tau_s/\rho_w)^{0.5}$. Average current velocities in the bottom of stratified lakes are generally not great enough resuspend most particles. However, Gloor *et al.* (1994) found that

occasional bursts of higher current velocities associated with internal seiches could cause resuspension of organic particles up to 100 μm and inorganic particles up to 1 μm, thus maintaining a well-mixed benthic boundary layer. In lakes that stably stratify, resuspension is especially prevalent during periods of overturn. Other factors may reduce the ability of currents to resuspend sediments. Chemical precipitates can create more cohesive sediments that are less likely to be resuspended. Biological activity may physically disturb sediments, or it may also consolidate materials. Examples of consolidation include bacterial mats that bind particles and fecal pellet production by benthic invertebrates.

Within lakes, the greatest amount of resuspension and redistribution of sediments takes place primarily along the littoral benthic zone (Shteinman *et al.*, 1997). Here, surface waves that are deep enough to interact with benthic sediments resuspend material into the mixed layer where it can be redistributed by currents. Deeper areas undergo more episodic events of sediment resuspension. These are related to the shoaling of solitary internal waves at the sloping lake edge (Horn *et al.*, 2001; Boegman *et al.*, 2003). Distinct zones of sediment resuspension and accrual occur because surface waves and currents routinely resuspend particles near-shore shallow areas, and sediments are less likely to be resuspended in deep waters (Håkanson and Jansson, 1983). This causes sediments to move laterally away from the shoreline with time until they are permanently buried, a process known as *sediment focusing*. On the other hand, littoral zones in sheltered bays can be areas of increased sedimentation and decreased resuspension. In addition, macrophytes may impart control on water movements and therefore create areas of increased sedimentation (Madsen *et al.*, 2001).

The release of soluble forms of nutrients from the sediments to the overlying water column may dictate the level of productivity in a lake. For phosphorus, this has classically been viewed as a chemically driven process depending on redox potentials and availability of Fe and S (Caraco *et al.*, 1991 and references therein). However, there is also the indirect mediation of redox potentials by bacteria and the direct role of bacterial utilization and release of P (Kalff, 2002). Movement of nutrients (or contaminants) from sediment to water is generally controlled by molecular diffusion driven by steep concentration gradients at the sediment–water interface. Bioturbation, convective porewater exchange, sediment resuspension, and bubble ebullition may increase the flux of substances across the sediment–water interface. In contrast, the formation of chemical and biological aggregates, such as iron oxides and oxyhydroxides (FeOOH), create barriers to molecular diffusion.

The movement of heat and soluble materials in the absence of advective forces is governed by vertical and horizontal eddy (turbulent) diffusion. Vertical movements during stratified periods are opposed by the stability of the water column imparted by the thermal density gradients. Therefore horizontal eddy diffusion coefficients (K_H) are generally much larger than the vertical coefficients (K_V). Since horizontal movements of water and dissolved materials are not usually impeded by density gradients and often are aided by large advective forces, horizontal movement of materials is generally not considered limiting. However, the magnitude of K_V is often a limiting factor in the supply of dissolved substances from the hypolimnion to the epilimnion.

Eddy diffusion of materials is a result of TKE. At steady state in a stratified system, the production of turbulent kinetic energy is balanced by losses to buoyant fluxes (B) created by density differences and dissipation of turbulent kinetic energy (ε) due to viscous forces (Imboden, 2004). The buoyancy flux, defined from Fick's First Law of diffusive transport, is, $B = -K_V N^2$. The ratio of the buoyant flux to the turbulent kinetic energy dissipation (ε) is the mixing efficiency (γ_{mix}). Rearranging this ratio reveals how the eddy diffusion coefficient is related to energy dissipation and the stability of stratification:

$$K_V = \gamma_{mix} \frac{\varepsilon}{N^2} \tag{22}$$

Thus K_V decreases as the intensity of stratification increases. The mixing efficiency, determined experimentally, ranges form 0.05 to 0.25, and ε can be determined from direct measurement to provide point estimates of K_V (Imboden, 2004). Empirical relationships of the form $K_V = a(N^2)^b$ have shown that b can range from -0.3 to -0.9 (Imberger and Patterson, 1990). Since K_V can vary in space and time, these point measurements may not accurately describe the basin scale vertical flux of materials.

Other methods for estimating K_V involve examining the rate of change of temperature or a tracer concentration, and providing an estimate that integrates over a longer period of time. Quay *et al.* (1980) found, in two lakes, that K_V in the metalimnion (5×10^{-5} and 8×10^{-4} cm^2 s^{-1}) was much less than in the hypolimnion (1.7×10^{-3} and 1.8×10^{-2} cm^2 s^{-1}). These differences were related to difference in the stability of the hypolimnion and metalimnion. Because the two lakes examined were small and well protected, the production of turbulence was small and the eddy diffusion through the metalimnion was very near that of molecular diffusion. In the larger Greifensee, Imboden and Emerson (1978) found a higher K_V (2.5×10^{-2} cm^2 s^{-1}) in the metalimnion. Using this K_V and the P concentration gradient between the hypolimnion and the epilimnion, they determined that the internal loading of P was of the same magnitude as external sources during periods of highest productivity. Within the metalimnion K_V can vary spatially, generally increasing in areas where the metalimnion

intersects the lake bottom, because higher amounts of turbulent kinetic energy are found there (MacIntyre *et al.*, 1999). Therefore, the importance of high eddy diffusion rates for benthic and pelagic coupling are dependent upon their interception with gradients of materials such as nutrients. In Mono Lake, the flux of ammonium from boundary mixing was enough to sustain the observed deep chlorophyll maxima (MacIntyre *et al.*, 1999).

A final process important in benthic and pelagic coupling is the entrainment of hypolimnetic water during periods of thermocline deepening. Factors controlling nutrient transport to the epilimnion during entrainment are: concentrations in the metalimnion, thermal stability of the water column, and timing and pattern of storm events. If concentrations are low in the entrained water, then entrainment has little influence in the overall budget. In Lake Mendota, entrainment was a dominant source of P during a year with average external loading from runoff and supplied nearly as much P to the epilimnion as external loading during a year of above-average runoff (Soranno *et al.*, 1997). Over a 20-year period in Lake Mendota, lake stability was an important predictor for midsummer water clarity (Lathrop *et al.*, 1999). In Lake Tanganyika, increased surface temperatures and decreased winds have increased stability and reduced mixing and input of hypolimnetic nutrients, thereby reducing productivity (O'Reilly *et al.*, 2003).

CONCLUSION

The physical processes of stratification and mixing are important for the chemical and biological functioning of lake ecosystems. Through these physical processes, geomorphology and climatic conditions can have direct and indirect impacts on water quality and biotic interactions. Geomorphology exerts a strong influence on the presence of seasonal stratification, as well as its timing. For example, the size and depth of a lake determines whether stratification will occur. Nutrient cycles are generally changed significantly if lakes stratify (Carpenter, 2003). Climatic conditions generate temporal variation in physical forcing and thereby create variation in the benthic and pelagic coupling within and among lakes. The impact of global climate change on the physical environment of lakes is an area of recent interest (McKnight *et al.*, 1996; Magnuson *et al.*, 2000). Mechanistic models that account for changes in the climate-driven physical forcing will be a useful tool to help understand the potential ramifications of climate change on the biology of lakes (De Stasio *et al.*, 1996). Therefore, further advances in the understanding of stratification and mixing processes and their relationship to benthic and pelagic coupling will increase our ability to predict a lake's response or resilience to natural and human-induced disturbances.

109: Reservoirs

G RICHARD MARZOLF[1] AND DALE M ROBERTSON[2]

[1] *United States Geological Survey, Office of Ground Water, Reston, VA, US*
[2] *United States Geological Survey, Water Science Center, Middleton, WI, US*

Reservoirs are surface water impoundments that result from the construction of dams on streams and rivers. Limnological principles are applicable to understanding reservoir functions and the processes that control them because they exhibit lake-like characters (see Lake Ecosystems – ***Chapter 108, Lake Ecosystems (Stratification and Seasonal Mixing Processes, Pelagic and Benthic Coupling), Volume 3****). The basic water qualities of reservoirs are dependent, however, on the river that was impounded in their formation. The river's inflow dominates the upstream reaches of reservoirs. Lacustrine processes become more controlling as advective forces diminish and wind-mixing and solar heating become influential forcing factors and as the cross section of the basin widens and deepens downstream. This transition from riverine to lacustrine imposes longitudinal gradients in reservoirs that emerge as their central feature. Designs of dams and their operating schedules have considerable influence on these in-reservoir patterns and on the effects of the dam in the downstream river downstream. Various models have been developed to describe the physical, chemical, and biological processes in reservoirs. Additional studies will lead to further information to improve the models, which in turn will lead to a better understanding and management of reservoirs.*

HISTORICAL BACKGROUND

Reservoirs by themselves are largely a secondary outcome of the development of dams. The earliest uses involved simple structures that provided for the diversion of water into channels so that the water could be released to irrigate crops. Later dams were constructed to control and store water for irrigation in dry seasons and for conversion of kinetic to mechanical energy used to mill grain and to drive machinery for textile production and machine-tool operation.

Most of the large rivers in the United States figured prominently in our history. They were critical avenues that supported the country's expansion and subsequent development. Examples include the Potomac, Delaware, and Hudson Rivers in the seventeenth and eighteenth centuries. The Mississippi, Ohio, and Missouri Rivers were crucial to the postrevolutionary expansion in the nineteenth century, and the full development of the West is clearly tied to the Colorado, Rio Grande, and Columbia Rivers. As the United States expanded, rivers were important transportation routes. The difficulty in moving boats through shoal reaches and up or down steep reaches stimulated the construction of dams and associated locks. There was a clear federal interest in such river engineering and the Army Corps of Engineers has been central to the enterprise since the late nineteenth century. The construction of dams in the headwaters of rivers to store water in wet seasons helped to control flooding and provided for release of stored water during drought and low-flow seasons, thus extending navigational uses. Federal interest in agricultural development in the arid West through irrigation led to the development of the Bureau of Reclamation and additional dam construction. Recently, dams have offered the benefits of electrical power generation and financing for water projects from the sale of this power. The history of water-resource development surrounding American rivers is colorful and the results are a source of national pride.

Early water-resource development activities were dominated by problems associated with the quantity of water available for various uses. Many reservoirs are important as sources of domestic supply, and many have been developed as habitat for commercial and recreational fishery

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

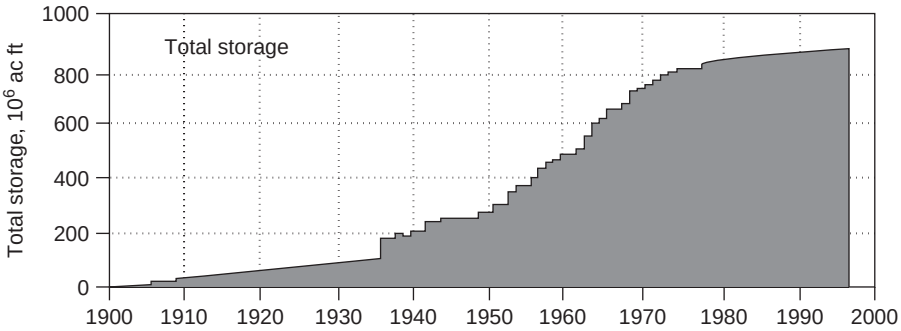

Figure 1 History of increasing total reservoir storage for the continental United States. Data from U.S. Army Corps of Engineers (1996) (Reproduced from Graf, 1999 by permission of American Geophysical Union)

development. Many reservoirs are sites for public recreation because of their lake-like characteristics.

With the emergence of these uses, the view of water-resource managers has shifted to include problems associated with the qualities of water: its temperature; the amount of oxygen dissolved in it; contaminants (e.g., industrial wastes, metals, agricultural chemicals, and pathogens in domestic sewage), and nutrients dissolved in it.

These characteristics of reservoirs have become more important to society as the number of reservoirs has increased, as people use them more for more purposes, and as reservoirs age. Furthermore, many essential characteristics of free-flowing rivers are changed with impoundment, and environmental concerns about these changes have become political, regulatory, and legal. There is general agreement that the era of dam-building in the United States is coming to an end (Figure 1; from Graf, 1999). Construction of new dams is slowing down because of rising costs, a diminishing number of sites where dam construction is feasible, and increasing pressure from environmental groups to limit construction.

There are broader contexts that incorporate dams in world history and use by aboriginal people in North America but the scope of this treatment is limited to development of water resources on the North American continent since European settlement (Worster, 1985).

RESERVOIRS COMPARED TO LAKES

Reservoirs have several basic features in common with natural lakes which means that many principles of traditional lake study (limnology) can be transferred to the study of reservoirs. Basic physical processes occurring in lakes also occur in reservoirs, such as surface warming from solar energy and daily and seasonal cooling, that, when coupled with wind mixing, yield seasonal thermal stratification. Low velocities restrict sediment suspension to the finest particles, allow for a more developed planktonic community, and selects for the survival of a fish community that is unlike that of the parent river. Light penetration defines an upper layer (photic zone) where photosynthesis is carried out by planktonic algae. Organic matter settling into unmixed deeper water may lead to development of anoxic conditions because of the microbial consumption of dissolved oxygen.

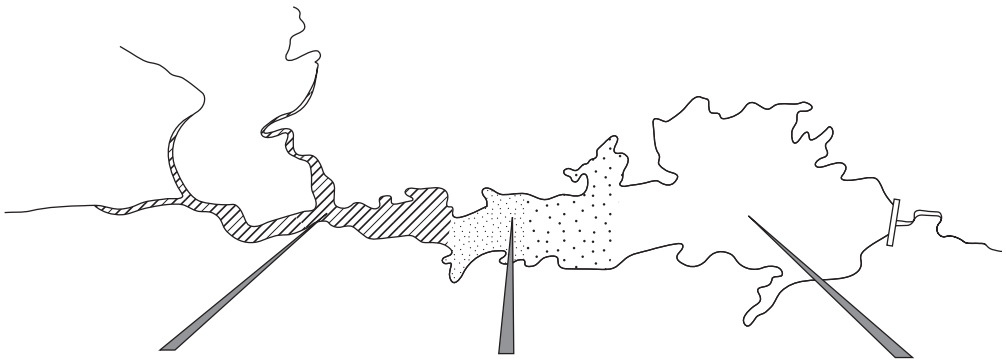
There are, however, some significant differences between reservoirs and natural lakes (Table 1). Reservoirs typically drain larger areas than natural lakes, and typically have shorter retention times than natural lakes. These physical differences often result in a more rapid decline in the water quality of reservoirs.

Natural lakes either have no outlets (seepage lakes) or have one outlet from which water from the surface of the lake exits the system. Reservoirs can also have one outlet; however, water is either released over a dam (spillway), from some intermediate depth (typically through penstocks), or near the bottom (typically through lift gates or release tubes), in addition to water often being transferred for water supply. The quality of the water released from a reservoir is somewhat controllable and can be much different from that of a natural lake because water quality varies so much with depth.

Thermal stratification in water bodies is controlled by solar heating, the temperature and momentum of influent

Table 1 Typical relative differences between lakes and reservoirs

Characteristic	Lakes	Reservoirs
Ratio of surface area to watershed area	Smaller ~10	Larger >500
Retention time	Longer	Shorter
Inflows	None to several	One
Outflows	None or one	One
Transparency	Uniform and clearer	Longitudinal gradients, variable in embayments



Riverine zone	Transitional zone	Lacustrine zone
• Narrow, channelized basin	• Broader, deeper basin	• Broad, deep, lake, like basin
• Relatively high flow	• Reduced flow	• Little flow
• High susp, solids, turbid, low light avail, *Z*p < *Z*m	• Reduced susp, solids, less turbid, light avail, increased	• Rel, clear, light more avail, at depth, *Z*p > *Z*m
• Nutrient supply by advection, rel, high nutrients	• Advective nutrient supply reduced	• Nutrient supply by internal recycling, rel, low nutrients
• Light-limited PPR	• PPR/m^3 rel, high	• Nutrient-limited PPR
• Cell losses primarily by sedimentation	• Cell losses by sedimentation and grazing	• Cell losses primarily by grazing
• Organic matter supply pri-allochthonous, *P* < *R*	• Intermediate	• Organic matter supply primarily autochthonous, *P* > *R*
• More “euthrophic”	• Intermediate	• More "oligotrophic"

Figure 2 Typical water-quality zones in reservoirs with characteristics listed for each zone. [Zp – Photic depth; Zm – Mean depth; P – Production; R – Respiration; PPR – Primary production] (Reproduced from Kimmel, 1990 by permission of John Wiley, Inc)

waters, and wind mixing. Wind mixing in natural lakes commonly establishes a uniform and warmer mixed layer (epilimnion) overlying a colder and denser relatively unmixed layer (hypolimnion). Shallow depths and relatively high flow velocities generally prevent the establishment of stratification in the upstream (riverine zone) reaches of a reservoir (Figure 2). Furthermore, the river flow may remain active and turbulent into the reservoir, further disrupting thermal stability. Frequently, however, if the river inflow is more dense than the water at the surface of the reservoir, the inflowing river water will submerge and enter the reservoir as an underflow (or density current) bounded by the basin and flowing along the bottom. If this river inflow is heavier than surface water but lighter than unmixed bottom water, then it will find its density-equivalent depth and enter the reservoir as an “interflow”, flowing down the long axis of the reservoir until it reaches the dam. Differences in density between river water and reservoir water are typically due to differences in water temperature, but density currents also can occur when inflowing river water contains a high concentration of dissolved materials or suspended sediment.

AGING OF RESERVOIRS

The sediment transported by rivers is often deposited at the upstream ends of reservoirs, with the coarsest particles settling first, thus forming foreset beds on a delta front. At high flow rates during flood stage, these deposits may be overtopped and the delta may be aggraded with topset beds and natural levees. Varying water levels through time create a complicated stratigraphy in the riverine and transitional zones (Figure 2). Through time these deposits provide a setting for invasion of submergent and emergent aquatic vegetation and the establishment of wetlands. Deposits exposed above the controlled water level may be invaded by riparian vegetation. Silt- and clay-sized particles may be carried into the downstream portions of the reservoir, often kept in suspension by wind-driven currents where the basin is shallow. Fine particles deposited in the downstream portions of the reservoir include sediments transported from the reservoir’s watershed and sediments eroded locally due to shoreline processes. Water leaving the reservoir through the dam carries a reduced sediment load relative to the influent river and tributary streams. The effects of sediment reduction on tailwaters and downstream reaches are varied but include: armoring and deepening of the channel bed, erosion of channel-margin deposits, and long-term alteration of habitat characteristics for the river biota. Eventually the reservoirs will fill with sediment and dredging or other management actions will be required.

Eutrophication is the natural process of physical, chemical, and biological “aging” of water bodies associated with the addition of sediment, nutrient, and organic matter. This

natural process often leads to common problems, such as excessive sedimentation, algal blooms, oxygen depletion in the hypolimnetic areas (deeper and cooler layer of water bodies), and excessive aquatic plant growth.

The subject of chemical and biological eutrophication gained substantial attention in the twentieth century, beginning in western Europe with the works of Thienemann (1928) and Naumann (1932) who understood the relations among nutrient contents of lakes, the lake's biota, and the sources of nutrients in the lake's watershed. By mid-century, lakes were frequently classified according to their trophic state, or nutrient content, which is expressed as productivity and biotic composition. Hasler (1947) connected the accelerated eutrophication process in some lakes to nutrient sources from human activity and proximity to urban centers. This accelerated aging caused by human influences is termed "cultural" eutrophication. The nutrients most closely implicated with eutrophication are phosphorus and nitrogen, but other nutrient elements were claimed to be causative as well, for example, carbon and silica.

It is significant and ironic that rivers typically are not identified as eutrophic despite the fact that they often transport high loads of nutrients. The high current velocities (low retention times) and high suspended-sediment loads often do not provide conditions for the expression of high productivities so characteristic of eutrophic lakes. When the rivers are impounded and sediments are deposited, the water becomes more transparent as sediments are deposited, and the retention times are more conducive to planktonic algal growth; as a result, the reservoirs can express the eutrophic state almost immediately.

Because reservoirs often drain much larger land areas than lakes, the eutrophication process often occurs much more rapidly than in lakes and often results in longitudinal gradients in water quality because of the slow downstream movement of water. Figure 2 demonstrates the spatial variability so common in reservoirs with an upstream riverine zone and a more lake-like downstream lacustrine zone. Downstream in the lacustrine zone, the reservoir water often becomes nutrient-depleted, but upstream the nutrient concentrations continue to be driven by advective loading from the impounded river. The position of the transitional zone between these two areas is variable, moving upstream during periods of drought or low inflow and moving downstream during flooding.

Retention time of reservoir segments increases from upstream to downstream along the longitudinal axis of the basin as the cross-sectional area of the reservoir increases. The expression of planktonic production rates is a result of balance between the downstream export of organisms thus depleting populations and the increased rates of production associated with increased light penetration that is adequate for phytoplankton growth.

TRIBUTARY EMBAYMENTS

Reservoirs are formed when river valleys are drowned upon impoundment; therefore, they reflect the dendritic morphology of the parent river's drainage, with isolated embayments extending from the axis of the mainstem reservoir. These embayments often experience limited mixing with the mainstem reservoir that can result in quite different characteristics within the embayments. Embayments are usually protected from winds and thus experience less intense mixing, which often results in greater transparency than in the mainstem reservoir even if the embayments receive additional sources of sediment and nutrients. These simple physical differences often result in higher primary productivity by phytoplankton and/or the invasion of submerged aquatic vegetation. If the embayments have additional sources of nutrients from tributary streams or shoreline human activities, their productivity can be greatly increased.

Embayments are often the focus of reservoir management because of the expression of eutrophication issues, the growth of submerged aquatic plants, and their importance as rearing habitat for the commercial and recreational fisheries. Clearly these same characteristics are valuable to recreational anglers, a feature that focuses additional management attention on embayments. The variability of water qualities among tributary embayments at various places along the main axis of the mainstem reservoir is, or should be, of great interest to reservoir managers. The exchange of water, nutrients, and contaminants between embayments and the mainstem reservoir is, however, not well understood.

MODELING THE PROCESSES IN RESERVOIR

A vast amount of information has been collected describing processes in water bodies and the response of these processes to changes in the external environment. This information can be used to understand these same processes in unmonitored systems, as well as to predict how a reservoir may respond to changes in certain conditions in the future. One way of making these predictions is through the use of models that incorporate results of these specific studies into a predictive tool. Models range in complexity from simple empirical equations that describe changes in a specific parameter to complex three-dimensional dynamic numerical models that describe changes in many parameters over a wide range of spatial and temporal scales.

Empirical models may be simple equations that describe physical characteristics, for example, thermocline depth. More complicated empirical models relate nutrient loading rates and residence time to summer average water-quality conditions, such as phosphorus concentration, chlorophyll *a* concentration, and water clarity. Several

empirical water-quality models are contained in the Wisconsin Lakes Modeling Suite (WiLMS, Panuska and Kreider, 2002, accessible at **http://www.dnr.state.wi.us/org/water/fhp/lakes/laketool.htm**).

Fundamental equations of physics, thermodynamics, and chemistry can be written for water parcels in a reservoir. Moreover, many investigations document specific processes described by these equations. Dynamic models were formed by assembling and linking the fundamental equations with the understanding provided by process studies. The first dynamic models were one-dimensional models that described changes in the thermal structure of lakes and reservoirs; however, these models have evolved to describe changes in the water quality and biology in reservoirs. With advances in the understanding of specific processes associated with improved sampling technology and advances in computer power, two- and three-dimensional models have been created and linked with other watershed and river models.

There are a number of dynamic and semidynamic models that are used to understand the processes in reservoirs. One commonly used semidynamic model is BATHTUB (Walker, 1985; 1986; accessible at **http://www.wes.army.mil/el/elmodels/emiinfo.html**), which performs steady state water and nutrient balance calculations in a spatially segmented hydraulic network to account for advective and diffusive transport, and nutrient sedimentation. Eutrophication-related water-quality conditions are then predicted using empirical relationships derived from assessments of reservoir data. Many commonly used dynamic models are described and made available by the U.S. Geological Survey Surface-Water Quality and Flow-Modeling Interest Group (Rounds, 2004; accessible at **http://smig.usgs.gov/SMIG/**). One commonly used dynamic model is CE-QUAL-W2, which is a water-quality and hydrodynamic model in two dimensions (longitudinal-vertical) for rivers, estuaries, lakes, reservoirs, and river basin systems (Cole and Buchak, 1995; accessible at **http://www.ce.pdx.edu/w2/**). CE-QUAL-W2 simulates eutrophication processes such as relations among temperature, nutrients, algae, dissolved oxygen, organic matter, and sediment.

By describing processes in reservoirs, models can be used to simulate the effects of various management strategies, such as nutrient- or sediment-load reduction, without the costs of implementing each strategy. Models are useful in describing what we know about reservoirs, but they also can be used to help point to what we don't know. Through additional study, we can obtain a better understanding of the processes in reservoirs that will, in turn, lead to better models; an appropriate heuristic cycle.

The study of the sedimentary record of nonmarine aquatic systems (paleolimnology) provides a tool for reconstructing the history of the basins themselves, as well as the history of the atmospheric and terrestrial systems that influence them. Such records allow us to understand environmental dynamics over periods longer than that of recorded history. Among inland aquatic systems, lakes have been studied more extensively; therefore, this review focuses on insights regarding environmental structure and function gained from studying lake sediments. Studies of the lacustrine paleolimnological record have been used to describe patterns of long-term climatic variation and the response of lakes to changes in climate and catchment vegetation and soils. Although ecological literature from the early decades of the twentieth century suggested that lakes became enriched over time (eutrophic), eventually filling with sediment and becoming wetlands, it is now clear that there are multiple developmental pathways for lakes. Some lakes indeed become enriched, whereas others show a long-term decline in nutrient concentrations and pH. Similarly, succession from lake to bog or wetland is not a universal trend. Paleolimnological studies also have been used to reconstruct the recent history of eutrophication, lake acidification, and atmospheric pollution. In these studies, the history archived in lake sediments provides a tool for measuring the magnitude of human impacts on the environment and for evaluating whether twentieth century patterns fall outside the natural range of environmental variation.

INTRODUCTION

Paleolimnology is the study of the history of nonmarine aquatic systems and how they are influenced by changes in their catchments, by atmospheric inputs, and by climate. Similarly, paleohydrology is the study of past fluctuations in the hydrologic cycle, including precipitation variation, evaporation rates, and surface and groundwater flow. Both are based on the study of lake, wetland, and river deposits, including components within the sediments, as well as geomorphic features of the basins and watershed. Paleohydrology also includes marine systems; however, such studies will not be discussed here. Here, we emphasize studies of sediments deposited in lakes, because these studies comprise the bulk of the paleolimnological literature.

The temporal framework of paleolimnology ranges from studies of contemporary lakes during recent decades or centuries (Smol, 2002) to the geologic record of thousands or millions of years of history of extant or ancient lake basins (Bradbury, 1997; Cohen, 2003; Colman *et al.*, 1995). Because of space limitations, this review will focus on approximately the last 25 000 years, which encompasses the most recent period of widespread continental glaciation in the Northern Hemisphere and the subsequent landscape evolution as the glaciers receded and climate warmed.

The reconstruction of lake history allows us to understand the patterns of variation in lakes over periods much longer than those of the written record and human observation. The longest written time series of lake characteristics span only the last century or so (Magnuson *et al.*, 2000; Nicholson, 1998); the majority are more limited and generally span less than a few decades (Edmondson, 1981; Goldman, 1981; Haworth, 1980; Maberly *et al.*, 1994). During recent decades and centuries, or in some cases millennia, the structure and function of many lakes have been influenced by human activities ranging from local land-use practices in the watershed to the deposition of pollutants transported over great distances via the atmosphere. The impact of these

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

human activities can be disentangled and understood only by reference to archives that predate this influence.

Paleolimnology emerged as a discipline in the early decades of the twentieth century. The pioneering studies explored some of the major ecological questions of the time concerning the extent to which long-term ecosystem development (succession) was self-regulating or driven by external forces. These early paleolimnological studies considered the relationship between changes in catchment vegetation and soils and changes in the morphometry, chemistry, and biology of lakes, primarily in forested regions of the temperate zone. In the late 1960s and 1970s, paleolimnological techniques were used increasingly to address applied questions regarding human impacts on lakes, particularly to determine the magnitude of cultural eutrophication. Later, when acidification of lakes from acid deposition became a major environmental concern, paleolimnological studies became a prominent tool in demonstrating that in some regions pH declines were correlated with increased fossil-fuel combustion and local deposition of atmospheric pollutants. During this environmental debate, the need to quantify reconstructed pH change led to the development of techniques for quantitatively reconstructing water-chemistry change from changes in biotic assemblages (transfer functions – see the following text). These methods are now a routine part of many paleolimnological studies.

Here, we will summarize the major insights regarding lacustrine and environmental structure and function that have emerged from studying the paleolimnological record. These include controls on lake ontogeny, the impact of natural disturbance on lake ecosystems, and the magnitude and nature of human impacts on lakes, including eutrophication, acidification, and alteration of food web structure. We will also consider lakes as important archives of atmospheric processes, particularly of the nature of climate variability, as well as the history of atmospheric pollution.

The Lake as a Sedimentary Archive

Lakes are natural collection basins for material produced within the lake itself and in the adjoining watershed and airshed (Figure 1). Materials enter the lake from outside the basin in surface flow from the catchment, in particulate or wet deposition from the atmosphere, and in groundwater inflow, and also are produced within the lake itself. These materials may sink to the lake bottom, where subsequently they are either recycled into the water column or become a permanent part of the sediment stratigraphy (Figure 2), in either original form or as some degradation product formed by diagenesis. Over time, lake sediments accumulate and preserve an archive of the history of the lake, watershed, and atmosphere. The rate at which sediments accumulate depends on the amount of material that enters the lake from outside, the rate of internal production, and the extent of decomposition of these

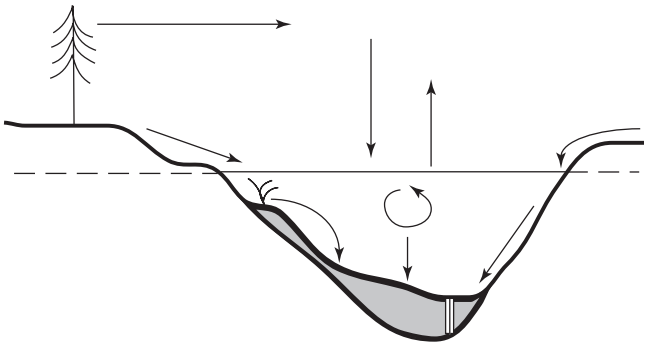

Figure 1 A sketch of sources, as well as losses, of material to lakes and lake sediments. The dotted line is the groundwater table. The shaded area represents accumulated lake sediments, and the striped rectangle is a core sequence through deep-water sediments

components in either the water column or sediments. For example, in relatively undisturbed lakes on hard crystalline bedrock in the Arctic tundra, sediment accumulation rates of $0.1\,\mathrm{mm\,year^{-1}}$ are common, whereas in easily eroded terrains, such as the temperate grasslands of North America, natural accumulation rates often are at least an order of magnitude higher. In disturbed watersheds, such as those dominated by arable agriculture, sediment accumulation rates may be much higher, approaching tens of mm per year.

Commonly, paleolimnological history is reconstructed from a single core from the deepest part of the lake. Studies that compare spatial patterns of deposition in different parts of the lake basin indicate that, in most cases, stratigraphic trends tend to be reproducible from one site to another, given continuous deposition. However, sedimentary concentrations or accumulation rates vary considerably from shallow to deep water because of differences in production and transportation rates. Therefore, basinwide accumulation rates cannot be reconstructed from a single core but require multiple cores from different water depths and depositional environments (Anderson, 1989; Engstrom and Swain, 1986). Multiple cores from within a lake basin have been used to calculate loading rates of pollutants, such as mercury or phosphorus, from watersheds into lakes (Balogh *et al.*, 1999) and thus to quantify the magnitude of human impact on aquatic systems (see the following text).

TOOLS FOR RECONSTRUCTION OF ENVIRONMENTAL HISTORY

Lake sediments sometimes are exposed in section above the contemporary lake surface or may be retrieved by coring. Many types of coring devices have been designed to core lakes of varied size, water depth, and sediment characteristics and to recover sequences that range from just

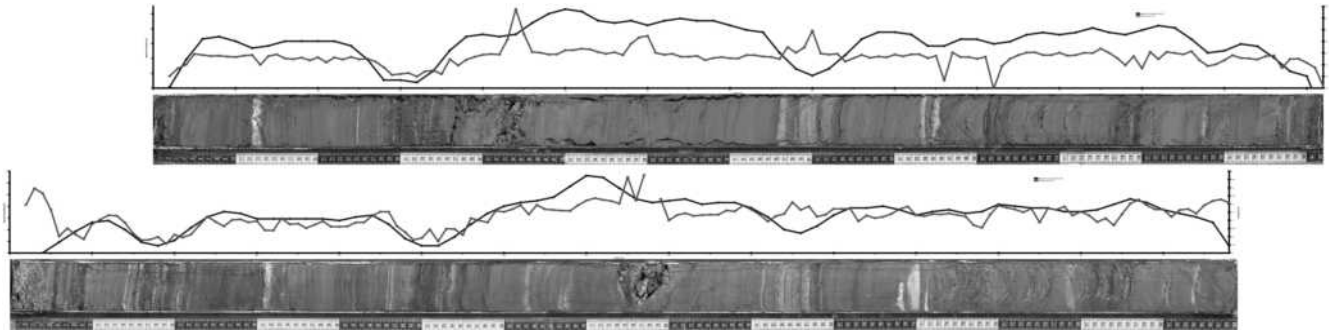

Figure 2 Photograph of sediment cores from Lake Titicaca, Bolivia/Peru. The two cores are from drill holes adjacent to one another and show the reproducibility of the sedimentary sequence. The cores are from an interval of lowered lake level, which resulted in the precipitation of carbonate (light bands) from the water column. The shaded scale bars are each 10 cm, so the upper core is 140 cm in length and the lower is 150 cm. Adjacent to the core photographs are graphs of sediment density (gray line) and magnetic susceptibility (black lines). Magnetic susceptibility is higher in units that have higher minerogenic content. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

the uppermost centimeters to many meters of penetration (Glew *et al.*, 2001). In large, deep lakes or in dried basins, drilling techniques may be utilized to recover sedimentary sequences (Leroy and Colman, 2001). Recovered sediments are generally stored at cold temperatures (~4 °C) and subsequently are processed to retrieve the component biological, physical, or chemical information.

Environmental history is reconstructed from visual features of the sediment (laminations or bedding characteristics, burrows, deformation, color) (Figure 2), other physical characteristics (grain size, porosity, density), and analysis of component biological or biogeochemical materials that form the sediment matrix. The analyzed components are often referred to as *proxies*, because each is assumed to represent some dominant environmental process or condition. For example, one cannot directly see past lake level, but changes in diatom groups that are characteristic of deep or shallow water can provide a proxy of lake-level variation through time. Generally, more than one set of conditions or processes can influence any particular organism, sediment component, or structure, and hence there may not be a unique historical sequence that can be derived from an individual proxy. In the best cases, a form of hypothesis testing is used in which multiple sedimentary components are analyzed, and the resultant data are used as a matrix to reject some potential explanations and hence to piece together a coherent sequence of past events or conditions, consistent with the multiple lines of evidence.

Many tools are available for paleolimnological reconstruction (Figure 3). For reconstructions of the history of the lake itself, these include lake organisms that preserve in whole or in part (e.g. diatoms, chrysophyte cysts and scales, chironomids, ostracodes, gastropods, pollen or seeds of aquatic plants) and organic (plant or bacterial pigments, lipids, fatty acids, humic and fulvic acids, isotopes) or inorganic (algal nutrients, major cations and anions, metals, isotopes, minerals) compounds that are formed or reactive with the water column or sediments. Atmospheric history can be reconstructed from chemical compounds in various forms (hydrogen and oxygen isotopes, S, N, Pb, Hg, pesticides) or particulates (carbonaceous particles, loess) that may be of atmospheric origin or atmospherically transported. A variety of tools exist for reconstruction of catchment history, such as chemical compounds that enter in dissolved or adsorbed form; particulate or mineral material that may be eroded or windblown; pollen, spores, charcoal, and macroscopic plant parts (leaves, twigs); and organic compounds of terrestrial origin (leaf waxes, fatty acids). However, because this review is concerned largely with limnological and hydrologic history, we will not consider many of these terrestrial proxies or dwell on studies focused on catchment history alone. In recent years, a series of books and review articles have been published on the methods, uses, and limitation of all major paleolimnological proxies (e.g. Last and Smol, 2001a,b; Smol *et al.*, 2002a,b). Therefore, rather than summarizing individual proxies here, we will rely on examples of paleolimnological reconstructions to illustrate the capabilities and uses of common proxies and techniques.

Statistical Tools

In recent years, statistical techniques have been used increasingly to derive or infer environmental variables, such as pH, salinity, total phosphorus concentration, or temperature from sedimentary proxies, particularly from complex biological assemblages (Birks *et al.*, 1998). Commonly, multivariate statistics, such as canonical correspondence analysis (ter Braak, 1986), are applied to large data sets from contemporary lakes and used to identify environmental variables that are strongly correlated with species distributions. Transfer functions can be generated for variables that have statistically significant and independent

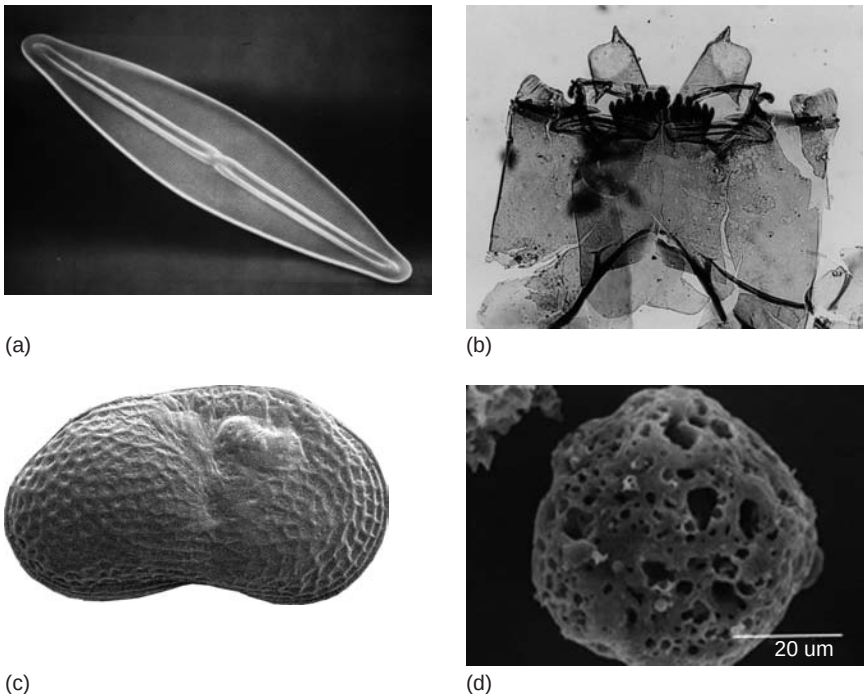

Figure 3 A selection of proxies used in paleolimnological studies: (a) Diatom (Photo: S. Fritz), (b) Chironomid head capsule (Photo: E. Barley), (c) Ostracode (Photo: A. Schwalb), (d) Spheroidal carbonaceous particle from fossil-fuel combustion (Photo: N. Rose). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

influence in these modern data sets and then applied to fossil data to derive a quantitative reconstruction of environmental conditions through time. These multivariate techniques were applied first to infer pH history from the stratigraphy of fossil diatoms in studies of lake acidification (Birks *et al.*, 1990), but are now used widely in paleolimnological studies of nutrient enrichment and climate change (see the following text). Another method used to infer past conditions from biological assemblages is analog matching, in which fossil assemblages are matched to the most similar assemblages in contemporary lakes, and a reconstruction of some environmental variable in the past is then generated from modern measurements in those systems (Smith, 1993). The accuracy of transfer functions can be determined in several ways. Most commonly, the observed environmental values and the values derived from the transfer function are compared for the samples that are used to generate the transfer function, often using bootstrapping or jackknifing techniques to calculate prediction error (Fritz *et al.*, 1999) (Figure 4). Occasionally, sufficient historic data may exist so that reconstructed values from proxies in a sediment core spanning the last century or so may be compared with instrumental measurements of the inferred variable (Dixit *et al.*, 1992; Fritz, 1990; Lotter, 1998; Schelske and Hodell, 1991) (Figure 5) or of climatic parameters that are presumed to drive that variable (Bigler and Hall, 2003; Laird *et al.*, 1998).

Statistical tools also may be used to quantify the pattern, timing, or rate of change in sedimentary variables. For example, multivariate techniques, such as PCA or DCA, can be used to summarize the pattern of change in species composition through time (Figure 6) or to evaluate variation in the rate of change of some proxy variable in the paleolimnological system (Laird *et al.*, 1998). These techniques essentially reduce multiple species or multiple parameters to a single variable or a small number of variables that statistically track the dominant patterns of variation in the larger data set. Similarly, time series analysis can be used to establish the dominant frequencies of temporal variation (e.g. Rodbell *et al.*, 1999).

Chronology

The chronology of environmental change observed in stratigraphic records can be determined via a suite of absolute and relative dating techniques. Some lakes produce annual layers (varves), which can be counted and used to establish a chronology; these are typical only in systems with seasonal inputs and conditions suitable for preservation of sediment structure (Lamoureux, 2001). The most commonly used methods for obtaining absolute ages are radiometric techniques, which include ^{210}Pb for sequences spanning the last ~200 years (Appleby and Oldfield, 1978) and radiocarbon dating of organic material (Björck and Wohlfarth, 2001), which can establish a chronology that

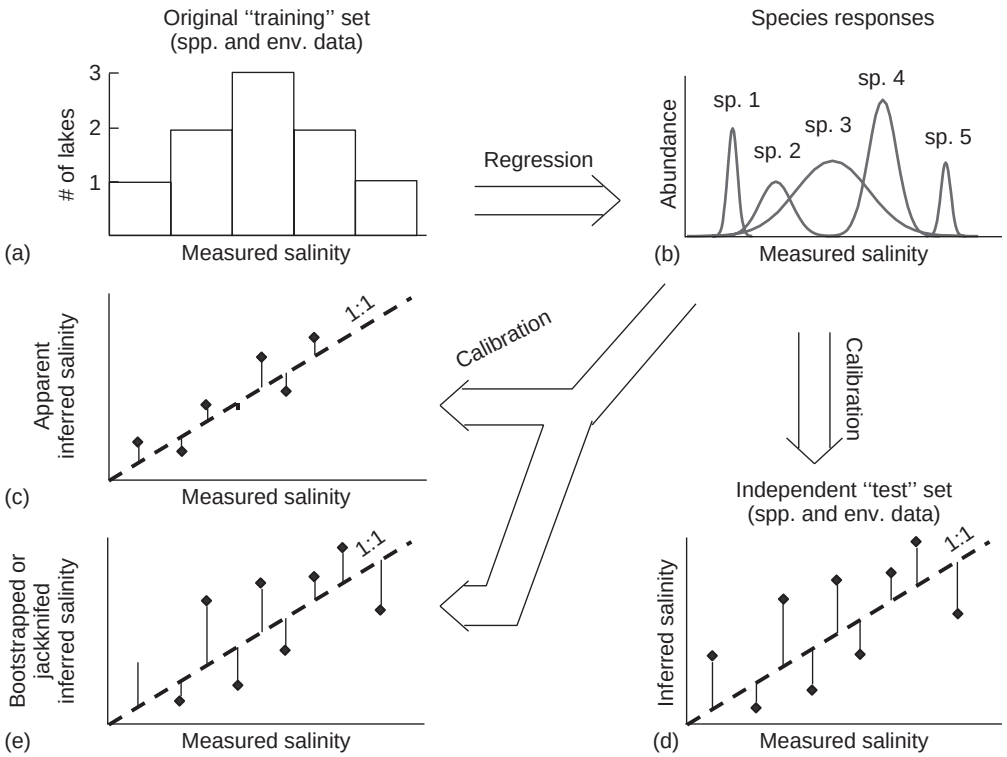

Figure 4 The typical steps involved in developing and assessing the predictive ability of a transfer function, including (a) selection of a modern set of lakes that span an environmental gradient of interest; (b) the regression step, where species responses are estimated based on the species distribution in the modern data set; and the calibration step, where (c) the set of lakes used to estimate species responses are used to generate and evaluate the transfer function; or (d) an independent set of lakes are chosen to evaluate the transfer function model; or (e) computer resampling techniques, such as bootstrapping or jackknifing, are used to evaluate the model (Reproduced from Fritz *et al.*, (1999) by permission of Cambridge University Press)

extends back approximately 50 000 years. Uranium-series dating techniques can be used to establish the age of authigenic carbonates in lacustrine sequences (Israelson *et al.*, 1997), particularly in lakes with evaporite minerals (Fritz *et al.*, 2004a). In suitable circumstances, these tools can be applied to deposits that date back several hundred thousand years. Luminescence dating also has been applied to lake sediments (Berger and Easterbrook, 1993), but this technique relies on high concentrations of quartz or feldspar grains that have been exposed to light (bleached) and consequently is generally only useful where eolian or fluvial input are major sources of sediment.

Some dating techniques produce sediment ages by identification of events or patterns of change in the sediment sequence that are of known age. The expansion of weedy species that spread with land disturbance, such as *Ambrosia* or *Salsola*, has been used to mark the timing of European settlement in North American lake cores that span this period (Bradbury, 1975; Jacobson and Engstrom, 1989). Spikes in the concentration of radionuclides produced by nuclear weapons testing, such as ^{137}Cs, which reached peak atmospheric concentrations in 1963, can be used to identify the age of individual layers of the sediment. In European sequences, profiles of pollutants have been tied to the history of fossil-fuel combustion (Renberg and Wik, 1984) and used to establish a chronology. Volcanic ashes of known mineralogy and age also can be identified in cores and used to establish the age of a single horizon (Sarna-Wojicki *et al.*, 1983; Turney and Lowe, 2001). Less frequently, measurement of paleomagnetic intensity changes are made and correlated to a dated master sequence (King and Peck, 2001).

INSIGHTS FROM THE PALEOLIMNOLOGICAL RECORD

Lake Ontogeny

The evaluation of how lakes age has been a recurring theme in limnology since Pearsall observed lakes of varied nutrient concentration in the English Lake District in the 1920s (Pearsall, 1932) and assumed that they formed a developmental sequence from oligotrophic to eutrophic. Because direct observation of lake development over centuries and millennia is impossible, limnologists have relied

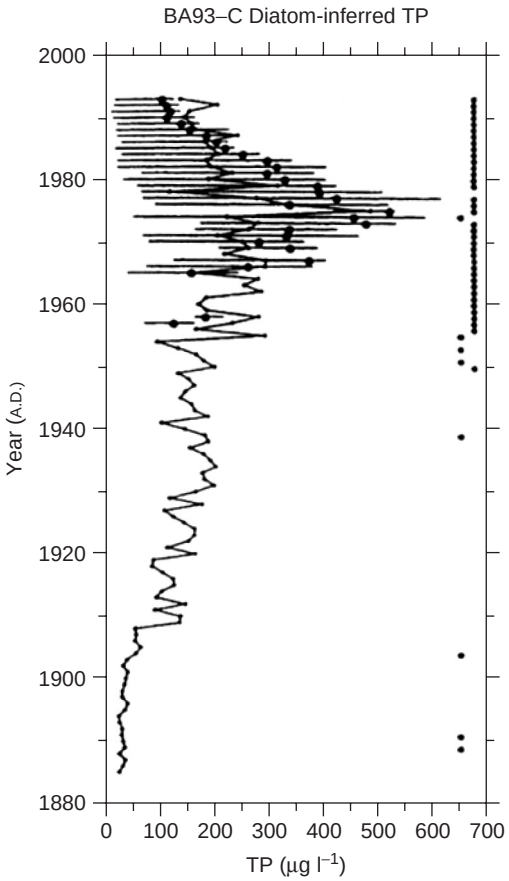

Figure 5 Comparison of diatom-inferred phosphorus (line) with measured concentrations of total phosphorus (TP) in a Swiss lake. The dots represent the measured annual mean TP, and the horizontal lines represent the annual range of TP in the uppermost 15 m of the water column (Reproduced from Lotter (1998) by permission of Arnold)

on sedimentary records to infer patterns of limnological change and to derive hypotheses about the factors controlling the direction and rate of change (Binford and Deevey, 1983). Pioneering paleolimnological studies from lakes in temperate latitudes emphasized changes in lake nutrient concentrations and correlative changes in productivity and hypothesized that lakes become enriched over time, eventually reaching a steady state (Figure 7) or trophic equilibrium (Deevey, 1942). The hypothesis of a trophic equilibrium was a product of one of the major ecological debates of the time regarding whether ecosystems were largely driven by internal dynamics culminating in a steady state (climax) or instead were forced by external, more stochastic, variables, such as climate. As the number of paleolimnological studies has increased in recent decades, it has become clear that there are multiple developmental pathways, rather than a single trajectory of nutrient enrichment with time. Similarly, with the proliferation of data, it is apparent that climate, lakes, and lake catchments are dynamic on all timescales and, therefore, that the concept of steady state is not applicable.

Paleolimnological studies from boreal regions suggest that lakes in areas of base-poor soils with moderate to high precipitation become progressively more acidic as a result of leaching of base cations from catchment soils (Ford, 1990; Pennington *et al.*, 1972; Round, 1961; Whitehead *et al.*, 1989) and/or decreased groundwater inputs caused by podzolization of soils (Engstrom *et al.*, 2000). Associated with the loss of alkalinity is a concomitant increase in water color (dissolved organic carbon, DOC) associated with the buildup of soil organic matter (Engstrom *et al.*, 2000; Pienitz *et al.*, 1999). Some of the early literature from boreal regions also suggested that lakes become progressively more oligotrophic with time, as cations and nutrients are depleted from surface soils (Pennington, 1981). Recent paleolimnological studies of multiple lakes in the boreal rainforest of southeastern Alaska (Figure 6) (Fritz *et al.*, 2004b) and Sweden (Bigler *et al.*, 2003) showed that, although increases in acidity and DOC concentrations over time were widespread in boreal regions of high rainfall, the rate and pattern of water-chemistry change was highly variable because of localized differences in surface hydrology and geomorphology. In southeast Alaska, the pattern of change in nutrient concentrations with time was spatially heterogeneous, and lakes did not show a common developmental sequence during the first few thousand years because of small-scale differences in vegetation change and consequent soil development.

The notion that lakes eventually fill in with sediment and become bogs or wetlands is well entrenched in the scientific literature (Wetzel, 2001). Certainly, infilling is common in some regions, such as in glaciated areas where shallow kettle holes are common and in areas of high precipitation where podzolization of soils and subsequent paludification lead to the growth and expansion of peatlands (Ugolini and Mann, 1979). However, clearly succession from lake to bog or wetland is not a universal trend and occurs only in places where basins are sufficiently shallow to be filled and where erosion rates are sufficiently high to fill the basins before the lakes are destroyed or altered by tectonic, geomorphic, or climatic forces.

Despite over a century of paleolimnological study that now spans many parts of the globe, there has been no recent synthesis of developmental trends in lakes, and most studies of lake ontogeny have focused on lakes in forested zones of north temperate and boreal latitudes. With the increase in sites from grassland, alpine, and arid regions, and from tropical and high-latitude areas, such a synthesis is timely to elucidate the common versus unique features and to further refine our hypotheses about patterns and rates of change and their environmental controls.

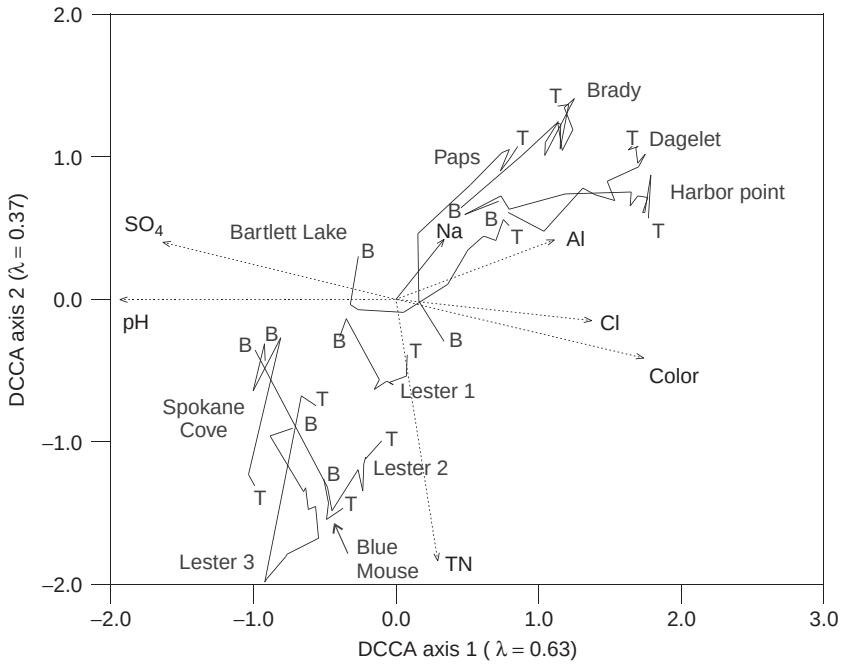

Figure 6 Patterns of change in diatom community structure in lakes from Glacier Bay, Alaska based on multivariate analysis (Detrended Canonical Correspondence Analysis). The arrows show the major water-chemistry variables correlated with the inferred change based on analysis of modern diatom communities. Thus, the first axis of variation is change in pH, whereas variation on the second axis is correlated with lakewater nutrient concentrations (Total Nitrogen). T marks the top of the core or recent times, whereas B marks the base of the cores. The lakes were all formed during the last 2000 years by Neoglacial ice retreat, and thus the pattern of change marks the trajectory of each lake from the time of formation. Note that most lakes show a change along axis 1, suggesting regional pH decline over time, whereas the pattern of change along axis 2 (nutrient gradient) is more variable (Reproduced from Fritz *et al.*, (2004b) by permission of Arnold)

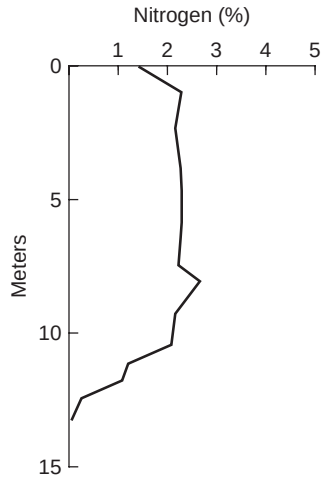

Figure 7 Changes in nutrient concentrations over the last ~10 000 years in Linsley Pond, Connecticut. The stable period is the period of ''trophic equilibrium'' as envisioned by early paleolimnologists (Reprinted from Hutchinson G. E. and Wollack A. (1973) Studies on Connecticut lake sediments. II Chemical analyses of a core from Linsley Pond, North Branford. *American Journal of Science*, **238**, 493–517, by permission of the American Journal of Science)

Response of Lakes to Natural Disturbance

A large portion of the sediment in a lake basin is usually derived from the watershed, and hence lake sediments can be used for reconstructing the history of watershed processes. In some cases, detrital sediments derived from catchment inwash provide a record of the timing of severe storms (Noren *et al.*, 2002) or, in appropriate coastal settings, of hurricane strikes (Liu and Fearn, 2000). These storm events, in turn, can be used to infer synoptic climate variation related to *El Nino* – Southern Oscillation (Rodbell *et al.*, 1999) or the North Atlantic Oscillation, for example.

Paleolimnological data also can be compared with independent evidence of landscape disturbance to evaluate the nature and rate of limnological response and subsequent recovery.

Pollen studies in both North America and Europe have demonstrated abrupt changes in mid-Holocene forest composition associated with pathogens, prehistoric activity, or a combination of the two. These situations provide an opportunity to examine the extent to which forest disturbance affects lakes via changing nutrient inputs, light transparency (erosion), mixing regimes, or hydrologic inputs (surface runoff) and whether or not the lake returns to its former

state and, if so, at what rate. In small lakes in Europe, the widespread decline of elm ~5000 years ago was associated with nutrient enrichment that persisted for several hundred years before recovery to prior conditions (Fritz, 1989). In this case, the role of natural forest disturbance by pathogens relative to Neolithic settlers is debated. In eastern North America, hemlock declined precipitously about 4800 years ago as a result of natural causes (insects and/or climate change), which produced a 2000-year-long change in forest composition before hemlock recovered to its former abundance. Paleolimnological studies from affected sites (Boucherle *et al.*, 1986; Hall and Smol, 1993) show that phosphorus concentrations and productivity, as reconstructed from diatom analysis, increased following the hemlock decline in lakes with large catchments relative to lake size, whereas in small catchments the impacts were limited. Lacustrine productivity subsequently declined as a result of reduced nutrient release during recovery of forest biomass, as forest gaps were colonized by early successional tree taxa. These patterns mirror those seen in experimental studies of the impact of forest clearance on nutrient release to aquatic ecosystems (Bormann *et al.*, 1974). The unique potential of the paleolimnological approach, however, is to show the longer aquatic response over hundreds of years as the early successional taxa were replaced by hemlock. The data suggest that as hemlock abundance increased, lacustrine nutrient concentrations also showed a moderate increase. This suggests that early versus late successional forests differ in their retention of nutrients by vegetation and soils (Hall and Smol, 1993; St. Jacques *et al.*, 2000).

Volcanic eruptions create plumes of airborne tephra that can be transported to great distances from the volcanic center. Tephra deposition in a lake provides a potential source of silica to enhance production by siliceous microorganisms, as well as preservation of siliceous remains in the sedimentary environment. Massive tephra inputs also have the potential for short-term depression of primary production, because of light scattering by particulate material in suspension. Stratigraphic studies reveal that in small lakes, tephra deposition may rapidly change diatom community composition, likely because it alters Si/P ratios and hence nutrient availability; these effects may persist for decades (Abella, 1988; Barker *et al.*, 2000). Studies of lakes affected by the Lacher See tephra, which blanketed large areas of western Europe ~11 000 years ago, suggest catchment lithology affects the impact of ash deposition, although it is unclear whether the lithologic impact is direct or indirect (Birks and Lotter, 1994). In catchments of acidic bedrock, diatom species composition changed, but not in catchments in calcareous terrain.

Climate Change

Lake sediments can be used to reconstruct climate change based on analysis of physical, biological, or chemical variables that preserve in the sediments and are sensitive to climate via either direct or indirect influences (Fritz, 1996). In subhumid to arid regions, paleolimnological studies of variation in lake-level or in ionic concentration (salinity) or composition driven by changes in the balance of precipitation relative to evaporation (P-E) have been instrumental in understanding the natural variability of drought. Drought variability commonly is reconstructed from changes in diatom (Fritz *et al.*, 1999) or ostracode (Smith, 1993) species sensitive to salinity or water depth or from changes in the chemistry (isotopic or trace-element composition) of authigenic or biogenic calcite (Holmes, 2001; Ito, 2001), which reflects the water chemistry at the time of formation. Lake-level change driven by drought also can be reconstructed in transects of cores from shallow into deep water by tracing sediments characteristic of shallow water (with coarse grain size and/or littoral macrophytes) and their migration lakeward at times of lake-level lowering (Digerfeldt *et al.*, 1993).

The magnitude of lake-level change driven by climate in prior millennia is massive by twentieth-century standards. In the tropical Andes, a combination of diatom and geochemical analyses of cores (Baker *et al.*, 2001) and seismic stratigraphy (Seltzer *et al.*, 1998) in Lake Titicaca showed that the lake dropped at least 80 m during a dry phase between 8000 and 4000 years ago. Just to the south in the contemporary salt flat, the Salar de Uyuni, lake levels were as much as 140 m higher during glacial times (Fritz *et al.*, 2004a). Lakes in the northern tropics of Africa underwent lake-level changes of tens of meters (Gasse, 2000; Scholz and Rosendahl, 1988), and paleolake deposits dated between 8000 and 4000 years ago in the now dry Sahara and Sahel (Figure 8) attest to massive hydrological changes caused by intensified monsoon precipitation (Gasse, 2000). An earlier lake-level lowering of tens of meters in East Africa about 11 000 years ago caused desiccation of Lake Victoria, which implies that the diverse assemblage of endemic cichlid fishes must have evolved since that time (Johnson *et al.*, 1996). The paleolimnological record provides an unusual tool for assessing how aquatic biota and ecosystems have responded to climate change in the past, which in turn can contribute to prediction of future responses. However, most paleolimnological studies have used lake records as indicators of climate, rather than analyzing lacustrine response.

During the last few thousand years, the major boundary conditions of the earth's climate system (orbital configuration, atmospheric CO_2 concentrations, extent of continental glaciation) have been roughly similar to those of today. Hence, this period provides a yardstick for reconstructing natural patterns of variation and, in doing so, to evaluate whether twentieth century climate patterns are different from those prior to potential human influences on the climate system. In many regions, paleolimnological

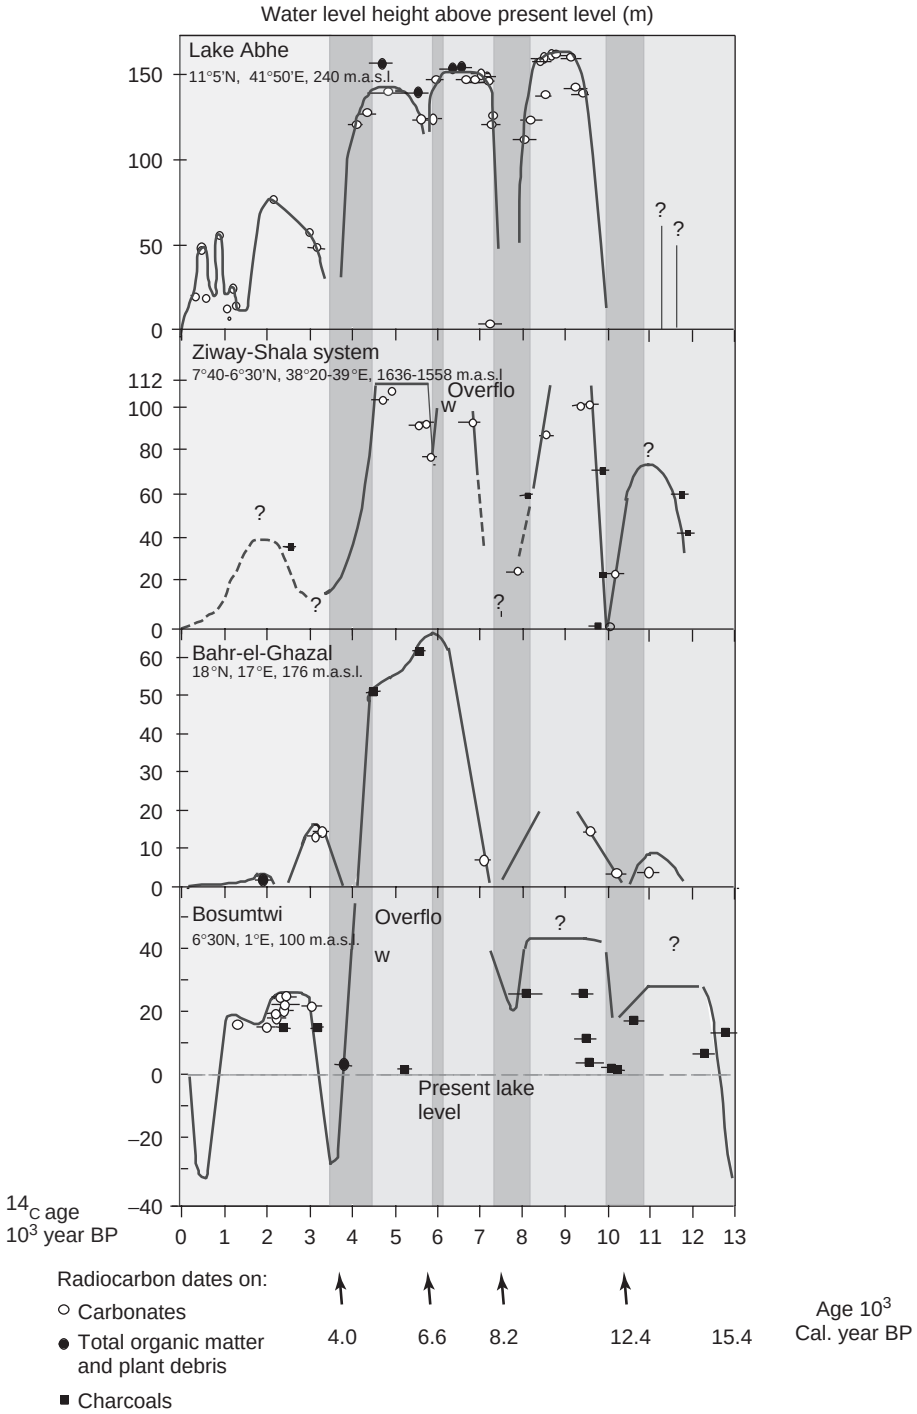

Figure 8 Lake-level changes during the last ~12 000 years in several African lakes in the Sahel and southern Sahara as inferred from paleolimnological data. Note the high lake-level relative to today for much of the period prior to 4000 years ago, as well as the abrupt short-term periods of lake-level lowering indicated by the arrows and shaded zones (Reprinted from Gasse, 2000. ©2000, with permission from Elsevier)

assessments of drought variation at high temporal resolution (decadal or subdecadal) during the last few thousand years indicate that the twentieth century does not encompass the full range of natural variation. In the northern Great Plains of North America, for example, it is clear that intervals of drought as severe and much longer than the Dust Bowl droughts of the 1930s were common in recent millennia (Fritz *et al.*, 2000). In both the Americas and

in Africa, extreme drought was characteristic of Medieval times (Stine, 1994) and coincident with prehistoric cultural collapse or emigration (Figure 9), suggesting that climate change may have contributed to cultural history (Binford *et al.*, 1997; Hodell *et al.*, 2001; Verschuren *et al.*, 2000).

The importance of hydrologic setting in mediating a lake's response to drought has become apparent in a number of paleolimnological studies (Fritz *et al.*, 2000). In a multiproxy study of a lake in central North America, ostracode species composition and shell Mg/Ca concentrations indicated increased lakewater salinity ~5000 years ago, whereas oxygen isotopic values of ostracode calcite became more depleted (Smith *et al.*, 2002). Modeling of basin groundwater flow suggested that during extreme drought, groundwater influx to the lake might have increased because of drying of shallower upstream basins, thereby increasing the input of isotopically depleted water to the lake (Donovan *et al.*, 2002). In contrast, the increased temperatures and evaporation characteristic of midsummer produced increased Mg/Ca in ostracode calcite. Groundwater influences also may affect the magnitude of lake response to decreased effective moisture, such that a lake whose water budget is dominated by groundwater inputs may be relatively stable in water chemistry over time in contrast to a neighboring basin with limited groundwater inflow (Reed *et al.*, 1999). In the Sand Hills of Nebraska, lakes actually formed during extremely dry periods, when migrating sand from destabilized dunes blocked drainage channels, causing dune-dammed lakes to form in response to a rising water table (Loope *et al.*, 1995). These examples of variability in hydrologic response highlight the importance of understanding the hydrogeomorphic setting and of using multiple indicators (Bigler *et al.*, 2002; Rosén *et al.*, 2001) and multiple lakes (Fritz *et al.*, 2000) for well-constrained reconstructions of past climate.

Both temperature and precipitation variation can impact the weathering of catchment soils and hence the input of major cations and anions to lakes. In subhumid or humid regions of base-poor soils, these changes in weathering rates may affect lakewater pH (Sommaruga-Wograth *et al.*, 1997), and hence, pH changes reconstructed from microfossils can be used to infer climate-driven variations in weathering rates (Psenner and Schmidt, 1992) in areas of stable vegetation and soil composition.

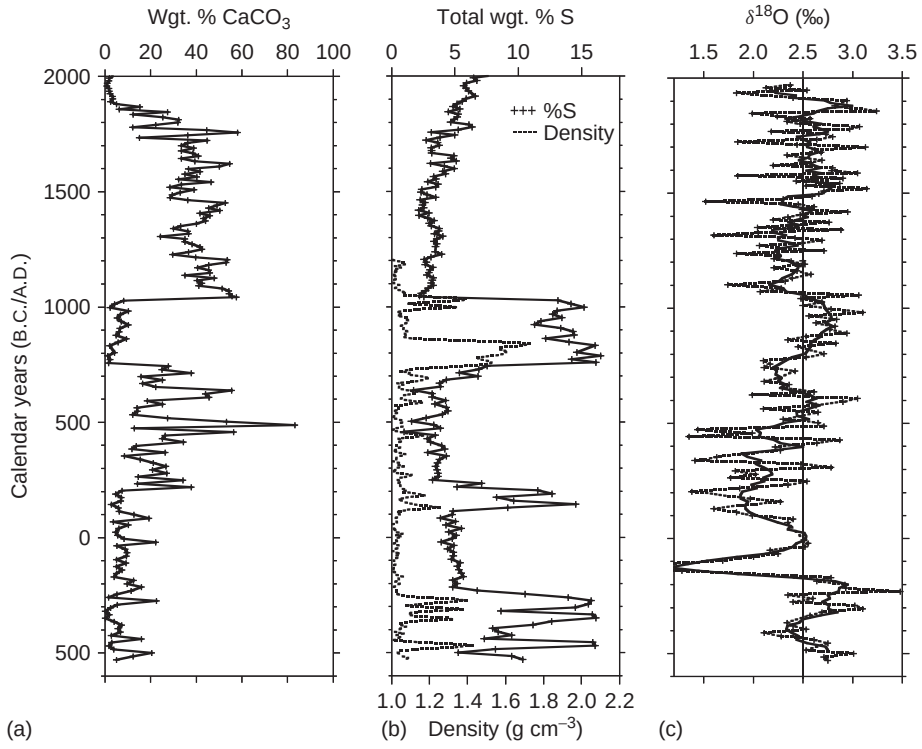

Figure 9 Weight % CaCO3 (a), weight % sulfur (b), sediment bulk density (dashed line), and isotopic concentration of calcite in the gastropod *Pyrophorus coronatus* (c) in a core from Lake Chichancanab, Mexico. Increased values of $\delta^{18}O$ are inferred to represent times of drought (increased evaporation relative to precipitation). The solid line through the isotopic data is a five-point running mean. During times of evaporative concentration of lakewater, gypsum ($CaSO_4$) precipitates from the lake, thereby increasing the % sulfur in the core. The massive increase in % S and enriched isotopic values ~A.D. 800–1000 coincides with the Classic Maya collapse (Reprinted from Hodell, D. A., Brenner, M., Curtis, J. H. and Guilderson, T. (2001). Solar forcing of drought frequency in the Maya lowlands. Science 292, 1367–1370. ©2001 AAAS)

Temperature change affects lakes directly by influencing surface-water temperatures, thermal structure, and the extent and duration of ice cover, and in some cases these variables can be reconstructed from paleolimnological data. In Arctic lakes, the duration of ice cover affects CO_2 exchange with the atmosphere and hence impacts pH in lakes with low buffering capacity. Thus, diatom-inferred pH trends can be used to infer long-term temperature trends (Wolfe, 2002). In Europe, several abrupt cooling episodes that persisted for hundreds of years (Younger Dryas, Preboreal Oscillation, 8.2 event) have been identified between 12 000 and 7000 years ago from records of $\delta^{18}O$ in carbonates, because isotopic fractionation is temperature dependent (Siegenthaler *et al.*, 1984; von Grafenstein *et al.*, 1999). In high northern latitudes, these cooling episodes produced pronounced decreases in lacustrine primary productivity, as evident from the analysis of biogenic silica and organic carbon profiles (Björck *et al.*, 1997). Transfer functions to reconstruct temperature directly from the species composition of chironomids and diatoms (Figure 10) have been derived from modern lakes that span a gradient of temperature and applied to stratigraphic records from lakes, particularly in high latitudes (Joynt and Wolfe, 2001; Levesque *et al.*, 1997; Lotter *et al.*, 1997; Pienitz *et al.*, 1995; Walker *et al.*, 1991). In northern Sweden, however, temperature reconstructions based on diatoms and chironomids were similar during the last 6000 years, but they differed in prior millennia (Figure 10) (Bigler *et al.*, 2002). In this setting, the diatom species composition was strongly affected by pH changes associated with long-term vegetation and soil development following deglaciation (see the preceding text). Thus, pH influences on diatoms overrode the influence of temperature until vegetation and soils stabilized, and therefore, the diatom-based temperature reconstructions during the millennia following lake formation are likely in error.

Temperature change in Arctic regions can be inferred from biological variables (Douglas *et al.*, 1994), as well as from the sedimentology of lakes that receive glacial meltwater and sediments during open-water periods. In Greenland and the Canadian Arctic, these records suggest that twentieth-century temperatures may be higher than at any time during the last 400 years (Lamoureux and Bradley, 1996; Lamoureux *et al.*, 2001; Overpeck *et al.*, 1997), although in some regions they may not be extreme in the context of slightly longer time frames (Hughen *et al.*, 2000).

Human Impacts on Lakes and Their Watersheds

Eutrophication

The first application of paleolimnology to applied limnological questions was the reconstruction of changes in nutrient concentrations over the last few centuries in individual European and North American lakes that were suspected of being enriched from various catchment activities, including sewage influx and land clearance for home building and timbering. Increases in eutrophic diatom and ostracode species and in pigment concentrations, particularly of cyanobacteria, often could be correlated with independent evidence of catchment disturbance (Bradbury, 1975; Engstrom *et al.*, 1985). Such data were pivotal in demonstrating that the nutrient concentrations in some contemporary lakes were considerably higher than their predisturbance state. In the North American Great Lakes, stratigraphic studies of biological indicators (Stoermer *et al.*, 1985) have been coupled with isotopic measurements on organic matter and carbonate (Hodell and Schelske, 1998; Hodell *et al.*, 1998) to evaluate productivity changes associated with enhanced nutrient loading. More recently, transfer functions have been applied to stratigraphic sequences in an attempt to quantify the magnitude of nutrient enrichment of individual lakes (Figure 5) (Bennion *et al.*, 1996; Fritz *et al.*, 1993; Hall and Smol, 1996) or populations of lakes. In the population-based studies, reconstructed nutrient concentrations in presettlement samples (ca. mid-1800s) are compared with modern conditions in multiple sites to assess overall regional trends and to quantify the proportion of regional lakes that have been affected by human activities (Figure 11). In both eastern and midwestern regions of North America, lakes in forested areas generally show little recent change in nutrient concentration, whereas those in regions with significant residential, urban, and agricultural land use show widespread increases in nutrient concentrations, productivity driven pH, and conductivity from road salt input (Dixit *et al.*, 1999; Ramstack *et al.*, 2003; Siver *et al.*, 1999). One of the real values of paleolimnological data is that they provide information on predisturbance conditions and hence can be used in management decisions to set realistic targets for lake restoration (Anderson *et al.*, 1993; Bennion *et al.*, 1996) or to evaluate the impact of efforts to reduce nutrient inputs (Anderson and Rippey, 1994; Hall *et al.*, 1999; Ramstack *et al.*, 2003).

In many stratigraphic sequences from North America, widespread land clearance in the late nineteenth and early twentieth centuries produced massive changes in lake ecosystems (Fritz *et al.*, 1993). However, paleolimnological data have demonstrated that land clearance does not always enrich lakes. A comparison of lakes in both eastern and western Canada in catchments logged for timber production with reference lakes showed that in several regions recent change in lakes with forest clearance in their catchments was no greater than the natural variability in nonimpacted lakes; only very oligotrophic lakes surrounded by steep slopes showed distinct responses to logging and even those responses were small and short-lived (Laird and Cumming, 2001; Laird *et al.*, 2001).

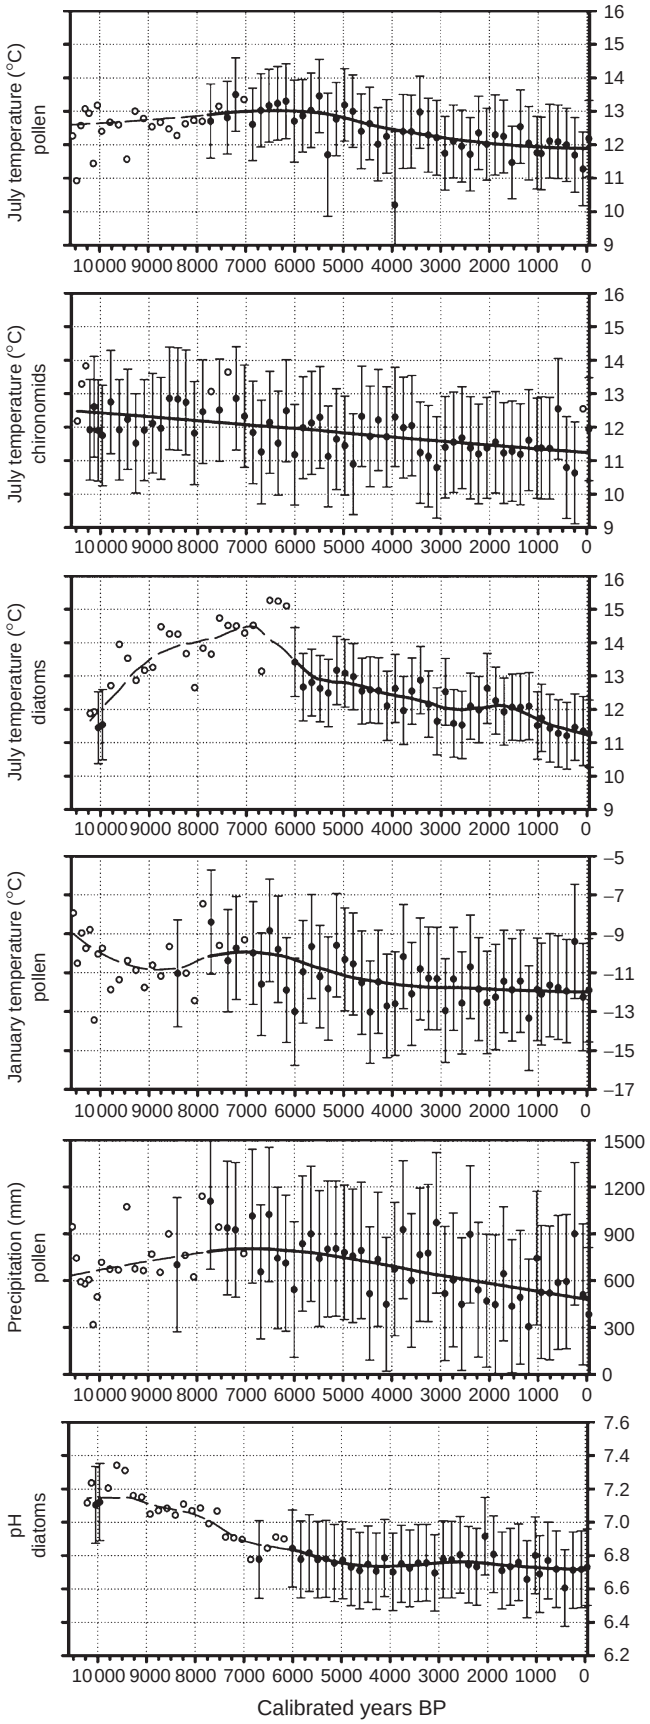

Figure 10 Reconstruction of temperature change in a lake in northern Sweden over the last ~12 000 years based on diatoms, chironomids, and pollen. Note the difference in the diatom temperature reconstruction relative to the other temperature proxies prior to 6000 years ago. Diatom-inferred pH suggests major changes in lake water pH during the early lake history. Thus, it is likely that pH change associated with early soil development exhibited a bigger influence on diatom community structure prior to 6000 years ago than did temperature change (Reproduced from Bigler *et al.*, (2002) by permission of Arnold)

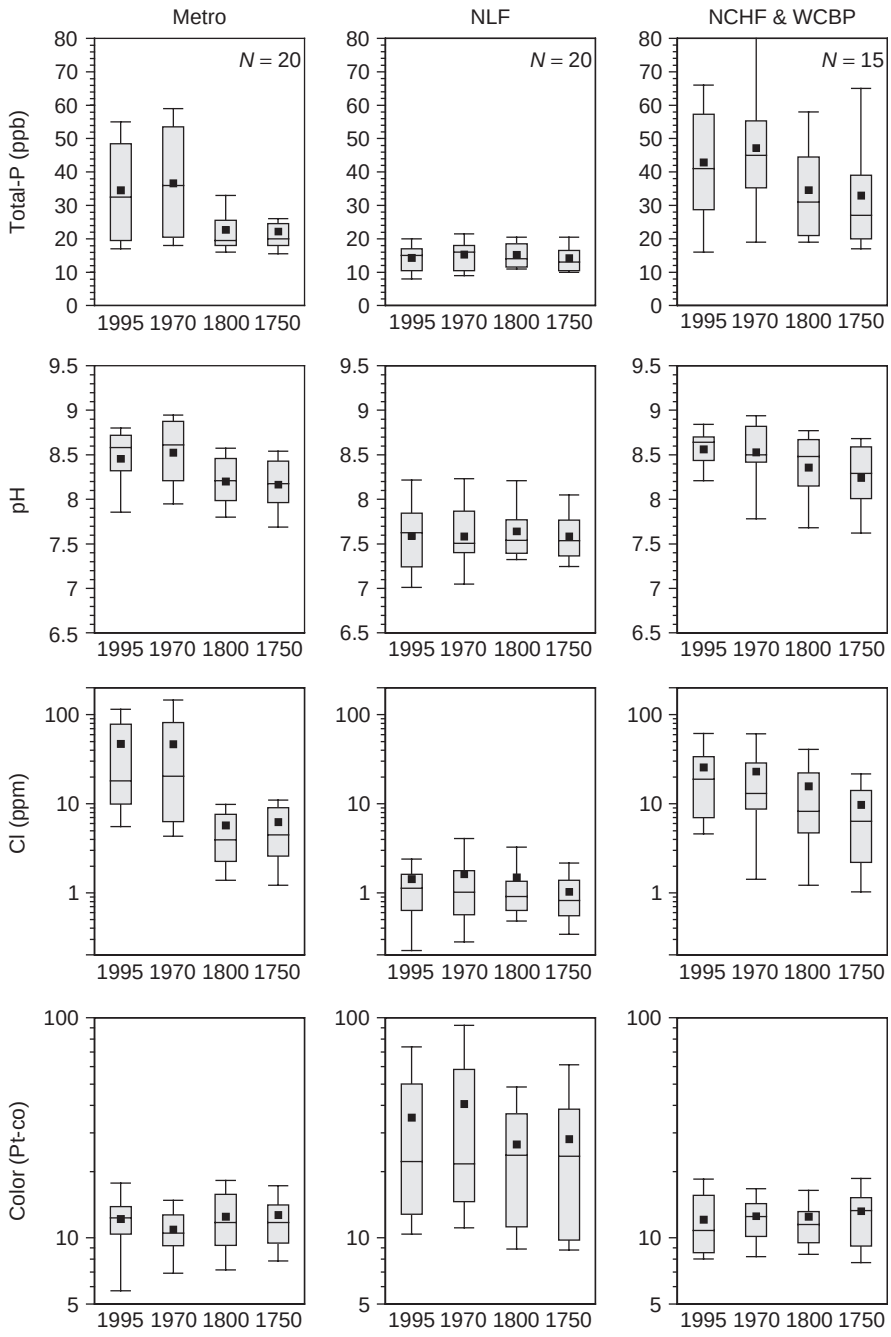

Figure 11 Diatom-based reconstructions of total phosphorus (TP), pH, chloride concentration, and color from core tops (recent times) and core intervals dated at 1970, 1850, and 1700 from a suite of 55 lakes in Minnesota. The lakes are grouped into urban lakes from the Minneapolis–St. Paul metro area, lakes in minimally impacted forested areas, and lakes from agricultural areas of the state. Means are the black squares, gray boxes represent interquartile ranges, the bars are the upper and lower 10%, and the centerline is the median (Reproduced from Ramstack *et al.*, (2004) by permission of NRC Research Press)

Paleolimnological research has demonstrated that in some parts of the world, prehistoric populations also had major impacts on nutrient concentrations (Binford *et al.*, 1987; Ekdahl *et al.*, 2004), particularly in areas of fertile soils. During the Bronze Age (~3000 years ago) in the lowlands of England, for example, the clearance of small patches of land for cereal cultivation within the deciduous forest caused short-lived blooms of cyanobacteria. More extensive land clearance in the Iron Age (~2000 years ago) resulted in massive eutrophication, which was exacerbated

in subsequent centuries with further cultivation and ultimately urban expansion in Anglo Saxon times (Fritz, 1989). One of the classic paleolimnological studies documented the impacts of road building in Roman times on the sedimentation and biotic community of an Italian lake (Hutchinson, 1970).

Clearly, not all nutrient enrichment is human induced. In the grassland regions of North America, for example, a progression from oligotrophic or mesotrophic to eutrophic diatom species parallels the transition from forest to prairie as the climate warmed following retreat of continental glaciers (Radle *et al.*, 1989). Similarly, stratigraphic diatom profiles from a number of European lakes show evidence of modest nutrient enrichment as catchments stabilized following deglaciation and as the climate warmed (Round, 1961).

Food Web Structure

With the implementation of fish stocking programs in western North American lakes in the early twentieth century, questions were raised about how this alteration may have affected food web structure. A comparison of fossil plankton records with contemporaneous limnological data from two manipulated Michigan lakes between 1940 to 1986 revealed that paleolimnological tools could be used to accurately reconstruct shifts in trophic structure (Leavitt *et al.*, 1989). The fish assemblages of Peter and Paul Lakes were manipulated several times during that period; plankton tows revealed that changes in zooplankton and phytoplankton communities accompanied these manipulations. The sediment record accurately reflected these shifts, providing information on changes in total primary production, in community composition of zoo- and phytoplankton, and in size structure of cladoceran populations.

In alpine lakes of the American west, lacustrine sediment records have been used to explore whether shifts in trophic structure have occurred with the implementation of fish stocking programs. In Mount Rainier National Park, sedimentary diatom profiles recorded assemblage changes following the introduction of nonnative trout in the 1920s to previously fishless lakes (Drake and Naiman, 2000). Diatom communities did not return to predisturbance assemblages after fish removal.

Turning the question around, fossil zooplankton assemblages have been used in an alpine lake to determine whether a seemingly native fish population was actually indigenous or became established through an undocumented introduction (Verschuren and Marnell, 1997). The abundance of fossil *Daphnia ephippia* in Avalanche Lake of Glacier National Park suggested heavy zooplanktivory and thus a sustained presence of native cutthroat trout prior to the 1930s. An increase in zooplankton populations in the 1930s and early 1940s indicated a disturbance to food web structure, possibly due to failed attempts at introducing nonnative trout species during this time. Overall, the reconstructions of food web dynamics presented here provide good examples of how paleolimnological tools can be used in hypothesis testing, particularly in remote lakes for which little historical data are available.

Acidification/pH Change

The impact of acid rain on aquatic ecosystems was a major environmental issue in the 1970s and early 1980s. Because historical time series of pH measurements were extremely rare, it was difficult to evaluate from contemporary data whether or not lakes had become more acidic as a result of the deposition of acids derived from fossil-fuel combustion or alternatively whether the acidity was of natural origin (Patrick *et al.*, 1981). Thus, the paleolimnological record became a major tool for historical assessment of long-term water-chemistry trends. The use of paleolimnological data in the political debate demanded rigorous hypothesis testing, high temporal resolution of the sediment record, quantification of the amount of limnological change, and generation of robust error estimates. As a result, paleolimnology rapidly evolved from a largely descriptive science to a more quantitative one that integrated analysis of multiple variables in individual cores.

The reconstruction of pH change from paleolimnological records commonly is based on changes in the species composition of diatoms and chrysophytes. Large data sets of surface-sediment samples (the upper $\sim 0.5-1.0$ cm of mud, which represent modern deposition) and associated water-chemistry measurements were collected from lakes in regions of base-poor soils that were potentially sensitive to acid deposition. Multivariate statistical techniques were used to identify the pH ranges of algal species in these modern samples and to generate transfer functions to reconstruct pH from diatom or chrysophyte assemblages (Birks *et al.*, 1990; Dixit *et al.*, 1993). Subsequently, these transfer functions were applied to fossil assemblages from cores to reconstruct pH conditions in the past. Application of regional transfer functions (Battarbee and Charles, 1987; Charles *et al.*, 1989; Cumming *et al.*, 1994) demonstrated that in acid-sensitive regions of Scandinavia and Great Britain, many lakes had acidified by 0.5–1.5 pH units since the onset of major industrialization in the late 1800s. In North American regions, downwind of major industrial and urban centers, large-scale acidification also had occurred in the decades following increased fossil-fuel combustion, whereas there was little evidence for acidification in acid-sensitive regions with low atmospheric deposition rates, such as in the Sierra Nevada and northern Rocky Mountains. Analysis of sedimentary profiles of trace metals that were components of fossil fuels, such as Pb, Cu, and Zn, as well as carbonaceous particles (Figure 3) resulting from combustion, served to demonstrate that these pH changes were associated with increased local deposition of atmospheric pollutants (Charles and Norton, 1986; Fritz *et al.*, 1989). Paleolimnological techniques also

were used to track the recovery of impacted aquatic systems and to evaluate the factors affecting patterns and rates (Battarbee *et al.*, 1988; Dixit *et al.*, 1992; Smol *et al.*, 1998).

The development of transfer functions for pH inferences also enabled the quantitative reconstruction of natural pH change in the millennia preceding industrialization (Jones *et al.*, 1989; Whitehead *et al.*, 1989). One of the most elegant paleolimnological studies ever conducted analyzed over 700 contiguous diatom samples spanning the last ~12 000 years from a lake in northern Sweden (Figure 12) to evaluate whether the magnitude or rate of recent pH change differed from that associated with natural processes (Renberg, 1990). Long-term pH decline caused by natural soil development had occurred in the millennia following lake formation (see Section on "Lake ontogeny"), but the rapid rate of acidification in the last century was unparalleled in the 12 000-year record. Also apparent in the stratigraphic record is a decrease in acidity about 2300 years ago at the time when agriculture expanded regionally, likely caused by plowing and the erosion of carbonate-bearing subsurface soils (Renberg, 1990; Renberg *et al.*, 2001).

Ultraviolet Radiation

Recent trends in stratospheric ozone depletion have raised concerns about the amount of potentially damaging ultraviolet (UV) radiation, particularly UV-B (280–320 nm), within aquatic environments. This has prompted the development of paleolimnological techniques for reconstructing UV conditions, as once again, direct observations are typically too brief to elucidate the magnitude and effects of changes in UV radiation. Paleolimnological investigations have focused on systems at high latitudes or altitudes, where the atmosphere is thinner, and the position of treeline fluctuates, which alters inputs of DOC to these lakes. The humic and fulvic fractions of DOC strongly absorb UV wavelengths and thus affect UV attenuation in the water column. Transfer functions relating diatom distributions to DOC concentrations and water transparency have been developed for a set of lakes in the Northwest Territories of Canada (Pienitz and Smol, 1993) and applied to sediment cores from boreal treeline lakes in that area to reconstruct DOC concentration (Pienitz *et al.*, 1999). These reconstructions reveal shifts over the Holocene in DOC concentration with changes in watershed vegetation, as confirmed by pollen

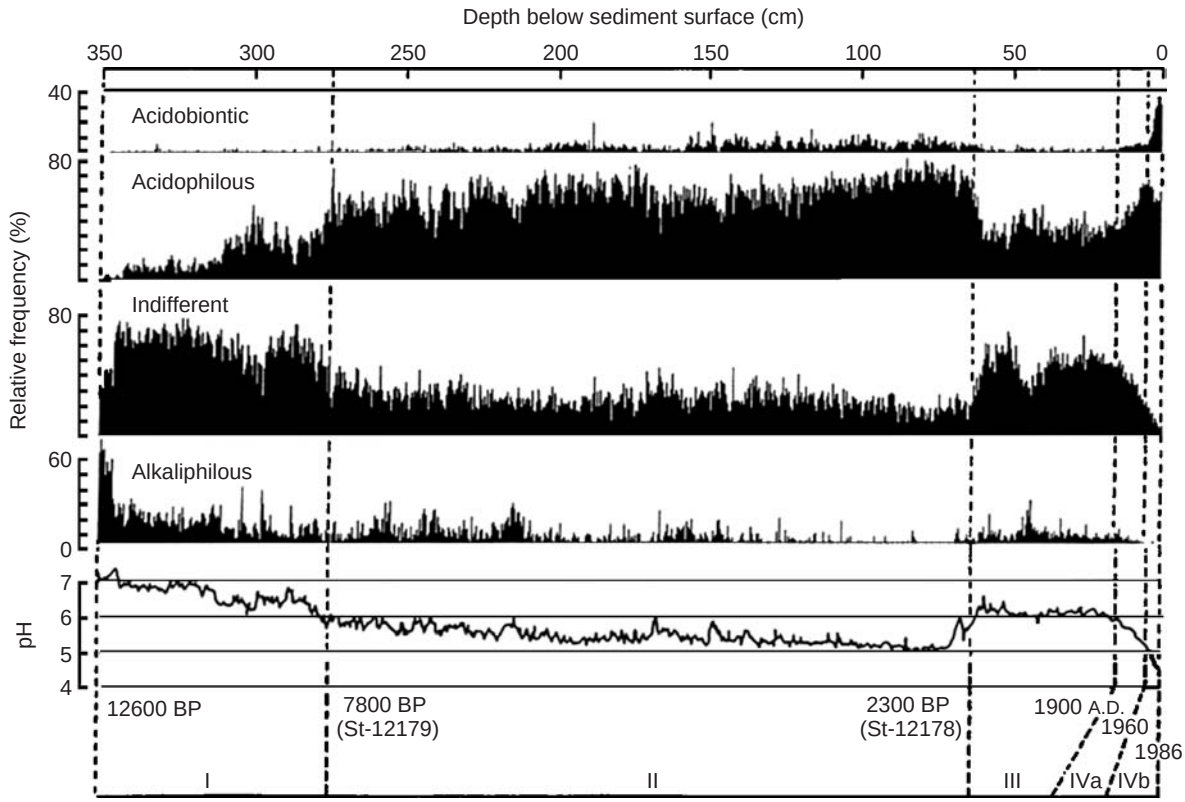

Figure 12 Changes in diatom-inferred pH from Lake Oresjon, Sweden. In the upper part of the figure, the diatoms species are grouped into acid requiring (acidobionitic), acid-preferring (acidophilous), pH indifferent, and alkaline preferring (alkaliphilous) taxa. The lower curve is the pH as reconstructed from these diatom data. Note the increase in pH ~2300 years ago associated with intensified prehistoric agriculture and the unprecedented rapid pH decline after 1900 A.D. (Reproduced from Renberg (1990) by permission of Royal Society of London)

analyses; these DOC changes, in turn, may affect UV penetration and hence aquatic communities.

Fossil pigments also have been used to investigate past UV exposure in aquatic systems, as some benthic algae produce unique pigments when exposed to UV. Two indicator pigments that are produced under high UV conditions have been identified, and the validity of their use in inferring past UV environments was tested in an experimentally acidified boreal lake (Leavitt *et al.*, 1997). Acidification reduced measured concentrations of DOC about fourfold and increased the maximum depth of UV-B penetration eightfold between 1982 and 1990. During this period, the sediment record indicated a 3- to 10-fold increase in these pigments, revealing that these fossil pigment records may provide insight into past UV environments in additional lakes.

Atmospheric Pollutants

Lacustrine sediment records also have provided information on deposition rates and patterns of atmospheric contaminants, particularly of metals, such as lead (Pb) and mercury (Hg). Studies of lead pollution in Swedish lakes have revealed a surprisingly early (about 3000 years ago) increase in Pb deposition, beginning well before industrialization and attributed to metal production (Brännvall *et al.*, 1999; Renberg *et al.*, 1994). Rates of Pb pollution have varied extensively over the past 3000 years, with clear peaks occurring during periods such as Greek–Roman times, the Industrial Revolution, World War II, and the 1970s (Brännvall *et al.*, 2001). Patterns of Pb deposition in lakes across Sweden reveal higher deposition rates in southern Sweden, supporting the idea that the main source of contamination is mainland Europe and Great Britain. Similarly, in the Bolivian Andes stratigraphic studies of metals associated with smelting have been used to document the extent of pre-Incan and pre-Colonial metallurgy (Abbott and Wolfe, 2003).

Mercury deposition patterns in lacustrine sediments of remote and semi-remote lakes of North America and northern Europe reveal that atmospheric Hg has increased by a factor of two to five since the beginning of the industrialized period (Bindler *et al.*, 2001; Lockhart *et al.*, 1998; Lorey and Driscoll, 1999; Lucotte *et al.*, 1995; Swain *et al.*, 1992; Yang *et al.*, 2002). Decreased inputs to midwestern lakes of the US since the 1970s are inferred from sediments in both urban and rural lakes and are attributed to reduced emissions from regional sources (Engstrom and Swain, 1997). In contrast, this decline was not evident in sediments of coastal lakes in southeastern Alaska, implying that global Hg emissions have not abated (Figure 13). Questions have been raised regarding the integrity of sedimentary Hg profiles, as redox conditions affect the form of Hg and the various forms have different mobilities in the sediments. A comparison of lake sediment records of Hg deposition with known histories of Hg contamination in three different Canadian lakes revealed good agreement between the two (Lockhart *et al.*, 2000).

The acidification of aquatic systems via acid deposition was addressed above; however, the nitrogenous component of acid deposition also has the potential to contribute to eutrophication in N-limited aquatic systems. Over the past century, human alteration of the global nitrogen (N) cycle has doubled the amount of fixed nitrogen (predominantly in the forms of ammonium and nitrate) transferred from the atmosphere to land-based ecosystems (Vitousek, 1997). Alpine lakes have served as a focal point for investigating the effects of enhanced N deposition (Psenner and Schmidt, 1992; Saros *et al.*, 2003; Wolfe *et al.*, 2001), because these systems typically have poor buffering capacities, as well

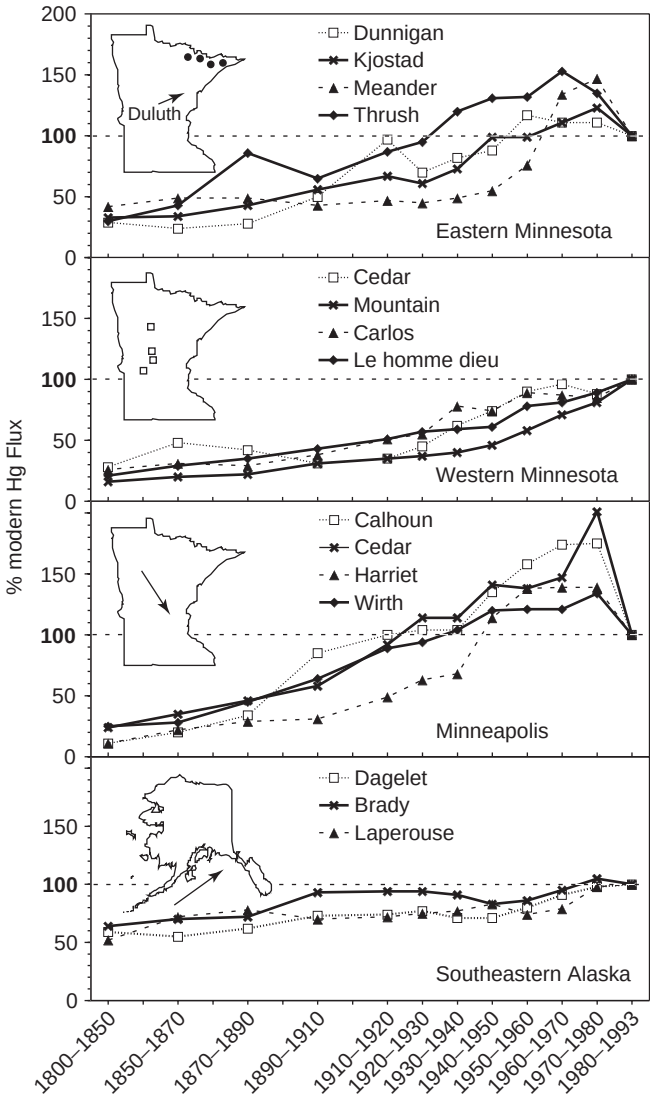

Figure 13 Changes in mercury accumulation rates in the sediments of lakes from 3 regions of Minnesota and from Alaska (Reprinted with permission from Engstrom & Swain 1997. ©1997 American Chemical Society)

as N-limited primary production. In lakes of the Colorado Front Range, shifts in fossil diatom assemblages intensified during the 1950s, with an increase in several diatom taxa typical of mesotrophic lakes (Wolfe *et al.*, 2001). The timing of the shift coincided with the widespread implementation of the Haber–Bosch process for the production of commercial N fertilizers. δ^{15}N analyses of sedimentary organic material in the cores also support the idea that these lakes received increased atmospheric N deposition.

Catchment Processes and Erosion Rates

Reconstruction of catchment erosion rates is possible, based on changes in the accumulation rate of the clastic portion of sediment (Dearing, 1994). Thus, comparison of presettlement versus postsettlement accumulation rates has been used to evaluate the impact of land clearance of varied scale and in different terrains. In the deciduous forests of northwest Europe, catchment sediment yield was low and relatively stable prior to human disturbance but increased about fourfold in the Iron Age and Roman period, when charcoal requirements for smelting of ore led to massive forest clearance and erosion of topsoil. In the Middle Ages, erosion rates returned to predisturbance conditions following reforestation, but accelerated more than 10-fold in progressive deforestation from the eleventh century onward. Interestingly, in this setting, the post-eleventh-century soil erosion rates related to human activities are similar in magnitude to those associated with the cold continental conditions at the end of the last glacial period, in a landscape dominated by unstable soils and tundra or early successional forest. In the Péten region of Guatemala, forest clearance and agriculture during Mayan times eroded topsoils and increased the loading of inorganic material (2–24 times) and phosphorus (1–10 times) into lakes, with increasing sediment accumulation rates, as land use intensified and population numbers increased (Binford *et al.*, 1987). Aquatic productivity apparently decreased, however, possibly because of water column shading associated with a high silt load or, alternatively, reduced availability of phosphorus.

CONCLUSIONS/FUTURE OF THE DISCIPLINE

In the latter decades of the twentieth century, paleolimnology was transformed from a descriptive science with a small number of practitioners to a mature quantitative field with its own journal (Journal of Paleolimnology) and with widespread application to both applied and nonapplied scientific questions. It has played a significant role in developing our understanding of the patterns and magnitude of natural environmental variability of nonmarine systems, their watersheds, and the atmosphere. The paleolimnological record can be used as a tool to describe the nature, magnitude, and rate of response to both natural and human-induced disturbances, and thus it can be used as a yardstick for evaluating the extent to which human-induced changes exceed those produced by natural environmental variation. In this respect, it has been used increasingly in environmental management by federal and state agencies to evaluate human impact, as well as to set suitable targets for restoration efforts. This review has focused on insights about the environment gained from the study of lake sediments and thus uses the term paleolimnology in a restrictive sense. However, many of the generalizations that we make here also apply to other sorts of inland aquatic systems.

The earliest paleolimnological studies focused on describing long-term changes in the lacustrine environment, but in recent decades the paleolimnological record has been used mainly to reconstruct external atmospheric or catchment processes. Thus, in recent times, the paleolimnological record has been underutilized as a tool for understanding how aquatic systems and species respond to perturbations, such as climate change, catchment disturbance, or atmospheric mercury deposition.

The increased emphasis on quantification of trends has led to the proliferation of modern calibration data sets for a variety of organisms and in diverse geographic areas that include both populated and remote regions. These calibration data sets, however, are primarily used to reconstruct past conditions and have not been used to their full potential. For example, although large databases of modern diatom and water-chemistry data are now supported both in the United States and Europe, only cursory attempts have been made to examine diatom distribution across large areas in order to expand our knowledge of the patterns of species distributions and hence their potential ecological and biogeographic controls.

The majority of paleolimnological studies still confine themselves to case studies of an individual lake or small number of lakes. Thus, the extent to which the observed patterns are representative of a broad population of lakes under similar environmental controls is often unclear. Only a relatively small number of studies of twentieth-century human impacts on lakes have utilized stratigraphic data from multiple lakes within a region to quantify the amount and nature of regional variability. Continued generation of statistically robust regional data sets is likely to continue where paleolimnology is applied to lake management at the federal or regional level. Considerably less has been done in terms of describing limnological variation of large regions at longer timescales, and spatial patterns of variation should be considered more explicitly in designing stratigraphic studies. In some cases, the time is ripe for more extensive synthesis of considerable data already generated in individual studies so that we can understand patterns and processes at the landscape scale.

Many paleolimnological records contain a wealth of information, particularly those analyzed at high temporal resolution and that utilize multiple proxies. However,

presently we are unable to interpret many features of stratigraphic records because of an inadequate knowledge of the multiplicity of factors that influence the physical, biological, and chemical structure of lakes. Thus, in many cases we can only speculate about why multiple lakes in a region show different patterns of change through time (Fritz *et al.*, 2000), why reconstructed environments from two different proxies are not identical (Smith *et al.*, 2002), or what the hierarchy of direct or indirect influences are on paleolimnological proxies (Saros and Fritz, 2000) in different settings. Understanding some of the more subtle features of stratigraphic records will require more frequent coupling of paleolimnological and modern process studies to understand the temporal dynamics of lakes. These might include meteorological and hydrologic measurements and modeling to better constrain lacustrine responses to climate (Donovan *et al.*, 2002; Doran *et al.*, 2002; Stone and Fritz, 2004), long-term monitoring of physical, chemical, and biological patterns of change (Interlandi *et al.*, 1999), field experiments of chemical and biological responses to perturbations (Leavitt *et al.*, 1989), and controlled laboratory studies of environmental physiology (Saros and Fritz, 2002).

These inadequately explored issues, such as how lakes respond to disturbance over long timescales, patterns of change at the landscape scale, exploration of species ecology and biogeography, and integration with modern process studies suggest that paleolimnology has incredible untapped potential to yield new insights in the fields of organismal, population, community, and ecosystem ecology, as well as evolution, hydrology, and climatology. The wealth of extant paleolimnological data can be used to describe patterns of variation at various temporal and spatial scales and hence to generate testable hypotheses regarding the behavior of organisms and complex systems. Thus, although paleolimnology has evolved into a mature discipline in its own right, it should strive to explore in greater depth the interactions among the atmosphere, geosphere, biosphere, and hydrosphere and their ultimate drivers, both in the modern world and through geologic history.

PART 10

Rainfall-runoff Processes

111: Rainfall Excess Overland Flow

ROGER E SMITH[1] AND DAVID C GOODRICH[2]

[1] *Civil Engineering Department, Colorado State University, Fort Collins, CO, US*
[2] *Southwest Watershed Research Center, ARS USDA, Tucson, AZ, US*

One of the processes that can generate surface runoff is rainfall excess, which is a process controlled at the surface of the soil. This occurs when rainfall reaches the soil at a rate in excess of the soil's ability to absorb, which is called infiltrability. This dynamic property can in uniform soil be described by a rather well-developed infiltration theory. Surface water flow toward a receiving channel may in geometrically simple conditions be described by the kinematic or diffusive wave equations. The surface water is in continuous interaction with the soil's changing infiltrability. Both infiltration theory and surface flow equations are introduced here, and the interactions and complexities arising from spatial variations are discussed. These processes are incorporated in modern hydrologic response models, using numerical solutions as well as analytic solutions. The application of this theory in hydrology, however, must be informed by scale considerations and the appropriate treatment of natural complexities. Some scale limitations and some approximate methods for treating spatial soil variations are illustrated in this article, with reference to relevant literature.

INTRODUCTION

Runoff generated from storm rainfall is largely determined by local interaction of the properties of the rainfall, ground cover, land use, and soil (*see* **Chapter 117, Land Use and Land Cover Effects on Runoff Processes: Urban and Suburban Development, Volume 3** and **Chapter 118, Land Use and Land Cover Effects on Runoff Processes: Agricultural Effects, Volume 3**). While vegetation, above ground cover, and land use play a critical role in the fate of rainfall, this article focuses on the interactions between rainfall and surface soils. Here we discuss the physical dynamics of those cases where rainfall generates surface runoff at the point where it falls. *Infiltration excess* occurs when the rainfall comes at a rate higher than the rate at which the otherwise unsaturated soil can absorb water. (*Saturation excess*, discussed below, occurs when the soil is saturated or filled with water from a subsoil restriction, such as a shallow bedrock. This mechanism is not rainfall rate dependent.) The runoff or surface water flow resulting from infiltration limitation is called *infiltration excess* runoff, and the (variable) limiting soil intake rate is called the soil *infiltrability*. Infiltration excess runoff is often also referred to as *Hortonian* runoff, after Robert Horton (Horton, 1933).

The infiltration and saturation excess–generating mechanisms are not mutually exclusive on a watershed, nor even mutually exclusive at a point on a watershed. The rainfall rate may exceed the infiltrability for some storms, and for others the rain may come slowly until the surface soil layer is saturated. Climate and geography will determine which mechanism is dominant at a given location and time. Figure 1 shows a world map with climate zones indicated. The predominance of relatively short high intensity storms in most subhumid and semiarid zones means that these areas are more prone to infiltration excess runoff. Conversely, saturation excess runoff is more common in humid areas, usually characterized by greater rainfall volumes but with lower intensities. Increasingly, human activity (e.g. urbanization, compaction, etc.) results in an overall decrease of soil infiltrability resulting in globally increasing areas of infiltration excess runoff generation.

Infiltrability changes with many factors, some of which are described quantitatively here. It can also change because of changes in the soil with freezing, thawing, compaction, and tillage. An intense rain on cultivated soil

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

can also create a surface crust or sealed layer. While these processes have been studied and described elsewhere, they are difficult to quantify outside local conditions such as soil cover, and will be omitted from this overview.

The timescale of infiltration and surface flow processes is important, insofar as hydrologic analysis often employs lumping in space and time to approximate the behavior of hydrologic processes. Changes in soil water and changes in runoff rates occur on the order of seconds in some cases, and a timescale of a few minutes is necessary to capture the dynamics of surface runoff. By contrast, the slow movement of water in an aquifer (*see* **Chapter 112, Subsurface Stormflow, Volume 3** and **Chapter 149, Hydrodynamics of Groundwater, Volume 4**) can be characterized by timescales on the order of days or months. Thus, infiltration excess runoff is one of the more dynamic or rapidly changing fluxes in the hydrologic cycle, and as will be seen below, requires knowledge of the temporal pattern of rainfall rates to characterize it accurately.

Historical Notes

Robert Horton was one of the early proponents of the concept that higher intensity rainfall rates on soils of finer texture can exceed the intake rate of the soil and runoff thus reaches upland channels by *overland flow* on the soil surface. He also recognized the mechanism of streamflow generation by flow through the soil mantle. Recent reanalysis of Horton's data from his laboratory watershed in upstate New York indicates, not surprisingly, that the catchment included areas likely to produce a variety of runoff mechanisms, including a small marshy area (Beven, 2004).

Horton termed the limiting soil surface intake rate the "infiltration-capacity" (Horton, 1933). While he recognized that the soil intake rate decayed in value through a storm, he attributed the reduction to surface soil compaction, soil colloidal swelling, or inwashing of fines from the surface (Horton, 1939). Horton made a rather insightful analysis of the hydraulics of overland flow, but his analyses generally used constant infiltration rates. While he was aware of the prescient work of Green and Ampt (1911), he did not believe it related to catchment infiltration:

> "The question naturally arises whether the infiltration-capacity may not vary with the depth of penetration of soil-moisture into a dry soil column. Thus far, the author has not found any definite evidence of an appreciable variation in this respect. The work of Green and Ampt has a bearing on this question although their mathematical analysis of the process appears to be faulty." (Horton, 1936)

Horton further expressed his belief that the counterflow and compression of air negated the ideas of Green and Ampt. Horton's work is a good example of an early appreciation of processes at work in the field, but with a mistaken view of the relative magnitudes involved.

THE DYNAMICS OF INFILTRATION DURING STORM RAINFALL

Unsaturated Soil Hydraulic Properties

Understanding the dynamics of infiltration and runoff requires some understanding of the hydraulics of water in unsaturated soil. Soil is a *porous medium* through which water can flow even when there is air in the spaces between soil grains. Water in unsaturated soil is at a lower pressure than that of the air surrounding it, due to the *capillary pressure*, which is a property of the interface between air and water. This capillary pressure may be expressed as an equivalent (negative) head of water, with the symbol ψ, and is the same force that causes water to rise in an open capillary tube from a free source of water (*see* **Chapter 73, Soil Water Potential Measurement, Volume 2** for a more thorough discussion).

The volumetric water content of a soil, for which the symbol θ [L^3 L^{-3}] is used, varies between zero and the soil porosity, which is the relative volume of the soil not occupied by solid matter. Figure 2(a) illustrates how the soil water pressure decreases dramatically (becomes more negative) as the soil dries. This relation is often referred to as the soil water *retention* relation. Figure 2(b) illustrates by example how the soil water conductivity also falls dramatically as the soil becomes drier. *Hydraulic conductivity, K*, [$L\,T^{-1}$] is defined as the rate of flow of water in soil in response to a unit gradient of hydraulic head. The expression for this is *Darcy's Law*:

$$v = -K\frac{dH}{dz} \tag{1}$$

where v is the rate of flow in units $L\,T^{-1}$, H is hydraulic head in terms of equivalent depth of water (L), and z is the measure of distance (L). The hydraulic head, H, is made up of capillary pressure head and gravitational potential: $H = \psi + z$. Thus, in a homogeneous soil of uniform water content, and thus uniform capillary pressure head (zero capillary head gradient), water may flow downward due to gravity alone. On the other hand, unsaturated flow normal to the gravitational vector moves only in response to capillary head gradients.

In unsaturated soils, as illustrated in Figure 2(b), K is a function of capillary head, $K(\psi)$, expressed as a relative conductivity, *kr,* which is the ratio of $K(\psi)/K(0)$. $K(0)$ is called *saturated hydraulic conductivity*, K_s. K can also be treated as a function of water content, θ, through the retention relation of Figure 2(a). During rainfall infiltration, surface soil water content increases from the initial value, θ_i. For large enough rainfall rates, the surface water can reach *field saturation.* This is the water content at zero capillary head, θ_s. Further discussion of soil capillary properties can be found in article (*see* **Chapter 74, Soil Hydraulic Properties, Volume 2**), in soil physics texts, or in Smith (2002).

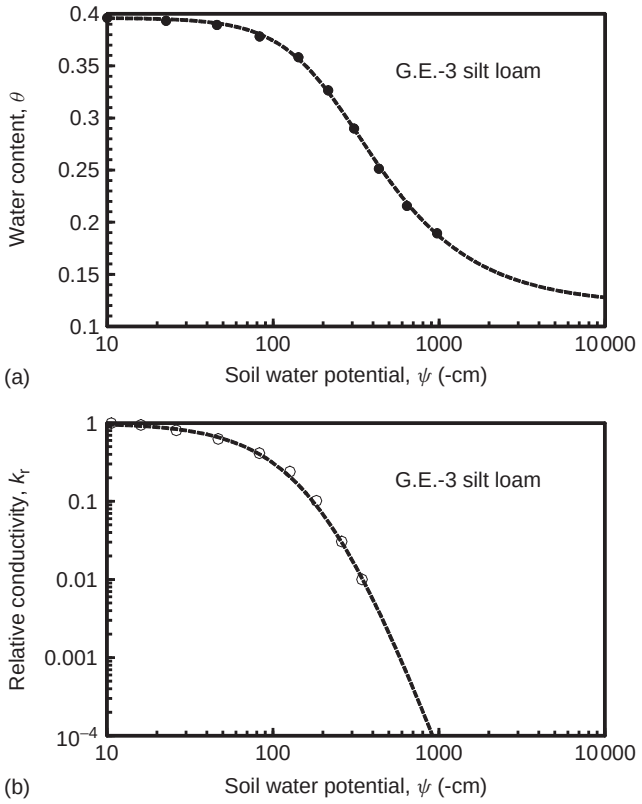

Figure 2 (a) example soil water retention curve, relating water content to soil water potential, and (b) soil relative conductivity relation for the same soil

Physical Basis of Models for Infiltration Under Rainfall

When a hypothetically unlimited supply of water initially reaches the relatively dry soil surface, the wetting at the surface creates extremely large hydraulic head gradients for flow into the soil, and the rate of influx, v, is extremely high, even though overall values of K may be low. As infiltration of rainwater continues, the hydraulic head gradient for absorption decreases, the surface value of K increases, and the rate of infiltration is dramatically reduced. When the capillary gradient at the surface ultimately approaches 0, the only head gradient is gravity, and from equation (1) it can be seen that the ultimate rate of infiltration will equal K_s.

Definitions

Hereafter, we will refer to the vertical infiltration rate at the soil surface with the symbol f. The limiting value of f, given an unlimited supply of surface water, and $\psi = 0$, is called the soil *infiltrability*, with the symbol f_c. Both vary continuously with time during rainfall as the rain intensity

and soil water conditions change. The rainfall rate, varying with time, is *r(t)*. Before a brief presentation of the origin of infiltration relations, we introduce the concept of soil water diffusivity. This concept is analogous to diffusion mathematics, where the flux of a quantity, such as heat, is a function of the gradient of that quantity. In terms of water in the soil, θ, one can use the relation illustrated in Figure 2(a) with equation (1) to obtain

$$v = D(\theta)\frac{\mathrm{d}\theta}{\mathrm{d}z} + K(\theta) \tag{2}$$

by using the definition of diffusivity, D:

$$D(\theta) \equiv K(\theta)\frac{\mathrm{d}\psi}{\mathrm{d}\theta} \tag{3}$$

Approximations for the relation $D(\theta)$ play an important role in the successful derivation of infiltrability relationships given below (Smith, 2002).

Soil Flow Dynamics and Infiltration

At the soil surface, when there is rain, the flow dynamics can be described by combining equation (2) with an expression for continuity of flow, representing the fact that the inflow rate must equal the change in soil water storage at the soil surface:

$$f = \frac{\mathrm{d}}{\mathrm{d}t}\int_0^L (\theta - \theta_\mathrm{i})\,\mathrm{d}z \tag{4}$$

where L is a depth below the advance of the wetting zone, and θ_i is assumed uniform. In this expression, we assume for relative simplicity that the initial water content is small enough for the initial downward (gravitational) flux of water to be negligible. Referring to the infiltrated water depth in the wetted soil adjacent to the surface as I, equation (4) in integral form is

$$I(t) = \int_0^t f\,\mathrm{d}t = \int_0^L (\theta - \theta_\mathrm{i})\,\mathrm{d}z \tag{5}$$

This expression in combination with Darcy's Law in the form of equation (3) yields the infiltration integral, from which at least two basic infiltration models come (see Smith, 2002 for a derivation):

$$I(t) = \int_{\theta_\mathrm{i}}^{\theta_o} \frac{(\theta - \theta_\mathrm{i})D}{v(\theta, t) - K(\theta)}\,\mathrm{d}\theta \tag{6}$$

From equation (6) and realistic assumptions about the form of the highly nonlinear functions $D(\theta)$ and $K(\theta)$ (see Parlange, *et al.*, 1982; Smith, 2002), the expressions for infiltrability are derived in terms of an important integral property of soils, called the *capillary length scale*, or capillary drive, G:

$$G = \frac{1}{K_\mathrm{s}}\int_{-\infty}^{0} K(\psi)\,\mathrm{d}\psi = \int_{-\infty}^{0} k_\mathrm{r}(\psi)\,\mathrm{d}\psi \tag{7}$$

where $\mathrm{K_s}$ is the saturated hydraulic conductivity and k_r is the relative hydraulic conductivity shown in Figure 2(b). This parameter is in effect the k_r-weighted mean value of soil capillary head. Another physically meaningful term that arises in the integration of equation (6) is the *initial water content deficit,* $(\theta_\mathrm{s} - \theta_\mathrm{i})$, hereafter referred to as $\Delta\theta_\mathrm{i}$.

Relations for infiltrability in terms of G, K_s, and the deficit, $\Delta\theta_\mathrm{i}$, include that of Green and Ampt (1911):

$$f_\mathrm{c} = \frac{K_\mathrm{s}(G\Delta\theta_\mathrm{i} + I)}{I} \tag{8}$$

and Smith and Parlange (1978):

$$f_\mathrm{c} = K_\mathrm{s}\left[1 - \exp\left(\frac{-I}{G\Delta\theta_\mathrm{i}}\right)\right]^{-1} \tag{9}$$

The infiltrability relation (8) is derived on the basis of the assumption of a $K(\psi)$ relation that approaches a step function, with K "jumping" from a negligible value to its maximum at some value of ψ (or θ) as the soil wets. This behavior is most like that of a uniform sand or silt. The relation of equation (9) is derived on the basis of the assumption that $K(\psi)$ rises exponentially as ψ increases toward 0. While this does not match the actual measured relation of most real soils, it is in most cases a better approximation than equation (8) (Parlange *et al.*, 1982).

Computational Forms for Infiltration Models

Notably, both equations (8) and (9) express infiltrability in terms of I rather than time, t. While relations between f_c, I, and time, t, can be mathematically derived, the relation of f_c to I is quite important in modeling infiltration during a storm. When a storm is sufficiently intense to create excess, the control on soil f changes from the rainfall to the infiltrability at some point. This is termed the *ponding time*. Owing to the highly nonlinear relation of $D(\theta)$, for most soil hydraulic relations there is a near equality between the infiltration relations $f_\mathrm{c}(I)$ under rainfall and that under unlimited water supply at the surface ("sudden ponding") (Smith, 2002). This allows one to use equations (8) or (9) to predict both the onset of ponding under rainfall, and the decaying function of f_c after that, when the soil exerts control through infiltrability. Because the unifying variable is I, this close approximation has been called the infiltrated depth approximation (IDA) by Smith (2002). It was earlier called the *time condensation* approximation by others (e.g. Sivapalan and Milly, 1989). The principle does not however

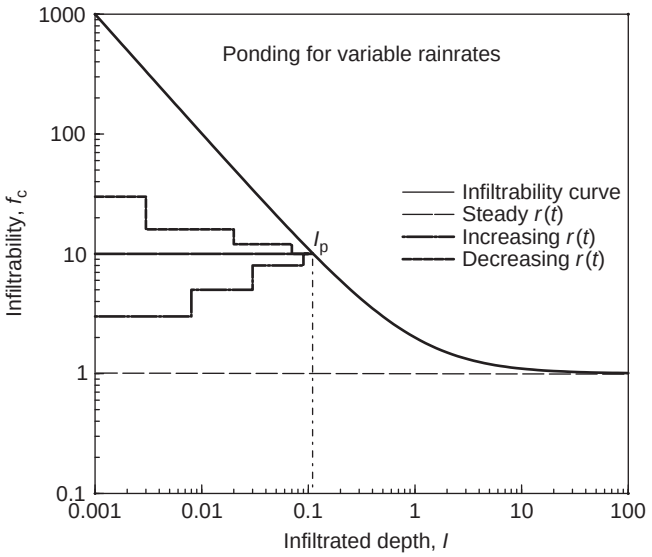

Figure 3 Relation of infiltrability to infiltrated depth, as described by equations (8) or (9), showing how ponding is predicted with this relationship. I_p is the accumulated infiltration depth at ponding

actually relate to the condensation of time. It assumes that the time at which the surface boundary condition changes from rainfall to soil control occurs when the relation between r and I_a matches that for $f_c(I_a)$, where I_a is the accumulated infiltration due to rainfall. This is termed the time of ponding, and subsequent variables with subscript p (such as I_p) refer to the value of the variable at that time. Figure 3 illustrates the fact that in the *f(I)* relation, ponding at I_p may be approached by any number of patterns of rainfall.

Nondimensional Forms

Different soils have a wide range of values of the hydraulic parameters G, K_s, and the initial soil deficit $\Delta\theta_i$ varies between storms. The infiltration equations may be unified and simplified by producing dimensionless forms, scaling I by the value of $G\Delta\theta_i$, and scaling f_c on K_s:

$$f_{c^*} = \frac{f_c}{K_s} \qquad I_* = \frac{I}{G\Delta\theta_i} \tag{10}$$

These dimensionless forms were used in Figure 3. Equation (8), using these variables, is thereby simplified to

$$f_{c^*} = \frac{I_* + 1}{I_*} \tag{11}$$

A dimensionless time may similarly be found:

$$t_* = \frac{t}{G\Delta\theta K_s^{-1}} \tag{12}$$

and rainfall rate may be scaled as for infiltrability: $r_* = r/K_s$. Relations between time and either I_* or f_{c^*} are obtained by substituting the relation $f_* = \mathrm{d}I_*/\mathrm{d}t_*$ into equations (8) or (9). The resulting expressions are implicit in time, but explicit expressions have been presented by Smith (2002), Paige *et al.* (2002), and Li *et al.* (1976), one of which will be presented here.

Infiltrability as a Function of Time

Time-explicit expressions are useful after ponding has been found using the IDA. The simplest approximate expression for post-ponding $f_{c^*}(t_*)$ can be given as (Smith, 2002):

$$f_{c^*} = (1 - \beta) + \sqrt{\beta^2 + \frac{1}{2t'_*}} \tag{13}$$

where β is a weighting parameter. This expression describes a relation intermediate between that of equations (8) and (9) for values of β between 0.5 and 1. Figure 4 illustrates the time-explicit equation (13) and time-f_c relations for both equations (8) and (9). The physics of infiltration requires that at small times the functions must be asymptotic to the line $f_{c^*} = (t_*)^{-1/2}$, and at large times asymptotic to $f_{c^*} = 1$. The variable t' is used to indicate that the time position of this curve must be adjusted to describe f_c after ponding time, t_p, (or ponding depth I_p) so that $f_{c^*} = r_{p^*}$ at $t'_* = t_{p*}$, where r_p is the rainfall rate at which ponding occurs. Using infiltrability expression, equation (9) for example, and solving for $I = I_p$ expressed as an integral of the rainfall rate pattern, the ponding time is found using the

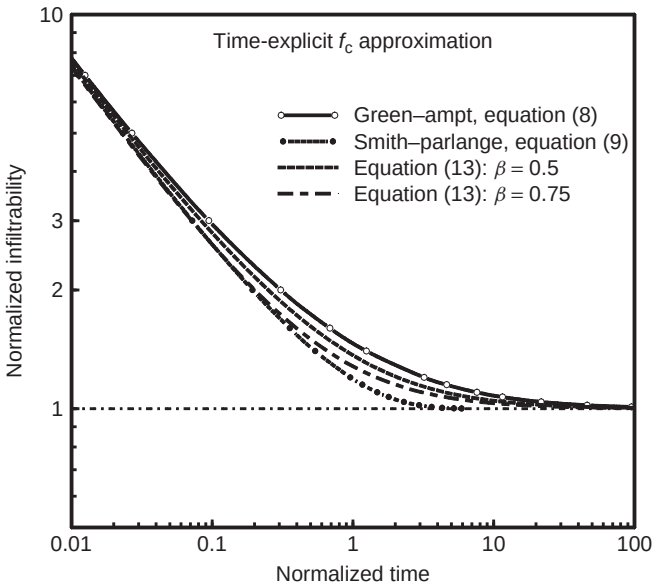

Figure 4 Illustration of the ability of the time-explicit $f_c(t)$ equation (13) to match the behavior of equations (8) and (9) when put in $t(f_c)$ form

IDA method:

$$I_p = \int_0^{t_p} r(t)\,\mathrm{d}t = G\Delta\theta_i \ln\left(\frac{r_*}{r_* - 1}\right) \qquad (14)$$

Clearly, the ponding time $t_p(r)$ can be determined directly for a rainfall of constant rate, for which $I = rt$. After ponding occurs, the infiltrability expression equations (8), (9), or (13) will estimate rainfall excess during the period of time when surface available water, including the rainfall and ponded water, equals or exceeds the infiltrability. This leads to the consideration of the dynamic interaction of infiltration and surface water flow, discussed below.

Irregular Rainfall and Recovery of Infiltrability During Rainfall Hiatus

The above methodology is robust for an unlimited variation in the pattern of rainfall, with the caveat that rainfall must stay greater than K_s, that is, $r_* > 1$. For the more general case, there needs to be an accounting for redistribution of water during breaks in rainfall (periods when $r = 0$), or any time infiltrability exceeds the rainfall. Local conditions can easily be simulated, given the soil hydraulic properties, by solution of the nonlinear convection diffusion equation (Richards' equation; *see* **Chapter 150, Unsaturated Zone Flow Processes, Volume 4** and **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2**), but this is not practical for most hydrological catchment models. Some early methods for treating breaks in rainfall patterns simply maintained a value of I through the hiatus (e.g. Mls, 1980). Corradini *et al.* (1997) and Smith *et al.* (1999) have proposed and demonstrated a method of intermediate complexity requiring minimum parameterization of the soil hydraulic properties, which simulates robustly the changes in infiltrability and soil water deficit $\Delta\theta_i$ for periods when rainfall rates fall to any value less than K_s. This method treats the wetting pulse in the soil as a distortable curve with conserved similarity and net volume of water, with Green–Ampt type assumptions on its distortion (changes in depth and surface water content) under low (or negative) surface flux values. The reader is directed to the above references, or Smith (2002), for details.

Surface Water and Infiltration Interdependence

Early methods of treating infiltration excess involved subtracting an infiltration pattern (often assumed constant) from the rainfall pattern and then routing the remainder ("rainfall excess") across the catchment toward a receiving stream (Crawford and Linsley, 1966; HEC-1, 1990). Not only does this ignore the interaction of rainrate and ponding time described above, which was generally unknown, but it also ignores the ability of the soil to continue to infiltrate whatever surface water exists after rainfall has fallen below the infiltrability. The result was an inability to estimate ponding time and an overestimation of the recession flow after runoff production had ceased. Also important in the interactions of surface water and infiltration is the microtopography of the surface and the spatial variability of infiltrability. Microtopography can confine the flowing water to some fraction of the total area, and thus limit the opportunity for infiltration losses during recessions. Significant spatial variability of infiltrability is known to vary on length scales as small as decimeters. These topics will be explored in more detail below.

RUNOFF DYNAMICS

The flow of the rainwater not infiltrated by the soil surface (rainfall excess) is at the small (mm) scale, a complex phenomenon with exact flow directions, unit discharges (discharge per unit flow width), and depths varying widely across the surface (Abrahams and Parsons, 1994; Fiedler and Ramirez, 2000). Runoff is, however, treated at a larger (m) scale as a free-surface hydraulic process. The physical description involves some reasonable assumptions that yield a useful and relatively accurate mathematical description of the runoff from most natural surfaces. Figure 5 illustrates diagrammatically the variables involved in the flow of water along a simplified hillslope.

The Surface Water Flow Equations

The primary assumption is that flow is downslope and locally can be approximated as one-dimensional. At larger scales, it is clearly two-dimensional as the land surface converges and diverges downslope, but even this may be treated as stepwise one-dimensional. The flow is incompressible, and the overall velocity is sufficiently low that the energy is largely in the form of momentum. Thus, the equations used are those that conserve momentum and mass. These equations were first written by de Saint Venant (1871), and are commonly referred to as the Saint Venant equations. The two equations include the conservation of momentum

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + g\frac{\partial h}{\partial x} = g(S_o - S_f) - \frac{u}{A}(r - a_f f) \qquad (15)$$

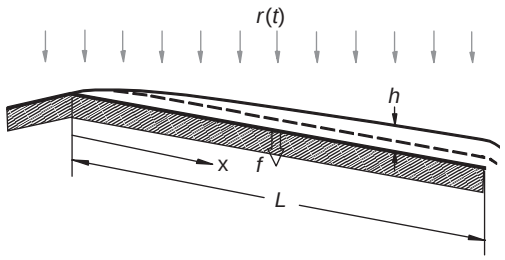

Figure 5 Definition diagram for kinematic approximation for runoff water dynamics

and the conservation of mass

$$\frac{\partial A}{\partial t} + \frac{\partial Q}{\partial x} = (r - a_f f)w \tag{16}$$

where

A is cross-sectional area of flow [L^2]
a_f is fraction of surface covered by infiltrating water
Q is discharge per unit width [$L^2\ T^{-1}$]
x is distance from upstream border [L]
t is time
u is flow velocity [$L\ T^{-1}$]
h is mean depth of flow [L]
g is gravitational acceleration [$L\ T^{-2}$]
S_o is mean bed slope
S_f is friction slope
w is width of flow [L].

The first terms in equation (15) represent changes in momentum and potential energy, and the last term on the right represents the change in momentum due to lateral inflows. The infiltrating area fraction a_f is 1.0 when $r > f_c$, and is reduced on irregular surfaces during flow recession when infiltration comes from surface water. The friction slope represents the shear friction along the flow perimeter, and is exemplified by the Chezy or Manning equation:

$$q = \alpha h^m = \frac{\sqrt{S_f}}{n} h^{5/3} \tag{17}$$

where q is unit discharge [$L^2\ T^{-1}$], α and m are the generalized friction relation parameters, and n is the Manning friction factor. Equation (17) represents experimental results from channels, in which hydraulic radius R replaces h, but the power law relation also reflects considerable experimental data from catchment experiments (e.g. Wu *et al.*, 1978; Abrahams and Parsons, 1994; Emmett, 1970). The form of the friction slope relation is also applicable to the Chezy friction law relationship ($m = 3/2$) (Eagleson, 1970). Note that h represents the mean depth or area per unit width. The relationship described by equation (17) simply states that the unit discharge is a function of a modeled average depth (or storage) in the abstract sheet flow representation of overland flow depicted in Figure 5. It does not imply that overland sheet flow must occur on a hillslope to represent the flow dynamics described in equations (15) through (17). While overland sheet flow has been observed in field settings (e.g. Emmett, 1970), it is not typical as surface water flows usually converge to rivulets in a relatively short distance due to natural microtopography (Dunne, *et al.*, 1991) (also *see* **Chapter 11, Upscaling and Downscaling – Dynamic Models, Volume 1**). The appropriateness of the discharge-storage relationship implied by equation (17) has been evaluated by several including Wu *et al.* (1978), as well as by microscale numerical simulation with a two-dimensional form of equations (15) and (16) (Fiedler and Ramirez, 2000).

Simplified Forms

The Saint Venant equations are generally applicable to channel and streamflow, but further simplifications are appropriate for overland flow. Because flow is shallow, it can be reasonably assumed that very little energy is contained in the form of inertia, and an order of magnitude analysis demonstrates that the addition of rainfall excess adds negligible net momentum to the flow. With these approximations, equation (15) can be reduced to

$$\frac{\partial h}{\partial x} = S_o - S_f \tag{18}$$

Equations (17) and (18) constitute the *diffusive wave equations* (Morris and Woolhiser, 1980), which are appropriate for certain flow conditions characterized by shallow slopes. A criterion for applicability is given by Morris and Woolhiser (1980).

For larger values of surface slope S_o, the value of dh/dx becomes negligible compared with S_o, and equation (18) reduces to $S_f = S_o$. In this case, the *kinematic wave equations* are appropriate. The flow-depth relationship in this case is a description of the relation of mean effective depth and mean effective discharge, equation (17). This relation plus the continuity of mass equation (16) constitute the kinematic wave equations. Equation (16) with equation (18) may be written in terms of h for unit width of overland flow, rather than area A:

$$\frac{\partial h}{\partial t} + m\alpha h^{m-1} \frac{\partial h}{\partial x} = r - a_f f \tag{19}$$

Woolhiser and Liggett (1967) developed a kinematic wave number, $k = S_o L / h_o F^2$, to measure the ability of equation (19) to represent well the Saint Venant equations. L is plane length, h_o is normal depth for a given flow q, and F is Froude number. Larger values of k indicate that the kinematic wave equations are better approximations. This analysis was further extended by Morris and Woolhiser (1980) to consider a larger range of Froude numbers.

Solving the Kinematic Wave Equations

Equation (19) may be solved under certain assumptions by use of the method of characteristics. This is a mathematical approach to solve sets of partial differential equations by transformation into sets of ordinary differential equations (Lighthill and Whitham, 1955; Wooding, 1965). This article is not an appropriate place to present the details of this method, but it is instructive to look briefly at the solution, as it describes the behavior of a surface water runoff hydrograph.

Characteristics are traces in the solution domain (in this case the x, t plane) along which a partial differential equation is reduced to an ordinary differential equation. The characteristic equations corresponding to equation (19) are as follows:

$$\frac{dx}{dt} = \alpha m \sqrt{S_o} h^{m-1} \tag{20}$$

$$\frac{dh}{dt} = r - a_f f \tag{21}$$

Equation (20) describes the *celerity* or characteristic velocity of the flow. In the characteristic method, equation (21) is valid along the line described in the (x, t) plane by equation (20). In turn, the change in h described by equation (21) changes the slope of the x, t characteristic.

Figure 6 illustrates some of the essential features of the characteristics as runoff begins along a slope. This is a very simplified schematic, but at some time after the start of rainfall, runoff begins. The upstream characteristic starts at $x = 0, t = 0$, and moves at an increasing rate downslope. To the right of this characteristic, the flow is unsteady and uniform. To the left, flow is steady and nonuniform. When the upstream characteristic reaches the lower bound, outflow becomes steady, and this is termed the *time to equilibrium*. In this example, and for many rainfalls and short runoff surfaces, this condition is not reached. After the end of rainfall, the characteristics exhibit decelerating celerities as $h(x)$ is reduced by infiltration, and at some time the characteristic velocity and h fall to zero. The locus of drying is shown on the schematic. Between the end of rainfall and the end of runoff, the hydrograph is in *recession*. For impervious surfaces where $f = 0$, the recession is extended considerably, and the recession characteristics are straight lines of differing slopes that depend on $h(x)$ at the time rainfall excess ends.

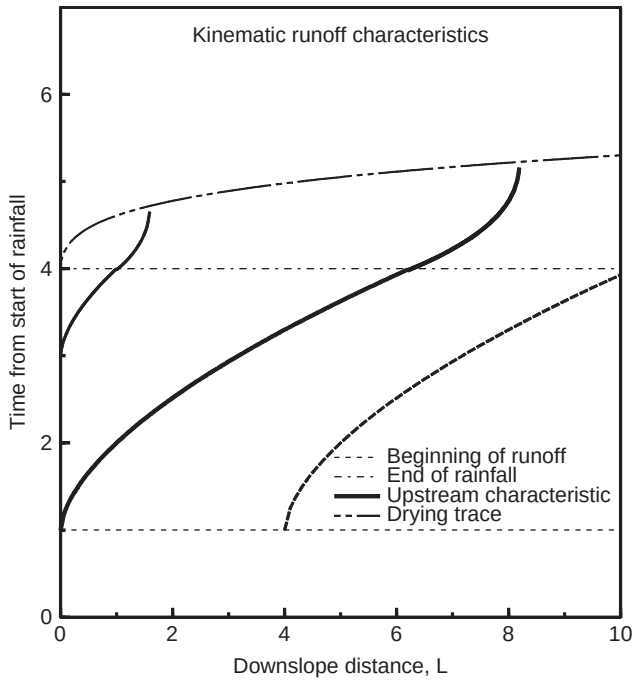

Figure 6 Solution of the kinematic wave equations in the (x,t) plane, for runoff assumed to start at $t = 1$ and end at $t = 4$. The dotted line in Figure 5 illustrates the water depth profile for a time (approximately = 2) when most of the surface is characterized by uniform unsteady flow

Computer models of runoff generally approach the solution of equation (19) with numerical methods, which can treat the time variation of f directly if not analytically. Several early numerical methods have been discussed by Brakensiek *et al.* (1966), and the robust *weighted implicit method* is described by Smith *et al.* (1995b). The characteristic solution is used in this model to estimate the arrival of the upstream characteristic at the first finite difference space node to prevent small solution oscillations. A full discussion of the merits and drawbacks of the various numerical solution techniques is beyond the scope of this article.

SURFACE AND SOIL WATER INTERACTION

It is through the right-hand term in equation (19) that the equations of surface water flow and the equation describing surface water infiltration are linked. From the point of view of the surface water calculations at any point, the input to surface flow is always $r - f$, and becomes negative (a loss) when the rainfall rate, r, falls below f_c, as long as there is free water on the surface. From the point of view of the infiltration calculations after runoff begins, the reduction of rainfall rate below f_c is not noticed, and infiltration rate continues at capacity f_c, as long as this rate can be supplied by surface water plus rainfall rate.

The solution characteristics during recession are also shown schematically in Figure 6. The case of a "flat" infiltrating surface and an impervious surface are two extremes in the behavior of the flow recession. Intermediate to these two is the case of a surface with microtopographic features, either irregular – such as grassed hummocks, or regular, such as furrowed paddocks. In this case, the area available for infiltration during recession flow is a function of the mean depth of surface water. The area is clearly zero at $h = 0$, and at some rather large depth, h_c, the entire area may be covered with water. For $0 < h < h_c$, a fraction of the area will be covered and the loss of water to infiltration during recession will be limited accordingly.

Another case where microtopography plays an important role in surface water interactions is the case of *run-on*. This term refers to situations where water is generated by rainfall excess at a location upslope or upstream of an area with a higher infiltration capacity. Surface microtopography and resulting flow convergence can limit the opportunity for infiltration of the run-on water as the effective wetted

perimeter is reduced. This in turn can affect the extent to which run-on will advance across the irregular surface. Woolhiser *et al.* (1996) studied, for example, the case of run-on caused by a spatial trend in infiltration due to variation in K_s, and showed that significant effects on hydrographs are possible. Small-scale random spatial variations are a somewhat different case.

Spatial Variability and its Effects on Runoff Processes

Like most natural processes, infiltration excess and its associated runoff are affected by the variability of nature. Some natural processes lend themselves to treatment in bulk, with processes characterized by parameters that represent the sum effect of many smaller scale variations. Runoff tends, however, to be a nonlinear process in many locations, and it is often affected by natural spatial variations at scales an order of magnitude less than the scale of interest (*see* **Chapter 3, Hydrologic Concepts of Variability and Scale, Volume 1**).

In applying the kinematic flow equations, microtopography can be abstracted to a simple microchannel geometry (Woolhiser, *et al.*, 1996; Smith *et al.*, 1995a). This can represent the ensemble result of extensive measurements of variations in relief across the flow direction, such that a composite geometry may represent the relative surface coverage between mean depths of 0 and some maximum.

Small-scale variations in surface conditions or soil conditions within a catchment can make it difficult to represent the catchment runoff processes by the mathematics described above. The infiltration parameter K_s is a very important one in estimating infiltration and runoff dynamics for Hortonian runoff, and it has been found consistently to exhibit random variation at small scales (cm to m) (Nielsen *et al.*, 1973). Several methods have been reported to deal with the effect of this variation on the runoff for small catchments (Smith and Hebbert, 1979; Sivapalan and Wood, 1986; Sharma *et al.*, 1980; Smith and Goodrich, 2000). In general, the difference between infiltration at a point and the behavior of an ensemble of points is illustrated in Figure 7. This graph uses scaled values as described by equations (10) and (11). The local value of K_s is assumed, on the basis of experimental evidence, to vary randomly with a lognormal distribution. The effect of random variation is to blur the existence of a single time of ponding, as shown, and further to alter the value of the large-time asymptotic value of f_c. The effect of variability on K_s is largely confined to smaller values of rainfall rate; for r_* values of 10 or more, where $r_* \geq$ the highest infiltration capacity, it is negligible. On the basis of the value of the coefficient of variation of K_s [CV(K_s)], Smith and Goodrich (2000) developed an ensemble infiltration model that uses the same parameters as equations (8) or (9), but includes the effect of CV(K_s) and rainfall rate.

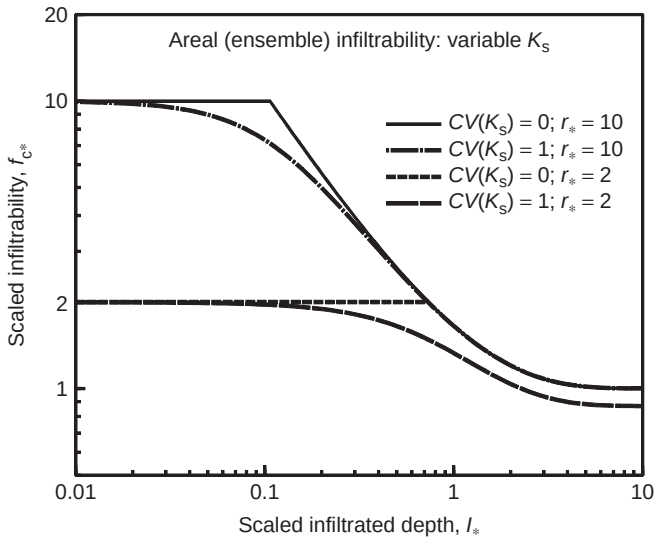

Figure 7 Examples of infiltration patterns for areas characterized by small-scale variability of K_s. Two rainfall rates are shown, and the interaction of variability and rainrate is illustrated

The effect of parameter variations in looking at larger-scale hydrology is an important problem related to *upscaling* in hydrology – simulating or predicting the performance of an ensemble of catchments that make up a larger catchment. Models of hydrology useful at one scale may not be successful at the scale an order or more larger. While the functional representation of small-scale K_s variations improves the prediction of runoff, especially for storms where the runoff is a small fraction of the rainfall, the interactions of variability during runoff are more complicated than the ensemble effect, due to run-on along the flow path. Another method to treat this, at least in a research-level model, distributes finite incremental variations in values of K_s randomly along the flow in a one-dimensional simulation, or divides the catchment into parallel strips of flow, each strip representing a portion of the random distribution expected in the value of K_s (Woolhiser and Goodrich, 1988).

Other characteristics of a catchment may also exhibit significant spatial variability. The effects of variation in slope and surface hydraulic roughness can be modeled at appropriate scales by treating the flow path as a cascade of smaller elements (Smith *et al.*, 1995b; Goodrich *et al.*, 2002; see also `www.tucson.ars.ag.gov/kineros`). This becomes impractical at very small or large scales; however, surface runoff becomes channelized into rills and microchannels before the scale becomes too large to consider such variations.

The scale of variation of runoff intensity is generally larger than that of K_s, but its variation is equally as important for treating infiltration excess on a catchment. Spatial

variability of rainfall and its effects on runoff generation on catchments scales of $1-100\,km^2$ and greater have been relatively widely studied (Balmer *et al.*, 1984; Iwasa and Sueishi, 1990; Niemczynowicz and Sevruk, 1991; Houser *et al.*, 2000; Syed *et al.*, 2002), with those at smaller areal scales typically geared toward urban storm runoff estimation (Berne *et al.*, 2004). Even in an urban setting, the normal scale of rainfall measurements, including those derived from radar, are often considerably larger than rainfall variations that are important for runoff generation. This is particularly true where small intense runoff-producing storm cells dominate runoff production. The USDA-ARS Walnut Gulch Experimental Watershed (WGEW) in southeast Arizona is such an area. In this experimental watershed, Reich and Osborn (1982) concluded that for 5-min maximum storm depths recorded at rain gauges greater then 5 km apart were statistically independent. At a smaller scale within the WGEW (~5 hectare catchment area), Goodrich *et al.* (1995) found rainfall gradients ranging from 0.28 to 2.48 mm/100 m with an average of 1.2 mm/100 m. These gradients represent a 4 to 14% variation of the mean rainfall depth over a 100-m distance but a much larger percentage in terms of total depth of runoff over the catchment due to the relatively low runoff to rainfall ratios that are common in arid and semiarid regions. In a follow-on study, Faurès *et al.* (1995) found that if distributed catchment modeling is to be conducted at the 5-hectare scale, knowledge of the spatial rainfall variability on the same or smaller scale is required. A single raingage with the standard uniform rainfall assumption can lead to large uncertainties in runoff estimation.

Scale Issues and Models of Runoff

Finally, it is important to consider the timescales of the processes of surface runoff. Surface water flows on natural topography do not travel far before converging in some manner into concentrated flow channels. Distributed surface flows prior to some kind of channelization rarely exceed 100 m in length, except in special cases of low-sloped tilled catchments (Dunne *et al.*, 1991; Abrahams and Parsons, 1994). This limitation in spatial scale also imposes a limitation in timescale. The timescale of variations and the rate of flow across the surface means that rainfall rate variations on the order of less than a minute can be important parts of the dynamics of runoff. Surface runoff cannot therefore be treated scientifically with information on rainfall that consists only of the daily depth of rain. For this lumped data approximation, the prediction of runoff will contain enormous uncertainty.

Models of Hortonian runoff generally employ the solution of the kinematic or diffusive wave equations by numerical methods. The wide variety of numerical solution is too numerous to be described here. Readers are referred to Singh (1995) for a good overview of numerical solution techniques. Again, there are practical limits for the numerical subdivision of the flow path, and these impose corresponding limits on the timescales. Moreover, the values of h that are involved in the solution are on the order of a few millimeters, and the solution of equation (19) over values of Δx that are tens or even hundreds of meters or longer are physically realistic treatments of shallow flow dynamics, but are rather simply nonlinear storage models. While some models have employed runoff elements at this scale, a valid numerical model of surface runoff should be confined to the length of flow expected before rills, channels, and other cascading concentrated flow paths begin to dominate the runoff hydraulics. If concentrated flows and rills do not dominate the hydraulics, changes in slope and convergence of flow can both be modeled by the use of cascading one-dimensional surfaces with varying slopes and widths (Woolhiser *et al.*, 1990; Smith *et al.*, 1995b).

SUMMARY

We have briefly shown how the theory of soil and surface water hydraulics has led to a model of surface water generation from rainfall for catchments on the scale of hectares. However, this should not tempt us to believe that a scientific knowledge of rainfall excess can easily be applied to hydrologic problems in general. The models are at best quasi-scientific insofar as nature's ubiquitous heterogeneities do not allow the hydrologist to make direct measurements at any point of many of the important parameters (e.g. surface roughness), or even determine a real effective average of parameters by any remotely sensed data. The theoretical basis of the processes described above does allow some confidence in the robustness of estimated parameters insofar as they are applicable to a wide range of rainfall conditions, but direct measurement of key properties, such as effective catchment values for K_s, remains a difficult undertaking.

Remotely derived topographic data using LIDAR is of sufficient accuracy and resolution that it can be used to aid in estimation of some of the geometric parameters (slopes and slope lengths, etc.) required for excess rainfall-runoff modeling (Carter *et al.*, 2001). Multispectral remotely sensed data has been widely used to estimate land use and ground cover, and if sufficient temporal resolution exists, the variation of ground cover conditions can affect hydraulic roughness and influence infiltration parameters. Land use and land cover data, combined with textural-based estimates of soil hydraulic properties can be used to provide crude initial estimates of needed parameters (Miller *et al.*, 2002; and see **www.tucson.ars.ag.gov/agwa**). However, these estimates are often based on simple look-up table relationships from incomplete field data relating soils and cover to surface and soil hydraulic parameters. This leaves hydrologic science with challenges for field data

collection and realistic characterization of the variability of important parameters for use in the mathematical models of rainfall excess runoff described herein.

Subsurface stormflow is a runoff producing mechanism operating in most upland terrains. In a humid environment and steep terrain with conductive soils, subsurface stormflow may be the main mechanism of storm runoff generation. In drier climates and in lowlands with gentler topography, subsurface stormflow may occur only under certain extreme conditions (high antecedent soil moisture), when transient water tables form and induce lateral flow to the channel. While an important contributor to the volume of flow in the stream, subsurface stormflow is also responsible for the transport of labile nutrients into surface water bodies. Since the flow path of water in the subsurface often determines the chemistry of waters discharging into the stream and hence the water quality, characterizing this subsurface flow path and the water's age and origin is important. Subsurface stormflow may also enhance positive pore pressure development in steep terrain and may be responsible for landslide initiation. Thus, subsurface stormflow is of great interest and importance beyond the conventional hydrological literature. This article examines the history of the study of subsurface stormflow processes, reviews theories on the generation of subsurface stormflow, and gives a detailed overview of current research in subsurface flow processes and the implication for future research.

INTRODUCTION

Subsurface stormflow is a runoff producing mechanism operating in most upland terrains. Subsurface stormflow occurs when water moves laterally down a hillslope through soil layers or permeable bedrock to contribute to the storm hydrograph in a river. In humid environments and steep terrain with conductive soils, subsurface stormflow may be the main mechanism of storm runoff generation (Anderson and Burt, 1990b; Gutknecht, 1996). In drier climates and in lowlands with gentler topography, subsurface stormflow may occur only under certain extreme conditions (high rainfall and high antecedent soil moisture), when transient water tables form and induce lateral flow to the channel (Wilcox *et al.*, 1997).

While an important contributor to the volume of flow in the stream, subsurface stormflow is also responsible for the transport of labile nutrients into surface water bodies (e.g. McGlynn and McDonnell, 2003b). Since the flow path of water in the subsurface often determines the chemistry of waters discharging into the stream and hence the water quality, characterizing this subsurface flow path and the water's age and origin is important (Burns *et al.*, 2003). Subsurface stormflow may also enhance positive pore pressure development in steep terrain (Uchida *et al.*, 1999; Wu and Sidle, 1995) and may be responsible for landslide initiation (Montgomery *et al.*, 1997; Sidle and Tsuboyama, 1992). Thus, subsurface stormflow is of great interest and importance beyond the conventional hydrological literature. This article examines the history of the study of subsurface

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

stormflow processes, reviews theories on the generation of subsurface stormflow, and gives a detailed overview of current research on subsurface flow processes and implications for future research.

TERMINOLOGY

Subsurface stormflow is also known in the hydrological literature as interflow, lateral flow, subsurface runoff, transient groundwater, or soil water flow. These multiple terms often confuse the process understanding of subsurface stormflow response to rainfall or snowmelt. While some studies have documented subsurface stormflow as unsaturated flow in the unsaturated zone, most studies have shown that subsurface stormflow is a saturated (or near-saturated) water flow phenomenon – due either to the rise of an existing water table into more transmissive soil above (with ensuing lateral flow) or the transient saturation above an impeding layer, soil-bedrock interface or some zone of reduced permeability at depth (argillic horizon, hard-pan, plough layer, etc.).

The literature on subsurface stormflow includes many references to both soil water and groundwater. Inconsistent definitions of these terms have also led to confusion. Here, we define groundwater or the saturated zone as any area in the soil profile with ≥ 0 kPa matric potential. Soil water, or the unsaturated zone, is the area in the profile with matric potentials of <0 kPa. Conversion from negative to positive potentials may occur very rapidly in the shallow subsurface. Therefore, modifiers such as "transient" groundwater will be used in some instances to indicate parcels of water in the subsurface that change from soil water to groundwater or from being an unsaturated to being a saturated zone, respectively, following our potential-based definition.

HISTORICAL DEVELOPMENT OF IDEAS PERTAINING TO SUBSURFACE STORMFLOW

As part of early studies on the influence of forest management on watershed hydrology in Switzerland, Engler (1919) was among the first hydrologists to recognize the importance of subsurface stormflow on runoff generation in forested environments. He made observations during numerous rainfall events in two neighboring catchments, conducted infiltration experiments, and performed detailed soil physical measurements of porosity, water content, soil texture, and hydraulic conductivity. He concluded from his experiments that overland flow did not occur even during high intensity rainfall. He observed that water infiltrated into the main root zone and flowed laterally in "uncountable veins" in the soil or at the soil-bedrock interface. Figure 1 shows the original conceptualization of these processes by Engler (1919).

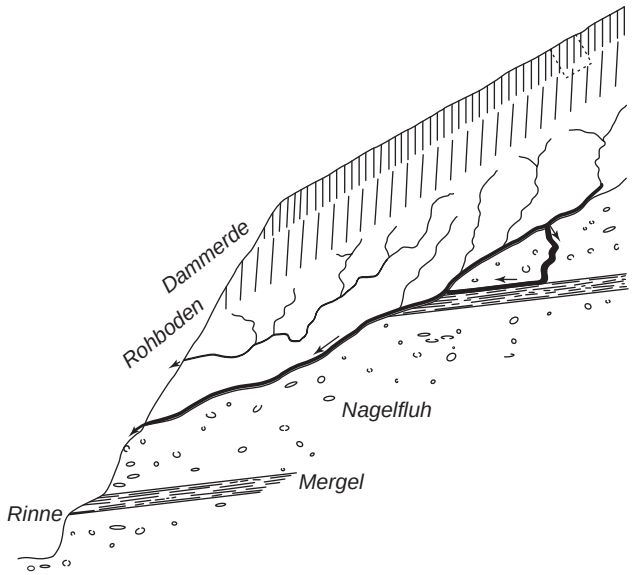

Figure 1 The original perceptual model of subsurface stormflow by Engler (1919). The hatched areas represent the uniform infiltration of water in the humus (*Dammerde*) and the soil (*Rohboden*). Deeper in the profile, water is flowing in ''veins'' laterally. *Nagelfluh* is the bedrock type for a specific geological setting in Switzerland

Hursh and Brater (1941) were the first to quantify the role of subsurface stormflow *senso stricto* in a watershed. This seminal work showed that the stream hydrograph response to storm rainfall at the forested Coweeta experimental watershed consisted of two main components: channel precipitation and subsurface stormflow. Later, Hoover and Hursh (1943) showed that soil depth, topography, and hydrologic characteristics associated with different elevations influenced peak discharge.

The rate of progress in the understanding of subsurface stormflow continued to increase through the International Hydrological Decade (IHD), with key works by Hewlett and Hibbert (1963) on moisture and energy conditions in a sloping concrete-walled hillslope, Whipkey (1965) on lateral preferential flow, Dunne and Black (1970) on subsurface stormflow around the toe of a hillslope and its interaction with near-stream saturated areas, and Weyman (1973) on saturated wedge development. The most important works during the IHD, however, were those that framed subsurface stormflow within the context of the variable source area concept: Hewlett and Hibbert (1967) in the United States, Cappus (1960) in France, and Tsukamoto (1961) in Japan. Later, Anderson and Burt (1978) provided clear field evidence for how topographic hollows were the key hot spots in the landscape for connected subsurface stormflow to the stream channel.

After comments by Freeze (1972) that subsurface stormflow could not be a dominant runoff process based on Darcy-Richards analytical approaches work by Beasley

(1978), Harr (1977) and Mosley (1979) showed clearly that the response time and lateral flux rate of subsurface stormflow on steep forested hillslopes could be fast enough to be a main contributor to channel stormflow in headwater catchments – often via noncapillary pore space or flow in addition to Darcy-Richards like flux in the matrix.

Considerable debate has also surrounded the age and origin of subsurface stormflow. The "Maimai debate" is a classic case study in this regard and, therefore, is used here as an example (see a more extended and detailed review by McGlynn *et al.*, (2002)). Mosley (1979, 1982) conducted the first comprehensive study of subsurface stormflow at the Maimai catchments in New Zealand. He found a close coincidence in the time of the discharge peak in the stream and the time of the subsurface stormflow peaks, suggesting rapid movement of water vertically in the soil profile and in lateral downslope direction in the form of a saturated wedge. The wedge almost intersected the ground surface at the toe of the slope and tapered off in the upslope direction (Mosley, 1979). Dye tracing experiments of Mosley showed that his excavated "pit faces" (i.e. small trenches roughly 1 m wide and dug down to the soil-bedrock interface) displayed points of concentrated seepage during storm events, usually at the base of the B horizon, at which high rates of outflow were observed. At one site, Mosley (1979) observed that water "gushed" out of two pipes discovered at the base of the B horizon. Mosley's perceptual model considered macropore flow (see details in the next section) to be a "short-circuiting" process by which water could move through the soil at rates up to 300 times greater than the measured mineral soil saturated hydraulic conductivity (Figure 2a).

Pearce *et al.* (1986) and Sklash *et al.* (1986) followed with work at Maimai where they collected samples of rainfall, soil water, and streamflow and analyzed for electrical conductivity (EC), chloride ($C1^-$), deuterium (δD), and oxygen-18 (δ^{18}O) composition. They found that: (i) most of the mixing of "old" (pre-event) and "new" (event) water occurred in the hillslope; and (ii) subsurface water discharge to the stream was an isotopically uniform mixture of stored water. In other words, the interpretations offered by Pearce *et al.* (1986) and Sklash *et al.* (1986) directly refuted Mosley's (1979) determination that rapid transmission of new water through macropores formed the majority

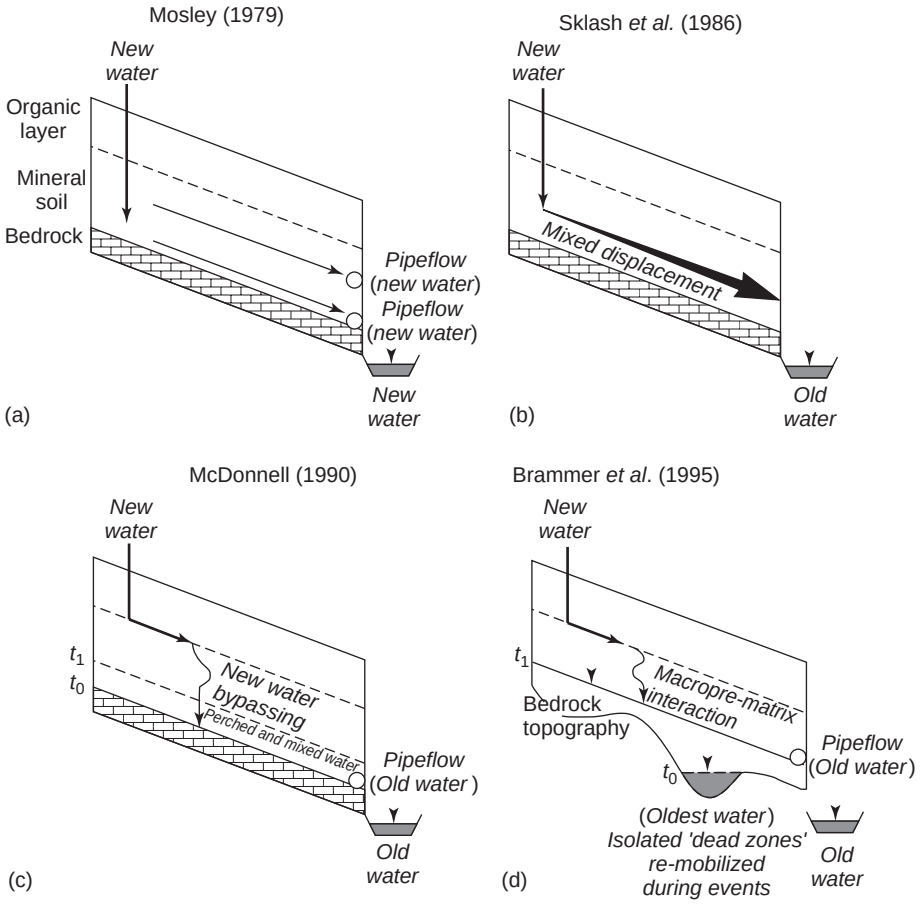

Figure 2 The evolving perceptual model of subsurface stormflow at the Maimai catchment in New Zealand (Reprinted from McGlynn *et al.*, 2002. © 2002, with permission from Elsevier)

of stream runoff. Sklash *et al.* (1986) postulated the conceptual model that saturated wedges on the lower slopes and groundwater ridges in the valley bottoms developed quickly as infiltrating rain converted the tension-saturated zone into groundwater. This perceptual model negated the need to invoke rapid transmission of new water down slope via macropores in order to explain the stream flow response, since stored water was the main component discharged into the stream channel during events (see Figure 2b).

McDonnell (1989, 1990) and McDonnell *et al.* (1991) combined isotope and chemical tracing with detailed tensiometric recording in an effort to explain the discrepancies between the earlier perceptual models. McDonnell found that: (i) water table longevity at the soil-bedrock interface was very short and showed a close correspondence with hillslope throughflow rate; and (ii) the interconnectedness of pipes in those zones was large enough to account for the rapidity of water table decline and pore water pressure dissipation. As a result, McDonnell (1990) proposed a new conceptual model where, as infiltrating new water moved to depth, water perched at the soil-bedrock interface and "backed-up" into the matrix, where it mixed with a much larger volume of stored, old matrix soil water. This water table was dissipated by the moderately well-connected system of pipes at the mineral soil-bedrock interface (see Figure 2c). These studies were followed by Woods and Rowe (1996) and Brammer *et al.* (1995) who showed that the topography of the bedrock surface was a key determinant of where subsurface flow was concentrated spatially across the hillslope (see Figure 2d).

The Maimai experiments, along with other field experiments through the early 1990s, achieved a general consensus that: (i) pre-event water stored in the catchment before the rain event is the dominant contributor to stormflow in the stream – averaging 75% worldwide (Buttle, 1994) (*see* **Chapter 116, Isotope Hydrograph Separation of Runoff Sources, Volume 3**); (ii) vertical (and often also lateral) preferential flow is a ubiquitous phenomenon in natural soils, particularly in steep catchments (Germann, 1990; Tsuboyama *et al.*, 1994) (*see* **Chapter 116, Isotope Hydrograph Separation of Runoff Sources, Volume 3**); and (iii) combining hydrometric, chemical, and isotopic observations in experimental work is necessary to constrain any perceptual model of subsurface stormflow or other runoff producing mechanism (Bonell, 1993; Bonell, 1998).

This scientific debate through the latter half of the twentieth century shows how scientific progress can be made by revisiting and reanalyzing data in one experimental watershed. However, it also highlights the danger in the field of hillslope hydrology of relying upon generalization of findings and processes of only a few selected hillslopes and watersheds. Few studies have compared subsurface flow processes and the dominant flow pathways across many sites (e.g. Beasley, 1978; Scherrer, 1997). The synthesis work of Dunne (1978) still stands as the most complete tabulation and intercomparison of subsurface stormflow data to date.

FLOW REGIMES OF SUBSURFACE STORMFLOW

Subsurface stormflow describes all runoff generation processes in the hillslope close to the soil surface that result in a stream channel hydrograph response during a precipitation or snowmelt event. This response may be coupled directly to flow in preferential pathways like macropores and layers or areas with high permeability. However, rapid subsurface stormflow response may also result from a fast hydraulic response of connected saturated areas in a hillslope in response to infiltrating precipitation (Burt and Butcher, 1985). The main flow regimes at the hillslope scale may be subdivided into homogeneous matrix flow and preferential flow.

Homogeneous Matrix Flow

Lateral matrix flow can be a viable subsurface stormflow process if water is already stored in the soil within connected saturated and close-to-saturated areas. These areas may respond quickly to an increase in hydraulic gradient and cross-sectional area due to infiltrating water. This process may occur in slopes where a high-permeable soil layer with high infiltration capacity is situated (parallel) above a low-permeable soil layer (e.g. bedrock, argillic horizon, etc). Since the water in storage on a typical hillslope is large relative to the rainfall depth, this matrix regime often results in a large contribution of pre-event water to the stream as only a small amount of event water is necessary to increase the hydraulic gradient and cross-sectional area in the slope and create a connected transient groundwater body. This flow process is described in the literature often in terms of translatory flow (Burt, 1989), transmissivity feedback (Rodhe, 1987), or lateral flow at the soil-bedrock interface (Tani, 1997).

Preferential Flow

Preferential lateral flow occurs either in distinctive structures in the soil where water flows only under gravity (macropores) or in areas with a higher permeability than the surrounding soil matrix. Macropores in the soil or fractures in the bedrock that are oriented predominantly slope parallel may transport water efficiently and rapidly from the hillslope to the stream (Beven and Germann, 1982). Laterally oriented macropore flow may dominate in many forest environments where macropores are generated by plant roots and burrowing animals. Macropores that are enlarged by erosion and connected over several meters are often termed *soil pipes* (Anderson and Burt, 1990a; Jones, 1971). If a connected network is developed because of internal erosion

and eluviation and connection of macropores, piping can provide effective drainage augmentation to hillslopes. However, disconnected macropores that connect hydraulically during storms can also result in an effective drainage of the hillslopes (Weiler *et al.*, 2003). If the underlying bedrock is more permeable, water can infiltrate into the bedrock and then percolate vertically into bedrock fissures and cracks – negating the macropore enhancement of subsurface stormflow on the timescale of a rainfall event. The preferential flow regime is described in the literature often in terms of lateral preferential flow (Tsuboyama *et al.*, 1994) and pipeflow (Uchida *et al.*, 1999), or lateral preferential flow at the soil-bedrock interface (McDonnell, 1990).

High permeability layers are areas in the slope with a coarse texture and large pore and void space. These are often found in talus slopes, landslide debris, peri-glacial solifluction deposits, or unconsolidated moraine material. Erosion of fine sediments by turbulent flow in areas with already coarse soil material increases the hydraulic conductivity and makes these areas particularly conductive. This flow regime can be best envisioned by an extension of the surface streams into the hillslope where many "small" subsurface streams connect preferentially the hillslopes with the streams (Sidle *et al.*, 2000). This flow process is described in the literature in terms of flow in "high-permeable layers" (Scherrer, 1997).

CURRENT RESEARCH IN SUBSURFACE FLOW PROCESSES

Subsurface Flow Initiation

Various experimental observations have shown that the water table development near the base of the soil profile can be very rapid following the onset of precipitation. This response is often a key control on the initiation of lateral flow due to the combination of four factors: (i) an increase of the hydraulic gradient; (ii) an increase of the cross-sectional area of flow; (iii) the rise of the water table into more permeable upper soil layers; and (iv) a connection of transient groundwater bodies across the hillslope. There is still debate among scientists about the controls on rapid water table response, but vertical preferential flow during infiltration and a decline of the drainable porosity with soil depth are thought to be the main causes for rapid subsurface flow initiation capable of generating subsurface stormflow.

Vertical Preferential Flow

Vertical preferential flow in natural soils is an almost ubiquitous phenomenon (Flury *et al.*, 1994; Weiler and Naef, 2003). Different types of heterogeneities in soils result in different preferential flow processes. For example, macropore flow is common in soils with animal burrows, roots, and earthworm channels; heterogeneous matrix flow (a type of preferential flow) in soil with spatially heterogeneous soil properties and wettability. How water is transported rapidly in the soil bypassing the unsaturated zone depends on the initiation processes of preferential flow and the interaction of the preferential flow pathways (e.g. macropores) with the surrounding soil matrix. How the two processes determine vertical water delivery into the lower soil profile can be distinguished experimentally. Figure 3 shows results from two sites where a dye (Brilliant Blue FCF) was added to 70 mm of simulated rainfall that stained the flow pathways upon infiltration into the soil. Later, the soil profiles were excavated and pictures were taken of the vertical soil sections. The stained areas can be then classified with image analysis techniques (Weiler and Flühler, 2004). Figure 3(a) shows that infiltration is governed by a high interaction between macropores and the soil matrix and that macropore flow is initiated close to the soil surface. These processes will result in a slow response in the lower profile. In the example in Figure 3(b), macropore flow is also initiated close to the soil profile but interaction between water flow in the macropores and the surrounding soil matrix is very low, resulting in narrowly stained features. Here, water flow in macropores is often turbulent and mostly driven by gravity. Hence, water delivery to the lower soil profile is very rapid. While macropores may comprise only a small part of the total soil porosity (e.g. 0.35–0.77%, e.g. Weiler and Naef (2003)), they account for almost all the water flow at or near saturation within the profile. The resulting water movement in the soils is very heterogeneous and certain areas within the soil may be completely bypassed. These processes often defy the Darcy-Richards formulations that rely exclusively on capillary-driven fluid flow (*see* **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2** for full treatment of classical flow in porous media theory).

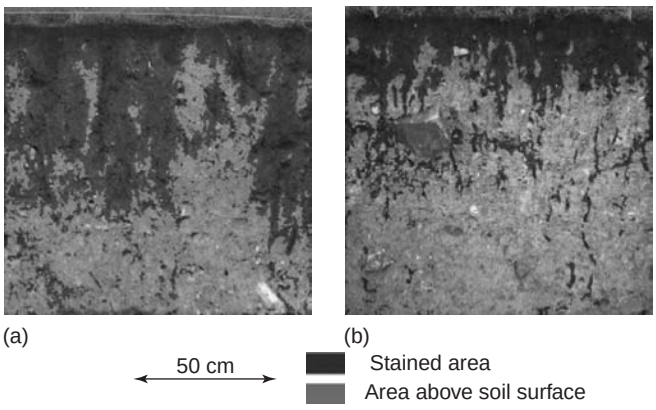

Figure 3 Dye patterns from two different sites: Rietholzbach experimental watershed, Switzerland, (a) and Heitersberg near Zurich, Switzerland (b). Note the spatial heterogeneity of dyed water and preferred nature of water flow vertically within the soil profile. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Another observation sometimes made in soils when water content is close to field capacity is that only a small fraction of water input into the soil results in a strong hydrodynamic response in the lower soil profile. Torres *et al.* (1998) found that this hydrodynamic response can be on an average 15 times greater than the estimated water and wetting front velocities. While these processes remain poorly understood, research to date shows clearly that rapid travel times of fluid pressure head or water content through the unsaturated zone could be mistaken as preferential or macropore flow (Rasmussen *et al.*, 2000; Smith and Hebbert, 1983).

Drainable Porosity

The conversion of unsaturated to saturated conditions or the rise of an existing groundwater table at depth depends on the drainable porosity (or specific yield) of the soil. Drainable porosity is commonly defined as the difference in volumetric water content between 0 kPa and 33 kPa soil water potential (approximately field capacity) (Weiler and McDonnell, 2004). This represents the porosity of the soil draining within a short duration – characteristic of water table rise in the saturated zone. Drainable porosity commonly decreases with depth because of an increase in the bulk density, a decrease in macroporosity, and a change in soil texture and pore structure.

The decrease in drainable porosity with depth can be observed in different soils by comparing measurements of the water content at saturation and field capacity at several depths within the soil profile. Figure 4 illustrates the change of drainable porosity with depth in three different soils. The values show a high-drainable porosity in the topsoil and a slower (site no. D3) or a more rapid (site no. B4) decrease in drainable porosity with depth. Since the drainable porosity cannot be zero within the soil profile, an exponential model

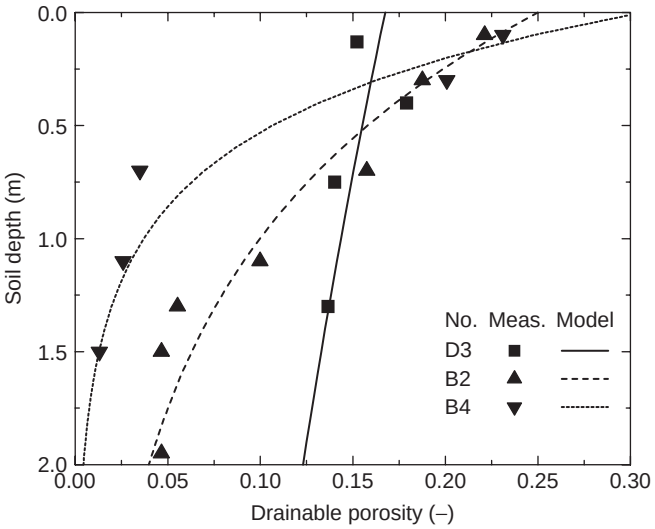

Figure 4 Measured and fitted drainable porosity with depths of three different soils (No. of sites see Table 1)

can be used to describe the observed change with depth:

$$n_d(z) = n_0 \exp\left(-\frac{z}{m}\right) \tag{1}$$

where n_0 is the drainable porosity at the soil surface, m is a decay coefficient, and z is the depth into the soil profile (positive downward). An exponential model can be fitted to the measured values to produce a depth distribution of drainable porosity. Table 1 gives the values of the two fitting parameters n_0 and m for 13 different soils. The fitted values of the parameter m show a pronounced decline of the drainable porosity with depth for almost all sites, except for site no. A4. At this site, the texture changes

Table 1 Values of the two parameters n_0 and m of the exponential depth function for drainable porosity and the goodness-of-fit information (efficiency) for soil data of 13 different sites

to a more sandy soil at depth, resulting in an increase of the drainable porosity with depth. For all other sites, the parameter m ranges from 0.294 (rapid decrease) to 6.496 (slow decrease). The drainable porosity at the soil surface n_0 does not influence the parameter m; however, the grassland soils generally show a lower n_0 than the forest soils. A low drainable porosity in the lower soil profile indicates that only a small amount of water is needed to raise the water table and, thus, to increase the potential for lateral subsurface flow.

For example, a sensitivity study implementing the exponential model for drainable porosity decline in Hillvi (**http://faculty.forestry.ubc.ca/weiler/hillvi.html**), a subsurface hillslope flow model, reveals that for a 10% steep hillslope using m-values of 0.3, 0.5, and 1.5, the response time is 14.4, 3.8, and 1.4 times faster, respectively, than for the same hillslope with a constant drainable porosity. The response time in this example is calculated as the time subsurface flow increases to half of the simulated constant rainfall intensity. This example highlights the importance of the drainable porosity decline in the soil profile for the vertical response of the groundwater level in the hillslope and, hence, the lateral response of subsurface flow.

Topographic Control on Lateral Subsurface Flow

There is now wide consensus that in areas with steep slopes, thin soils, and matrix hydraulic conductivities above the maximum rainfall intensity, water moves vertically to depth (as matrix or preferential flow), perches at the soil-bedrock or an impeding layer at depth, and then moves laterally along the lowest depths of the profile (Freer *et al.*, 2002; McDonnell, 1990; Peters *et al.*, 1995; Sidle *et al.*, 2000; Tani, 1997; Tsukamoto *et al.*, 1982; Uchida *et al.*, 2002). Hence, the bedrock topography may control the direction and accumulation of flow more directly than the topography of the surface. Hillslope experiments using piezometer and tensiometer data as well as flow volumes recorded at a trench face suggest that rapid saturated subsurface flow occurs as narrow "ribbons" of saturated flow along the bedrock topographic surface (Hutchinson and Moore, 2000; Woods and Rowe, 1996). The bedrock surface is the main "pathway" for mobile transient saturated flow during events (Freer *et al.*, 2002; McDonnell *et al.*, 1996).

Isotope composition and major ion concentration of subsurface flow have been used to test the physical mechanisms revealed by the pore water pressure and topographic analysis. ^{18}O analysis of collected trench flow often showed little evidence of "new water" breakthrough during storm events (Burns *et al.*, 1998). The Panola hillslope at Panola, Georgia, USA, is a useful example of hillslope flow behavior. For example, the Panola trench SO_4 chemistry showed no concentration-discharge relationship (Burns *et al.*, 1998). The only variability in concentrations of subsurface flow at the trench face was between neighboring troughs, suggesting waters of slightly different ages were mobilized within the hillslope. Burns *et al.* (1998) found that base cation concentrations in hillslope subsurface stormflow were generally related to flushing frequency, where parts of the trench with the highest bedrock surface drainage area had consistently lower mean base cation concentrations than other trench face positions with lower bedrock surface drainage areas.

The relative contributions of different parts of the Panola hillslope change with total precipitation, antecedent wetness, total flow, and season (Tromp-van Meerveld, 2004). This suggests that the bedrock topography might not be the only dominant control on subsurface flow as was suggested by the analysis of only a few storms by McDonnell (1997) and McDonnell *et al.* (1996) and Freer *et al.* (1997, 2002). Together with bedrock contributing area, soil depth may control subsurface stormflow dynamics during storms, especially for smaller events (Buttle *et al.*, 2004). At the Panola hillslope, subsurface storm flow volume of smaller events (less than the 55 mm rainfall threshold) or events with dry antecedent conditions are controlled largely by soil depth variations in space (Tromp-van Meerveld, 2004), while the bedrock topography is the primary control during medium to large storms. The shift in dominant areas of flow appears to be related to increasing antecedent soil moisture, storm size, and total flow (Freer *et al.*, 2002).

Despite the fact that bedrock topography and soil depth variability are important controls on subsurface stormflow, few models have conceptualized and implemented this into simulation models. Recently, Weiler and McDonnell (2004) incorporated soil depth variability into a subsurface flow model and simulated subsurface stormflow for the Panola hillslope. They could show that soil depth variations not only have a large influence on the spatial variation of subsurface flow but control largely the total subsurface flow volume produced. Figure 5 shows observed and modeled subsurface flow for simulations using Hillvi (**http://faculty.forestry.ubc.ca/weiler/hillvi.html**), a spatially explicit saturated and unsaturated water balance model for the actual measured soil depth variations at the Panola and Maimai experimental hillslopes and for an assumed constant average soil depth at those sites. All other model parameters were kept constant. For the Panola hillslope in particular, the differences in subsurface stormflow response are considerable – changes are also notable for the Maimai hillslope. These differences seem to be related mainly to the total variance of soil depth and the measured spatial correlation length of soil depth.

The preferential nature of flow along the soil-bedrock interface may also partly account for the often observed discrepancy between measurements of saturated hydraulic

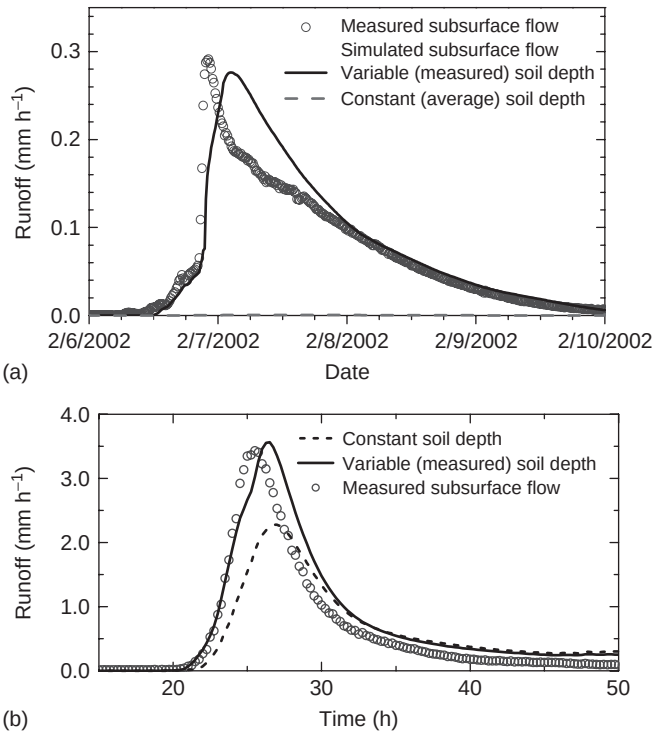

Figure 5 Simulated and measured subsurface flow response for the experimental hillslope at Panola (USA) – (a) and Maimai (NZ) – (b) assuming a constant soil depth and the measured variable soil depth. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

conductivity at the plot scale and the calculated hydraulic conductivity assuming lateral homogeneous matrix flow from measurements of lateral subsurface flow at the hillslope scale (Brooks *et al.*, 2004; Uchida *et al.*, 2002; Weiler *et al.*, 1998). As the results in Figure 5 show, subsurface flow can increase by orders of magnitude because of the variations in soil depth without changing the saturated hydraulic conductivity.

Subsurface Flow in Soil Pipes/Macropores

In many environments, subsurface stormflow is dominated by lateral macropore flow, ranging from subarctic wetland (Woo and DiCenzo, 1989) and boreal forest (Roberge and Plamondon, 1987) to tropical rain forest (Elsenbeer and Lack, 1996) and semiarid land (Newman *et al.*, 1998). These macropores are commonly referred to as *soil pipes* and concentrated subsurface flow in these natural soil pipes is called as *pipeflow* (e.g. Jones, 1971; Jones, 1981). Empirical studies of lateral pipeflow found in the literature show that lateral pipeflow controls hillslope response (e.g. Uchida *et al.*, 1999), nutrient flushing (Buttle *et al.*, 2001), and old water delivery to streams (Freer *et al.*, 2002; McDonnell, 1990) and to riparian zones (McGlynn and McDonnell, 2003a).

Recently, soil pipe morphology has been studied by means of dye tracer, fiberscope, and ground penetrating radar. Results show that: (i) soil pipes in gentle moorland environments are complex and long (>50 m) (e.g. Holden and Burt, 2002; Jones, 1987), while soil pipe connectedness and length mapping in forested steep hillslopes show that soil pipes are highly discontinuous with maximum lengths of usually only a couple of meters (e.g. Michihata *et al.*, 2001; Noguchi *et al.*, 1999); and (ii) the position of soil pipes in gentle moorland environments varies from being shallow to deep within the peat layer. The pipe can be entirely within the peat, at the peat-substrate interface, or entirely within the substrate (e.g. Holden and Burt, 2002). The position of the soil pipes in steep forested hillslopes is often at or near the soil-bedrock interface (e.g. McDonnell, 1990; Terajima, 2002).

Runoff characteristics of pipeflow have been examined at hillslopes in Japan, the United Kingdom, North America, and Peru. These studies suggest that the maximum discharge of pipeflow is determined mainly by soil pipe diameter. Many studies have also shown that a precipitation threshold exists when pipeflow starts to dominate subsurface flow. The observed precipitation threshold depends strongly on the antecedent soil water content (Noguchi *et al.*, 2001; Tromp-van Meerveld, 2004; Uchida *et al.*, 1999). Figure 6 shows the linear relationship between pipeflow and total subsurface stormflow that was observed in several forested hillslopes around the world (Uchida *et al.*, 2005).

Only recently have some models considered the role of pipeflow on runoff generation (Faeh *et al.*, 1997; Jones and Connelly, 2002; Kosugi *et al.*, 2004; Weiler *et al.*, 2003). Nevertheless, these studies have not yet fully incorporated field perceptions into their numerical models. Although they are now viewed as a major subsurface flow control, the effect of soil pipes and other structures on lateral flow and transport at the hillslope scale still awaits good model-process integration.

Thresholds and Nonlinearities

Since the IHD, hydrologists have believed that subsurface stormflow rate changes linearly with changes in rainfall magnitude (Hewlett and Hibbert, 1967). Only recently has the nonlinearity of the subsurface stormflow process been fully realized (Buttle *et al.*, 2004; McDonnell, 2003). Many recent studies have examined the relation between the amount of precipitation and the volume of subsurface storm flow – documenting thresholdlike, nonlinear relationships between the two. In this section, we describe briefly how subsurface storm flow volume changes with rainfall amount and discuss what processes control the change in the hydrological response of subsurface storm flow.

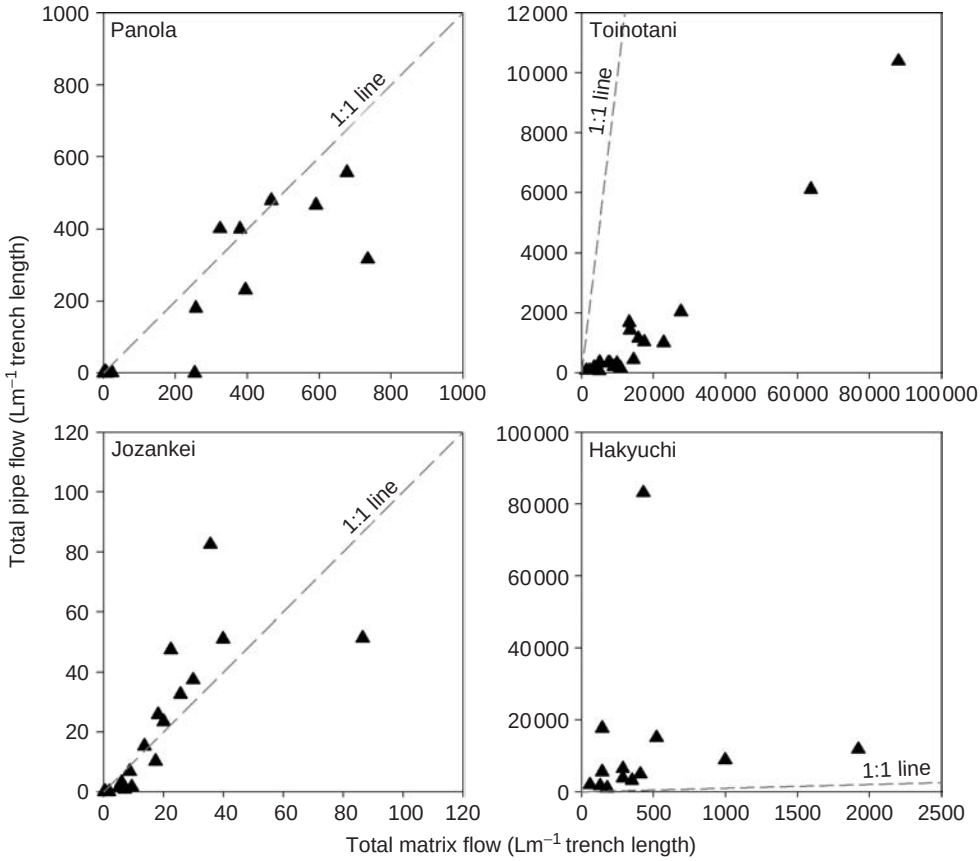

Figure 6 Relationship between total stormflow and total pipe flow of each storm at (a) Panola, Georgia, USA, (b) Toinotani, Kyoto, Japan, (c) Jozankei, Hokkaido, Japan and (d) Hakyuchi, Tokyo, Japan. Data for Jozankei and Hakyuchi compiled from Kitahara *et al.* (1994) and Ohta *et al.* (1981), respectively

Field Evidence of Threshold and Nonlinear Responses

Despite the lack of any formal recognition conceptually, data in the hillslope hydrology literature suggest that precipitation thresholds for subsurface stormflow generation may be a widespread phenomena. Revisiting data from many trenched hillslope studies (e.g. Mosley, 1979; Whipkey, 1965) suggests that the precipitation threshold for subsurface stormflow commencement lies commonly between 15 and 35 mm. More recent studies show that the precipitation threshold depends on the antecedent moisture conditions in the hillslope (Guebert and Gardner, 2001; Noguchi *et al.*, 2001; Peters *et al.*, 1995; Uchida *et al.*, 1999). Tani (1997), for example, has pointed out that after the threshold was reached, there was an almost 1 : 1 relation between precipitation above the threshold and subsurface flow. A simplified summary of the relation between storm total precipitation and the threshold for subsurface flow is given in Figure 7 for four sites. These relations suggest that while hillslopes vary tremendously from place to place, the subsurface stormflow initiation threshold and the slope of the line thereafter may be an emergent property of the hillslope hydrological system.

The recent analysis of 147 storms at the Panola trenched hillslope in the United States is one of the first to explicitly examine and document the relation between rainfall and subsurface stormflow over a large range of storm sizes, seasons, and antecedent wetness conditions (Tromp-van Meerveld and McDonnell, 2004). They found that macropore and matrix flow had very similar thresholds (around 55 mm) for significant (>1 mm) subsurface flow at the trench. The value of the threshold precipitation was related secondarily to antecedent soil moisture. Only 8 of the 147 storms (an average of 4.3 storms per year) exceeded the precipitation threshold to produce significant lateral subsurface stormflow in the Panola watershed. For these storms, the total amount of subsurface flow was between 30% and 80% of the total precipitation after the precipitation threshold.

Searching for First-order Control of Thresholdlike Responses

Notwithstanding the observation of thresholdlike subsurface stormflow, hydrologists still lack a clear understanding of the processes responsible. Recent studies have

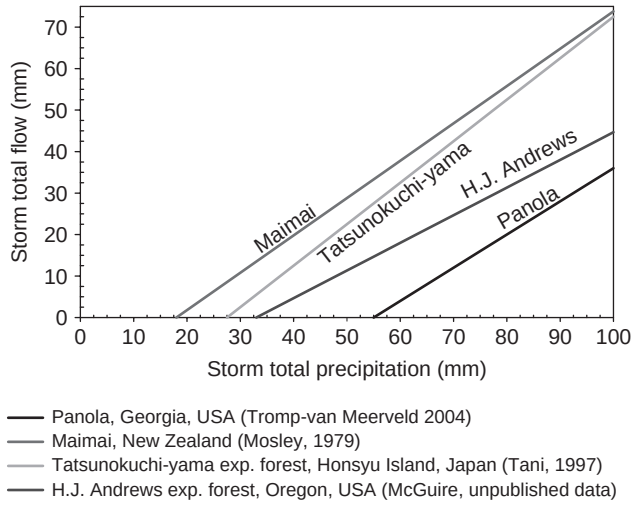

Figure 7 Schematic representation of the thresholdlike relationship between total storm precipitation and storm total flow under wet antecedent conditions. The lines represent the best fit lines through maximum storm total subsurface stormflow data points. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

shown that there are at least two common controls for a threshold response: (i) interconnection of lateral preferential flow paths; and (ii) development and extension of transient saturated areas. Tani (1997) observed a large subsurface runoff response after smaller areas of transient saturated zones in the hillslope became connected. Using data from another catchment in Japan, Sidle *et al.* (2000) postulated that with increasing wetness, subsurface flow expands over greater slope distances, such that during very wet conditions the hillslopes become linked to the channel system to enhance subsurface flow significantly.

Recently, Spence and Woo (2003) and Tromp-van Meerveld and McDonnell (2004) proposed a fill and spill mechanism to account for threshold behavior at the hillslope scale. Tromp-van Meerveld and McDonnell (2004) used a spatially distributed grid of piezometers to obtain spatial and temporal information of transient saturation at the Panola trenched hillslope. Both piezometer data and a two-dimensional finite element model indicated that for storms smaller than the observed precipitation threshold, subsurface saturation occurred first in areas where the soil was shallowest and then expanded to areas with deeper soils, but did not flow further downslope because it was blocked downslope by a bedrock ridge. During larger storms, transient saturation filled up local depressions in the bedrock microtopography before water spilled laterally over the bedrock ridges between the depressions and flowed further downslope through the bedrock lows (Figure 8). Only during storms larger than the precipitation threshold did these transient saturated areas become connected to the trench face, resulting in significant (>1 mm) subsurface flow. Figure 8 illustrates how soil depth and bedrock microtopographic relief (i.e. the bedrock lows) together control the connection of subsurface saturated areas to the trench face causing the observed threshold for subsurface flow (see also Figure 7).

OUTLOOK AND CONCLUSION

Subsurface stormflow is the main mechanism of runoff generation in many catchments around the world and is significant for the initiation of landslides, for the flushing of labile nutrients and hence the water quality changes, and the hydrograph response in streams. Most subsurface stormflow studies published to date have focused on only a few storms at any given site. Up until recently, it has been difficult to derive general hydrologic principles from single research studies within intensively studied small basins (Jones and Swanson, 2001). Comparing different well-instrumented sites allows extraction of the commonalities or major differences between sites and helps define the first-order controls on subsurface stormflow generation and flow pathways.

A question for future research on subsurface stormflow is how we should compare different sites and what tools we should use to define first-order controls. First, we need to continue with our experimental investigations to understand better the internal processes. New experimental technologies like ground-penetrating radar (Huisman *et al.*, 2003) or electromagnetic induction (Sherlock and McDonnell, 2003) will be important. Detailed measurement of flow combined with isotope and chemical tracing in time and space will be essential to constrain our conceptual and numerical models of subsurface stormflow.

Site intercomparison will require an organizational framework to summarize and evaluate the comparative analysis. Scherrer and Naef (2003) proposed a decision tree to define the dominant hydrological flow processes on a variety of grassland sites in Switzerland. They showed, rather convincingly, that the decision tree approach can be a powerful tool to clarify the first-order controls on dominant runoff processes. A decision tree may be a useful organizational framework for subsurface stormflow science to summarize and organize comparative analyses and to provide a structure for defining the hierarchy of process controls that are necessary for model development.

Process controls and new conceptualization for model development will also be a prerequisite for simulating and predicting the links between biogeochemical-hydrological aspects of subsurface stormflow. Recently, attempts have begun to derive the primary controls of transport processes and nutrient flushing in hillslopes dominated by

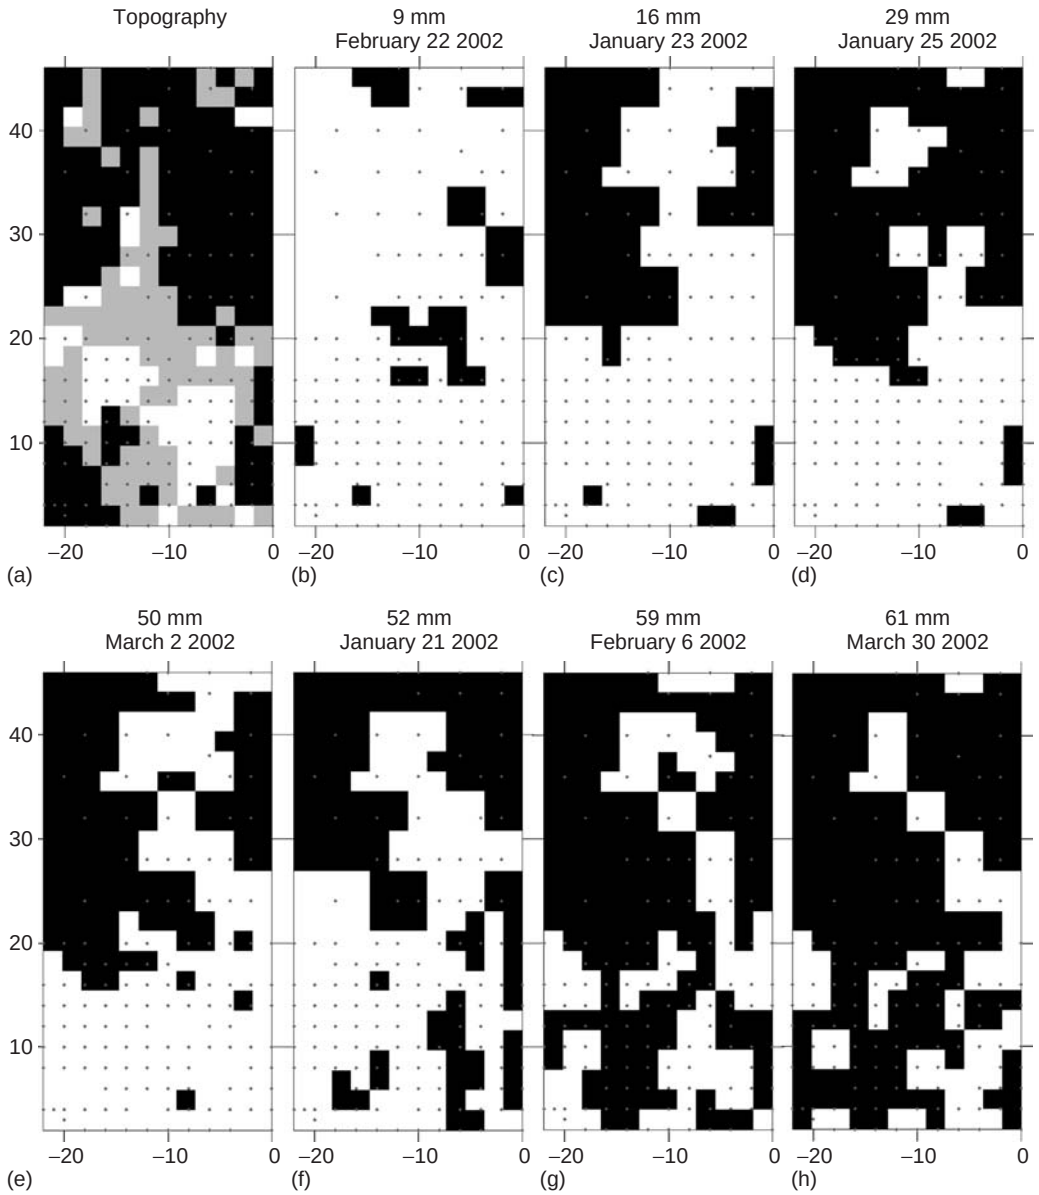

Figure 8 The location of areas of shallow soil depth (<0.75 m) (in black) and the areas with high (>4) bedrock topographic index (grey) (a) and the observed spatial distribution of subsurface saturation at the soil-bedrock interface across the Panola hillslope with increasing precipitation (b–h). The shaded area represents the area where transient subsurface saturation was observed; the unshaded area indicates the area where no subsurface saturation was observed. The diamonds represent the locations of the piezometers. Linear triangulation was used to interpolate between the measurement points. subsurface stormflow (e.g. Stieglitz *et al.*, 2003; Weiler and McDonnell, 2005). Nevertheless, the observed variability for soil properties and structural features (e.g. macropores and pipes) still need to be implemented and conceptualized. When introducing variability (as shown, for example, in Figure 5), we may not be able to predict deterministically where and when water is flowing at a specific location, but we may be able to describe the distribution of subsurface flow variability and its effects on water age, origin, and timing.

113: Hyporheic Exchange Flows

KENNETH E BENCALA

United States Geological Survey, Menlo Park, CA, US

Water having entered a stream channel from the surrounding catchment may continue to have connections with the catchment. In the stream's hyporheic zone, water "in the channel" exchanges with "groundwater" in the bed of the stream. Hyporheic exchange flows typically occur at scales small relative to the length and volumetric transport characteristics of the stream. Nevertheless, it is well documented that hyporheic exchange flows significantly influence nutrient dynamics. Additionally, there is evidence of hyporheic exchange flows similarly influencing the processes establishing the concentrations of major-ions and metals in stream-catchment systems. It is within the contexts of (i) solute transport and (ii) the continuing connections of streams to their catchments that the hydrologic aspects of hyporheic exchange flows are studied. The Transient Storage Model (TSM), a pseudo-two-dimensional representation of stream and hyporheic zone solute transport, is used to identify characteristics of hyporheic zone, physical size, and solute residence times. The TSM is further extended to simulations of reactive solute transport to understand and interpret the biogeochemical processes of streams influencing the solute dynamics of catchments. Active hydrologic research continues to advance the process basis from which quantitative assessments of the role of hyporheic exchange flows will be made.

INTRODUCTION

Hyporheic exchange flows are one of several mechanisms of the interaction of the groundwater and surface water (Winter *et al.*, 1998, *see* **Chapter 145, Groundwater as an Element in the Hydrological Cycle, Volume 4**). In the *hyporheic zones* of streams, water that is flowing in the stream channel flows into the subsurface materials of the streambed and then returns to the stream. Hyporheic zones function as continuing points of connection between the transport of water and solutes in the stream channel and the stream's catchment (Bencala, 1993).

Hyporheic zones are significant in the dynamics of nutrients within the stream-catchment system (*see* **Chapter 96, Nutrient Cycling, Volume 3**) and in the processes establishing the concentrations of major-ions and metals. The influence of hyporheic exchange upon the transport and transformation of solutes occurs in the environments where hydrologic and biogeochemical processes are dynamic and highly heterogeneous. Documenting the biogeochemical function of hyporheic exchange has thus been primarily accomplished in detailed high-sampling-intensity research studies. In spite of the inherent difficulties in isolating the function of hyporheic exchange amidst many other stream and catchment processes, it is clear that hyporheic exchange can be quantified as influencing the establishment of major-ion chemistry and the ongoing transformation of reactive constituents. Numerous investigators have completed extensive field studies documenting the biogeochemical processes active in the hyporheic zones of individual streams. An overview of a small sample of these studies forms the first sections of this article. The understanding of biogeochemical processes within hyporheic zones has further value when utilized in the context of quantitative assessment of solute transport and solute residence within the stream channel and the stream-catchment system. One approach to providing this context, the Transient Storage Model, is discussed below along with current research directions, suggesting that much work remains in interpreting the basic hydrologic mechanisms by which streams and their catchments are connected.

NUTRIENT DYNAMICS

The substantial body of empirical evidence establishing that surface-subsurface exchange significantly influences

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

nutrient dynamics in stream ecosystems is presented in the review article of Mulholland and DeAngelis (2000). As these writers state, "the expectation [of this exchange influence] is based on two factors: (1) high ratios of surface area of sediments to volume of water within sediments should result in large effects of microbial processes on subsurface water, and (2) relatively slow advective flow of water within the subsurface zone retards the downstream movement of soluble materials compared with the surface environment." Using a simple "nutrient spiraling" model, Mulholland and DeAngelis (2000) go on to demonstrate conceptually that the size of the subsurface zone and the rates of water exchange between surface and subsurface zones have substantial effects on nutrient dynamics and uptake lengths in stream ecosystems.

The influences of surface-subsurface exchange upon nutrient dynamics are recognized as being spatially heterogeneous and temporally variable. Butturini *et al.* (2003) present detailed data from a 2-year study of stream-aquifer hydrology and nitrate removal in which they observe a "riparian groundwater system characterized by drastic hydrological changes and by mixing of stream water with hillslope groundwater". In part due to the hydrologic change throughout the year, both nitrate removal and nitrate release are observed within the studied riparian system. The variability in hyporheic zone processes is further evident when considering the range of ecosystems now being studied. Butturini *et al.* (2003) studied an intermittent Mediterranean stream. Edwardson *et al.* (2003) studied Arctic tundra streams. The frank conclusions of Edwardson *et al.* (2003) highlight the difficulty in drawing sweeping inferences about the specific function of hyporheic zone processes. Edwardson *et al.* (2003) conclude: "...we expected that the presence of continuous permafrost in [the] Arctic environment would limit the importance of hyporheic processes, either physically (i.e., through the presence of a restricting thaw bulb in the permafrost) or biogeochemically (i.e., through low temperatures). Instead, we found that biogeochemical processes in the hyporheic zone of [the] Arctic streams are at least as important as it is in similar temperate stream ecosystems".

In addition to the numerous field studies of nutrient dynamics in hyporheic zones, experimental laboratory work has also been reported. Using sediment perfusion cores to study nitrogen transformations, Sheibley *et al.* (2003a,b) have measured the rates of nitrogen transformations in river-bed sediments. These laboratory studies integrate the hydrology of hyporheic exchange with the study of biological transformations to verify that groundwater-surface mixing controls the nitrification–denitrification coupling occurring in the river-bed sediments.

PROCESSES ESTABLISHING THE CONCENTRATIONS OF MAJOR-IONS AND METALS

In addition to influencing the nutrient dynamics of stream-catchment systems, hyporheic exchange flows similarly influence the processes establishing the concentrations of major-ions and metals in streams. The role of hyporheic exchange has been documented in pristine systems as well as in those with a high level of anthropogenic impacts.

Working in a glacial meltwater stream in Antarctica, Gooseff *et al.* (2002) studied the contribution of primary weathering to the in-stream concentrations of silica and potassium. The study of weathering in these streams represents an extreme example of a hydrologic situation in which there were no hillslope processes occurring to influence stream chemistry. Their analysis suggested that the continuous saturation and rapid flushing of the streambed sediment due to hyporheic exchange did facilitate chemical weathering.

Harvey and Fuller (1998), working in a drainage basin in Arizona contaminated through copper mining, found that manganese distributed in the stream–groundwater system affected the transport of trace metals. The cumulative effect of hyporheic exchange in the basin was to remove approximately 20% of the dissolved manganese flowing out of the drainage basin. Their further studies (Fuller and Harvey, 2000) demonstrated that decreased loading of trace metals in the stream was attributable to uptake of the trace metals by manganese oxides in the hyporheic zone that is enhanced by the ongoing manganese oxide formation.

Because the hyporheic zone is an interface between surface and subsurface waters, gradients may exist in oxidation/reduction conditions. For arsenic, the toxicity of this metal can be significantly different for the different oxidation states. Nagorski and Moore (1999) have demonstrated that this gradient has an influence on the form of arsenic mobilized in the hyporheic zone of a contaminated stream in Montana. The continual flux of the reduced form of arsenic to the stream maintains higher concentration of this form than would otherwise be expected in oxygenated surface water.

TRANSPORT MODELING – TRANSIENT STORAGE

The biogeochemical functions of the hyporheic zone occur in the context of solute transport along the stream. Solute transport models are a tool used in conjunction with field data to analyze, and interpret, exchange processes. Models of the transport processes of the interactions of streams and hyporheic zone have been developed over a wide range in physical complexity (Packman and Bencala, 2000). The relatively simple concept of "transient storage", which

has been used by several investigators, is included in the US Geological Survey modeling code OTIS (One-dimensional Transport with Inflow and Storage) (Runkel, 1998). The code and applications information are available at `http://co.water.usgs.gov/otis/`. The Transient Storage Model (TSM) builds upon the standard convection-dispersion model of one-dimensional solute transport down the length of the stream. To the convection-dispersion model, the TSM adds fixed-volume solute storage "boxes" along the stream channel. Solute exchange between the open stream channel and the storage boxes is modeled as controlled through first-order mass-transfer. The storage boxes are effectively the simplest attempt to model the influence that the hyporheic zone has on the transport of solutes; that is, solutes are continually being exchanged between the open stream channel and the storage boxes.

The TSM results in a pseudo-two-dimensional representation of stream and hyporheic zone solute transport; solute transport is one-dimensional (longitudinal) in the stream channel with the storage zones adding a limited second (lateral) dimension. In discussing the TSM, as it is implemented in the OTIS code, Harvey and Wagner (2000) explain both the degree to which the TSM can be used to characterize solute transport in the hyporheic zone and the limitations inherent to this simple representation of complex processes. Harvey *et al.* (1996) present detailed field hydrometric data showing that analysis of solute transport using the TSM leads to a bias in only characterizing the most rapid components of hyporheic exchanges. Wagner and Harvey (1997) then develop guidance for assessing the reliability of TSM characterizations. Scott *et al.* (2003) and Gooseff *et al.* (2005) have recently demonstrated the significance in using objective parameter estimation techniques as part of the application of OTIS to stream tracer data sets.

A further issue in the use of the TSM has been the comparison of results between stream systems. Runkel (2002) discussed several of the comparisons that have been proposed and developed a metric specifically for comparing, stream-to-stream, the significance of transient storage. The TSM can also be implemented to characterize solute transport and storage in terms of temporal moments of concentration–time distributions. Schmid (2003) discusses the development of this approach by several investigators. Wörman (2000) and Schmid (2004) compared the temporal characteristics of TSM solutions to other transport model formulations. Jonsson *et al.* (2004) extended the temporal moments approach to consideration of sorption behavior and long-term retention of reactive solutes in hyporheic zones. In analysis of their field studies, "the method of temporal moments was found to be inadequate for parameter determination, whereas fitting versus the entire tracer breakthrough curves with special emphasis on the tail indicates that [their] proposed model could be used to represent both conservative and reactive transport".

RESIDENCE TIME AND CONNECTION TO THE CATCHMENT

The hyporheic zone influences stream biogeochemistry by increasing solute residence time within the stream-catchment system. The influence of the increased residence time may be enhanced in cases in which the overall biogeochemistry and extent of contact with sediment is distinct within the hyporheic zone compared to the adjacent open stream channel. A variety of approaches are being taken in identifying characteristic solute residence time in hyporheic zones as a significant factor in the connections of streams to their catchments. Harvey *et al.* (2003) used an analysis based on OTIS simulations of five stream tracer experiments to "conclude that relatively simple measurements of channel friction are useful for predicting the response of hydrologic retention in streams to major adjustments in channel morphology as well as changes in streamflow". Identifying characteristic storage zone residence time with a TSM was a step in the work of Thomas *et al.* (2003) to estimating the proportion of reactive nitrogen solute uptake occurring within hyporheic zones.

Although OTIS is used by several investigators and it is the implementation of the TSM that is the context for most of the discussion in this article, the TSM is a highly idealized representation of the function of hyporheic zones. A consequence of an analysis based on OTIS is that a hyporheic zone is characterized by a single residence time distribution. (The single residence time distribution is of exponential form. See Harvey *et al.* (1996) for discussion of this distribution form. The analysis is well beyond the scope of this article to show that a single form is indeed an implicit assumption of the TSM.) Haggerty *et al.* (2002) studied a power-law residence time distribution showing that "the hyporheic zone has a very large range of timescales". Gooseff *et al.* (2003) continued this line of work with analysis of three tracer experiments using a General Residence Time Distribution (RTD) model that is not bound by the implicit assumption of an exponential distribution. The basic result of the analysis is that the General RTD model allowed for a more accurate characterization of longer solute residence times compared to the characterization from OTIS. Gooseff *et al.* (2003) conclude: "Consequently the two models will result in different views of the hyporheic zone and its role in stream ecosystem processes." Haggerty *et al.* (2002) and Gooseff *et al.* (2003) have identified a significant aspect (significant for the understanding of solute transport and transformation in streams) of the complexity of hyporheic zone processes that the TSM's simplicity does not represent.

Residence time in the hyporheic zone is typically considered, as in the discussion above, in the framework of in-stream solute transport. Chanat and Hornberger (2003) use the concept of a "near-stream zone" to develop an analysis showing that mixing in this zone of chemically distinct catchment waters influences the timing of the solute balance flowing into a stream. Although they are using a different terminology for a somewhat different conceptualization of stream-catchment connections, the results of Chanat and Hornberger suggest that residence in the hyporheic zone can also be a factor in catchment-scale transport to a stream.

STREAMS TO RIVERS AND AQUIFERS

Most research papers written on hyporheic zones are undoubtedly about work done in streams, most often low-order, high-gradient streams. A few investigators have started working in the hyporheic zones of higher-order streams or rivers. Paralleling the main discussion above, the listing of a small sample of papers is given here in the sequence: solutes observed in monitoring river hyporheic zones, TSM applications to solute transport in rivers, and investigation of the function of hyporheic zones in connecting streams to aquifers.

Cox *et al.* (2003) completed a tracer experiment in the Upper Santa Clara River (Los Angeles and Ventura Counties, California; 645 square-mile basin) in which tracer added to the surface water was measured in several hyporheic zone sampling locations. In the Willamette River (Oregon; 12 000 square-mile basin) Hinkle *et al.* (2001) demonstrated nitrate reduction occurring along hyporheic flowpaths.

In nine rivers in the Willamette Basin (Oregon), Laenen and Bencala (2001) used OTIS to characterize the transient storage that occurred in 20 tracer additions to surface water. The tracer additions were conducted for other study purposes and there was no direct sampling in likely areas of hyporheic exchange. Thus, the influence of hyporheic exchange could only be inferred from the modeling exercise. However, Fernald *et al.* (2001) completed a study focused upon hyporheic exchange in the Willamette River. Their work included tracer additions, tracer sampling in the subsurface, and modeling analysis with OTIS. They concluded that "significant amounts of water follow flow paths with 0.2–30 hour transient storage zone residence times".

In addition to increasing the scale of studies of hyporheic zones to river systems, the scale can also be increased in the sense of linking hyporheic processes into conjunctive stream-aquifer modeling. Two such model development efforts were presented by Lin and Medina (2003) and Fox and Durnford (2003). Development of these new models will potentially be significant in providing tools for analysis in systems in which the geohydrologic framework is on spatial scales larger than typical for low-order, high-gradient streams.

HYDROLOGIC PROCESSES

The significant environmental influences of hyporheic zones are definitely upon biogeochemical processes. In order to understand these processes, the hydrologic processes that determine the characteristics of hyporheic flow need to also be investigated and understood. Harvey and Bencala (1993) made field measurements of the topography of a streambed. They concluded that solute transport occurred along well-defined subsurface flow paths. They observed hyporheic flow paths as determined by meter-to-meter scale topography, with the flow paths beginning at the transition from pools to steeper channel units. Cardenas and Zlotnik (2003) used ground-penetrating radar to develop a three-dimensional model of channel deposits. The channel deposits were clearly heterogeneous and nonisotropic. Their measurements document that it is an oversimplification to characterize a streambed by a constant width and thickness.

Cardenas *et al.* (2004) took their work further to show that heterogeneity causes significant additional hyporheic zone flux. The presence of heterogeneity can either decrease or increase residence times in the hyporheic zone. Salehin *et al.* (2004) concluded that (when compared to hyporheic exchange in homogeneous streambeds) "the structural heterogeneity of the streambed sediments produces more spatially limited hyporheic exchange that occurs with greater spatial variability and at a higher overall rate".

Solute transport in the hyporheic zone has been predominantly investigated as an adjunct to solute transport in the open stream channel. A groundwater focus has also been taken by a few investigators. Kasahara and Wondzell (2003) used groundwater flow models to investigate the morphologic features that controlled hyporheic exchange flow. Their interpretations are consistent with other studies in finding that surface-visible channel morphologic features controlled the development of the hyporheic zones. Also using groundwater flow models, Storey *et al.* (2003) conclude that the key factors controlling exchange flow within the alluvial (hyporheic) zone were (i) hydraulic conductivity of the alluvium, (ii) the hydraulic gradient between upstream and downstream ends of the riffle, and (iii) the flux of groundwater entering the alluvium from the sides and beneath.

Work to study the environmental fluid mechanics of hyporheic flows has been carried out through experimental tests in recirculating flumes. Bedforms are one control of the rate of solute delivery from the stream to the streambed. Further, bedform-induced pumping can be produced in a

flume to be the dominant exchange mechanism. Marion *et al.* (2002) demonstrate the effects on solute exchange of the longitudinal dimension of bedforms. Zaramella *et al.* (2003) show that the TSM can represent advective exchange with shallow beds that have a defined exchange layer restricted by the presence of an impermeable boundary. However, the TSM does not represent well exchange with a relatively deep sediment bed, where flow along different advective paths in the bed yields a wide distribution of exchange timescale. Clogging of the streambed surface will often isolate deeper regions of the bed from the streamflow. Laboratory flume experiments reported by Packman and MacKay (2003) show kaolinite clay deposition in a sand bed and the resulting alteration of hyporheic exchange flows. Ren and Packman (2004) observed that "reactive colloids can substantially mediate the stream-subsurface exchange of contaminants and the colloid deposition can provide a mechanism of contaminant immobilization that is generally not considered in field studies . . .".

Transient storage of solutes may occur due to features of a stream (e.g. vegetation) that are unrelated to hyporheic flows. In one example of work on this issue, Salehin *et al.* (2003) studied solute transport and hyporheic exchange in vegetated and unvegetated stream reaches. Their work demonstrates the considerable inherent difficulties in trying to differentiate the effects of multiple individual processes from solute breakthrough curves.

CONTINUING WORK

This article focuses upon the hydrologic processes influencing solute transport. The process hydrology of hyporheic exchange flows continues as an area of active investigation. Hyporheic zones have an ecological role in the life cycle of stream organisms. For example, Malcolm *et al.* (2004) have studied the implications for salmon egg survival of hydrological influences on hyporheic water quality. In considering the ecological role of hyporheic waters, it is found that the transport of heat is also influenced. Malcolm *et al.* (2004) observed that "the amplitude of surface water temperature signals was damped considerably with depth into the hyporheic zone". Several authors have provided discussions of the open issues and potential directions for research. Again listed in parallel with the themes of this chapter, examples of these discussions are: (i) Stanley and Jones (2000); potential directions for hydrologic studies needed to support research on the biogeochemistry of hyporheic zones, (ii) Runkel *et al.* (2003); potential directions for development of solute transport modeling in the hyporheic zone, and (iii) Bencala (2000); potential directions for research to understand the hydrological framework of which hyporheic zones are a critical linkage element.

114: Snowmelt Runoff Generation

MING-KO WOO

School of Geography and Geology, McMaster University, Hamilton, ON, Canada

Snowmelt runoff has major influence on water supply and hazards for many temperate and polar regions. The magnitude and timing of runoff depend on the processes of snow accumulation and melt, which are controlled by factors that include latitude, topography, and land use. The amount of runoff production is affected by meltwater loss to evaporation and infiltration, the latter is often limited by frozen soil conditions. Runoff is delivered as flow in the snow, overland flow on bare ground, channeled flow in rills and interhummock cracks, or as subsurface flow in organic soils. The flow may be modified by the presence of snow or river ice in the channels, which often causes runoff delay and amplification of peak flows. Streamflow hydrographs for small basins typically show diurnal cycles with high discharge during warm days and declines in the cool and terminating periods of snowmelt. Hydrographs of large basins are an integration of the runoff patterns of their subbasins. In terms of snow management, the control of snowmelt floods is a consideration, yet many arid regions look to snowmelt runoff as a source of water supply.

INTRODUCTION

In winter, snow covers many parts of the temperate latitudes and almost everywhere in the polar regions. For these areas, meltwater runoff is an integral component, if not the principal element, of the hydrological cycle. Here, snowmelt runoff is considered as that part of the snow precipitation, which contributes to stream discharge (see Chow's, 1964 definition on runoff). Snow, as a portion of annual precipitation, increases poleward and hence the incremental importance of snowmelt in runoff generation relative to the contribution of rainfall. In North America, for example, snowfall accounts for under 30% of annual precipitation in temperate zones, rising to over 50% in boreal areas and exceeding three-quarters of total precipitation in the Arctic. Where above-freezing conditions occur frequently in winter, multiple melt runoff events are common, but a protracted snow accumulation season without intervening thaw episodes can eventually lead to late-season melt when the snow collected over months is released rapidly to runoff, often producing the annual flood. The availability of snow, the melt pattern, and the flow delivery mechanisms are major considerations in understanding and predicting snowmelt runoff generation.

SNOW ACCUMULATION AND MELT

The amount and timing of meltwater production depends on the processes of snow accumulation and snowmelt, both of which are controlled by climatic conditions. Of importance is the spatial variability of the snow cover and snowmelt rates; the former is due to uneven snowfall and snow drift and the latter is attributed to variations in energy available to melt the snow (*see* **Chapter 159, Snow Cover, Volume 4** and **Chapter 160, Energy Balance and Thermophysical Processes in Snowpacks, Volume 4**). Several locational and land use factors affect the regional and microclimate and therefore play an indirect role in influencing melt runoff generation.

Latitude

Many temperate latitude locations experience intermittent snow melt during winter to cause runoff events. At higher latitudes, snowfall generally decreases, but there, winters are long, spanning 6 to 10 months, during which very little melt occurs. The snow can accumulate to considerable amounts before the melt season arrives.

Topography

Snowfall tends to increase with elevation, as does the length of the snow-covered period. In autumn and spring, it is also

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

common to see a snowfall line in mountainous areas, with simultaneous occurrence of snow accumulation above this line and rain-on-snow melt of any snow cover that exists at low elevations. Furthermore, snowmelt in mountainous terrain can span weeks or even months, with runoff generated first at the low altitudes and then proceeding to the high grounds. Snowmelt at high elevations is retarded by an altitudinal decrease in air temperature that reduces sensible heat flux and by frequent presence of clouds that cut down the radiation input. Late runoff from the highlands provides a summer source of water that is often important to crop irrigation on the plains, particularly in the arid and semiarid regions. On a local scale, snow accumulation and melt rate can vary between slopes. Shady slopes, such as those of northern exposure in the northern hemisphere, can have snowmelt delayed by weeks after the melt season has begun. Steep terrain that enhances radiation contrasts between the sunny and the shady aspects further exaggerates the differential melt rates within short distances, leading to asynchronous runoff generation within a basin.

Open Environment

Blowing and drifting of snow is common in the tundra, grasslands, and open fields, resulting in extensive redistribution of snow, with deep snow accumulated in sheltered areas such as gullies and lee slopes, but thin snow on exposed hill tops and windswept slopes (Woo and Marsh, 1978). Unevenness of snow cover quickly leads to its fragmentation when melt commences, and patchy snow distribution favors heat advection from bare ground to accelerate snowmelt (Liston, 1995; Neumann and Marsh, 1998). The area that contributes to snowmelt runoff changes rapidly in the melt season and large accumulation of snow in the valleys not only prolongs melt runoff production but can also temporarily block the flow in stream channels.

Vegetation

Vegetation intercepts precipitation and trees are particularly effective in intercepting snowfall, which can be driven by wind to reach the surface at oblique angles. Some of the snow intercepted by vegetation is sublimated without ever reaching the ground and this reduces the snow precipitation that is available to runoff generation. Interception loss can be substantial. Experiments that weighed entire trees in northern forests during winter demonstrated that, depending on tree type, about one-third of the total snowfall could be sublimated (Pomeroy *et al.*, 1998). Stand closure of a forest also plays a role as it limits the amount of snow that can reach the ground directly as throughfall. However, forest edges may trap the snow that drifts from adjacent open fields to create a narrow belt with deep snow. These considerations increase unevenness of snow distribution, hence the variations in the areas of melt runoff generation.

Snowmelt rates are modified by the type and size of trees, and the density and geometry of the forests, all of which have significant effects on radiation and turbulent heat exchanges that govern the melt energy balance. Although trees, when warmed, emit long-wave radiation to the snow, sometimes creating snow hollows (or tree wells) around the trunks, the trees block off direct beam solar radiation and sun flecks reach the snow only through gaps in the forests (Woo and Giesbrecht, 2000). These conditions render the snow in the forest to become more uneven as melting progresses. Snowmelt rate is often lower in the forest than in open areas because of the reduction in short-wave radiation by tree shadows; but whether the snow stays longer in the forest depends also on the amount of snowfall accumulated under the canopy. Small forest openings usually trap more snow than open fields. In areas where the forests are cut, parts of the logged patches may have residual snow that generates runoff after both the forest and the open fields have become bare.

Built-up Areas

Large variations in snow accumulation pattern are not only caused by local modifications of wind flow because of buildings but also by human removal and compaction of the snow. Urban snow contains many impurities, including salt and sand added by highway crews, and dirt particles from industrial fallout and automobile exhaust. The salts depress the melting point and the dust cover greatly lowers the snow albedo to enhance radiation melt. Snow melt is further complicated by multiple short-wave reflection and long-wave radiation exchanges between the buildings and the snow cover, and by large local variations in turbulent fluxes as well as heat advection from the buildings or bare ground (Semádeni-Davies and Bengtsson, 1998). Snowmelt in built-up zones tends to begin earlier, and the melt is more intense than in rural areas. Urban runoff is generated from a mixture of permeable and impervious areas and flow delivery is affected by artificial drainage that includes sewers, ditches, and pavements that enhance overland flow.

Hydrological models that compute snowmelt runoff generation apply widely different treatments of snow accumulation and melt that may or may not explicitly express the effects of the above factors. Lumped basin models may use melt computation methods that range from degree-days to full energy balance. Melt calculation may be adjusted for elevation and vegetation cover effects (e.g. SSARR model), and distributed models (e.g. SHE model) include topography and cover conditions, but none would have a component to cope with heat advection when the snow becomes patchy. A good summary of the various models with a snowmelt runoff generation component is available in Singh (1995).

FLOW PRODUCTION

From an increase in energy supply in the spring, through snowmelt events, to runoff generation, there are time lags that postpone the flow responses. Water produced by melting may be detained temporarily in the snow, especially if it is dry and has large water retention capacity, or if it is very cold and the meltwater refreezes. This delays meltwater release from the snow cover (*see* **Chapter 161, Water Flow Through Snow and Firn, Volume 4**). The released meltwater may enter the soil, or pond on ground surface before running off. The effects are best illustrated in the Arctic where intense winter coldness delays snowmelt until around the time of summer solstice (time of maximum incoming solar radiation). Figure 1 gives an example of the sequence of events leading to melt and runoff in McMaster River basin (area 33 km^2) near Resolute in arctic Canada (74°45′N; 95°05′W). Solar radiation reached high values around the solstice of 1978, but net radiation received by the snow remained low due to high snow albedo. Snowmelt began at about the time when air temperature rose above 0 °C. Runoff was released to hillslopes after several days of delay when the water-holding capacity of the snow was exceeded. It then took several days before the stream commenced to flow in earnest.

Infiltration is an important process to be considered in snowmelt runoff generation because should meltwater infiltrate the soil, it becomes unavailable to immediate runoff. Highly porous organic soils permit infiltration (Carey and Woo, 2001), while the abundance of soil cracks enhances meltwater entry into the soils. Even crystalline bedrock may be fractured and meltwater can infiltrate through the rock fissures (Spence and Woo, 2002). For most frozen soils, the presence of ice in the pores hinders meltwater infiltration.

Frozen ground conditions prevail during the snowmelt season in most areas other than the warm temperate zone where the ground may not freeze or may undergo alternating freeze–thaw during winter. Frozen soils with low ice content permit rapid infiltration (Kane and Stein, 1983) and this accounts for an absence of meltwater runoff from slopes in silty soils in the subarctic (Carey and Woo, 1999). However, frozen soils with most of their pore space sealed by ice tend to be impermeable to infiltration. Infiltration capacity depends on soil type, moisture content, and the thermal regime, and these factors have been considered in developing equations for frozen soil infiltration. According to Gray *et al.* (1985), infiltration in frozen prairie soils can be distinguished into unlimited (unimpeded infiltration), restricted (very little infiltration), and limited categories. Semiempirical equations that describe limited infiltration would include such independent variables as soil moisture content, soil temperature, and duration when water is available for infiltration (Zhao and Gray, 1999).

In spite of the significance of frozen soil in snowmelt runoff generation, it is rare to find a hydrological model that incorporates a frozen soil routine. In an experiment to demonstrate the role of frozen soil, Gray *et al.* (1985) added a frozen soil infiltration algorithm to the Sacramento model of the United State National Weather Service and obtained an improvement in the calculated runoff for a prairie catchment.

FLOW DELIVERY MECHANISMS

Meltwater released from the snow is subject to evaporative and deep seepage losses, but most of it usually runs off following several modes of delivery.

1. Meltwater can move downslope without first reaching the ground. When the snowpack becomes saturated at its base, it behaves as a porous medium through which meltwater flows laterally down gradient, with the input varying during the course of a day depending on the melt rate (Dunne *et al.*, 1976). Saturation of an entire snowpack will generate flow within and even on the snow surface. One special mechanism of delivery is slush flow, which is a rapid movement of snow–water mixture down slope or down valley (Gude and Scherer, 1998).
2. Unless the soil is impervious, meltwater will infiltrate. The infiltrated water may perch upon the frost that remains in the soil, or it may continue to drain downward to replenish the nonsaturated zone or to enter into groundwater storage. At the surface, water that is not infiltrated will fill the depression storage. In many places, the thinly thawed soil will be saturated and the abundance of water at or near the ground surface provides unlimited moisture supply for evaporation. In some regions, such as the polar deserts where spring melt is the main period with surface water, this can be the time of maximum evaporative loss.
3. After some initial delay to satisfy surface and subsurface storages, runoff is quickly delivered from hillslopes, in the form of overland flow. In impervious areas such as urban locations or frozen soil with concrete frost, overland flow is particularly prevalent. Even in more porous soils, such as of the temperate forests, rapid meltwater production can saturate the ground and generate overland flow on the forest floor (Figure 2a). In low-lying areas and streambank locations, flooding occurs when rapid meltwater production and inflow from high grounds cannot be shed quickly due to flat topography or channel blockage by snow and ice. Overbank flow and spring flooding of deltaic areas or wetlands become a recurrent phenomenon in the cold temperate, subpolar, and polar landscape.

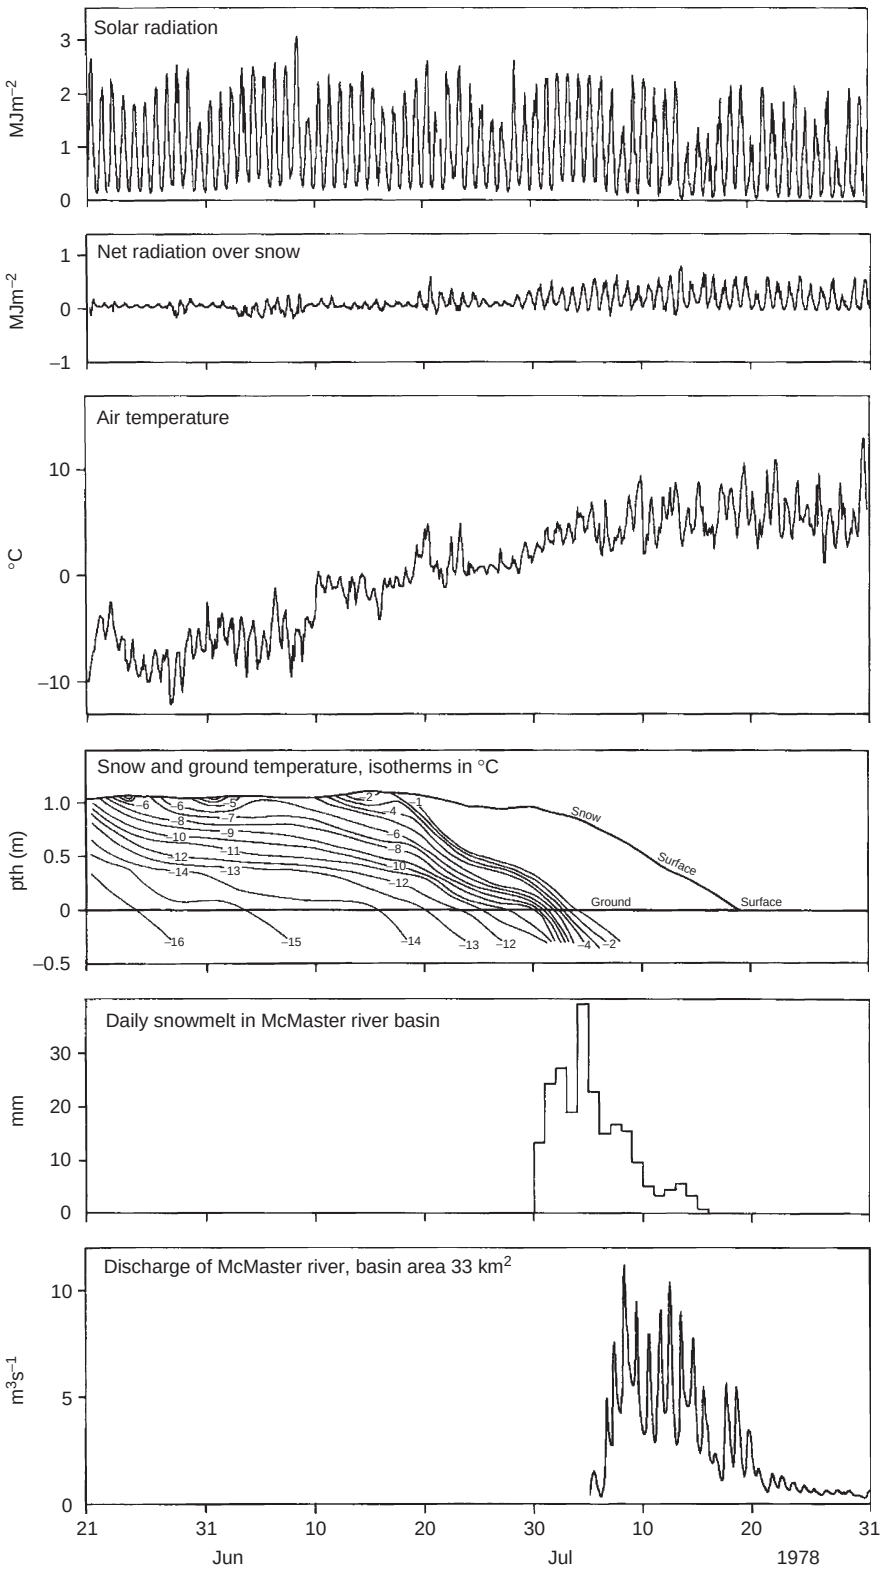

Figure 1 Progressive delay from an increase in melt energy supply to the initiation of streamflow, McMaster River basin, Cornwallis Island, Canada. While solar radiation attains peak values around the summer solstice, net radiation over snow remains low due to high albedo. Only after the air temperature has risen above 0 °C, the snow loses its cold content, followed by delayed runoff. Streamflow shows diurnal fluctuations that reflect the daily melt cycles. Depletion of the snow cover leads to seasonal decline in runoff

(a)

(b)

Figure 2 (a) Meltwater runoff producing overland flow on the floor of a temperate forest. (b) Concentration of meltwater runoff along interconnected shallow depressions between tussocks in an arctic landscape

4. Runoff may follow soil cracks and may concentrate along well-defined or poorly delineated channels on hillslopes, thus activating pathways that are normally dry except during snowmelt or intense rain storms. Preferred paths include cracks between tussocks and earth hummocks. Figure 2(b) shows the concentration of surface flow along shallow, but interconnected, depressions between tussocks. At a larger dimension, runoff may be channelled in rills, gullies, water tracks (which are inconspicuous trough lines on the slope, saturated only in the melt period), and zero-order headwater streams.
5. Water that infiltrates the soil, either in areas without concrete frost or in shallow thawed zone above the frost, moves as subsurface flow, which is often considerably lower in magnitude than overland and channelled flows (Dunne and Black, 1971; Woo and Steer, 1983). Many areas in the cold region have an organic layer composed of lichens and mosses, covering the mineral soils. The organic soil is often highly porous and permits infiltration even when frozen. Upon reaching the frozen mineral substrate, percolation ceases, and a perched saturated zone rises into the organic soil, issuing subsurface flows that include Darcian flow in the soil matrix, and quick flows through macropores that include soil pipes (Carey and Woo, 2001).

SOURCE AREA OF SNOWMELT RUNOFF

Contribution of snowmelt runoff to streamflow depends on (i) location and amount of meltwater production, which change with snow distribution and melt rates, and (ii) connectivity of meltwater to stream channels. Generally, surface runoff conveys water faster and carries more water downslope than subsurface flow, and the area that contributes to quick runoff varies within and between days.

At the beginning of the melt season, snow may cover most or all parts of the hillslopes or small catchments, but, as melt progresses, the snow coverage shrinks unevenly across the land. Not only do the areas that contribute to runoff become discontinuous but also, owing to differential melt rates that arise from topographical and land cover contrasts, the spatial pattern of flow generation becomes increasingly variable. The source area of runoff is dictated by snow distribution and by meltwater infiltration. Some soils with unlimited infiltration may not generate any surface runoff at all.

With frozen soil where most of the pore is sealed by ice (concrete frost), infiltration is limited and overland flow prevails. Where large quantity of meltwater is delivered from upslope, even permeable soils are saturated, and the saturated zone perched on the frozen substrate will rise above ground to generate overland flow. As meltwater production diminishes, such as during cool spells or when the snow cover retreats upslope, the perched water table subsides and only a small amount of subsurface flow is maintained. Where the soil is not frozen, as in some temperate latitude slopes, an abundance of meltwater can infiltrate and then saturate the soil to produce saturation overland flow. Regardless of location, source area varies during and between days and the resulting expansion and contraction of overland flow areas is analogous to the variable source concept that applies to rainfall events (Dunne and Black, 1971). Uneven snow distribution and overland flow patterns are best seen on the barren Arctic slopes, as is illustrated by Figure 3, which shows such a pattern during the melt season for an area in Ellesmere Island, Canada. As melt progresses, snow cover becomes

Figure 3 Uneven snow cover pattern in a barren arctic setting (Hot Weather Creek, Ellesmere Island, Canada) where only topography affects the microclimate to cause differential snow accumulation and melt, and the source area of meltwater runoff changes during the melt season

increasingly patchy and the source area for runoff shrinks. Ultimately, the snow disappears, but, in cold regions, snowbanks may linger well into the summer. Late-lying snow can be a local water source that extends the flow period of streams in high latitudes and high altitudes (Young and Lewkowicz, 1988).

On the scale of small to medium basins, elevation differences, soil and land use factors affect the timing and location of meltwater release. Towards the latter parts of the melt season, the principal source area of melt runoff often shifts from the open, low-lying zones to the forested or higher ground where residual snow remains.

Over a large area, it may not be practical or necessary to examine in detail the snow distribution and differential melt rates during the melt season, though it is useful to consider the changing fraction of snow cover in a basin throughout the melt period. One approach is to devise an empirical snow depletion curve for a basin by plotting the residual fraction of basin snow cover against time or cumulative degree-days or melt, or by plotting the snow-covered fraction against the ratio of basin snow-water equivalent average to the peak snow-water equivalent (Luce *et al.*, 1999). The fraction of snow-covered area in the basin estimated from the depletion curve can be used as a weighting factor to obtain basin snowmelt. One consideration in applying this method is that land use and melt pattern should not vary much from year to year, otherwise a new depletion curve has to be obtained for the basin.

FLOW IN STREAM CHANNELS

Meltwater runoff follows the melt rhythm of snow and therefore responds to energy input that generates melt and to the storage that retards flow delivery. Streamflow may be derived from individual snowfall events, as is common in warm temperate areas where cold spells are quickly followed by melt episodes. Similarly, spring and autumn snowfall in cold temperate regions or summer snowfall in high altitudes and polar latitudes is subject to rapid melting to generate streamflow responses with little delay. These fast responses may be termed snowfall runoff (Yang *et al.*, 1993) in contrast to the snowmelt runoff produced from a snow cover that accumulates over multiple snowfall events over a period of days to months.

With deep snow, the melt season can extend for days or weeks and streamflow usually lags melt events. The initial melt events are subdued. When runoff reaches the valleys, it may encounter several situations in the channels.

1. The stream channels have little snow or ice, so that water can move down the channel network in direct response to the rhythm of snow meltwater input from basin slopes.
2. Snow infills most channels in the Arctic (Woo and Sauriol, 1981) and even in the windswept plains of the temperate region. Snow in the valleys hinders the development of an integrated flow system when the melt season arrives. Streamflow may begin at isolated segments along the valleys, depending on local supply of meltwater and flow blockage by snow jams. A typical example is provided in Figure 4(a) where snow infills channels that are dry in winter (no winter flow). The uneven valley snow blockage temporarily impounds the meltwater that runs off from adjacent slopes, but prevents the linkage of individual ponded segments to form a continuous drainage network. When these snow jams are breached, water retained upstream of the snow dams is released rapidly to generate floods downstream. Such episodes of ponding and snow dam breakage will eventually establish an integrated channel network for flow delivery. For these channels, the rise of streamflow includes an initial low flow stage indicative of the preintegrated phase of flow delivery. Once established, the drainage network along the mostly snow-lined channels will be very effective in carrying meltwater downstream.
3. An ice cover is often formed over the winter in the cold temperate and subarctic rivers, and the ice breaks up in the spring thermally through melting, or mechanically through fracturing. Snowmelt runoff flowing down the channel will cause the river ice to fragment and move downstream, frequently forming ice jams that block the flow. Ice jams cause the upstream water levels to rise and failure of the jams creates high flows to down-stream areas (Beltaos, 2000). Ice breakup lags behind snowmelt, but amplifies peak flows so that flooding due to ice jamming is a common occurrence (Figure 4b). At the time of high flow, ice floes drift downstream until they are jammed, with speeds that often exceed

(a)

(b)

Figure 4 (a) Stream channels in Arctic Canada (Iqaluit, Baffin Island) jammed by snow, causing streamflow to occur in segments until the snow jams are breached to permit the integration of the drainage network. Note the many bare patches on high grounds because melting has proceeded for days to deplete the snow on the ridges and on most slopes. (b) A river-side village in subarctic Canada (Fort Liard) threatened by ice jam flood. Note that many ice floes are much larger than the houses, and these floes move down channel at speeds that often exceed 5 m s^{-1}

5 m/s. The thickness of river ice increases poleward and large ice floes in cold temperate and subarctic regions have tremendous destructive power. Hydraulic models have been developed to forecast peak discharges and their associated flood stages (e.g.Blackburn and Hicks, 2002).

SNOWMELT HYDROGRAPHS

The effect of snowmelt on streamflow increases for basins located in high altitudes and high latitudes. For these areas, the highest flows of the year may be realized in a brief melt period that lasts for about two to three weeks. Where snowmelt exerts a preponderant influence on stream discharge, the term *nival* (or *snow-dominated*) *regime* has been applied to describe the seasonal rhythm of streamflow (Church, 1974). In some warm temperate areas, such as the west coast of British Columbia and the Pacific Northwest of the United States, both snowmelt and winter rainfall are important generators of runoff, and high flows are produced by mixed processes of rainfall and snowfall (Waylen and Woo, 1982). The Coquihalla River (basin area 740 km^2, with an elevation range of about 2500 m), for example, receives much winter precipitation that comes as rainfall at the low elevations and as snowfall at the higher parts of the basin. The rain produces high flows in the fall and the winter and when the snow melts at high elevations, spring melt runoff is generated (Figure 5a).

The hydrograph for small to medium basins that have a nival regime of streamflow typically shows prominent diurnal cycles that reflect runoff contribution from snowmelt (Figure 1). Owing to time lag in runoff delivery to the streams, daily peak discharges are usually attained in the late afternoon or evening and low flows occur in early mornings. A period of intense melt raises the daily peaks, while a cool spell dampens melt and diminishes the amplitudes of the diurnal flow cycles. Depletion of the snow cover is reflected in a gradual reduction in discharge, but a steeper recession for the daily low flow, the latter suggesting a decline in meltwater storage available to feed the baseflow.

A large basin combines the flow regimes of its subbasins. The storage effect of the large basin dampens the short-term fluctuation in discharge, such as the diurnal cycles in the hydrograph. On the other hand, subbasins may have different magnitude and timing of snowmelt due to location, altitude, and land use. The integrated effect is manifested in multiple snowmelt hydrograph rises and falls. Figure 5(b) is an example from the Liard basin in northwestern Canada (area 2 75 000 km^2), showing a downstream increase in snowmelt hydrograph rises and falls as more subbasins with different timing and amounts of flows enter the main trunk valley.

SNOW MANAGEMENT FOR RUNOFF AUGMENTATION

The control of snowmelt flood hazards plays a major role in snow and snowmelt management. This includes the building of dykes to protect structures, increasing the size of culverts and storm drainage system to accommodate large flows, good forecasting of flood arrival, and providing flood warning. It may not be economically feasible to implement flood protection works, and river-side residents may have to adapt to the flood events and clean up their properties

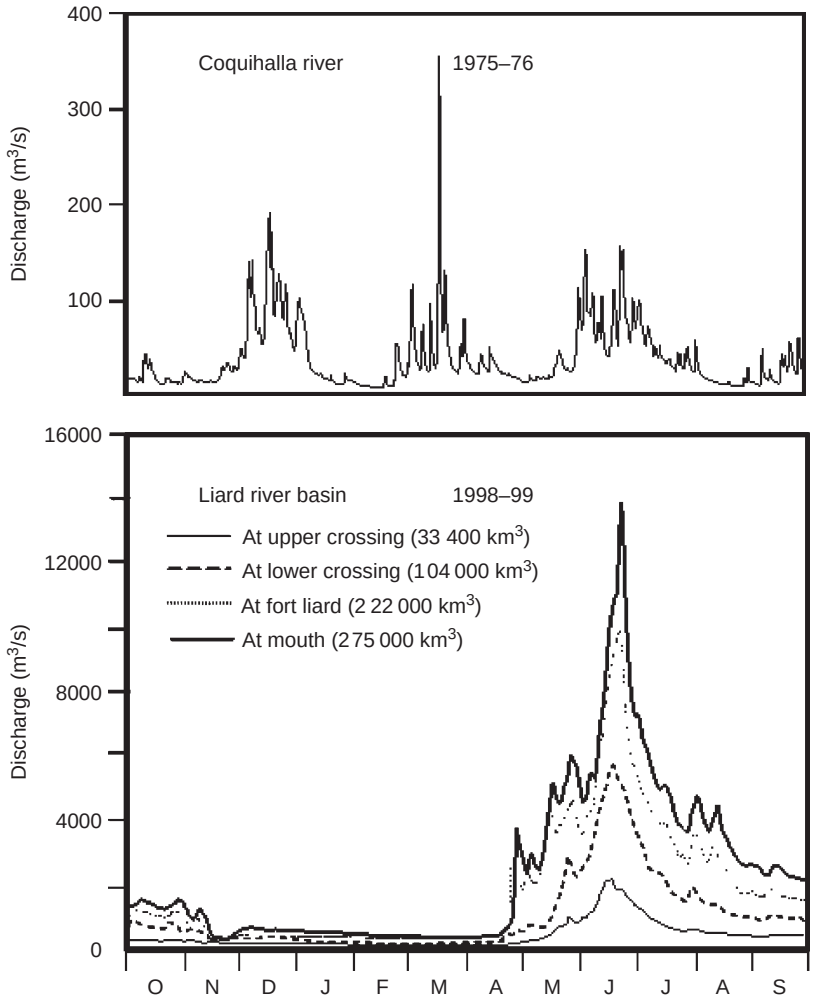

Figure 5 (a) Hydrograph of Coquihalla River in western Canada, a river in the warm temperate region with high flows produced by a mixture of winter rainfall and spring snowmelt events. (b) Hydrographs of the Liard Basin in Canada (a subarctic and mountainous catchment traversed by the 60°N parallel), showing downstream increase in multiple melt-related peaks due to meltwater runoff from its subbasins

after spring melt (e.g. Figure 4b shows the village of Fort Liard in northern Canada encountering ice jam flooding that recurs every spring).

On the other hand, an increase in snowmelt runoff and possibly an extension of the melt period are important to the water supply of many parts of the world. Several examples of snow management practices for runoff augmentation are noted below.

Many parts of Central Asia adopt the ancient practice of using the karez system. The karez or qanat, a water conveyance system developed by the Persians in about sixth century B.C., is a hand-dug subterranean (to limit evaporation loss en route) conduit with a gentle gradient that brings meltwater from the mountains to the oases in arid lowlands, for irrigation and community water supply. Construction of the karez involves the excavation of vertical shafts that are extended laterally to form a shallow tunnel under the desert. The melting of late-lying snow in the mountains provides runoff, which is captured by the karez. This is an example of taking advantage of the natural melt rhythm for water supply.

Agricultural fields in the Canadian prairies can benefit from leaving the crop stubbles over winter to trap snow (Stepphun, 1981). Snow is trapped by the stubbled fields and spring meltwater runoff will increase soil moisture in the semiarid environment. This is a case of encouraging snow accumulation to augment runoff for agriculture. A third example is land-use intervention through logging to modify the snow regime. Experiments have been conducted to examine the logging patterns that alter snow accumulation, melt, and runoff in temperate forests (Anderson and Gleason, 1960; Ffolliott *et al.*, 1989). However, economical and environmental considerations have limited such logging practices and prevented large-scale applications.

CONCLUSIONS

Important to the subject of snowmelt runoff generation are the considerations of timing, quantity, and the location where meltwater is produced. In terms of the magnitude and the source area of runoff, it is necessary to determine the amount of snow accumulation that is subject to sublimation losses, the spatial pattern of snow distribution that is often modified by snow drifting and that changes as melting progresses. The timing and the intensity of meltwater release depend on the melt rate, which, in turn, is energy driven.

Connectivity between meltwater sources and the drainage network dictates whether runoff can be conveyed out of a slope or a basin. Meltwater may be lost to infiltration to become unavailable for immediate runoff, and evaporation reduces the meltwater that would otherwise support flow. The rate of meltwater delivery depends on the flow mechanisms such that, for instance, overland flow is orders or magnitude faster than subsurface flow. Channel blockage may temporarily retard the flow by withholding the water for short periods, but breaching of the blockages would exaggerate the discharge, leading to flood events.

By adapting to or manipulating snow accumulation and melt, snowmelt runoff production can be modified to the advantage of human activities.

115: Landscape Element Contributions to Storm Runoff

JAN SEIBERT[1] AND BRIAN MCGLYNN[2]

[1]Department of Physical Geography and Quaternary Geology, Stockholm University, Stockholm, Sweden
[2]Department of Land Resources and Environmental Sciences, Watershed Hydrology Laboratory, Montana State University, Bozeman, MT, US

Hydrological conditions and the corresponding land area contributions to streamflow vary across the landscape. Landscapes are mosaics that can be described in varying levels of detail. This document describes the importance of different landscape elements for storm runoff generation. Since topography is often a first-order control on hydrological processes, topographic indices can be used to describe the spatial variations of hydrological conditions. Another approach is the delineation of landscape elements. We suggest that riparian and hillslope areas are the two most basic landscape elements that need to be considered; however, additional landscape elements including urban areas, floodplains, croplands, wetlands, and so on, can also be important. Landscape elements can be defined through hydrological analysis. This analysis can further define their lateral connections and organization along the stream network, providing valuable interpretation of the dominant controls on hydrological response across the landscape. Additionally, approaches to represent landscape elements in hydrological modeling are reviewed.

INTRODUCTION

Dominant hydrological processes and runoff source areas are spatially variable across the landscape. While it is generally agreed that various landscape elements contribute differently to catchment runoff, quantification of runoff source areas and dominant processes among different landscape elements is poorly understood. We refer to landscape elements as different spatial elements, which have certain hydrologic dynamics. Catchments consist typically of a mosaic of landscape elements. This mosaic can be described in varying levels of detail depending on data and application. One can, for instance, divide a catchment into two landscape elements such as riparian and hillslope zones or into a large number of elements defined by an overlay of spatial information such as topography, soils, land use, and vegetation. Hillslopes might be further delineated according to slope or position relative to the ridge or valley. Other examples of landscape elements might be bedrock outcrops, wetlands, glaciers, or areas largely affected by human activities such as urban areas and agricultural land. The latter might further be separated into pasture, crop, and fallow as well as irrigated (or drained) land. Different dominant hydrological processes follow from the characteristics of various landscape elements. These dominant processes are those needed to define the hydrological functioning of individual landscape elements. Here, we focus on hydrologic function with regard to runoff events, that is, the runoff generation processes for storm runoff.

Capturing the spatial variability of hydrological processes across the landscape is difficult and many modeling approaches have been shown to be only partly successful when tested against spatially distributed field observations. However, while not fully successful, these approaches at least consider the mosaic nature of catchment hydrology. The consideration of different landscape elements, their spatial distribution, and connectivity can provide a more realistic representation of catchment hydrology than a lumped description.

Fully distributed models that typically divide the catchment into small grid cells, have the potential to represent spatial variability. Inadequate input data and computational

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

burden, however, significantly limit this potential in most applications. Lumped models are therefore still widely used and often found to be able to simulate catchment runoff with acceptable accuracy. These models, however, use effective parameters, which are hard to measure and difficult to interpret. Assume a catchment with 10% paved areas (and high infiltration capacities in the remaining catchment). A simple lumped infiltration-capacity based model might be able to simulate runoff in this case, but the required infiltration-capacity parameter value will be an effective value somewhere between the extremes (zero and high infiltration) and the simulations will be some average behavior, but will not reflect reality and the associated variability in runoff processes. The importance of considering spatial variable parameter values instead of a mean (or effective) value has been illustrated by, for instance, Woolhiser *et al.* (1996) and Merz and Plate (1997).

Topography is often a first-order control on the spatial variations of hydrological conditions. It affects the spatial distribution of soil moisture and often groundwater flow. Variables other than topography, such as soils and vegetation, might also largely control hydrological processes. However, topography is often easiest to obtain as spatially distributed data. Therefore, much of the work presented in this article utilizes topographic data although we do acknowledge the importance of other types of data.

Catchment topography is not only important for runoff quantity but also for runoff quality. Beaujouan *et al.* (2002), for instance, applied a model to theoretical catchments and demonstrated that catchment-wide denitrification depended on the topographic shape of the catchment. Despite these findings, the topographic shape of a catchment is not typically represented in lumped models.

In this article, we discuss both the importance of different landscape elements for storm runoff and review approaches to represent landscape elements in hydrological modeling.

SPATIAL AND TEMPORAL SOURCES OF STORM RUNOFF – THE ROLE OF LANDSCAPE ELEMENTS

The relative contributions of different landscape elements to catchment runoff depend to a large degree on prevailing runoff generation processes. In other words, the answer to the question "where does runoff originate?" depends partially on understanding dominant runoff generation processes across the landscape. For example, if **infiltration-excess overland flow** (Horton, 1933, **Chapter 111, Rainfall Excess Overland Flow, Volume 3**) is assumed, areas with the lowest infiltration capacities are the dominant contributors to catchment runoff. Topography in this case is of less importance for the generation of runoff (but still important for the routing of runoff). If **saturation-excess overland flow** (Hewlett and Hibbert, 1967; Dunne and Black, 1970) is assumed to be the dominant runoff process, soil depth and topography are controlling factors on those locations where most catchment runoff is generated. Saturation-excess overland flow is likely on those portions of catchments with water tables near the ground surface – most often, riparian areas and wetlands. **Subsurface flow** (*see* **Chapter 112, Subsurface Stormflow, Volume 3**) is ubiquitous in most catchments, although it is believed that subsurface flow as a storm runoff mechanism is most important in steeply sloped environments with shallow soil. Recent research (McDonnell *et al.*, 1996; Freer *et al.*, 2002) has suggested that both surface and bedrock topography control the magnitudes and spatial variability of subsurface runoff across hillslopes. **Transmissivity feedback** runoff generation (Bishop, 1991; Kendall *et al.*, 1999) refers to increasing magnitude of lateral flow as the water table rises into more transmissive shallow soil. As such, transmissivity feedback depends on water table fluctuation during storm events and therefore is a function of soil depth, hydraulic conductivity profiles with depth, and both surface and subsurface topography.

A realistic representation of the unique landscape elements that incorporates their different contributions to catchment runoff is important for the quantification of spatial and temporal sources of storm runoff. This information can provide insight into the controls on the chemical composition of runoff water since flow pathways and residence times vary for different landscape elements. The identification of different landscape elements might also help researchers design observation networks to best represent the landscape variability (Park and van de Giesen, 2004). The degree of detail with which landscape elements are defined depends on the available information. On the basis of detailed field studies, Naef *et al.* (2002) and Uhlenbrook *et al.* (2004) were both able to distinguish several landscape elements with different runoff generation properties. Such detailed information is usually not available and only more fundamental differences are represented by landscape elements. The most basic catchment discretization separates catchments into two major landscape elements: riparian zones (RZ) and hillslope zones. These zones are often distinct in their dominant runoff processes, water table dynamics, topography, soils, vegetation characteristics, and biogeochemical environments (McGlynn and Seibert, 2003a).

The RZ can be defined as the strip of land between the stream channel and the hillslope. The RZ is sometimes also called *buffer zone* (Lowrance *et al.*, 1985), floodplain (Bates *et al.*, 2000), or near-stream zone (Cirmo and McDonnell, 1997). The RZ differs from upslope zones with regard to hydrology, vegetation, and soils (Swanson *et al.*, 1982; Hill, 1996; Naiman and Décamps, 1997; Butterworth *et al.*, 2000). Distinguishing characteristics are anoxic zones (Pritchett and Fisher, 1987; Megonigal *et al.*, 1993), gleyed

soils (Faulkner and Patrick, 1992; Phillips *et al.*, 2001), color (Blavet *et al.*, 2000), organic content (Mitsch and Gosselink, 1993), breaks in slope (Merot *et al.*, 1995), and near-surface water tables (Brinson, 1993). Because of their location, riparian zones have significant potential to regulate the movement of material in surface and subsurface runoff that flows from upslope areas to the stream (Brinson *et al.*, 1981; Hill, 1996).

McGlynn and McDonnell (2003a,b) suggested that the relative timing of riparian and hillslope source contributions to streams, and the connections and disconnections of dominant runoff contributing areas or landscape elements, were the first-order controls on stream dissolved organic carbon (DOC) fluxes and stream silica from a steeply forested basin at Maimai in New Zealand. The RZ has also been shown to be of high importance for ecological issues such as biodiversity and biogeochemical cycles (Naiman and Décamps, 1997).

The origin of runoff can be described by defining the temporal and spatial sources. A useful temporal distinction is new and old water (also referred to as *event* and *pre-event water*). New water is water entering the system as rainfall or snowmelt in association with the current event, whereas old water is water that resided in the catchment prior to the event. It has been widely demonstrated across the world that old water dominates storm runoff hydrographs in most catchments (Genereux and Hooper, 1998; Buttle, this volume, **Chapter 116, Isotope Hydrograph Separation of Runoff Sources, Volume 3**). Quantifying new and old water fractions in stormflow is important for understanding controls on stormflow geochemistry, interpreting the spatial sources of storm runoff, and understanding dominant runoff processes at the catchment scale. Runoff can also be described by its spatial source. For instance, one can distinguish between hillslope and riparian water. Hillslope water is water originating from upland hillslope zones, whereas riparian water is water originating from riparian zones. Both spatial sources can contribute with both event and pre-event water.

The analysis of landscape element contributions to storm runoff integrates measurements or estimations of spatial and temporal runoff sources, assessment of dominant runoff processes, the spatial extent of landscape elements, and the spatial organization or topology of landscape elements at the catchment scale.

CASE STUDY – CATCHMENT INTERCOMPARISON

The Maimai (New Zealand), Panola Mt. (Georgia, US), and Sleepers River (Vermont, US) research catchments are long-term experimental sites where researchers have sought to elucidate the fundamental controls on runoff sources, flowpaths, and streamwater residence times. The rich history of research at each site provides context for analysis of landscape element contributions to storm runoff. Here we review results of discretization of each catchment into its fundamental landscape elements (hillslopes and riparian zones) and assess the relative contributions of each landscape element to catchment runoff utilizing three-component tracer mass-balance hydrograph separation techniques (McGlynn, in press). Hydrograph separations were based on high-resolution temporal sampling of source water and streamwater ^{18}O, silica, and calcium as tracers (McGlynn, in press; McGlynn and McDonnell, 2003a).

The first step in this analysis was to discretize each catchment into its component landscape elements (McGlynn, in press). In each catchment, riparian zones and hillslopes are the dominant landscape elements. We utilized a combination of detailed field surveys and terrain analysis of high-resolution digital elevation models (DEMs) to delineate riparian zones and hillslope zones (McGlynn, in press; McGlynn and Seibert, 2003a). We found that the riparian zones accounted for 4.5% of the total catchment area (17 ha) at Maimai, 6.4% of total catchment area (40 ha) at Sleepers River, and 10% of total catchment area (40 ha) at Panola Mt. We then separated comparable stormflow hydrographs at each catchment to determine the contributions of each landscape element (riparian zones and hillslope zones) and the proportion of old and new water in each stormflow hydrograph (Figure 1).

We found that old water dominated the storm hydrographs at each site and that the proportion of riparian source water in each storm hydrograph was proportional to the riparian extent in each catchment (Figures 1 and 2). The discretization of each catchment into its component landscape elements, in this case riparian and hillslope zones, and the separation of storm runoff into its spatial sources (landscape elements) and temporal sources (old and new water) provided new insight into the linkages between landscape structure and runoff generation at the catchment scale. We suggest that the combination of landscape discretization and analysis of the contributions of each landscape element to catchment runoff provides a way forward for catchment intercomparison and a potential method for quantifying the relative roles of various landscape elements from the headwaters to the meso-scale (McGlynn *et al.*, 2004).

TOPOGRAPHIC INDICES

Topography has become widely used as a surrogate for the spatial variation of hydrological conditions. Topography has a major impact on the hydrological processes in a catchment and spatially distributed topographic data is readily available (Moore *et al.*, 1991). A major reason for the increased use of topography in hydrological analysis is the wide availability of DEMs, from which various topographic indices can be computed. Usually, gridded elevation data is used for computations, although other methods such as triangulated

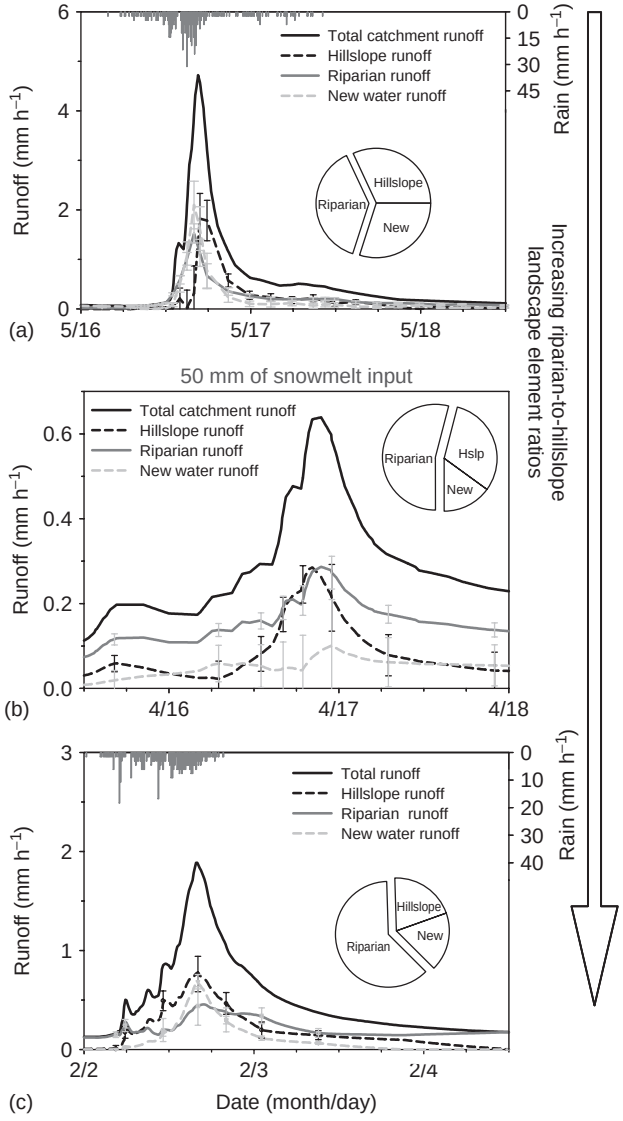

Figure 1 The contributions of riparian and hillslope landscape elements to storm flow in three catchments with increasing riparian-to-hillslope area ratios. (a) Maimai: 65 mm rain event and a runoff ratio of 0.5. (b) Sleepers River: 50 mm snowmelt event and a runoff ratio of 0.5. (c) Panola Mountain: 62 mm rain event and a runoff ratio of 0.54. irregular networks (TINs)might be more efficient (Tucker *et al.*, 2001).

Topographic indices allow evaluation and the use of important topographic information. Topographic indices have been used to describe spatial soil moisture patterns (e.g. Burt and Butcher, 1985) and other hydrological variables (*see* Moore *et al.*, 1991 for a review). By topographic index, we refer to spatially distributed values, which have been calculated from a DEM and capture some feature of the topography. These indices can be grouped into locally determined indices such as elevation, slope, aspect, and curvature; indices that also consider the elevations at more distant points, such as upslope accumulated area, distance to stream, or elevation above the stream; and combinations of different indices such as the topographic wetness index (TWI) (as discussed below).

The TWI developed by Beven and Kirkby (1979) within the runoff model TOPMODEL is one of the most widely applied indices. This index is defined as $\ln(a/\tan\beta)$ where a is the local upslope area draining through a certain point per unit contour length and $\tan\beta$ is the local slope. The first is assumed to be a measure of water flowing towards a certain location and the latter a measure of water draining from a certain location. A downslope index has recently been suggested by Hjerdt *et al.* (2004) as an alternative to the local slope. This index is calculated as d/L_d where L_d is the distance to the nearest cell having a height $\geq d$ length units (e.g. 5 m) below the cell. By taking downslope topography into account, the slope of the groundwater table and, thus, the drainage from a certain location might be better estimated by this downslope index than by the local gradient.

The TWI has been used to study spatial scale effects on hydrological processes (Beven *et al.*, 1988; Famiglietti and Wood, 1991; Moore and Grayson, 1991; Sivapalan and Wood, 1987; Sivapalan *et al.*, 1990), prediction of the spatial pattern of saturated areas (Güntner *et al.*, 2004), and identification of hydrological flow paths for geochemical modeling (Robson *et al.*, 1992), as well as biological processes such as annual net primary production (White and Running, 1994), vegetation patterns (Moore *et al.*, 1993), biodiversity (Zinko *et al.*, in press), and forest site quality (Holmgren, 1994).

Topographic indices have also been used to predict the spatial variation of soil characteristics (McKenzie *et al.*, 2000). Pachepsky *et al.* (2001) found soil water retention to be related to topography. Studying a hillslope transect in a boreal landscape, Giesler *et al.* (1998) found

pH and nitrogen to increase with the increasing upslope accumulated area.

Obviously, factors other than topography influence local groundwater levels and soil moisture status. Correlations between TWI and groundwater levels or soil moisture values are therefore usually not very strong (e.g. Seibert *et al.*, 1997; Western *et al.*, 1999). Topographic indices may be improved by including additional information. Pellenq *et al.* (2003), for instance, found soil depth to improve topographically based soil moisture predictions. Güntner *et al.* (2004), however, found only slightly improved predictions of the spatial patterns of saturated areas when they combined different additional information with the topographic wetness index.

HYDROLOGICAL LANDSCAPE ANALYSIS

Catchments can be discretized into their component pieces or dominant landscape elements (McGlynn and Seibert, 2003a). These elements typically consist of, but are not limited to, hillslopes, riparian zones, extended wetlands, and stream reaches. We refer to hydrological landscape analysis (HLA) as the examination of topographic and topologic attributes of DEMs and indices derived from topography and other spatial data. Topology refers to the relative arrangement or configuration of landscape elements or the functional arrangement, that is, hydrologic connections and disconnections.

An important issue is the hydrological functioning of the RZ, with its often distinctive soil properties. The RZ is of special importance for water quality since water from upslope positions passes through the RZ before entering the stream network and, thus, the RZ, to a large degree, controls the chemistry of the runoff contributions along the stream network.

Hydrologic dynamics within landscape elements and the connections between them partially control the sources, flowpaths, amount, and age of water exiting the catchment through each segment of the RZ. Each landscape unit type has characteristic hydrologic and geomorphic attributes that can be assessed through field investigations and topographic analysis of emergent patterns and connections between landscape elements (landscape organization). Landscape analysis coupled with hydrological process investigation provides a context for scaling-up process knowledge from plot- and reach-scale hydrological/hydrochemical investigations to the catchment level. But HLA alone, without being tightly connected to field studies, risks being a theoretical exercise. Thus, there is a need to test landscape descriptors obtained by HLA against field observations.

While the linkage of catchments to water chemistry and aquatic biota is generally accepted, defining this relationship remains a challenge. Large-scale patterns in geology, soils, climate, and land use can define some degree of regional variability in mean water quality parameters (e.g. Lepistö *et al.*, 1995). There remains, however, a significant degree of small-scale variability in water chemistry, especially in the flow-related changes often crucial for the aquatic biota (Levin, 1992). Efforts to understand the controls on flow-related water quality in specific sites have increasingly recognized the riparian (near stream) zone as the key to understanding how water quality is linked to catchments (Hooper *et al.*, 1997). This realization grows out of research from parts of the globe as disparate as Antarctica (Gooseff *et al.*, 2002) and New Zealand (McGlynn and McDonnell, 2003a), on a range of issues from eutrophication to mercury and carbon budgets.

Hillslope hydrology is predominantly controlled by topography in catchments with shallow soil and poorly permeable bedrock, which are typical for boreal regions. McGlynn and Seibert (2003a) recently examined the variability in, and controls on, hillslope inputs to stream networks and the potential for riparian zones to regulate hillslope inputs and thereby both quantitatively and qualitatively buffer, or modify, stream responses to hillslope hydrology. We found that the ratio of riparian zone storage to hillslope inputs was the most important plot-scale measure of the buffering capacity of the riparian zone. One particularly important finding was that the catchment-wide proportion of the riparian area might be misleading. At the 280 ha Maimai research area, the ratio was 0.14. When we calculated this "buffer capacity" for each 20 m stream reach along the stream network, the values were below 0.14 for 75% of the stream length and the median was 0.06 (Figure 3). Using the catchment-wide ratio, thus, would significantly overestimate the "effective" riparian-to-hillslope area ratio.

Clearly, catchments will differ in the degree to which riparian zones buffer the delivery of water from hillslopes to streams, thereby affecting the amount, timing, and quality of hillslope water inputs expressed in streamflow (McGlynn *et al.*, 1999; McGlynn and McDonnell, 2003a). The functioning of the riparian zone depends on the interaction of different variables. Vidon and Hill (2004) studied the nitrate removal in riparian zones and suggested linkages between landscape characteristics and nitrate removal. Important characteristics were topography, riparian soil texture, and the depth of permeable sediments in the riparian as well as the upslope zone.

Field-based mapping of riparian zones is usually not feasible for larger catchments. In this case, a DEM might be used. Calculation of the "elevation-above-stream" along flowpaths to the stream and then specifying a threshold can be used to delineate the riparian zone (Figure 4a). This assessment, when combined with the lateral upslope accumulated area, can be used to determine the reach buffering capacity (Figure 4b).

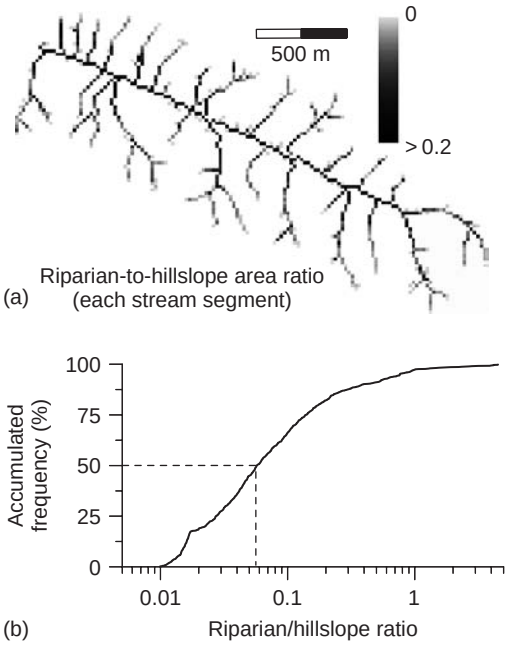

Figure 3 (a) Spatial distribution of riparian buffering potential (riparian/hillslope ratios) along the 280 ha Maimai catchment (Adapted from McGlynn and Seibert, 2003a). (b) Probability distribution of riparian-to-hillslope area ratios corresponding to figure 3(a)

Hydrological landscape analysis can also provide a quantification of the topographic control on water age or residence time distributions. Often, it is expected that mean stream water age for runoff increases with catchment area. However, this has not yet been demonstrated. Both McGlynn *et al.* (2003) and McGuire *et al.* (2005) found that mean streamwater age was not correlated to catchment area. McGlynn *et al.* (2003) found that the median subcatchment area was correlated with mean residence time, whereas McGuire *et al.* (2005) found that the median flowpath length and gradient of all catchment flowpaths were best correlated with residence time (Figure 5, adapted from McGuire *et al.* (2005).

The term *connectivity* is widely used in landscape ecology (Goodwin, 2003), but it is also of importance in hydrology (Western *et al.*, 1998; Stieglitz *et al.*, 2003). Spatial variability of soil thickness might be a major control

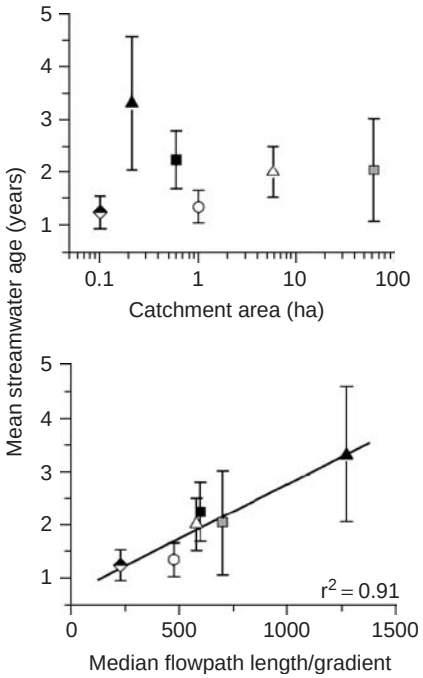

Figure 5 The relationships between mean residence time estimated by modeling $\delta^{18}O$ variations in stream water and catchment area and the ratio of median flowpath length to median flowpath gradient. Median flowpath values were determined from all potential flowpaths defined by a DEM analysis (McGlynn and Seibert, 2003b, adapted from McGuire *et al.*, 2005)

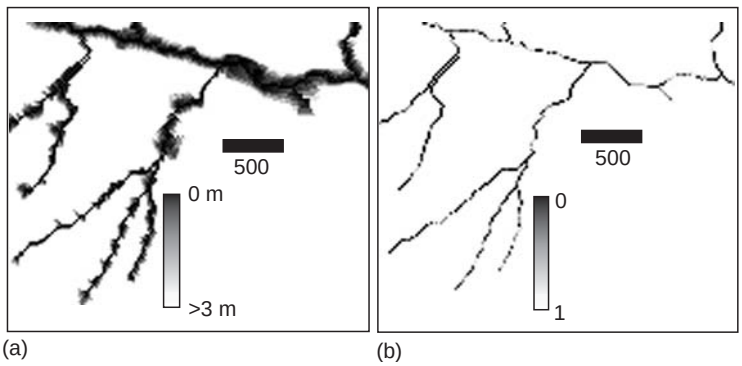

Figure 4 (a) Riparian area delineation on the basis of a threshold elevation (3m) above the stream channel following flowpaths to the stream within the West Fork Catchment, Big Sky Montana. (b) Distributed riparian buffering potential (the ratio of riparian area flowing into each stream cell relative to the hillslope area flowing into each stream cell) along the stream network within the West Fork Catchment, Big Sky, Big Sky Montana (0 = poor potential, 1 = high potential)

on hydrologic connectivity (Buttle *et al.*, 2004). Connections and disconnections of dominant runoff contributing areas are not only important for the runoff volume, but also for its chemical composition. In the latter case, the major process might be a simple mixing of the flux from the hillslopes with the water stored in the riparian zone or a complete biogeochemical resetting of the chemical composition in the riparian zone (Buttle, this issue). For the Maimai catchment, the relative timing of riparian and hillslope source contributions, and the connections and disconnections of dominant runoff contributing areas, were the first-order controls on stream DOC fluxes (McGlynn and McDonnell, 2003b).

LANDSCAPE ELEMENTS IN HYDROLOGICAL MODELING

In hydrologic modeling, various methods are used for dividing catchments into spatial units. The catchment can be treated as single unit (lumped approach) or divided into a large number of small grid cells (fully distributed approach) (**Chapter 127, Rainfall-runoff Modeling: Distributed Models, Volume 3**). In between these fall approaches that divide the catchment into functional units on the basis of landscape information. Such units, which can be distributed continuously or discontinuously over the catchment, might include subcatchments, elevation zones, or zones for which similar hydrological behavior is assumed based on landscape characteristics. Terms such as hydrotopes, landscape elements, or hydrological response units (HRUs) are used for these zones, which are delineated on the basis of overlay of different spatial information. The basic concept is to overcome the crude simplification of lumped approaches while avoiding the computational burden of fully distributed approaches. On one hand we know that hydrological conditions vary within a catchment; on the other hand, we also often recognize that there are areas with fairly similar conditions. Recent research using TINs has incorporated the concept of hydrological similarity into TIN derivation (Vivoni *et al.*, 2004). We suggest that the delineation of areas with similar hydrological functioning allows consideration of the spatial variability of the most important controls on hydrological processes.

Dividing the catchment into subcatchments is a common approach to account for some spatial variation. The delineation into different elevation zones is also a common method for the representation of spatial variability. The latter approach is useful for snowmelt modeling as in the HBV model (Bergström, 1976), which is a conceptual model of catchment hydrology that in its simplest application is a purely lumped model. In other applications of the HBV model however, the catchment can be divided into elevation zones, vegetation zones, and subcatchments.

The Precipitation-runoff Modeling System (PRMS) developed at the US Geological Survey (USGS) (Leavesley and Stannard, 1995) divides the catchment into HRUs that are assumed to be homogeneous in their hydrologic functioning. The hydrology of each HRU is simulated using a daily time step and the sum of the runoff of all HRUs, weighted by the respective areas, is computed as daily catchment runoff. The Semidistributed Land-Use-based Runoff Processes (SLURP) model (Kite, 1995) is another example of the approach to divide the catchment both into subcatchments and into hydrologically similar subunits. The latter may be discontinuous within a subcatchment and are aggregated into aggregated simulation areas (ASA). Topography and land use information are used to define these areas.

In many landscape-element-based modeling approaches, there is no lateral flow between the elements, but the assumption is that each element contributes directly to the stream network. Obviously, consideration of lateral flow between elements is important, such as in the connections between upslope and riparian zones. Examples where lateral flow between landscape elements has explicitly been considered are WATBAL (Knudsen *et al.*, 1986), the PRMS application by Flügel (1995), TAC-D (Uhlenbrook *et al.*, 2004) and, for large-scale modeling, Güntner and Bronstert (2004). These models mainly use a semi-distributed approach with the exception of TAC-D, which is a grid-based model in which runoff generation routines and model parameters are assigned to the grid cells on the basis of HRUs.

Topographic indices can be used to delineate landscape elements; however, they can also provide another way to represent spatial variability. The assumption is that the locations with the same index value are hydrologically similar. The topographic index can be computed from gridded digital elevation data at high resolution, but model simulations are not needed for all grid cells. Instead, the simulations are executed for a small number of index value classes and then mapped back into space using the spatial distribution of the topographic index. One example of this approach is the TOPMODEL. The TOPMODEL approach (Beven and Kirkby, 1979; Beven *et al.*, 1995) has become one to be widely used for hydrological catchment modeling, because it allows consideration of topography while avoiding the complexity of fully distributed models. In contrast to the above-mentioned models, the catchment is not divided into homogeneous units, but rather the heterogeneity (i.e. topography) and its effects on hydrological processes are represented by the distribution of the TWI. The local wetness status is computed on the basis of a catchment average and the local TWI value. Therefore, the distribution of wetness states over a catchment can be simulated easily with low computational demands. For runoff simulations, only the distribution function of TWI is necessary, since

it determines the percentage of saturated areas, given a certain catchment average wetness status. Although the spatially distributed predictions of TOPMODEL usually appear reasonable, validation of spatial variations of groundwater levels (or surface wetness) simulated by TOPMODEL have often been unsuccessful (e.g. Burt and Butcher, 1985; Iorgulescu and Jordan, 1994; Seibert *et al.*, 1997).

Topographic indices are widely used for snow modeling (Hock, 2003; **Chapter 114, Snowmelt Runoff Generation, Volume 3**). Most models use elevation zones and a temperature lapse rate to represent the snow dynamics at different elevations. There are, however, other approaches that make more use of topographic data. Winstral *et al.* (2002) used topographic indices to predict the effects of wind-redistribution on spatial snow accumulation. The simple degree-day method for snowmelt modeling can be modified to allow spatially distributed simulations by using topographically based radiation indices (Cazorzi and Dalla Fontana, 1996; Hock, 2003).

While these approaches are promising, it must be recognized that topographic indices have limitations for modeling. An index provides only a part of the information available from a DEM, and important factors other than topography exist. It might be valuable to combine the landscape-element-based modeling approaches with topographic indices, which can be used to describe variability within an element.

As discussed in reference to landscape-unit-based modeling approaches, topographic-index-based modeling approaches usually do not consider lateral connections. In many cases, the spatial pattern of a topographic index map is of no importance other than its distribution function. Hydrological landscape analysis as discussed above (e.g. the computation of riparian-hillslope ratios along the stream network) is a way to consider lateral connections explicitly and, thus, to address the effects of spatial patterns and landscape organization.

LANDSCAPE ELEMENTS AND HETEROGENEITY

The use of landscape elements implies the consideration of heterogeneity and homogeneity. However, it is not simply that heterogeneity is limited to between-element variations and that each unit is homogeneous. Even within elements there is heterogeneity to some degree. The assumption, however, is that this heterogeneity and its effects are small compared to that between elements, or that this heterogeneity can be described statistically. The first applies to the concept of landscape elements as discussed in this article. While there are obviously large variations within, for instance, the riparian and respective hillslope zones, we argue that the major functional difference is between the two landscape elements rather than within each element. If necessary, further division of landscape elements (e.g. concave hillslopes and convex hillslopes) might be necessary to ensure functional homogeneity.

The statistical description of within-unit heterogeneity follows a different and partly a contradictory approach. Instead of seeking (functional) homogeneity, the idea is rather to "average out" the heterogeneity by sampling over a large enough area. The optimal size of such landscape elements for hydrological modeling is an open question. Wood *et al.* (1988) and Beven *et al.* (1988) proposed the representative elementary area (REA) as a fundamental building block of catchment modeling (Blöschl *et al.*, 1995). The REA can be compared to the REV in soil science (Bear, 1972) – an area where variability is minimized. The idea is that, at a certain area the landscape is amalgamated sufficiently to represent a mixture of the important characteristics contributing to variability at smaller spatial scales. While the frequency distribution of those characteristics may still be important, the spatial pattern is less important at this scale (Beven, 1995). In initial studies, the REA was determined on the basis of hydrologic modeling (TOPMODEL), where topography and rainfall were considered to vary in space (Wood *et al.*, 1988). Later, the REA concept was also tested on measurements of runoff and runoff chemistry (Woods *et al.*, 1995; Wolock *et al.*, 1997; Shaman *et al.*, 2004). Fan and Bras (1995) raised doubts about the existence and potential utility of the REA concept. A major problem with the REA approach is that the landscape characteristics vary at a range of different scales and that the size of an REA might depend on the considered variable (e.g. storm flow, baseflow, chemistry, or evaporation). The REA concept represents an attempt to quantify the spatial scale where variability in landscape element topology is subsumed.

CONCLUDING REMARKS

We suggest that landscape analysis might be the basis for new model approaches that fill the gap between fully distributed models using a regular grid and models that are more or less lumped. Hydrological landscape analysis allows for identification of crucial landscape elements and their lateral connections utilizing digital elevation data and the assumption that flow paths follow topography. The wide use of the TWI has promoted the value of topographic data in hydrology. We suggest that there is a suite of additional topographical indices worth testing that can be derived by landscape analysis. On the basis of this, modeling efforts might be distributed more rationally than modeling each grid cell. For instance, it might be reasonable to have a more detailed model for the relatively small riparian zones, whereas a simpler approach might be sufficient for the larger upslope areas. Explicit consideration of lateral connections between landscape elements is critical for

a realistic description of the evolution of water quality along the flow pathways through mixing or biogeochemical processes. Even when landscape elements derived from, for instance, soil or vegetation data are used, the topographical data might still be useful to establish the linkages between these landscape elements. Advances in remote sensing and other measurement techniques as well as improved interpretation and the use of observed spatial patterns (Grayson *et al.*, 2002) will support the further development of hydrological landscape analysis and associated modeling approaches.

116: Isotope Hydrograph Separation of Runoff Sources

JIM M BUTTLE

Department of Geography, Trent University, Peterborough, ON, Canada

Use of isotopic tracers to characterize water ages, origins, and flow pathways in drainage basins is reviewed, along with the assumptions that underlie isotopic hydrograph separations (IHSs). Points of agreement regarding the use of the IHS approach in small drainage basins are examined, as are some of the key challenges associated with application of the approach in future research. Despite a growing awareness of the limitations of IHS, the method offers a powerful tool to examine a number of critical issues in hydrology, particularly when employed in conjunction with hydrometric techniques and the use of other tracers. These issues include the estimation of water residence times, the identification of process thresholds, the assessment of hydrological response to land use change, and the use of isotopic data to calibrate and test hydrological models.

INTRODUCTION

Isotope tracers and isotopic hydrograph separations (IHSs) are important tools for quantifying the age, origin, and pathway of water to streams in drainage basins, and thus for extending our understanding of streamflow generation (*see* **Chapter 111, Rainfall Excess Overland Flow, Volume 3** and **Chapter 112, Subsurface Stormflow, Volume 3**). They can also provide complementary information on water sources and pathways that are often required in order to draw conclusions about such ecological issues as the degree of closure of nutrient cycles (e.g. Elsenbeer *et al.*, 1995) and the hydrological effects of ecosystem disturbance (e.g. Bruijnzeel, 1990). This article reviews the basic approach and underlying assumptions of IHSs, summarizes the major points of consensus and disagreement regarding results that have been obtained using this approach, examines the challenges facing the use of isotopic tracers, and suggests current research issues in hydrology that would particularly benefit from the use of the IHS technique.

THE ISOTOPE HYDROGRAPH SEPARATION APPROACH

IHSs have generally been conducted using tritium (^{3}H or T), oxygen-18 (^{18}O), and deuterium (^{2}H or D) (Buttle, 1994). Oxygen-18 and D have been used in the majority of IHSs (Sklash, 1990) since they are stable and do not undergo radioactive decay. Ratios of ^{18}O and D to their more common counterparts in the hydrosphere (^{16}O and H) are 1 : 500 and 1 : 6700 (Drever, 1988). Abundance of stable isotopes in a water sample is based on isotopic ratios (e.g. ^{18}O/^{16}O and D/H) and is reported as δ values in parts per thousand (‰ or per mil):

$$\delta^{18}\mathrm{O} \text{ or } \delta\mathrm{D} = \left(\frac{R_{\mathrm{sample}}}{R_{\mathrm{VSMOW}} - 1}\right) \bullet 1000 \qquad (1)$$

where R_{sample} is the ratio of the heavy to light isotope in the sample and R_{VSMOW} is the ratio in the reference standard, which is Vienna Standard Mean Ocean Water (VSMOW) for ^{18}O and D (Kendall and Caldwell, 1998)

Isotope tracers have several unique virtues as water tracers in basin studies:

1. Their natural application over entire basins avoids problems of realistic application extents and rates associated with artificial tracers (Sklash, 1990).
2. Their isotopic ratios are generally unaffected by reactions with soil/regolith at temperatures encountered at or near the earth's surface (Drever, 1988).
3. Fractionation during evaporation results in the relative depletion of heavy isotopes in water vapor while the remaining liquid water becomes progressively enriched in D and ^{18}O; conversely, there is

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

preferential movement of heavy isotopes to the liquid phase during condensation. This leaves the remaining vapor relatively depleted in D and ^{18}O, such that meteoric water has negative δ values that decrease with surface air temperature, increasing latitude, increasing altitude, increasing distance of vapor transport, and increasing amounts of precipitation (Dansgaard, 1964; Ingraham, 1998).

4. Variations in the isotopic signature of precipitation are often dampened during infiltration (Ingraham and Taylor, 1991). Groundwater δ values may approach uniformity in time and space, and are changed only by mixing with waters of different isotopic contents (Sklash, 1990). This often leads to differences between input water δ and that of water stored in the basin before the event.

This difference between the isotopic signature of inputs (event or "new" water) and water stored in the basin before the event (pre-event or "old" water) may allow the stormflow hydrograph to be partitioned into event (new) and pre-event (old) components:

$$Q_t = Q_p + Q_e \tag{2}$$

$$C_t Q_t = C_p Q_p + C_e Q_e \tag{3}$$

$$X = \frac{C_t - C_e}{C_p - C_e} \tag{4}$$

where Q_t is streamflow; Q_p and Q_e are contributions from pre-event and event water; C_t, C_p, and C_e are δ values in streamflow, pre-event, and event waters respectively; and X is the pre-event fraction of streamflow (Figure 1). C_p and C_e must bracket the C_t δ values in order to separate the streamflow hydrograph into event and pre-event components; in addition, IHS is based on several key assumptions.

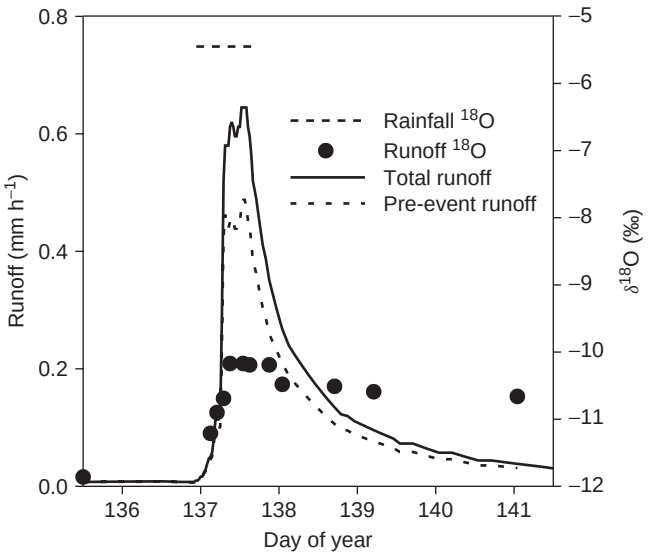

Figure 1 Isotopic hydrograph separation results from the PC1-08 basin during a large spring rainfall, Ontario, Canada (From Peters *et al.*, 1995)

ASSUMPTIONS UNDERLYING THE IHS TECHNIQUE

Use of equations (2)–(4) to solve for the event and pre-event fractions of streamflow assumes:

1. a significant difference between the isotopic content of the event and pre-event components;
2. an event water isotopic signature that is constant in space and time, or that any variations can be accounted for;
3. a pre-event water isotopic signature that is constant in space and time, or that any variations can be accounted for;
4. negligible water contributions from the vadose zone or a soil water isotopic content similar to that of groundwater;
5. negligible contributions to streamflow from surface storage.

Assumption 1 is met in most (if not all) IHS studies, since they have largely been conducted in mid-to-high latitude environments (Buttle, 1994). These regions often experience pronounced annual oscillations in the isotopic signature of precipitation (Figure 2). This increases the possibility of a significant difference between δ for a particular precipitation event and pre-event water, the mean δ of which approximates the mean δ of annual precipitation (Clark and Fritz, 1997; Gremillion and Wanielista, 2000).

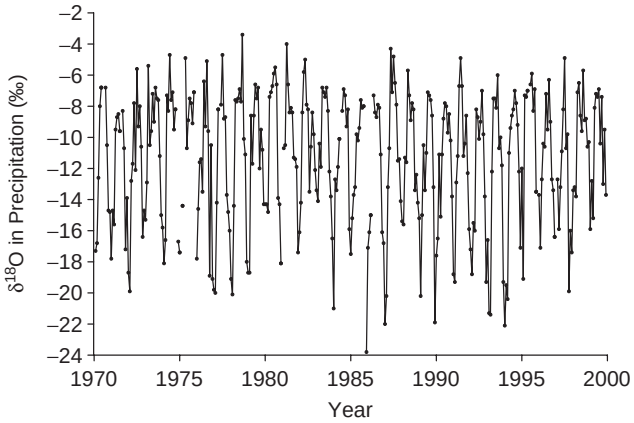

Figure 2 Time series of $\delta^{18}O$ in precipitation sampled at Ottawa, Canada (114 m asl; 45.32 °N latitude). Data from International Atomic Energy Agency/World Meteorological Organization (2001)

Potential violations of the remaining assumptions were often downplayed in many initial IHS studies. Event water δ was often represented by samples from a single rain gauge, snowcore, or snowmelt sample that may have been taken from outside the basin (Unnikrishna *et al.*, 2002), thus assuming spatial uniformity in input δ. The use of bulk rain or snowmelt samples necessitated the frequently untested assumption that temporal variations in event water δ were insignificant. Both assumptions have been shown to be violated in small basins (e.g. McDonnell *et al.*, 1990; DeWalle and Swistock, 1994; Bariac *et al.*, 1995). Precipitation in many IHS studies is measured and sampled at open sites. This presents a problem in forested basins, where interception may enrich the precipitation isotopic signature (Saxena, 1986; DeWalle and Swistock, 1994; Brodersen *et al.*, 2000) and thus reduce the difference between the isotopic content of the event and pre-event components to such a degree as to preclude IHS. Interestingly, many IHS studies have addressed the hypothesis that pre-event water δ was constant in time and space. Sklash (1990) argued that baseflow δ is the best index of C_p on the grounds that baseflow integrates the δ of near-stream groundwater likely to reach the stream during an event. This assumption has been supported by the close correspondence between groundwater and baseflow δ in some studies (e.g. Hooper and Shoemaker, 1986; Hill and Waddington, 1993), but has been called into question by substantial variability in baseflow δ along the stream channel and by significant differences between δ in near-stream groundwater and in baseflow (Buttle *et al.*, 1995; Bonell *et al.*, 1998; Burns and McDonnell, 1998; Gremillion and Wanielista, 2000). These differences have been attributed to spatial variations in groundwater residence times arising from geological complexity (Bonell *et al.*, 1998), and to evaporative enrichment of river water baseflow relative to contributing groundwater (Gremillion and Wanielista, 2000).

Invocation of assumption 4 allowed some early workers (e.g. Sklash and Farvolden, 1979) to assume that X represented both the pre-event and groundwater fraction of total stormflow. This requires that C_p has a constant value, such that C_t equals its pre-storm δ once discharge returns to baseflow values (e.g.Bonell *et al.*, 1990). Several studies have noted a shift in baseflow or groundwater δ in response to inputs during snowmelt or rainfall (e.g. Hooper and Shoemaker, 1986; Buttle *et al.*, 1995; McDonnell *et al.*, 1991a). Under these circumstances, C_p must reflect these temporal variations in baseflow or groundwater δ if X is to be interpreted as the groundwater fraction of discharge at the time of streamflow sampling.

Substantial differences between δ in soil water and in groundwater or baseflow have been shown (e.g. Kennedy *et al.*, 1986; DeWalle *et al.*, 1988; Peters *et al.*, 1995), although the ability of soil water to make significant contributions to stormflow is often unclear. This question has been addressed using two basic approaches. The first infers a soil water component of stormflow on the basis of an inadequate explanation of runoff sources using the standard two-component model (e.g. DeWalle *et al.*, 1988; Ogunkoya and Jenkins, 1993; Hinton *et al.*, 1994). The second uses hydrometric measurements to quantify soil water contributions to basin streamflow (e.g. Buttle and Peters, 1997). In situations where significant contributions to stormflow from one or more additional flow components (e.g. soil water) have been identified, the standard mixing equations have been modified:

$$Q_t = Q_1 + Q_2 + Q_3 + \cdots + Q_n \quad (5)$$

$$C_t Q_t = C_1 Q_1 + C_2 Q_2 + C_3 Q_3 + \cdots + C_n Q_n \quad (6)$$

where

Q_t = streamflow
Q_n = discharge of a particular runoff component
C_t = tracer concentrations in streamflow
C_n = tracer concentration of a particular runoff component.

These equations can be solved using matrix algebra, with the caveat of additional constraints and increased output uncertainty. Thus, solution for three flow components (e.g. event water, soil water, and groundwater) requires either a second tracer or a physical measurement of flow from one component (Genereux and Hooper, 1998). Stable isotope tracers have been used in conjunction with a geochemical hydrograph separation (GHS) to identify contributions from three flow components (e.g. Wels *et al.*, 1991; McDonnell *et al.*, 1991b; DeWalle and Pionke, 1994; Hinton *et al.*, 1994). Unlike isotopic tracers, geochemical tracers provide information about hydrologic flowpaths provided the kinetics of tracer reactivity in the subsurface are known (Burns and McDonnell, 1998; Burns *et al.*, 2001). A good example of attempts to quantify flow for a particular component is that of DeWalle *et al.* (1988), who estimated channel precipitation (direct supply of event water to streamflow) as the product of throughfall and stream surface area. The latter was obtained through regression of measured stream surface areas on the corresponding streamflow rate. In the absence of such hydrometric measurements, n tracers are required to separate stormflow into $n + 1$ components.

Many initial IHS studies purposely avoided basins with appreciable surface storage (e.g. lakes, ponds, wetlands). This appears to have been well advised, since mixing within wetlands can complicate interpretation of results from traditional two-component IHSs (e.g. Buttle and Sami, 1992; Hill and Waddington, 1993; Burns and McDonnell, 1998; Metcalfe and Buttle, 2001).

In addition to greater evaluation of the assumptions underlying the IHS approach, there has been an increased analysis of the errors associated with IHS results. Rodhe (1987) used a first-order uncertainty propagation approach to an explicit error analysis that was later refined by Genereux (1998). Conversely, Bazemore *et al.* (1994) used a Monte Carlo approach to analyze error in hydrograph separation results. Both methods assume that the variability in the flow components signatures follows normal distributions. Joerin *et al.* (2002) combined a Monte Carlo approach with component frequency distributions determined directly from field samples to estimate statistical uncertainty in hydrograph separations. This study is also noteworthy for its distinction between statistical uncertainty and the "model uncertainty" arising from such assumptions as temporal uniformity of flow component signatures.

RESULTS OF IHS STUDIES IN SMALL BASINS

The most important overall finding from the use of IHS in small basins is the significant contribution that pre-event water makes to peak stormflow and the total stormflow hydrograph in many environments (Buttle, 1994; Richey *et al.*, 1998). Although there is a great range in pre-event water fractions (X) of stormflow for various basin sizes, land uses, and event types (Shanley *et al.*, 2002), two salient points have emerged. The first is that X is generally smaller for basins with land uses (e.g. urban – Halldin *et al.*, 1990; Buttle *et al.*, 1995; Gremillion *et al.*, 2000) or surface types (e.g. permafrost – Cooper *et al.*, 1991; Metcalfe and Buttle, 2001) that promote the contribution of surface runoff to stormflow production through infiltration excess overland flow. This process likely generates a greater event water fraction of stormflow from such areas. The second is that X is generally smaller in forested basins in humid temperate climates during spring snowmelt, attributed to greater surface runoff as a result of frozen soils, which may develop during some winters, and maximum extents of saturated near-stream areas.

Beyond these general findings, a broader consensus regarding IHS results is more difficult to discern. For example, there is no agreement on the effects of basin size on new/old water partitioning. Thus, some studies have observed increased new water percentages with increasing basin size (Shanley *et al.*, 2002; McDonnell *et al.*, 1999) while others have found the reverse (Brown *et al.*, 1999). There is also some question as to the degree to which IHS results have been accepted by the broader scientific community. Although some hydrologists have argued that the significant contribution of pre-event to stormflow has promoted a paradigm shift in hydrological thought, there is abundant evidence that IHS results have not been incorporated into many current basin-scale hydrological models. In addition, the pre-event water paradigm largely applies in environments where infiltration excess overland flow is relatively rare, and intense rainfalls in parts of the humid tropics may mean that such overland flow is more prevalent than in the western European and North American studies that have used environmental isotopic tracers (Elsenbeer, 2001).

What other areas of agreement exist with regard to the results of IHS studies? First, we must recognize that the interpretation of IHSs occurs in the context of equifinality (similar outcome generated by a range of alternative mechanisms). Various hydrological processes may be responsible for the rapid delivery of significant quantities of pre-event water to the stream channel, and their degree of importance varies both spatially and temporally within a basin (Buttle, 1994). Equifinality seriously compromises attempts to infer intra-basin processes from the isotopic response at the basin outlet. It also provides a compelling case for integrating isotopic tracers with other tracers as well as with hydrometric techniques to constrain a process interpretation more fully. This leads to the second point of agreement, which is that hydrological science is not advanced appreciably by using IHS alone (Bonell *et al.*, 1998; Rice and Hornberger, 1998; Burns, 2002). We must combine isotopic and geochemical tracers with hydrometric measurements in order to infer the correct hydrological pathways in a basin (Elsenbeer *et al.*, 1995). Third, we must recognize that IHS and GHS studies at the basin scale are black-box approaches that assume homogeneous distributions of flowpaths and other hydrologic properties along with uniform isotope and chemical compositions of input waters (Kendall *et al.*, 2001). The spatial lumping that generally underlies application of the IHS/GHS technique in isolation at the basin scale does not shed light on intrastorm changes in water sources, flowpaths, and the processes acting along these flowpaths (Kendall *et al.*, 2001).

CHALLENGES FACING THE IHS APPROACH

There are a number of conceptual and methodological challenges facing the IHS approach to identifying runoff sources and pathways that need to be addressed in future work:

The Influence of in-channel Processes on Basin Isotopic Response

Many of our conceptual models of streamflow generation envisage that water delivery via various pathways from slope to stream channel occurs normal to the channel margin, and the models often ignore the role of in-channel processes. Nevertheless, complex transfers of water between the stream and its bed and banks during channel flow (hyporheic exchange – Bencala, 2000, *see* **Chapter 113, Hyporheic Exchange Flows, Volume 3**) may alter the isotopic signal of slope runoff from the point of entry to the channel to the sampling point at the basin outlet.

This presents both a challenge and an opportunity. The challenge is determining how divergences between flood wave and water particle travel times are influenced by mixing processes in the hyporheic zone. The opportunity is the potential to use isotopic tracers to distinguish between water residence times on slopes and in the hyporheic zone. Knowledge of the latter would be particularly valuable in aquatic ecological studies given the control water residence time exerts on such key metrics as dissolved organic carbon (DOC) and dissolved oxygen. Research that has addressed the implications of channel processes for IHS results include Bonell *et al.*'s (1998) observation of an initial rise in pre-event water at the start of each hydrograph pulse in the Babinda basins in northeastern Australia. This was attributed to a mechanism first suggested by Nolan and Hill (1990), whereby sudden upstream inputs of new water set up a flood wave composed of pre-event channel water that reaches downstream locations in advance of the translation of the subsequent event water. This process is distinct from the evaporative enrichment of streamflow during passage along the stream channel (Sklash *et al.*, 1976; Gremillion and Wanielista, 2000). Such enrichment would result in the overestimation of X in streamflow by shifting the δ in streamwater toward the groundwater isotopic signature, and should be considered when using IHS in situations where water residence times in the stream channel are appreciable (see below).

Incorporation of Temporal Variations in Event Water δ in IHS Studies

There are a range of approaches to treating temporal variations in event water δ and their influence on IHS results, including volume weighted means, incremental means, and incremental input intensity (McDonnell *et al.*, 1990). Nevertheless, each approach assumes that input water δ early in the event still exerts an influence on the stream water signature by the end of the event. This may be realistic when dealing with short-lived storms. However, these initial water inputs may be exported from the basin before the end of long duration episodes (e.g. entire snowmelt periods), and their δ should not have any influence on the stream water signature at that time. This problem has been addressed through the use of the unit hydrograph concept to estimate event water travel times in the basin (Joerin *et al.*, 2002), and a "runoff corrected event water" approach (Laudon *et al.*, 2002) that estimates input water δ at a given time on the basis of the amount of event water discharged from the basin prior to that time. Both approaches are consistent with Bonell *et al.*'s (1998) call for the use of event water δ that corresponds to the composition of lagged current water inputs. These and other approaches need to be tested across a greater range of basin and water input characteristics.

Incorporation of Temporal Variations in Pre-event Water δ in IHS Studies

Sklash and Farvolden (1979) provided an early example of the use of IHS results to argue for rapid groundwater contributions to streamflow. They assumed a temporally constant C_p signal in their hydrograph separations, while (as noted earlier) numerous studies have observed a shift in the isotopic signature of groundwater during the event. Rodhe (1987) attributed this to the recharge of isotopically different inputs and pre-event soil water and subsequent mixing, and to water table rise into the overlying unsaturated zone and conversion of isotopically different soil water to groundwater. It has also been previously noted that this temporally varying C_p signal has been used in IHS to solve X as the groundwater fraction of discharge. This assumes the instantaneous input of the sampled groundwater to the stream channel, which is physically unlikely. A promising approach to overcoming this problem is that of Weiler *et al.* (2003), who used a transfer function based on the instantaneous unit hydrograph to translate both event and pre-event water into the stream channel (*see* **Chapter 128, Rainfall-runoff modeling: Transfer Function Models, Volume 3**). The transfer functions represent the travel time distributions of event and pre-event water within the basin. The method provides a means of assessing the spatial extent of groundwater that could potentially contribute to basin streamflow during the course of an event. This information in turn would provide valuable guidance in deciding what groundwater δ data obtained from spatially distributed samples in a basin should be used to estimate C_p in an IHS, and the associated groundwater travel times. We need to test whether this and other approaches to estimating pre-event water travel times from different points within a basin to the outflow are physically realistic. Such tests could be based on a combination of hydrometric techniques, use of reactive tracers to examine water flowpaths within basins, and the spatial pattern of point-scale estimates of groundwater residence times in a basin (e.g. Buttle *et al.*, 2001a).

The Fate of Event Water Falling on Saturated Areas

It is often assumed that near-stream saturated areas are connected to the stream channel such that event water falling onto these areas can actually reach the channel with little or no change in its isotopic signature (Kendall *et al.*, 2001). However, most overland flows may move only a few meters before infiltrating (Crayosky *et al.*, 1999), such that the reinfiltration and exfiltration of event water inputs to saturated areas may induce differences between the input signature and that of overland flow. Bonell *et al.* (1998) concluded that regions of lateral interflow and exfiltration in basins will inevitably promote the mixing

of event and pre-event water within saturation overland flow, thus modifying the isotopic content of this flow. Observations in the Sleepers River basin in Vermont in the United States suggest that the degree of mixing in the near-stream saturated zone varies down-valley, depending on the local groundwater exfiltration fluxes into this zone (McGlynn *et al.*, 1999). Srinivasan *et al.* (2002) documented the temporal and spatial dynamics of surface saturation areas and surface runoff source areas (generating infiltration excess and saturation excess overland flow) in relation to water table dynamics and slope runoff using innovative surface saturation sensors. The complexity of stormflow generation revealed at the slope scale challenges the simplistic view of stormflow generation based on isotopic, geochemical, and hydrometric observations made at a few locations within a basin and at the basin outfall. There is a need to couple similar sensor arrays with tracer studies to address this question.

The Type of Water Obtained from Standard Soil Water Samplers

DeWalle *et al.* (1988) found insignificant differences in δ from soil water samplers (assumed to favor matrix water) and from pan lysimeters (assumed to favor macropore water). However, Leaney *et al.* (1993) argued that suction lysimetry preferentially removes soil water from larger soil pores, thus biasing samples toward the δ of soil water infiltrating via relatively rapid pathways. This debate can be avoided by using throughflow trenches to sample soil water for IHS and GHS (Burns *et al.*, 2001), thus ensuring sampling of mobile slope water that may participate in stormflow generation. Whatever approach is adopted, the effect of sampling on end member definition and description should be noted in any IHS study.

Rationale for the Inclusion of Additional Runoff Components

Failure of the two-component IHS to describe flow components in a realistic manner may suggest contributions from one or more additional flow components (e.g. soil water). However, inclusion of these components in IHS needs to be supported by independent observations of the hydrological processes; otherwise they simply become mathematical corrections to apparently erroneous IHS results (Bonell *et al.*, 1998). The key issue is our ability to define *a priori* what these additional components might be and to sample them adequately. Uhlenbrook and Leibundgut (2002) developed a conceptual watershed model by defining three components contributing to streamflow in the Brugga basin in Germany. They found that direct runoff (with a mean residence time (MRT) of a few months), shallow groundwater (32 months MRT), and deep groundwater (MRT of 7.1 years) could be blended to give the combined stream signal. They then validated the model output with silica concentration data where each component could be characterized by uniquely different silica end member concentrations. This combination of conceptual watershed model development and runoff component characterization offers a way forward to identifying the minimum set of components that define a given hydrological system.

The Influence of Temporal and Spatial Variations in Hydrologic Linkages Between Landscape Units (Slopes – Riparian Zone – Stream) on a Basin's Isotopic and Chemical Response

We must quantify the processes affecting the spatial distribution of solute concentrations in source water throughout basins if we are to predict the hydrochemical response to such perturbations as forest harvesting and climate change (Welsch *et al.*, 2001). Processes influencing the slope – riparian zone linkage may range from simple mixing where a small volume of slope runoff is diluted by a larger volume of riparian storage during water transit (e.g. Burns *et al.*, 2001) to a complete biogeochemical resetting of solute signatures as slope runoff transits the riparian zone to the stream (e.g. Robson *et al.*, 1992; Hill, 1993). These processes in turn may exert a major control on a basin's hydrochemical response to inputs. Thus, McGlynn and McDonnell (2003) suggested that the relative timing of riparian and slope source contributions, and the connections and disconnections of dominant runoff contributing areas, were the first-order controls on stream DOC fluxes from a forested basin at Maimai in New Zealand. Further study of mixing and geochemical interactions in the riparian zone is required to address this issue.

The Scale Dependence of IHS Results

As noted earlier, there is no agreement on how partitioning between event and pre-event water in streamflow changes with basin scale (Figure 3). Some have noted an increase in X with basin size (Sklash *et al.*, 1976; Brown *et al.* (1999), attributed in the latter case to increased flux of shallow perched pre-event groundwater in larger basins during an intense storm. Conversely, Pearce (1990) suggested that saturated floodplains comprised a greater portion of larger basins at Maimai, thus enhancing the event water contribution to stormflow. McDonnell *et al.*'s (1999) work at Maimai showed that greater pre-event water contributions as one moved from the plot to the small basin scale, but a decrease in X as basin scale increased from $\sim$1 to $\sim$10 km^2. The pre-event fraction of stormflow also decreased with basin scale for forested basins in Vermont in the United States during snowmelt and rainfall, the exception being a small basin largely in pasture (Shanley *et al.*, 2002). Further work is needed to determine whether there is a relationship between basin morphology and the relative

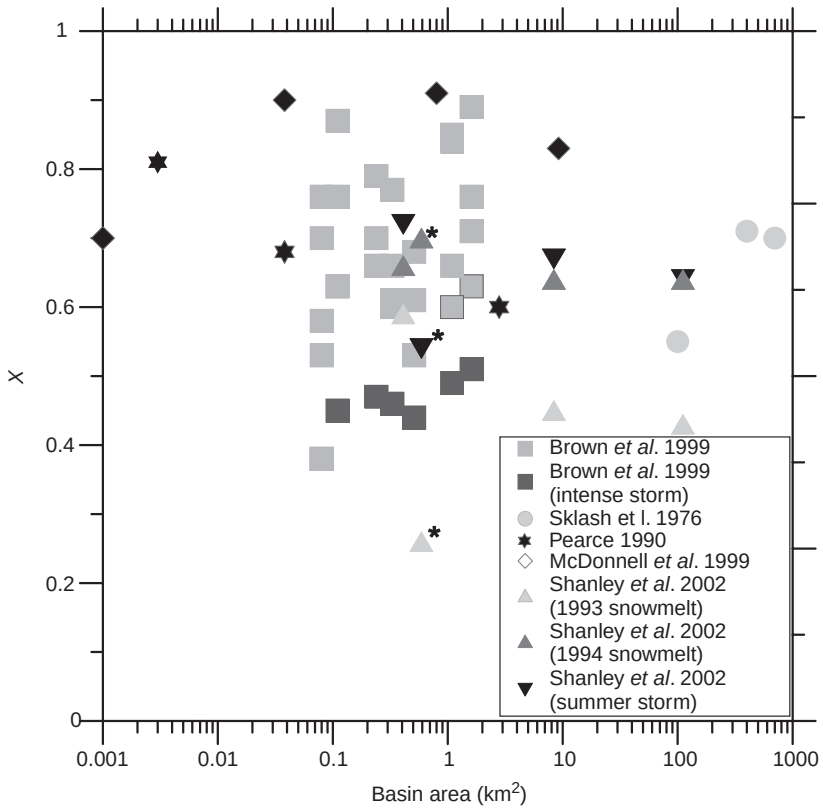

Figure 3 Reported pre-event water fractions in streamflow (X) versus basin area. The * associated with the Shanley *et al.* (2002) results indicates data from a small basin largely in pasture. The other basins from Shanley *et al.* (2002) were forested. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

partitioning of event and pre-event water in stormflow, and the degree to which inter-basin differences in land use, pedologic, and geologic characteristics might influence any scale dependence of IHS results. Another scale-related issue associated with the IHS approach was highlighted by Gremillion *et al.* (2000), who compared the standard IHS approach (that treats equations (2)–(4) as a steady-state model with negligible temporal changes in the volume and isotopic signature of channel storage) with nonsteady-state solutions. They found little difference in predicted pre-event water fractions from a basin in central Florida, but increasing divergence between predicted pre-event water fractions with increasing water residence times in the stream channel. This should be considered when applying IHS to large basins where flow time on slopes is small relative to the residence time of water routed along stream channels (Bras, 1990).

APPLICATION OF IHS TO ADDRESS FUTURE RESEARCH NEEDS

The problems noted above relate to improving our understanding of how hydrological processes govern the isotopic signature of water at the point, slope, and basin scales, as well as more clearly indicating when the IHS method can be appropriately applied to investigate hydrological questions. Despite these challenges, there are a number of outstanding research issues in hydrology that would benefit from the inclusion of environmental isotope tracer techniques, including the following:

Estimation of Water Residence Times at the Point, Slope, and Basin Scales Using Environmental Isotopic Tracers

There is abundant evidence from the literature demonstrating the important control that water residence time exerts on soil water, groundwater, and streamflow chemistry. Isotopic tracers provide a valuable means of estimating MRTs at various scales in basins, and recent examples of estimating MRTs in soil water, groundwater, and streamflow using environmental isotopes include Rodhe *et al.* (1996), McDonnell *et al.* (1999), and Buttle *et al.* (2001a). These MRTs may be used for such purposes as estimating the time required to observe basin response to treatment or disturbance (DeWalle *et al.*, 1997), the proportion of atmospheric NO_3 deposition in streamflow samples (Williard *et al.*, 2001), and the travel time distribution for rainfall

of a particular isotopic composition when conducting IHSs (Bonell *et al.*, 1998 – see above).

Identification of Process Thresholds

Partitioning between event and pre-event water in slope runoff and basin stormflow may have important implications for the transport of reactive substances to receiving water bodies. IHS studies in the same basin have often noted changes in the partitioning of event and pre-event water between events (e.g. Kendall *et al.*, 2001; Buttle *et al.*, 2001b) that have been attributed to shifts in the dominant hydrological processes governing slope runoff in response to changes in input characteristics and soil wetness. Greater understanding of the controls on these process transitions operating at the slope and basin scales is important for our ability to monitor and model basin hydrochemistry, and might be most effectively obtained through the use of controlled field experiments using environmental isotopes. These allow us to explore the role of specific hydrological processes and controlling factors by manipulating input rates and isotopic signatures, thus avoiding the complication of marked temporal variations in the δ of natural precipitation inputs and the resulting overlap between event and pre-event water signatures that precludes IHS (Turton *et al.*, 1995; Collins *et al.*, 2000). Such studies range in the degree of experimental control from the Coos Bay artificial irrigation of a deforested slope in the Coast Range in Oregon in the United States (Anderson *et al.*, 1997; Montgomery *et al.*, 1997; Torres *et al.*, 1998; Anderson and Dietrich, 2001), through the Gårdsjön-covered basin experiments in south-western Sweden (Nyberg, 1995; Rodhe *et al.*, 1996; Lange *et al.*, 1996), to the Hydrohill 490 m^2 artificial basin experiment in China (Kendall *et al.*, 2001).

Identification of Hydrological Response to Land Use Change

Hydrological response to land use change has generally been characterized using such metrics as soil moisture content, evaporation fluxes, and hydrograph properties (*see* **Chapter 117, Land Use and Land Cover Effects on Runoff Processes: Urban and Suburban Development, Volume 3**; **Chapter 118, Land Use and Land Cover Effects on Runoff Processes: Agricultural Effects, Volume 3** and **Chapter 120, Land Use and Land Cover Effects on Runoff Processes: Fire, Volume 3**). However, shifts in the relative proportion of event and pre-event water before and after disturbance or land use alteration also provide a useful detection tool, offering the potential to quantify changes in hydrograph *composition* following disturbance. Vertical profiles of MRTs estimated from soil water $\delta^{18}O$ time series during snowmelt in central Ontario indicated that forest harvesting restricted deep infiltration of inputs and diverted a portion of incoming event water laterally downslope, with important consequences for the quantity and quality of slope runoff reaching receiving waters (Murray and Buttle, in press). A combined IHS–GHS approach to studying water flowpaths in forested and deforested (pasture) basins in French Guiana showed peak flow from the forest basin was largely via subsurface flow, whereas flow through the superficial soil layers dominated peak streamflow in the pasture basin (Bariac *et al.*, 1995). The two-component mass balance approach in equations (2)–(4) also assists studies of the effects of forest road construction on water rerouting at the basin scale. Ditch flow can be separated into direct road runoff (event water) and intercepted subsurface flow from the cut back (pre-event water), enabling these relative inputs to be quantified at specific cross drain and road culvert sections. Ziegler *et al.* (2001) demonstrated the value of this approach in studies of forest road runoff in the humid tropics of Thailand, and Luce (2002) has called for greater use of hydrograph separation in land use change studies involving roads. Urban and suburban development may also result in a shift in stormflow pathways from largely subsurface during the predevelopment phase to overland and channelized flow after development (Buttle, 1990). IHS provides a useful tool for identifying water sources in urban and suburban basins, particularly if the link between event water generation and infiltration excess overland flow from modified surface cover can be made (Halldin *et al.*, 1990; Buttle *et al.*, 1995). For example, Gremillion *et al.* (2000) noted greater event water contributions to stormflow from a suburban sub-basin of the Econlockhatchee River in central Florida, attributed to an increased proportion of surface runoff in the storm hydrograph. This change in water flowpaths to the river may alter groundwater flow through riparian zones, with implications for river water quality and riparian zone ecology (Gremillion *et al.*, 2000). Information on event and pre-event water partitioning of stormflow also assists in interpreting and modeling basin export of surface-applied chemicals, such as radionuclides deposited in fallout from the Chernobyl accident (Halldin *et al.*, 1990) and deicing salts (Buttle *et al.*, 1992).

Integration of Isotopic and Geochemical Tracers and Hydrometric Techniques with Greater Consideration of Topographic Properties

Increased availability of digital topographic information can help estimate where most of the hydrological/hydrochemical action is going to take place in a basin (Kendall *et al.*, 1999; Welsch *et al.*, 2001), and can be used to design field experiments to maximize the amount of information obtained. For example, topographic indices such as the $\ln(\alpha/\tan\beta)$ index of Beven and Kirkby (1979) have been used to estimate the depth to groundwater (Moore

and Thompson, 1996; Seibert *et al.*, 1997) and to interpret spatial variations in the $\delta^{18}O$ of groundwater (Rodhe *et al.*, 1996). This approach should be expanded to include the use of different types of topographic data (e.g. surface topography vs. bedrock topography – Freer *et al.*, 1997) and different topographic indices (e.g. Barling *et al.*, 1994; Chaplot *et al.*, 2000).

Explicit Integration of Models into Our Study Designs

Hydrologists continue to call for greater integration between field and modeling studies (Dunne, 2001). This integration would encourage the adoption of sampling strategies that generate environmental isotope data that could be used to test a range of models (Hooper, 2001). It would also allow us to extend the model calibration process (traditionally based on "hard" data such as the streamflow hydrograph) to incorporate tracer information and hydrograph separation results as "soft" data in a multicriteria model calibration exercise (Seibert and McDonnell, 2002).

CONCLUSIONS

The initial enthusiasm with which some hydrologists greeted the advent of the IHS approach has since been tempered by greater recognition of its assumptions and limitations, and the need to integrate the use of IHS with other tracing and hydrometric methods. There are numerous challenges facing the application of the IHS approach to address hydrological questions, and hydrologists must be alert to these when interpreting the results of tracing studies using environmental isotopes. Nevertheless, isotope hydrograph separation provides a powerful addition to the hydrologist's toolkit of approaches available to examine water age, origin, and pathway during its movement through drainage basins to receiving water bodies.

117: Land Use and Land Cover Effects on Runoff Processes: Urban and Suburban Development

THEODORE A ENDRENY

Program in Hydrological Systems Science & Engineering, State University of New York College of Environmental Science and Forestry, Syracuse, NY, US

Urban and suburban development alters watershed imperviousness and connectivity, resulting in alterations to the hydrologic and hydraulic runoff response. Stormwater conveyance devices have been incorporated into most development to address the goal of floodwater removal for protection of life and property. Urban and suburban development laws generally consider the stormwater drainage system as part of the basic infrastructure and leave right of way and space to locate the component parts. Drainage systems are designed to protect life, enable vehicular access, extend pavement life cycle, control the volume and velocity of stormwater runoff along curbs and gutters, and convey stormwater runoff to natural or human constructed drainage ways and receiving waters. Engineering equations have been developed to design construction for optimal runoff behavior, such as timing, volume, and rate, into, through, and from conveyance devices. Design equations are also utilized for assessing the performance of constructed environments, to ascertain whether stormwater devices need rehabilitation or expansion. New frontiers in stormwater include model spatially distributed development that incorporates high-density elevation maps, radar rainfall, and details of remotely sensed infrastructure as well as ecological restoration simulation, including groundwater and river remediation for wildlife and recreation.

HYDROLOGICAL FEATURES OF DEVELOPED AREAS

INTRODUCTION

Urban areas are distinct from suburban based on the type and density of development, where urban typically exceeds 50% impervious cover, and includes industrial uses in addition to commercial and residential cover. There is a continuum, however, of hydrological impacts due to these development schemes. Estimates of urban runoff timing, depths, and volumes are often initially addressed by civil and water resources engineers as part of the design for development of the urban and suburban area. Design objectives for runoff are typically to control against flooding, standing water, and device scour (ASCE, 1993; Mays, 1999; Chin, 2000) within the constructed environment, focusing primarily on storm flows, and have been expanded to simultaneously address water quality and restoration concerns (WEF/ASCE, 1998; Chin, 2000, *see* **Chapter 97, Urban Water Quality, Volume 3** by Bryan Ellis for more on urban water quality and **Chapter 191, Environmental Flows: Managing Hydrological Environments, Volume 5** for more on urban restoration). According to Urbonas and Roesner (1993), urban and suburban development laws consider the stormwater drainage system as part of the basic infrastructure and leave right of way and space to locate the component parts, such that drainage systems can (i) remove stormwater to enable vehicular access and extend pavement life cycle, (ii) control the volume and velocity of stormwater runoff along curbs and gutters to reduce human hazards and pavement damage, and (iii) convey stormwater runoff to natural or man-made drainage ways and receiving waters. Design equations are also utilized for assessing the performance of constructed environments, to ascertain whether stormwater devices need rehabilitation or expansion. Bedient and Huber (2002) define three separate, but incrementing tasks faced by the urban water resources engineer, as prediction of peak flows, runoff volumes, and complete hydrographs.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Engineering design formula for estimating the timing and magnitude of runoff includes hydrologic and hydraulic approaches. Hydrologic design includes formula from both empirical design, such as Curve Number (CN) based rainfall abstractions, as well as those derived through reduction of the phenomena via the Reynolds Transport Theorem (see Chin, 2000) in a Eulerian control volume analysis of mass, momentum, and energy. Hydraulic design is comprised primarily of the latter approach, but also includes a Lagrangian analysis via differentiation of the changes in mass, momentum, and energy along the entire system. In summary, urban environments were planned to uphold properties of runoff timing and magnitude that generally complied with engineering design equations.

The as-built condition of constructed environments and the actual machinations of the runoff phenomena within the urban and suburban neighborhoods contain elements that deviate from the design. A combination of hydrologic- and hydraulic-based equations is common in practice, weighted more toward the more readily solved and stable hydrologic approach (ASCE, 1993; Maidment, 1993; AASHTO, 1999; Mays, 1999; Chin, 2000). Designed or otherwise, urbanization has been demonstrated to reduce the degree of infiltration and increase the volume of stormwater runoff by changing slope, form, or cover, alter the amount of depression storage by regrading terrain, reduce the amount of evapotranspiration by removing vegetation and reducing infiltration, and reduce the travel time to a receiving waterbody by increasing the efficiency of surface and subsurface drainage networks (ASCE, 1993; WEF/ASCE, 1998; Butler and Davies, 2000).

Runoff processes considered in this article are primarily storm flow across and within constructed conveyance systems, including stormwater management facilities such as gutters, culverts, stormsewers, swales, infiltration trenches, bioretention filters, wet and dry detention basins, and retention ponds. The chapter focuses on the most common engineering design equations used in estimating runoff across the constructed environment, and also addresses the utilization of current research methods that enhance the analysis of runoff processes.

Density of Residents

Urban and suburban areas and their constructed runoff devices are built within, and surrounded by, natural hydrological regimes, making delineation of the developed and natural runoff phenomena often difficult. Delineation is important because it provides a control volume within which the engineering runoff equations are applied, and through which the external forcing of precipitation, evaporation, and water supply and removal are considered. Population density is the traditional means by which government census bureaus define an urban area, and these numbers vary between nations. In 2000, urban areas for the US Census Bureau were defined as populations of at least 390 people/km^2, while for the Canadian Census they were defined as concentrated populations of at least 1000 with no fewer than 400 people/km^2. The US Census defines metropolitan statistical areas (MSA) as concentrated populations of at least 10 000, and when 50% or more of a county resides within an MSA, the entire county is classified as an MSA. All other land is defined as rural, with limited distinction of suburban features as a lower density settlement along the fringe of the urban area.

Table 1 Category of suburban density based on dwellings and effective impervious area (Modified from Dinicola, 1989)

Classification	Dwellings hectare^{-1}	Effective impervious area (%)
Low density	<2.5	<4
Medium density	2.5–10.0	4–10
Suburban density	10.0–20.0	10–24
High density	20.0–40.0	24–48
Urban residential	>40.0	>48%

Constructed development intensity as an urban metric might be useful in stratifying the impact of construction on the runoff processes. One definition of development intensity considers dwellings per unit area (see Table 1), where the area in the denominator might be the designed lot size or the local watershed size (Dinicola, 1989), and is structured discretely from low to high. Ideally, in assessing runoff alterations, the location of the development relative and its impact on recharge, discharge, or conveyance should be considered in addition to its footprint size.

Imperviousness and Constructed Land Cover

Another definition of intensity is to consider impervious area (Schueler, 1994), proposed by the Water Environment Federation (WEF) and American Society of Civil Engineers (ASCE), as a single unifying measure for the effect of urbanization on watershed hydrology (WEF/ASCE, 1998). Impervious area is structured continuously from 0 to 100%. The total or effective impervious area estimate may be based on *in situ* or remote observation (Lunetta and Elvidge, 1998; Doyle, 2001; Steitz and Chandler, 2001), or on empirical functions that assume a road, house, sidewalk, and driveway area for each dwelling or resident.

Imperviousness of the urban area, as surveyed in 11 residential areas in Olympia, Washington, comprises between 63 and 70% transportation-related structures and 30 to 37% occupation-related structures. In regard to water quality, Schueler (1994) has delineated 10% impervious area as the extent where watersheds move from sensitive to impaired, and 25% impervious area as the extent where they become nonsupporting (CWP, 1998). Prior to advanced mapping sources, Brater (1968) attempted to identify hydrologically

significant impermeable area (HSIA) ratio for drainage basins, ranging in size from 23 to 475 km^2, in various stages of urbanization around Detroit, Michigan, by dividing the observed total volume of discharge by the computed effective precipitation volume across the entire watershed. The HSIA ratio is then multiplied by the total basin area, which gives the impermeable area of watershed contributing runoff. In an era when impermeable surfaces were difficult to map, this technique provided a first estimate.

Constructed area stormwater conveyance extent is an important urban attribute not provided by either lot size or impervious area estimates. Leopold (1968) used the extent of stormwater conveyance together with impervious area to estimate the ratio of post- to predevelopment runoff peaks. Rather than just impervious area, more emphasis is now placed on estimates of impervious areas directly connected to the stormwater system and the receiving water, referred to as *directly connected impervious area* (DCIA) or as *the effective impervious area* (CWP, 1998; WEF/ASCE, 1998). DCIA estimates provide the basis for adjusting Curve Number values central in the simple engineering runoff models such as the TR-55 approach (Chin, 2000), which is explained more at the end of this article. Urban stormwater conveyance devices, along with other water resource infrastructure such as water delivery and waste removal, are typically associated with a minimum density of 3500 people/km^2 (McGhee, 1991). Dinicola (1989) has shown that dwellings per unit area can be used to predict impervious cover, but estimating the impervious cover from population numbers is a moving target; the US Census Bureau has reported that the number of residents per dwelling has diminished from 3.1 in 1970 to 2.7 in 2002 as the average floor size per dwelling increased from 140 to 205 m^2. The US Environmental Protection Agency estimates that approximately 6 m of stormwater sewer is needed per person (USEPA, 2001b).

Data products used in estimating development intensity and change primarily originated from airborne and satellite imagery (Lunetta and Elvidge, 1998). USGS and USEPA National Land Cover Database (NLCD) maps, derived from LandSat Thematic Mapper Multi-Resolution Land Cover data (see Table 2), is used to simply denote low-intensity residential as class 21, and high-intensity residential as class 22, with transportation, industrial, and commercial lumped into class 23. These NLCD values are for approximately 30×30 m pixels (picture elements), and per area assessment can be aggregated for an entire watershed. NLCD 2001 uses Landsat 7 ETM+ and high-resolution imagery to assess the subgrid spectral signals within the 30×30 m raw data, providing vegetation cover and impervious cover estimates as a second layer in the variable attribute data files (Huang *et al.*, 2001; Yang *et al.*, 2003). Other projects are not as in-depth. 4-m horizontal resolution IKONOS satellite imagery has been privately used to delineate road networks (Gibson, 2003), and advances in aerial orthoimagery are now used to map entire states at submeter resolution (New York State GIS Clearinghouse, 2003) and provide oblique angle views of city landscapes in places like Los Angeles, CA, and Syracuse, NY (Pictometry, 2003). Advanced remote sensing work in Switzerland by Fankhauser (1999) has also demonstrated detection opportunities with orthoimagery.

Table 2 Category of suburban density for 900 m^2 pixels based on constructed material and vegetation coverage

Classification	Constructed material (%)	Vegetation (%)
Low intensity	30–80	20–70
High intensity	80–100	<20

Drainage Infrastructure of Urban Development

Features of the landscape that distinguish an urban center and suburban area, beyond higher human density and the general class of impervious area, include transportation networks, residential, public, commercial, and industrial buildings, power supply grids, water supply facilities and supply lines from groundwater and/or surface reservoirs, wastewater sewers, facilities for removal of gray and black wastes from the buildings, and receiving water modification to coastal, lake, wetland, and river areas. Receiving water impacts are a significant impact of urban development, with rivers comprising the largest category of receiving water (WEF/ASCE, 1998). Waterside development sites are common given that the services of water supply, waste removal, transportation, and hydropower, and activities of farming and fishing, which established and supported the urban area and its suburban surroundings, either required or benefited from proximity to water resources (Mays, 1999; Butler and Davies, 2000).

Graff (1977) noted that a key hydrological feature of urban development are road networks that add numerous artificial surface channels, separate from stormsewers, designed to efficiently collect and route stormwater such that the lag time and kurtosis of storm hydrographs shift to the left and become flashier. Not only do the gridded networks redirect runoff from predevelopment paths, but the impermeable and relatively smooth paved surfaces prohibit infiltration and reduce friction to increase runoff magnitude and velocity. In short, the urban surface has elements with natural runoff processes and yet has a greater impervious surface cover and hydraulically more efficient drainage networks than undeveloped areas. Urbonas and Roesner (1993) and Mays (1999) provide an overview of the typical hydrologic design for urban drainage and flood control, identifying changes to the channel, floodplain, and watershed surface and subsurface that enhance drainage and flood

control, with more recent alternative design methods also treating degraded urban water quality.

History of Drainage

A brief history of runoff conveyances and urban drainage networks adds context to the importance of this phenomenon. Walesh (1989) and Mays (1999) recount that storm drains were constructed as far back as 1000 B.C., and into the mid- to late 1800s most subsurface masonry or wooden drains were constructed solely to remove stormwater, while wastewater was deposited into privies, streets, and courtyards. Burian *et al.* (2000) go on to describe the evolution of combined sanitary sewers in their historical review of wastewater management in the United States, explaining that the earliest systems of the 1850s in Chicago, Illinois, Brooklyn, and New York were fashioned after the first Combined Sewer Overflow (CSO) built in Germany. According to Burian *et al.* (2000), while separate sewer systems (SSS) were advocated at this same time, they were not built due to cost and a lack of precedent in European cities. Today in the United States, there are approximately 800 000 km of stormwater sewers in the cities (USEPA, 2001b), and the 20-year cost of updating these systems reaches into trillions of US dollars (Congressional Budget Office, 2002).

When vitrified clay replaced brick, wood, and stone sewer material, sewers could be constructed at smaller diameters, SSS costs became more competitive, and sewers were built in Lenox, Massachusetts, in 1875, and in Memphis, Tennessee, in 1880. Despite some failures in the early SSS designs, the technology disseminated, and by 1892, of the 27 cities with wastewater treatment works, 26 had adopted SSS designs to reduce treatment volumes and by the 1930s most cities were building with SSS designs. Combined sewers reduce the volume of stormwater reaching the local stream by routing the mixed waters to the treatment plant, capturing the entire storm for small events and spilling a fraction of the storm during larger events.

External Impacts of Construction

Land-use types altered by urban and suburban development, and associated runoff processes, are spatially extensive and locally significant, yet not considered central to the urban focus in this chapter. Such alterations are listed, however, for identification. Transportation corridor linkages with exterior communities are an alteration associated with urban areas of all sizes to facilitate transport of supplies, equipment, and labor to the development site. Features of larger projects that often accompany the on-site construction are the development of separate sites, locally, regionally, or internationally, as iron ore mines, stone and sand quarries, and timber harvests to provide construction materials and the local clearing of staging areas for storing and assembling development components. Final components for major urban development that extend beyond the urban area include the tapping of new water supplies, either surface or subsurface, with associated conveyance systems; the deposition of stormwater runoff and treated wastewater into receiving water supplies, at times creating interbasin transfers; the utilization of new energy supplies, in many regions using water withdrawals for hydropower or cooling, and removal of trees for transmission lines to the urban area; and the excavation and compaction of soils using new garbage and trash-handling facilities.

Delineation of Developed Catchments

McPherson and Schneider (1974) identified the difficulty of delineating the urban catchment area due to determining drainage divides in stormsewer areas when development grading, cut and fill, and road curb and gutter construction may have changed mapped elevations. Stormsewers may also run at subterranean slopes that are opposite in direction to surface terrain slopes. Djokic and Maidment (1991) recognized similar limitations in delineating urban watersheds when man-made structures divert stormwater from the predevelopment map prediction of steepest descent to alternate conveyance systems. Rather than collect current and dense terrain data of the current urban surface, the authors presented an algorithm based on integrated analysis of triangular irregular network (TIN) terrain datasets (Jones *et al.*, 1990), stormwater intakes, and the drainage network, within the Environmental Systems Research Institute (ESRI) Arc geographical information system software (Djokic and Maidment, 2000). The integrating algorithm is a privately owned expert system shell called *Nexpert Object*, and is demonstrated in the city of Asheville, North Carolina, where the required drainage network and stormwater intake maps are available.

An alternative approach is to find elevation maps with spatial resolution that capture the path of steepest descent, including 2% transverse sloping roads from the crown at approximately 3 m per lane width, 6% sloping gutters, 25 cm curb breaks, and stormwater intake depressions (AASHTO, 2002), and then use the standard terrain analysis algorithms, such as D8, multiple flow (MF), and D-Infinity, discussed in this article. Aerial orthophotos with 2.54 cm to 330 m scale imagery provided 0.6 m contours to test the use of this approach in two $<1\,km^2$ suburban watersheds in New York City's Croton watershed drinking water supply area within Westchester and Putnam Counties. Road longitudinal slopes ranged from flat to 6% grades, and predictions of flow path across 2 m grid cells provided relatively high success in capturing observed surface flow paths (Endreny *et al.*, 2002). Subsequent use of 0.3 m contours, generated by the same photogrammetric technique at a scale of 2.54 cm to 165 m, in a $<1\,km^2$ urban watershed in Syracuse, NY, failed to capture some road crowns

and curb breaks that delineated drainage inlet networks, necessitating site visits and manual delineation.

RUNOFF FROM URBAN AND SUBURBAN CATCHMENTS

Evaporation

Evaporation rates and lengths from urban land cover types are generally smaller than those from forested, grass, and agricultural land cover types. *In situ* and remote sensing studies have shown that urban structures are primarily non-vegetative and create a heat island effect (Lo *et al.*, 1997) due to a higher heat capacity than vegetation and a tendency to reemit heat into the surrounding environment (Stone and Rogers, 2001). Further, the absence of a large area of moist vegetation and soil restricts net radiation fluxes to partition predominantly into sensible heat fluxes, rather than latent fluxes via evaporation. In rural areas, moist vegetation and soil land cover allow for a significant percentage of the heat energy flux to go toward latent heat of vaporization and increase the atmospheric water vapor, cooling the surrounding air. Dow and DeWalle (2000) found that evaporation declined by 12 cm as urbanization increased from 0% up to 60% from 1920 to 1990 for 51 eastern United States watersheds. Because of the different patterns of irrigation supply and utilization of stormwater retention basins, there was significant variability in watershed response. Patterns in urban climate are under greater study as part of the National Science Foundation support of Long-term Ecological Research watersheds in Baltimore, Maryland and Phoenix, Arizona (Brazel *et al.*, 2000).

Precipitation

Urban heat island sources that are advected and diffused through the urban area contribute to the creation of temperature gradients and upstream and downstream thermals, an effect that has been examined in laboratory models under calm and stratified conditions (Noto, 1996). Any intense updraft of this thermally warm core, with greater moisture content, contributes to vertical clouds, moist convection, and storm formation (Baik *et al.*, 2001). This work showed that as the urban heat island intensity increased, cloud water formation times decreased and horizontal proximity to the heating center decreased. Baik and Chun (1997) also noted that when the heating depth is greater, precipitation is greater downstream.

Precipitation alterations have been confirmed in the field with gage, ground-based radar, and satellite radar detection systems. Changnon (1984) analyzed 50 years of gage measured rainfall data, as part of the 1970 Metropolitan Meteorological Experiment, for the Chicago metropolitan area and determined that there were 76% more occurrences of 2.54 cm or greater rains in the city than in the surrounding rural areas. In addition to the favorable thermal regime, the difference was explained by greater accumulations of required condensation nuclei through urban atmospheric particulate matter, which is a trend now identified in other United States' metropolitan regions (Changnon and Easterling, 2000). Satellite analysis by Shepherd *et al.* (2002) of Tropical Rainfall Measuring Mission's (TRMM) precipitation radar measurements for several storms over five southern United States cities identified a 28% average rainfall increase between 30 and 60 km downwind of the urban area, and a 6% average rainfall increase in the urban area. Important radar-based urban rainfall research from Europe has been reported by Thomas and Schmitt (2001).

Infiltration

Soils in suburban and urban systems are observed to have greater incidences of compaction and lower permeability, thereby reducing infiltration rates. The ability to predict the distribution and infiltration behavior of disturbed soils has been investigated with field and laboratory tests by Hamilton and Waddington (1999) in the Philadelphia, Pennsylvania area and by Pitt and Lantrip (2000), and Pitt *et al.* (2003) in the Birmingham, Alabama area. These studies have demonstrated that soils of similar texture and class showed significantly different infiltration rates, where infiltration declined with field- and lab-determined increases in compaction. Significant variability in infiltration was found between adjoining yards (Hamilton and Waddington, 1999), and the scatter for a single soil texture was great enough that decay functions could be replaced with horizontal lines with random scatter. Pitt and Lantrip (2000) conclude that very large errors in soil infiltration rates should be expected if published soil maps are used in conjunction with recommended texture-based infiltration model parameters for the Horton exponential decay model, and recommend that knocking and cone penetrometer studies be used to adjust parameters based on compaction. Dr. David Goodrich provides more details on infiltration dynamics and associated runoff in this series (*see* **Chapter 111, Rainfall Excess Overland Flow, Volume 3** in this series).

Urban and Suburban Hydrological Storages

Depression storage is the depth or volume of ponded water accumulated at a low point with no possibility of escape as runoff, but is lost to the atmosphere by evaporation or to the soil by infiltration. Detention storage is different, and is defined as the depth or volume of water in motion over the land and contributes to runoff and possibly to infiltration and evaporation (AASHTO, 1999). Depression storage for different urban land cover types is provided in Table 3. A functional relationship for mean depression storage, d (cm), across generic urban land cover has been derived based on

Table 3 Depression storage (mm) for various land cover types

Land cover type	Depression storage range (mm)
Large paved area	2–4
Roofs – flat	3–8
Roofs – sloped	2–3
Lawn grass	5–13
Wooded areas/open fields	5–15

Table 4 Ratio of peak runoff rates after and before development from single family residential sites (Modified from Urbonas and Roesner, 1993)

Return period	Washington DC	Denver, Colorado	Canberra, Australia
2	10.8	57.0	9.0
10		3.1	4.7
15			
100	4.1	1.9	1.9

slopes by Kidd (1978), as an exponential decay function based on the area's percent watershed slope, S, with data from Holland, United Kingdom, and Sweden fitting with a correlation coefficient of 0.85.

$$d = 0.077 \cdot S^{-0.49} \quad (1)$$

Viessman *et al.*, (1977) used data from small impervious areas near Baltimore, Maryland and constructed a linear relationship that is approximated for depression storage d (cm), based on percent watershed slope, S, by

$$d = 0.341 - 0.076 \cdot S \quad (2)$$

STORMWATER GENERATION, COLLECTION AND DRAINAGE

Runoff Timing and Volume

Butler and Davies (2000) explain that the effects of urbanization on runoff are to change the relative proportions of water that infiltrates, evaporates, travels as subsurface flow, and is carried as surface stormwater. In some urban areas, the magnitudes are changed not only due to evaporation, but also due to alterations of the convective cycle and increases in precipitation as well as from interbasin transfers of drinking water that is released within the constructed area through services and irrigation, such as pipe exfiltration, septic discharges, car washes, sprinklers, and so on (Lerner, 2002). Calder (1993) provides a series of interception and evaporation equations to predict the hydrologic effects of land-use change, focusing the review primarily on afforestation and deforestation, but does not address the replacement of these natural systems with suburban or urban infrastructure.

Studies from the 1960s onward have documented that urbanization increases the volume of direct runoff and magnitude of peak discharge, decreases the time to peak discharge, and decreases the volume of subsurface runoff and baseflow (Lazaro, 1979; Bedient and Huber, 2002). Pre- and postdevelopment assessment of stormwater runoff has been reported for a small set of watersheds, some of which are reported in Table 4. In short, flood peaks of shorter recurrence intervals (less than a 50-year event or greater than a 0.02 probability) are increased by urbanization, creating new flood frequency distribution curves that shift to the left. Paired watershed monitoring is another method for identifying urban effects on hydrology, but given the challenge in controlling for covariates, computer modeling has become the most favorable method for urban effects assessment (Walesh, 1989). The difference in runoff efficiency between impervious and pervious surfaces decreases with increasing storm intensity, duration, and return period. As would be expected, as events extremity increases, soils become increasingly saturated and depression storage is more completely filled, causing a direct translation of runoff into the major drainage.

Impervious cover and compacted soils (Hamilton and Waddington, 1999; Pitt *et al.*, 2003) are the principal urban features causing runoff to increase as a result of development. Such a scenario is captured in Figure 1. The values of runoff provided in this figure are estimates based on assumed cover classes and precipitation regimes, and the subtleties of how these change with effective impervious area connectedness and storm intensity and duration are not addressed. The efficiency with which the urban and suburban impervious areas convert rainfall to runoff correlates strongly with the percent impervious cover, but more recent studies have increased this correlation by limiting the analysis to impervious areas directly connected to the drainage system (e.g. DCIA) and not surrounded by pervious surfaces.

Anderson (1970) observed that typical drainage system improvements, such as road networks and stormsewers, reduced lag time to one-eighth that of an undeveloped watershed, creating a "flashiness" in response, where the flood centroid arrives sooner. The flashiness combined with increased impervious cover resulted in flood peaks increasing by a factor of 2 to 8 times that of a natural watershed. Lazaro (1979) reports on studies that corroborated these findings, noting a tripling of peak flows and a reduction in rise time by one-third depending on channel modifications, impervious cover extent, and drainage facilities. Regional, and possibly dated, regression equations that predict increase in flood peak, lag time of flood peak, and magnitude of mean annual flood based on the watershed runoff coefficient, slope, and area were developed by Carter

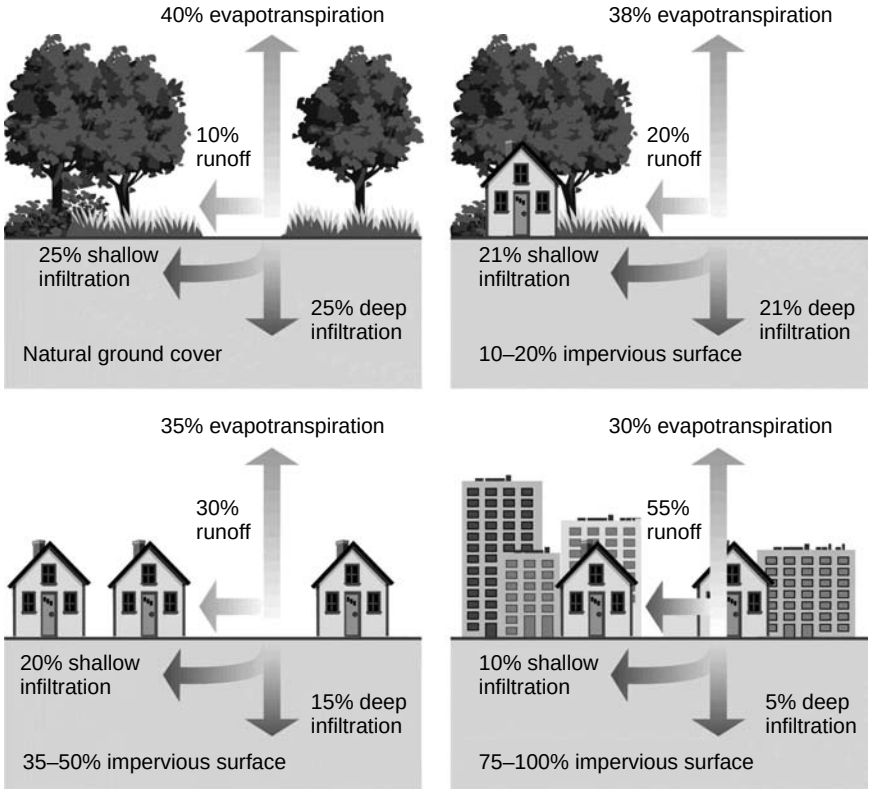

Figure 1 The augmentation of runoff from 10 to 55% that generally corresponds with land-use change toward urban development is schematically shown. Borrowed from the USEPA

(1961) based on watersheds in the Washington, DC area. Urbonas and Roesner (1993) quantitatively demonstrate how the runoff coefficient increases with impervious cover, which was developed for Denver, Colorado area and may have limited application in other areas. Regional limits are common to empirical methods.

Runoff Generation and Routing

Several approaches are used to estimate the runoff from urban areas as discharge, Q ($m^3\,s^{-1}$), and include the unit hydrograph, the Epsey–Altman hydrograph, the Natural Resources Conservation Services (NRCS) dimensionless hydrograph, the kinematic-wave model, the nonlinear reservoir model, and the Santa Barbara urban hydrograph model. Runoff prediction can take the form of field-measured responses, where the ordinates in the unit hydrograph are multiplied by effective rainfall based on different storm durations, or the synthetic urban hydrograph shown below may be employed to estimate instantaneous discharge, Q ($m^3\,s^{-1}$), for each time, t (s), based on peak discharge, Q_p ($m^3\,s^{-1}$), time to peak (s), and an exponential decay parameter, k (s^{-1}) (Butler and Davies, 2000).

$$Q = \frac{t}{t_p} \cdot Q_p \text{ for } 0 < t < t_p \tag{3}$$

$$Q = Q_p \cdot e^{-\frac{t-t_p}{k}} \tag{4}$$

Epsey–Altman 10-min unit hydrographs estimation (Epsey and Altman, 1978) is a technique derived from 41 small watersheds ($<40\,km^2$) with impervious cover extending from 2 to 100%. Runoff hydrograph shape and magnitude were estimated as a function of drainage area, A (km^2), impervious cover, I (%), main channel length, L (m), main channel slope, S, and a dimensionless catchment conveyance factor, Φ. Time to peak, T_p (s), peak discharge, Q_p ($m^3\,s^{-1}$), time of base, T_b (s), and hydrograph width at 50% and 75% peak discharge, W_{50} (s) and W_{75} (s), are given below (Chin, 2000),

$$T_p = 246 \frac{L^{0.23} \Phi^{0.57}}{S^{0.25} I^{-0.18}} \tag{5}$$

$$Q_p = 359 \frac{A^{0.96}}{T_p^{1.07}} \tag{6}$$

$$T_b = 98700 \frac{A}{Q_p^{0.95}} \tag{7}$$

$$W_{50} = 15120 \frac{A^{0.93}}{Q_p^{0.92}} \tag{8}$$

$$W_{75} = 5700\frac{A^{0.79}}{Q_p^{0.78}} \quad (9)$$

Figure 2 provides conveyance values for different main channel Manning's n values and percent impervious cover. Width of flow, as a time interval, at 50% and 75% Q_p is split such that one-third precedes the peak and two-thirds are allocated to the falling limb.

Natural Resources Conservation Services (NRCS, formerly the SCS) dimensionless unit hydrographs, while developed for natural catchments, are frequently applied to urban catchments (Chin, 2000), particularly in development planning. Storm event hydrograph plotting positions are derived from estimates of time to peak, T_p (h), and peak discharge, Q_p ($m^3 s^{-1}$), using estimates of excess rainfall duration, t_r (h), time lag, t_l (h), watershed area, A (km^2), and the dimensionless ratios in Table 5, as given by Chin (2000),

$$T_p = 0.5t_t + t_l \quad (10)$$

$$Q_p = 2.08\frac{A}{T_p} \quad (11)$$

If time lag is not known, an estimate is obtained from the time of concentration t_c (h), given below, and in urban catchments should account for increased efficiencies of stormsewers and drainage ways.

$$t_l = 0.6t_c \quad (12)$$

The NRCS triangular hydrograph is often used to approximate the dimensionless hydrograph, which has the same peak discharge and volume under the rising and falling limb, but the triangular hydrograph uses a total event time of 2.67 T_p, rather than 5 T_p as in the dimensionless estimation. Figure 3 shows the NRCS triangular and dimensionless hydrographs.

The kinematic-wave model is derived from a one-dimensional solution of the continuity and momentum equations, where the momentum terms for local acceleration, convective acceleration, and pressure slopes are neglected, leaving friction as the dominant term. Overland flow depth, y (m), is solved as a function of flow per unit width, q ($m^2 s^{-1}$), based on effective rainfall intensity, i_e ($m s^{-1}$), coefficient α, and a term for laminar or turbulent flow, m. The combined continuity and momentum equation is given as

$$\frac{\partial y}{\partial t} + \alpha m y^{m-1}\frac{\partial y}{\partial x} = i_e \quad (13)$$

The solution for flow depth, based on effective rainfall intensity, is then substituted into the momentum equation

Table 5 Dimensionless unit hydrograph ratios of time to time to peak (T_p) and discharge to peak discharge (Q_p)

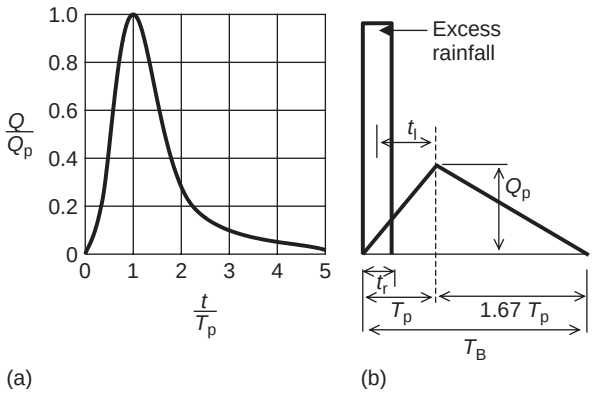

Figure 3 NRCS (a) dimensionless and (b) triangular unit hydrographs

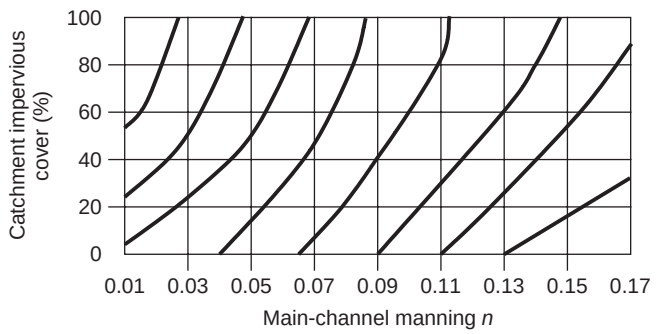

Figure 2 Conveyance factor Φ nomograph based on main channel Manning roughness and impervious extent (%)

to find runoff per unit width,

$$q = \alpha y^m \tag{14}$$

A finite element approximation of the kinematic-wave model is given as

$$y_x^t = q_1 \Delta t + y_x^{t-1} - \alpha m \left(\frac{\Delta t}{\Delta x}\right)\left(\frac{y_x^{t-1} + y_{x-1}^{t-1}}{2}\right)^{m-1} \times \left(y_x^{t-1} - y_{x-1}^{t-1}\right) \tag{15}$$

The kinematic-wave model does not simulate hydrograph attenuation, which is negligible in urban drainage systems, making the equation useful in urban settings. Overland inflow entering a channel per unit length of channel, q_0 ($m^2\,s^{-1}$) and cross-sectional flow area, A (m^2), are used in the kinematic-wave equation for channel flow, given as

$$\frac{\partial A}{\partial t} + \alpha m A^{m-1}\frac{\partial A}{\partial x} = q_0 \tag{16}$$

The nonlinear reservoir model simulates the urban catchment as a shallow reservoir with inflow equal to rainfall excess and outflow a nonlinear function of flow depth y (m), and depression storage, y_d (m). Estimates of runoff depth are given as a function of average excess rainfall over the time step, i_e (m), a representative catchment width, W (m), Manning's roughness, n, an average catchment slope, S_o, and watershed area, A (m^2), given in finite difference form by Chin (2000) as

$$\frac{y_2 - y_1}{\Delta t} = i_e - \frac{W S_o^{0.5}}{An}\left(\frac{y_1 + y_2}{2} - y_d\right)^{5/3} \tag{17}$$

Equation (17) is solved iteratively for y_2, the depth of flow at the end of the time step, which is then substituted into the following discharge equation as y.

$$Q = \frac{W}{n}(y - y_d)^{5/3} S_o^{1/2} \tag{18}$$

The Santa Barbara Urban Hydrograph (SBUH) model assumes that the runoff is derived from the directly connected impervious fraction of the catchment, and may neglect abstractions such as depression storage and rainfall on pervious areas or account for them with a submodel. While the model was developed for Santa Barbara, CA, it has been applied for other urban areas in the United States (Chin, 2000). Instantaneous runoff, q ($m^3\,s^{-1}$), is computed for each time interval, Δt (s), based on watershed area, A (m^2), fraction of watershed that is directly connected impervious, x, rainfall intensity, i ($m\,s^{-1}$), and rainfall excess intensity, i_e ($m\,s^{-1}$), given as

$$q = [ix + i_e(1.0 - x)]A \tag{19}$$

Instantaneous runoff is distributed through time using a routing constant, K_r, based on the time of concentration, t_c (s), given as,

$$K_r = \frac{\Delta t}{2t_c + \Delta t} \tag{20}$$

Ordinates of the routed runoff hydrograph, Q ($m^3\,s^{-1}$), are then computed for each time step, j, as

$$Q_j = Q_{j-1} + K_r(q_{j-1} + q_j - 2Q_{j-1}) \tag{21}$$

Depending on the application, the most common equations available for engineering design are the Manning equation and the Darcy–Weisbach equation (Mays, 1999; Chin, 2000; Haestad, 2002). In stormwater runoff computations, the Manning equation is the predominant form for estimating discharge (ASCE, 1993; Mays, 1999; AASHTO, 2000; Haestad, 2002), and is derived as a function of flow cross-sectional area, A (m^2), Manning's roughness, n, hydraulic radius, R (m), and water surface slope, S.

$$Q = \frac{A}{n}R^{2/3}S^{1/2} \tag{22}$$

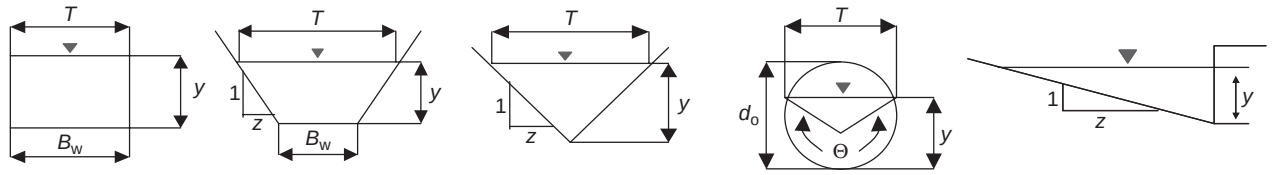
Equation (22) application should be limited to normal flow conditions, where water surface slope, or the energy grade line, parallels channel slope, and when flow is hydraulically rough (Chin, 2000). Hydraulically rough flow is maintained when the following condition is true (Chin, 2000),

$$n^6 > \sqrt{RS} \geq 1.9E - 13 \tag{23}$$

Solution of runoff equations typically requires basic geometric properties for the conveyance devices, which are sketched in Figure 4, along with the equations needed to compute top width, T (m), area, A (m^2), perimeter, P (m), and hydraulic radius, R (m). Values for Manning's roughness factor are provided in Table 6, but a single value should be used with caution. Instead, a range should be used to represent the uncertainty in their values, as noted by Johnson (1996), who documented field estimated values for n have errors between 5 and 35%.

Runoff in Minor and Major Systems

Urban and suburban areas are designed to handle stormwater runoff for frequent (e.g. minor events based on intensity for a given duration) and infrequent (e.g. major events) systems. The minor drainage system is comprised of gutters, drainage inlets, and subsurface stormsewers, and when its capacity is exceeded, the major drainage system of surface runoff along the streets serves as a conveyance route. In both systems, the velocity and discharge are estimated using a form of the conservation of momentum equation. Urban



Dimension	Rectangle	Trapezoid	Triangle	Circle	Gutter
Top width	$T = B_w$	$T = B_w + 2 \cdot z \cdot y$	$T = 2 \cdot z \cdot y$	$T = \left(\sin\left(\frac{\theta}{2}\right)\right) \cdot d$	$T = y \cdot z$
Area	$A = B_w \cdot y$	$A = (B_w + zy)y$	$A = z \cdot y^2$	$A = \frac{1}{8} \cdot (\theta - \sin(\theta)) \cdot d^2$	$A = y^2 \cdot \frac{z}{2}$
Perimeter	$P = B_w + 2y$	$P = B_w + 2 \cdot y \cdot \sqrt{1 + z^2}$	$P = 2y \cdot \sqrt{1 + z^2}$	$P = \frac{1}{2} \cdot \theta \cdot d$	$P = y \cdot \left(1 + \sqrt{1 + z^2}\right)$
Hydraulic radius	$R = \frac{B_w \cdot y}{B_w + 2y}$	$R = \frac{(B_w + zy)y}{B_w + 2 \cdot y \cdot \sqrt{1 + z^2}}$	$R = \frac{z \cdot y^2}{2y \cdot \sqrt{1 + z^2}}$	$R = \frac{1}{4} \cdot \left(1 - \frac{\sin(\theta)}{\theta}\right) \cdot d$	$R = \frac{y \cdot \frac{z}{2}}{1 + \sqrt{1 + z^2}}$

Figure 4 Basic elements in urban stormwater runoff with equations for their top width, area, perimeter, and hydraulic radius

highways, streets, or roads are constructed with fairly standardized engineering plans (NYSDOT, 2001; AASHTO, 2002; Dewberry, 2002), and are classified as principal arterial interstates, principal arterial expressways, minor arterials, collectors, and locals, which have traffic volumes, in vehicles of one-way traffic per hour, that exceed 500 and may be less than 200. Urban local and collector roads are typically not elevated above the 100-year or 500-year floodplain as are principal arterial interstates and expressways, and often are located below the immediate surroundings (Lazaro, 1979) such that sections may flood during high-frequency events.

Drainage is incorporated into road design to maintain structural integrity by removing water (NYSDOT, 2001). A cross section of a typical design is shown in Figure 5, where the road is constructed with a concrete or asphalt top, about 300 mm of well-graded sand and gravel compacted subbase layer, about 100 mm of a coarse aggregate permeable base layer, and a 100 mm diameter edgedrain surrounded by compacted filter material, with the invert extending upward of 100 mm above the top of subbase in limiting slopes but preferably 200 mm below the subbase.

Rooftop Runoff

Drainage systems that begin with roof drainage in a residential house first collect into the eaves gutter, which is a 75-mm half-round channel, and which feed into down pipes that are closed 75–100 mm rectangular channels (Butler and Davies, 2000). In larger urban buildings, the roof drainage is often directly connected to the subsurface stormsewer system, but more innovative, green building design has now incorporated rooftop gardens to capture and evapotranspire the rainfall.

Street and Gutter Runoff

Surface runoff along streets in the United States has a maximum design spread or extension into the traffic lane set by the Federal Highway Authority based on a 5-, 10-, and 50-year return interval storm. Design spreads depend on the design vehicular velocity and traffic volume for that road, and for local streets, generally extend across half a driving lane, whereas for highways, they are typically constrained to at most 1 m into the driving lane while the shoulder is designed to route the majority of the flow (AASHTO, 1999). Lane widths in urban areas vary between 2.7 and 3.7 m depending on the number of vehicles of one-way traffic per hour, and maximum longitudinal slopes range from 5 to 11% depending on the design maximum vehicular speed and the topographical relief (NYSDOT, 2001). Road crown sections are normally sloped at 2%, but the superelevation of the crown may reach a maximum slope of 8% from the shoulder on certain ramps (AASHTO, 2002). In certain designs the crown will be flattened and the entire road will slope between 2 and 8% away from the point of rotation to improve vehicle traction and promote drainage (NYSDOT, 2001). Parking lanes have cross slopes of 4%, and shoulder slopes are normally 6%. Slopes from edge of shoulder along the embankment are normally 2% and limited to a maximum of 3.3% to prevent vehicle turnover.

Minor stormsewer drainage systems typically require curbing, defined as a narrow, raised element placed at the

Table 6 Manning *n* roughness estimates for channel and pipe flow above a variety of materials

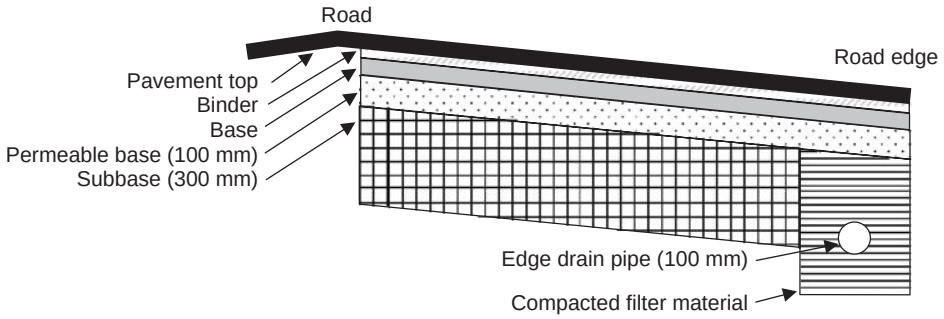

Figure 5 Road cross sections for asphalt pavement showing the crown, edge, top of pavement, binder, base, permeable base, subbase, compacted filter material, and edge drain pipe

edge of pavement, to control drainage and vehicular access, and gutters to channel flow from the road to the storm-sewer. Gutters are defined as a broad shallow ditch placed at the edge of a paved area and designed to primarily collect and carry surface water to a drainage system, and are sometimes partially congruent with shoulder or parking area functions. In the absence of curbs, runoff will continue along the transverse road and should slope into ditches that have a vertical depth set about 1.2 m below the edge of the traveled way to provide subbase drainage more than to provide hydraulic capacity (NYSDOT, 2001). Drainage from beneath the road via the edgedrain is released by connections to ditches, stormsewers, and other drainage devices.

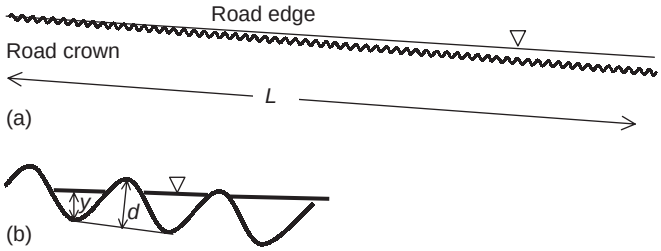

Figure 6 (a) Water film increasing in thickness as it flows from the road crown toward the road edge. (b) Detailed view showing that initially, the water depth does not exceed the road texture depth

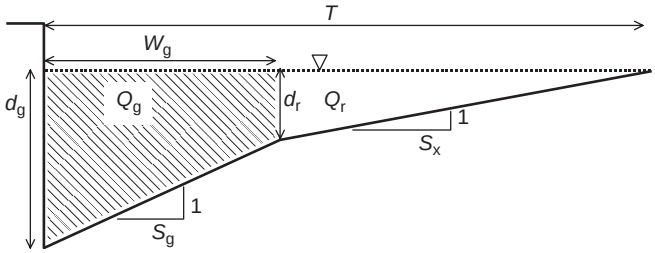

Figure 7 Composite gutter and road section showing distinct flow elements, with the gutter shaded in hash marks, the water surface indicated by a dotted line and inverted triangle, and the pavement and curb boundary indicated by the thick solid line

Rainfall on sloped pavement forms a thin film at the upper slope or road crest, and increases in thickness as it flows toward the edge of the pavement (see Figure 6). At the beginning of the storm, the film depth, y (mm), is beneath the pavement roughness depth, d (mm), and is considered a negative depth and is retained or infiltrated depending on the porosity of the surface. As the runoff length, L_f (m), increases and flow accumulates, it covers the macroasperities, and the film depth increases and behaves as channel flow (AASHTO, 1999). Runoff across a road has a final resultant flow path length and slope, S_r, that is determined on the basis of the road width, L (m), cross slope, S_x, and longitudinal gradient, S_l, as shown in equation (24).

$$S_r = \sqrt{S_x^2 + S_l^2} \tag{24}$$

$$L_f = L(S_r + S_x) = L\sqrt{1 + \left(\frac{S_l}{S_x}\right)^2} \tag{25}$$

Film depth is not appreciably affected by the road longitudinal grade (AASHTO, 1999) because as the grade is steepened, the flow path is lengthened and the flow velocity increases, which offsets increases in depth. As a result, the film water depth does not significantly change at the pavement edge. The film depth, y (mm), is estimated based on the above parameters as well as rainfall intensity, I (mm h^{-1}).

$$y = 0.01485\cdot(d^{0.11}\cdot L_f^{0.43}\cdot I^{0.59}\cdot S_r^{-0.42}) - d \tag{26}$$

Curb flow in composite sections is predicted for each section, illustrated in Figure 7, with two separate equations (Dewberry, 2002; Haestad, 2002). For the gutter section, with a depth of water at the curb, d_g (m), and a depth of water adjacent to the roadway section, d_r (m), discharge, Q_g (m^3 s^{-1}), is computed as a function of the two vertical depths, the road longitudinal slope, S_l, the Manning's roughness, n, and the gutter cross slope, S_w, as

$$Q_g = \frac{0.376\cdot(d_g^{8/3} - d_r^{8/3})\cdot S_l^{1/2}}{n\cdot S_g} \tag{27}$$

For the road section, with a road cross slope of S_x, discharge, Q_r (m^3 s^{-1}), is computed as follows:

$$Q_r = \frac{0.376\cdot d_r^{8/3}\cdot S_l^{1/2}}{n\cdot S_x} \tag{28}$$

The depth of gutter flow along the curb, d_g, can be estimated with the following relation:

$$d_g = T\cdot S_x + W_g\cdot(S_g - S_x) \tag{29}$$

The depth of road flow adjacent to the gutter section, d_r, can be estimated as,

$$d_r = (T - W_g)\cdot S_x \tag{30}$$

Drainage Inlet Runoff

Roadside stormwater is traditionally directed toward storm drain inlets that are designed to capture the street runoff and deliver it to the subsurface stormsewer. Drainage inlets are typically grates in the gutter, openings along the curb, slots within the street, or combinations of grate and gutter (see Figure 8).

Haestad Methods Software Company provides simulation tools (Haestad, 2002) to examine how typical drainage gutter and inlet sections perform for different return interval storms. Drainage inlets are placed either along sloped roads, called *on grade*, or at local minimum elevations where water gathers, called *on sag*. On-grade drainage inlets have a capture efficiency that varies with inlet design type (grate or curb and roughness and sizing of the material), the longitudinal and transverse slope, and the runoff volume, while on-sag inlets pond the water until all is delivered to

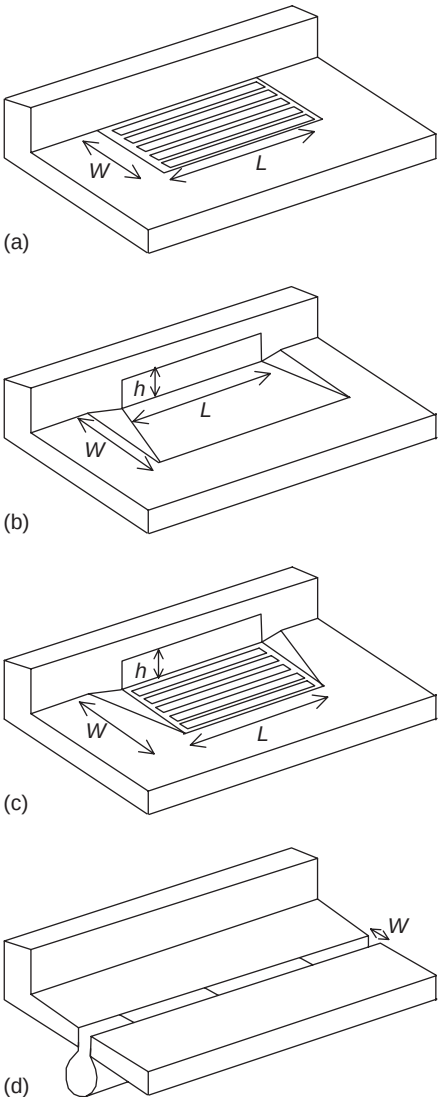

Figure 8 Street runoff drainage inlet styles of (a) grate inlet, (b) curb inlet, (c) combination inlet, and (d) slotted drain inlet

the stormsewer. Such ponding may increase the spread of runoff into the road. Stormsewer manholes used to access stormdrains are typically spaced at a minimum interval of 90 m, and are also placed at system origin, changes in direction, changes in gradient, changes in size, and major junctions (Butler and Davies, 2000).

Stormwater systems are preferably gravity driven rather than pump based to reduce the chance of failure. System slopes and dimensions are selected to maintain subcritical flows, which reduce the potential of scour, but may enhance the chance of backwater effects at junctions and constrictions (Walesh, 1989). As reported by Walesh (1989), safety measures recommended for surface conveyance systems with high flows include fencing or guardrails along steep channel sidewalls, ladders along armored channel walls to allow for escape if swept away, drop structures within channels to reduce flow velocity, and freeboard extending above the design stage.

Curb inlets experience reduced efficiencies when clogging debris blocks the flow, and have increased efficiency when placed to capture flows less than $0.08\,m^3\,s^{-1}$, longitudinal slopes are 2% or less, and local depressions surround the curb opening (ASCE, 1993). The curb operates in three flow regimes – as a weir with depths equal to the opening height, transitionally, and as an orifice with depths greater than 1.4 times the opening height (Chin, 2000). Effective head, d (m), for the curb inlet is computed as a function of the throat type for the curb, depending on the inclination of the curb, θ, the curb throat opening height, h (m), and the depth at the lip of the curb, d_i (m), as illustrated in Figure 9.

$$d_o = d_i - \frac{h}{2}(\sin\theta) \tag{31}$$

For a curb inlet operating as a weir with a depressed gutter width, W(m), an opening length, L(m), a depth of flow, d(m), and a weir coefficient, C_w, discharge, Q ($m^3\,s^{-1}$) are given by (Chin, 2000)

$$Q = C_w(L + 1.8W)d^{1.5} \tag{32}$$

$$C_w = 1.27 \tag{33}$$

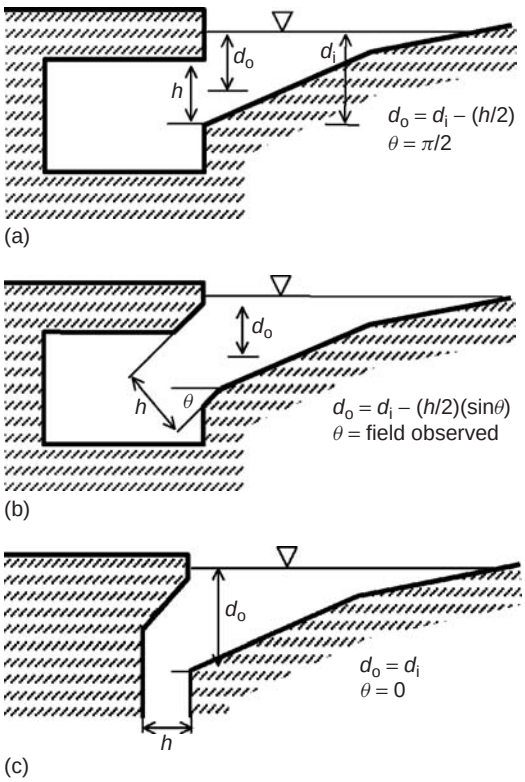

Figure 9 Different types of curb inlets, with (a) a horizontal throat, (b) an inclined throat, and (c) a vertical throat

Without a depressed gutter under weir flow, the discharge is given by (Chin, 2000)

$$Q = C_w L d^{1.5} \tag{34}$$

Curb inlets operate under orifice flow when the depth is $1.4h$, where h (m) is the opening height. Orifice flow estimates require an orifice coefficient, C_o, where discharge is given by (Chin, 2000)

$$Q = C_o A \sqrt{2g\left(d - \frac{h}{2}\right)} \tag{35}$$

$$C_o = 0.67 \tag{36}$$

Grate inlets also operate as weir or orifice flow, and the effective head, d (m), is simply the height of flow along the curb. Weir flow is achieved with a depth of flow, d (m), less than or equal to 0.12 m, and is based on the perimeter of grate opening excluding any length adjacent to the curb, P (m). Discharge is given by (Chin, 2000)

$$Q = C_w P d^{1.5} \tag{37}$$

$$C_w = 1.66 \tag{38}$$

For grates that are within a depressed gutter or other local depression, the perimeter, P (m), in the following equation is estimated as a function of the grate length, L (m), and width, W (m), (Haestad, 2002).

$$P = L + 1.8W \tag{39}$$

When depths of flow exceed 0.43 m, flow is orifice controlled and the area of the grate opening, A (m^2), is then used to determine discharge, given by (Chin, 2000)

$$Q = C_o A \sqrt{2gd} \tag{40}$$

$$C_o = 0.6 \tag{41}$$

For transitional flow at $0.12\,\text{m} < d \leq 0.43\,\text{m}$, the discharge through the grate inlet is predicted by the tangent line connecting the bounds of the weir and orifice curves (AASHTO, 2000; Chin, 2000).

Runoff not captured by drainage inlets on grade is passed back into gutter flow. Grate drainage inlets along the grade have a limited capture efficiency, which is higher for frontal flow than side flow, and is thereby increased by extending the grate toward the road. The ratio of intercepted frontal flow to the total frontal flow is a function of the gutter velocity up gradient of the inlet, V ($m\,s^{-1}$), the inlet splash-over velocity that jumps the grate and is obtained by grate manufacturers, V_o ($m\,s^{-1}$), and the frontal coefficient, k_f, given as (Haestad, 2002),

$$R_f = 1 - k_f(V - V_o) \tag{42}$$

$$k_f = 0.295 \tag{43}$$

For side flow, the length of the grate or depression, L (m), the road cross slope, S_x, and the side coefficient, k_s, are required as well as the velocity in the gutter at the inlet. The ratio of intercepted side flow to the total side flow is given as (Chin, 2000; Haestad, 2002)

$$R_s = \left(1 + \frac{k_s V^{1.8}}{S_x L^{2.3}}\right)^{-1} \tag{44}$$

$$k_s = 0.0828 \tag{45}$$

Culvert Runoff

Culvert flows route water collecting in ditches and along gutters under roads, driveways, or other structures. Culvert hydraulic equations are traditionally approached with conservation of energy equations to solve for headwater depths and flow rates. Nomographs derived from field experiments are typically used to find the design discharge, velocity, and headwater depth for different culvert barrel diameters (AASHTO, 2000), but the Federal Highway Authority has also developed a set of equations, in US customary units, to approximate design conditions (Haestad, 2002). The computational challenges stem primarily from the many flow regimes that might exist in the culvert including gradually varied flow, such as backwater condition, and rapidly varied flow, such as a hydraulic jump. Submerged culvert inlet flow typically provides more discharge capacity than unsubmerged inlets, but unsubmerged inlet flow is often the design target when the crown of the culvert barrel forms the base of a roadway (Chin, 2000). Roadway overtopping does occur in some cases, and is quantifiable (AASHTO, 2000).

Inlet-controlled culverts are characterized by turbulence energy losses near the culvert entrance when the flow passes from subcritical to supercritical depths, rather than to friction energy losses in the culvert barrel. Inlet-controlled flow is characterized by one of three conditions, an unsubmerged inlet, a transitionally submerged inlet, and a submerged inlet above $1.2D$, where D is the diameter of the culvert barrel (Chin, 2000). Several scenarios for inlet-controlled discharge are shown in Figure 10, with each case described in text. In culvert design, the headwater depth is the unknown variable, but for stormwater runoff analysis, the culvert equations are used to solve for discharge.

For cases (a) and (b), the culvert behaves similarly to a weir, with an unsubmerged inlet with a headwater depth, h_i (m), upstream velocity, V_i ($m\,s^{-1}$), critical flow depth, h_c (m), entrance losses, h_e (m), the entrance loss coefficient, k_e (which varies between 0.2 and 0.9 depending on the

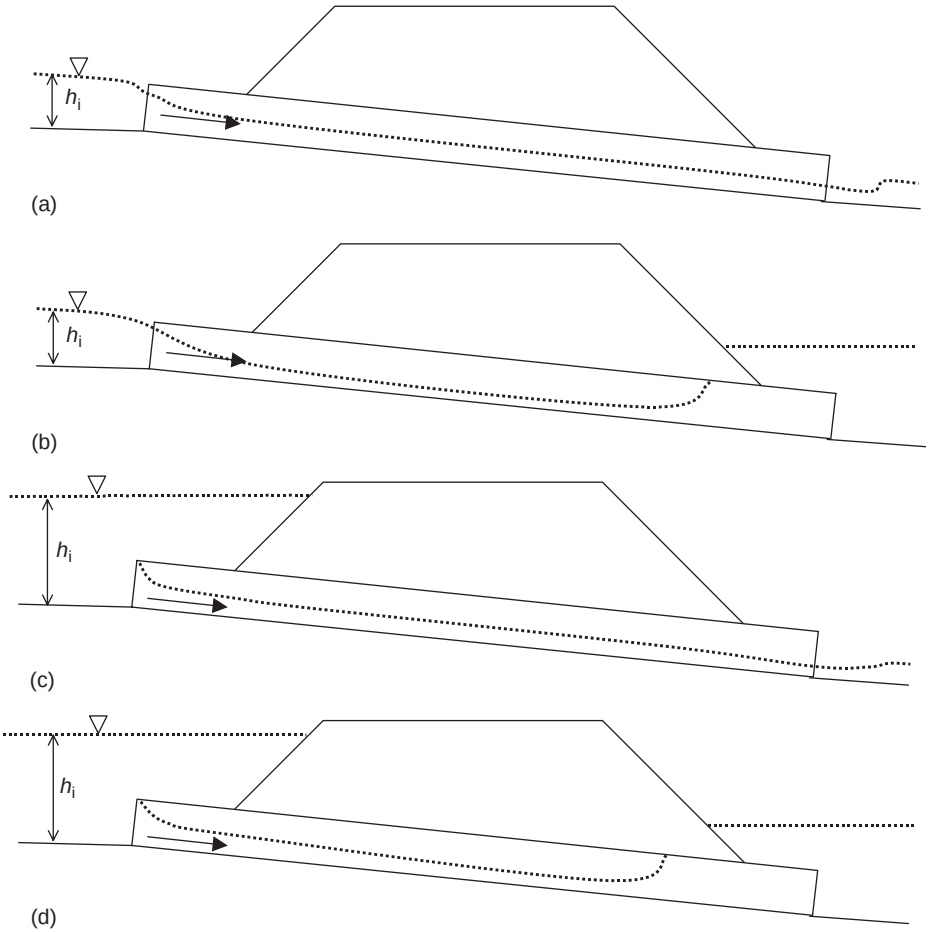

Figure 10 Inlet-controlled culverts passing beneath a road with (a) unsubmerged inlet and free flowing outlet, (b) unsubmerged inlet and submerged outlet, (c) submerged inlet and free flowing outlet, and (d) submerged inlet and submerged outlet. Water surface is shown as a dotted line, with the arrow indicating flow direction

entrance material and shape), a flow area at the critical flow section, A_c (m^2), and gravitational acceleration of g ($m\,s^{-2}$). Discharge is given by (Chin, 2000)

$$Q = A_c \sqrt{2g\left(\Delta h + \frac{V_i^2}{2g} - h_e\right)} \tag{46}$$

$$\Delta h = h_i - h_c \tag{47}$$

$$h_e = k_e \frac{V_1{}^2}{2g} \tag{48}$$

For cases (c) and (d), the culvert behaves similarly to an orifice, with a submerged inlet, with a coefficient of discharge, C_d, that ranges between 0.62 for a square edged entrance and 1 for a well-rounded entrance, a culvert cross-sectional area, A (m^2), and a vertical distance from the center of the culvert inlet to the depth of water at the inlet, Δh. Discharge is given by (Chin, 2000)

$$Q = C_d \cdot A\sqrt{2g\Delta h} \tag{49}$$

$$\Delta h = h_i - h_m \tag{50}$$

Outlet-controlled culverts are characterized by energy losses along the barrel length as well as some entrance losses. Several scenarios for inlet-controlled discharge are shown in Figure 11, with each case described in text. In cases where the flow does pass below critical depth (cases (d) and (e)), this occurs near the culvert outlet rather than near the inlet. For cases (a) and (b) with a submerged outlet and case (c) with an unsubmerged outlet, discharge is controlled by the driving energy head, Δh (m) equal to the difference between the headwater and tailwater elevations, the hydraulic radius, R (m), the length of the culvert, L (m), and the Manning's roughness, n. Discharge is given

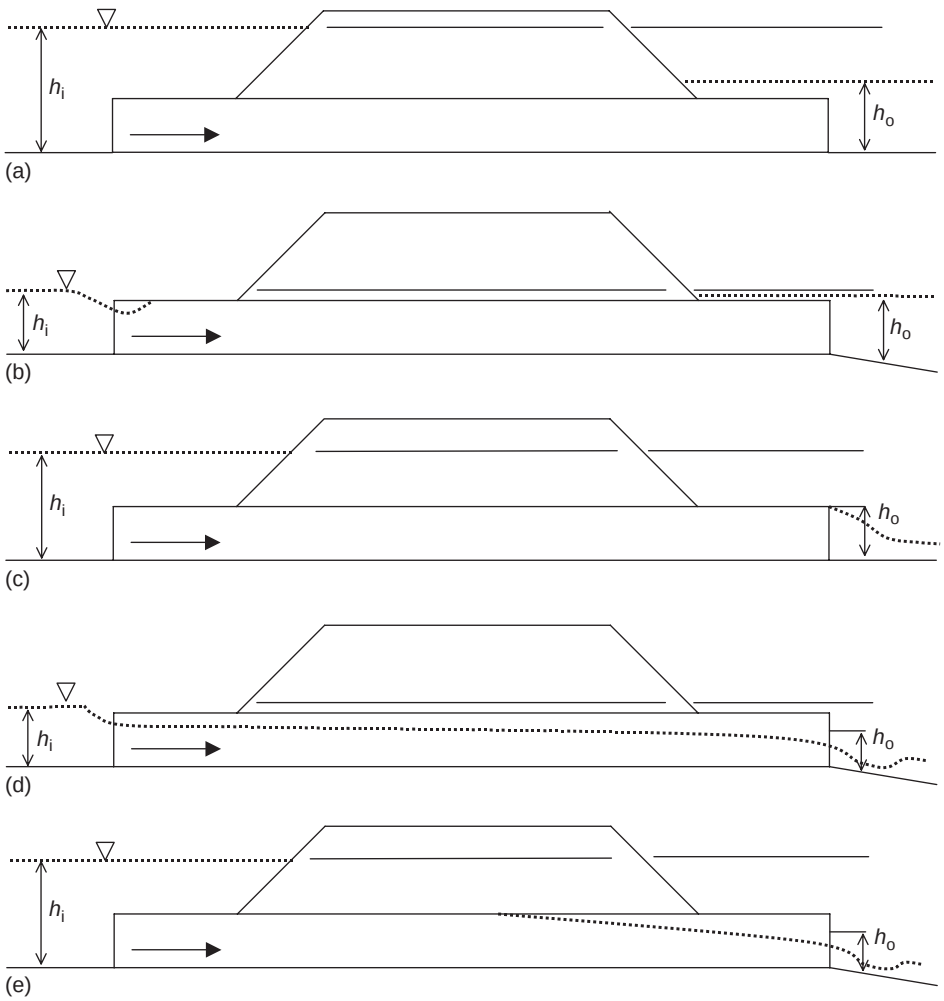

Figure 11 Outlet-controlled culverts passing beneath a road with (a) submerged inlet and outlet under full flow, (b) unsubmerged inlet and submerged outlet with full flowing barrel, (c) submerged inlet and unsubmerged outlet under full flow with normal depth greater than barrel diameter, (d) unsubmerged inlet and free flowing outlet below critical depth, and (e) submerged inlet and free flowing outlet below critical depth. Water surface is shown as a dotted line, with the arrow indicating flow direction

by (Chin, 2000)

$$Q = A\sqrt{\frac{2g\Delta h}{19.62n^2\dfrac{L}{R^{4/3}} + k_e + 1}} \tag{51}$$

$$\Delta h = h_i - h_o \tag{52}$$

For cases (d) and (e), the culvert experiences critical flow near the outlet, and discharge is predicted with an equation similar to that used for inlet-controlled flow, but depends on the friction losses in the barrel. Solutions to the discharge are implicit, as the friction losses are a function of the barrel velocity, V ($\mathrm{m\,s^{-1}}$), as well as many terms defined above. Discharge is given by (Chin, 2000)

$$Q = A_c\sqrt{2g\left(\Delta h + \frac{V_i^2}{2g} - h_e - h_f\right)} \tag{53}$$

$$h_f = \frac{n^2V^2L}{R^{4/3}} \tag{54}$$

$$\Delta h = h_i - h_o \tag{55}$$

Runoff Surcharge

Surcharge, or stormsewer discharge into lower level residences or streets, may occur when the hydraulic grade line (pressure and elevation energy slopes) rises above the crown of the stormsewer system (Mays, 1999). In such cases, drainage inlet discharge is reversed, and additional runoff may be released into gutters and roadways.

Surcharge is more common in older systems, where they may be undersized for the increased development within the drainage area and have lower capacities than in newer designs built to handle growing populations.

Stormsewer Runoff

Bisecting the urban watershed is the hydraulically improved drainage system. Drainage is often based on a combination of artificial and natural conveyance structures that collect and dispose of water. Details of stormsewer runoff exceed the scope of this chapter, and are primarily solved with application of the coupled hydraulic continuity and momentum equations to simulate the unsteady one-dimensional gradually or rapidly varied flow typical of stormwater systems. The Water Wave equations or Saint Venant equations are the coupled set of conservation of mass and momentum equations, in implicit or explicit structure depending on known variables, solved with finite difference, finite element, or the method of characteristics as described by Zoppou (2001).

The momentum equation has four components, known as *local acceleration slope, convective acceleration slope, pressure slope*, and *friction slope*. Complex routing is also achieved with simplifications to the momentum equation. The Diffusion Wave Model ignores the convective acceleration and local acceleration terms in the momentum equation, and the kinematic-wave equation, developed above, neglects the local acceleration, convective acceleration, and pressure slopes in the momentum equation. Models useful in applying these equations include StormCAD developed by Haestad Methods Software Company (Haestad, 2002) and the Storm Water Management Model (SWMM) developed for the US Environmental Protection Agency (Huber and Dickinson, 1992).

Runoff Detention and Storage

Urbonas and Roesner (1993) provide a broad overview on detention and retention facilities, which became components in urban stormwater management to limit the magnitude of hydrograph peaks in the early 1970s. Engineers size the volume of basins according to their type (e.g. detention or retention) (Mays, 1999; AASHTO, 2000; Chin, 2000), local ordinances, and the climatic patterns for rainfall. Detention basins (see Figure 12a) are designed to dry out by drainage through a low head culvert or weir outlet and infiltration through the base soils before the next rainfall event. Retention basins (see Figure 12b) are designed to remain wet between events, but drain excess storm volume through a high head riser or weir. Either basin design is able to control a range of events, from the 1.25 cm rain depths to 1-, 2-, 5-, 10-, and 100-year return interval events. Studies on the physical placement of basins have shown that when located near the mouth of a small watershed, the timing of their release may overlap with headwater flood wave arrival, which can exacerbate the flood peak, suggesting that central and headwater placement is more efficient (Urbonas and Roesner, 1993). Inflow and outflow structures for the basins must control for erosion, deposition, and scour, and need regular maintenance to remove windblown and storm-carried debris and trash (WEF/ASCE, 1998).

Storage basins attenuate the increases in runoff peak and time to peak from upslope urban development inflow

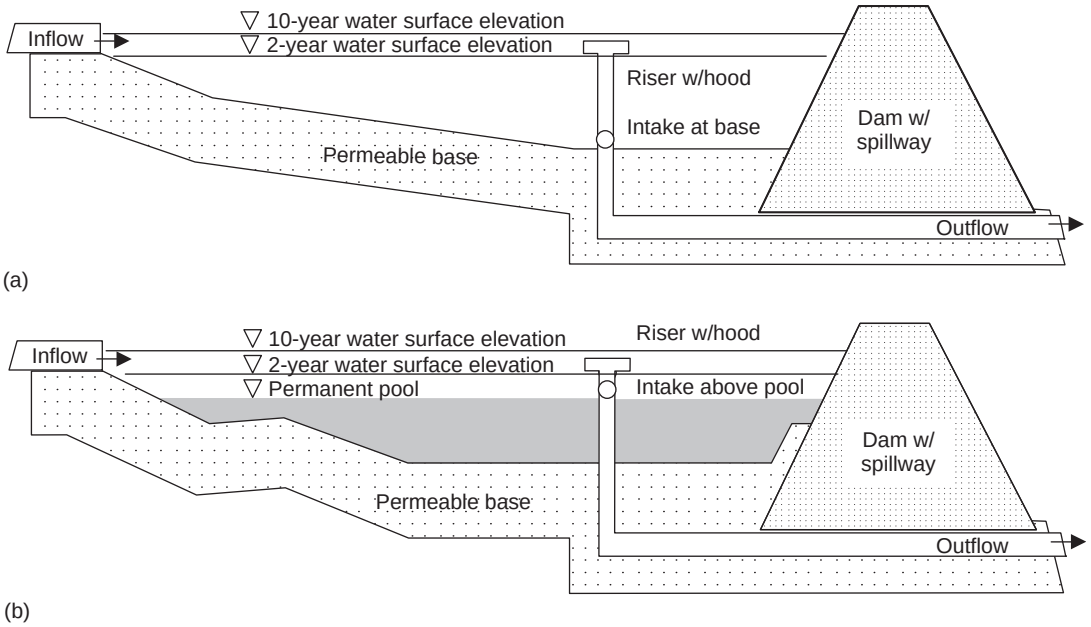

Figure 12 Storage basins for the (a) detention and (b) retention of stormwater, with the inflow, water surface elevation, riser and intake, permeable base, dam, and outflow illustrated

hydrograph by delaying the outflow hydrograph through increases in storage, as illustrated in Figure 13. Storage device outflow hydrographs as a function of time, O_t ($m^3\,s^{-1}$), are predicted given the inflow hydrographs as a function of time, I_t ($m^3\,s^{-1}$), the hydrograph time step, Δt (s), and the storage volume as a function of time, S_t (m^3), using the level pool routing continuity equation (Mays, 1999), otherwise known as *the storage indication method* (Chin, 2000),

$$\left(\frac{2S_{t=2}}{\Delta t} + O_{t=2}\right) = (I_{t=1} + I_{t=2}) + \left(\frac{2S_{t=1}}{\Delta t} - O_{t=1}\right) \tag{56}$$

Solution requires an initial estimate of the outflow hydrograph at time step 1, which is typically set to zero. The above equation is solved using a look-up table relating storage volume, or the storage stage, h (m), to discharge. Such relations often take the form of a weir or an orifice discharge function based on the outlet device. Weir-type discharge requires information about the crest length of the weir, b (m), the elevation of the water surface above the weir crest, h (m), the weir discharge coefficient (frequently set to 0.62), and are often formulated as (Chin, 2000)

$$Q = \frac{2}{3} C_d \sqrt{2g} \cdot b h^{3/2} \tag{57}$$

Orifice type discharge through a fully submerged culvert requires information on the cross-sectional area of the culvert, A (m^2), the elevation of the water surface above the center of the culvert entrance, and the orifice discharge coefficient, C_d, and is given as (Chin, 2000)

$$Q = C_d A \sqrt{2gh} \tag{58}$$

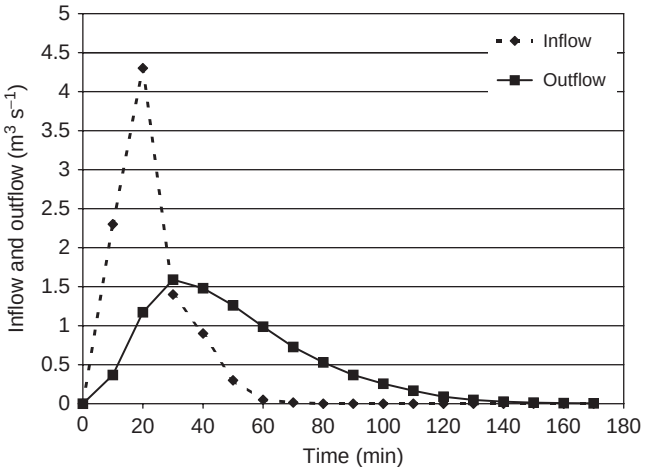

Figure 13 Illustration of how the storage in a basin can attenuate an inflow peak hydrograph by extending the falling limb of the outflow hydrograph

Subsurface Runoff Processes

Urban soils are generally more compact than rural soils, are often construction-based fill materials, receive less infiltration, have artificial conveyance devices bisecting the subsurface environment, and in places, have on-site treatment and disposal systems (OSTDS) or septic systems that provide a replenished subsurface reservoir of drainage. In areas with relatively undisturbed soil matrices, the processes of subsurface flow behave according to that described by Dr. Jeffrey McDonnell (*see* **Chapter 112, Subsurface Stormflow, Volume 3** in this series). In disturbed areas, the subsurface moisture dynamics drain toward decreasing piezometric pressure and increasing suction, but the details have not been fully characterized. Lerner (2002) points out that the dynamics of urban recharge are poorly characterized, and that much more research is needed to quantify the impacts on subsurface water stores.

An important feature for designing artificial subsurface conveyance capacity is the diffuse addition of new water sources. Infiltration and inflow (I and I) that enter storm and sanitary sewers through poor joints, cracked pipes, and the walls of manholes are a cause for some system failures and subsequent surcharge (McGhee, 1991). Inflow enters perforated manhole covers, roof drains connected to sewers, and drains from flooded cellars. Inflow is associated with runoff events, while infiltration is drawn from the soil and may occur in dry weather. Inflow may be detected by smoke tests and video to find sources (Butler and Davies, 2000). Specifications for new sewer projects limit infiltration to $45\,L\,km^{-1}\,day^{-1}\,mm^{-1}$ diameter pipe, but older systems have been as high as $35\,000–115\,000\,L\,km^{-1}\,day^{-1}\,mm^{-1}$ diameter pipe (McGhee, 1991).

Collected Urban Runoff, Channel Flow, and Receiving Waters

Runoff from urban areas is engineered to collect within river channels that leave the urban area to abate local flooding (Mays, 1999) rather than within infiltration devices to increase groundwater recharge and delay the hydrograph peak (WEF/ASCE, 1998). Infiltration devices include detention and retention basins (AASHTO, 2000), swales, infiltration trenches, bioretention devices, and percolation or exfiltration trenches (USEPA, 1999a; USEPA, 1999b; USEPA, 1999c). Porous pavements are also increasingly used to encourage infiltration on-site (Urbonas and Roesner, 1993; AASHTO, 2000).

Channel Runoff Volume

Rose and Peters (2001) analyzed stream flow and precipitation data between 1958 and 1996 on how urbanization affected river runoff between stream flow and precipitation recorded for larger (hundreds of square kilometers) urban and nonurban watersheds in the greater Atlanta, Georgia

area. The authors found that annual runoff coefficients for the urban watershed, with more than 50% of its land cover classified as urban, were not significantly different from the less urbanized watersheds, but that for the 25 largest storm flows, peak flows were 30–100% greater, storm recession was 40–100% greater, and baseflow was 25–35% smaller in the urban watershed than in the nonurban watersheds, trends explained by increased impervious cover, shorter lag times, and less infiltration. Brun and Band (2000) found similar trends in baseflow decreasing by 20%, while runoff ratios stayed relatively constant during an 18-year longitudinal study of suburban growth in a 170 km^2 watershed northwest of Baltimore, Maryland. The authors did not test for the magnitude of increases in peak flow, which likely occurred to balance the water budget.

Channel Degradation

Urbonas and Benik (1995) review stream degradation and erosion patterns resulting from urbanization in semiarid regions and provide recommendations on management strategies to check erosion and return the stream to stable conditions. They illustrate how urbanized runoff to ambient runoff ratios increase from close to 1.5 for 100-year events to 3 for 5-year, and 50 for 2-year storms in Denver, Colorado. Damages to the urban waterway, both natural and man-made, from significant increases in event peaks and volumes include gullied channels, collapsing infrastructure, eroded riparian habitat, and scoured aquatic habitat.

Several researchers have recorded a variety of stream adjustments to cross-sectional area, width, and depth due to altered runoff processes within urban and suburban watersheds. In general these studies examined how unarmored streams responded at different rates and in different directions to the increased frequency of bank full flow, watershed erosion, and alternating patterns of in-channel aggradation and degradation (Lazaro, 1979). Walesh (1989) reports on how urbanization has encouraged the shortening of rivers, thereby increasing the channel slope and increasing discharge efficiency, as predicted by discharge equations such as Manning's formulas. Such alterations are typically designed to increase the efficiency of the floodway. In the United States, the National Flood Insurance Act of 1968 generally uses the 100-year floodplain to define the floodway zone.

Hammer (1972) studied streams in 50 suburban watersheds and 28 rural watersheds of 1 km^2 in the Philadelphia region and found an enlargement ratio of stream cross-sectional area that ranged from 1 to 7, increasing with valley slopes and the extent of stormsewers. Hammer (1972) noted that the changes in stream adjustment were detectable after 4 years of development, most pronounced for development between 4 and 30 years and less severe for development greater than 30 years, possibly due to losses in the deteriorating stormwater infrastructure and healthier pervious areas with larger trees and greater infiltration. Leopold (Leopold, 1973) noted during 20 years of urbanization for Maryland's 9.5 km^2 Watts Branch watershed, the average stream cross-sectional area decreased by a ratio of 0.8.

Receiving Waters

Urban receiving waters are predominantly streams and rivers, followed by estuaries and oceans, and then lakes, small ponds, and backwater areas (WEF/ASCE, 1998). The effects of stormwater runoff on stream ecosystems is to increase the magnitude and/or frequency of runoff events, increase surface runoff and reduce subsurface runoff, and increase storm flow velocity (WEF/ASCE, 1998). The morphology of the stream changes to have an increased cross-sectional area appropriate for the higher storm flows, accelerated down-cutting of the channel base if floodplain infrastructure prevents widening, increased sediment loads due to bank erosion and possibly watershed construction, modification of the streambed material to finer material, and increased slopes by straitening. The water quality impacts of stormwater discharge on receiving waters are not discussed in this section.

MODELS FOR URBAN AND SUBURBAN CATCHMENTS

Spatially Lumped Flow Paths

Lumped subcatchment areas delineated by stormwater drainage inlets rather than DEM pixels, are often used to collect and then deliver to the stormsewer. The use of this approach is rather common, and employed by the USEPA SWMM (Metcalf and Eddy Incorporated, 1971; Huber and Dickinson, 1992), and is illustrated in Figure 14. In this approach, the effective width of the contributing area determines both the flow path length and the time of concentration. Given this direct influence on hydrograph timing and the fact that the actual width and length arrangement of irregularly shaped subcatchment areas delivering runoff to the drainage inlet are not traditionally measured, the width parameter, W, is often adjusted to calibrate the model. Figure 15 shows several possible arrangements for a subcatchment area and how these arrangements influence the time of concentration for the stormwater runoff event.

Spatially Detailed Flow Paths

An alternative to this approach is to use explicit routing across each DEM pixel. The D8 (O'Callaghan and Mark, 1984), MF (Quinn *et al.*, 1991), DEMON (Costa-Cabral and Burges, 1994), and D-Infinity (Tarboton, 1997) algorithms process raster DEM data to identify local slopes and create flow direction maps charting a path between each pixel and one or more of its adjacent eight neighbors. Pixel-specific flow direction data are then passed to a standard routing algorithm that maps flow from its source to sink.

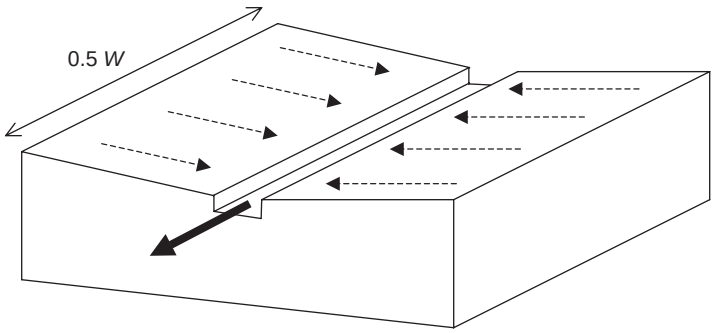

Figure 14 Aggregated subcatchment bisected by the street gutter drainage, where the total width of the contributing pixel is twice the street length. Runoff from the subcatchment is accumulated, but not simulated, as shown by the dashed arrows, and computed as the solid black arrow that goes to the drainage inlet

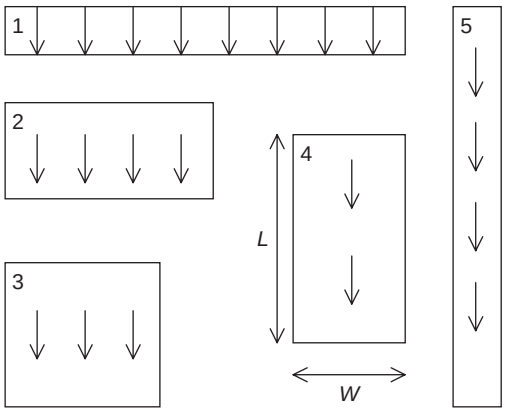

Shape	Area (ha)	W (m)	L (m)	t_c (s)

5	0.372	15.25	244.00	19.7

Figure 15 Subcatchment 1, 2, 3, 4, and 5 have the same areas of 0.372 ha, but different widths, *W* (greatest for 1 and least for 5), and lengths, *L*. Each area has a 1% watershed slope, 100% imperviousness, 0 cm of depression storage, a Manning's roughness of 0.02, a rainfall intensity of 25.4 mm h^{-1}, an equilibrium outflow of 0.026 $m^3 s^{-1}$, and a simulation time step of 300 s. The table illustrates how time of concentration, t_c, increases as *W* decreases

The D8 algorithm uses a "nearest neighbor" approach to compute elevation differences between the central pixel and its eight surrounding neighbors, and uses a steepest descent method to point to the neighbor joined by the steepest downward slope. Endreny and Wood provide a description of each algorithm and demonstrate its stability given vertical uncertainties in elevation estimates (Endreny and Wood, 2001).

Simulation of overland flow with D8, or single-sided flow in the path of steepest descent, requires an ordering scheme to route the water toward the outlet. Smith and Brilly (1992) developed an automated DEM grid-ordering algorithm for GIS-based routing to get connectivity network. The algorithm requires the filling of all sinks within the DEM, uses the D8 methodology of steepest descent to identify each grid's overland flow direction, delineates the watershed based on flow directions, identifies the number of neighbor grids that inflow into each DEM grid, flags all grids with no inflow as start grids, and flags all grids with two or more inflows as junction grids. The algorithm then makes many passes across DEM, tracing overland paths from start grids to the watershed outlet. For each start grid path, start grid and junction grid path segments are recorded. Start grid path segments begin with the start grid and end with the first detected junction grid. Junction grid path segments begin with a junction grid and end at the first down-gradient junction grid. A countervariable called *inflow* is assigned to each junction grid and increased each time the algorithm has traced an overland path through it. Listing of watershed paths proceeds by assigning the top left start grid a path number of one. When that path reaches the first junction grid, path number one terminates and path number two begins.

In the Smith and Brilly (1992) algorithm, all grids in each path are numbered based on the path number and sequence in the path, where the sequence begins at 1 and ends when a junction or outlet grid is reached. When the outlet is reached, the ordering continues at the next start grid. For this second and all subsequent passes through the DEM, if the junction grid has an inflow counter value of 1 or greater, a junction grid path segment is not created, but the inflow counter is increased. Once all start grids have been assigned a path number, they are ranked from 1 to N, where N is the number of start grids, for the connectivity network. Junction grids are then assigned a rank from $N + 1$ to $N + M$, where M is the number of junction grids, with the first rank assigned to the lowest inflow counter, and the last rank assigned to the highest inflow counter. For junction grids with identical inflow counters,

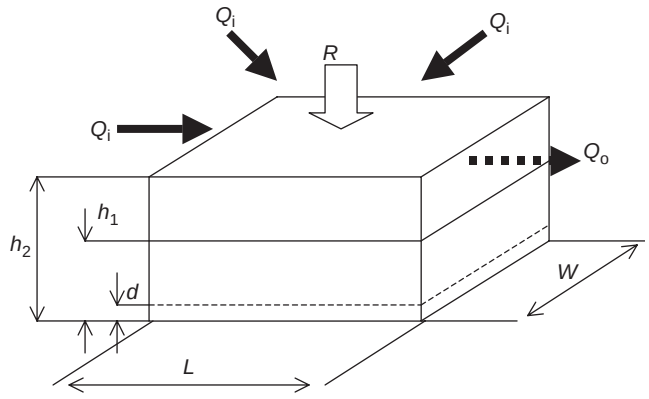

Figure 16 Cell dimensions, where the solid black arrows signify inflow from adjoining cells, the dashed black arrow signifies outflow, and the box white arrow signifies precipitation. Depth of depression storage is given as d, depth of water at the beginning and end of the time step is given as h_1 and h_2, respectively. Cell length is given as L, and width as W

rank is increased. Smith and Brilly (1992) demonstrated the utility of this connectivity network in an urban nonlinear reservoir stormwater simulation of the 9.4 hectare Gray Haven watershed near Baltimore, Maryland, where they closely matched the observed hydrograph.

Runoff Continuity

Smith (1993) developed an urban stormwater model that couples the continuity equation and Manning's turbulent flow equation for wide shallow channels to route overland flow to stormsewers, where a time shift approach rather than explicit dynamics is used. On the basis of Figure 16, a grid of width W (m), length L (m), is defined to have a depression storage depth, d (m), a water depth at the beginning of the time step, h_1 (m), with net rainfall R (m). The element has a known slope, S, Manning's surface roughness, n, and inflows, Q_i ($m^3\,s^{-1}$). Unknowns for each time step, t (s), are water depth at the end of the time step, h_2 (m), and outflow, Q_o ($m^3\,s^{-1}$). The continuity equation for the grid is written as

$$h_2 = h_1 + R + \left(\frac{\sum Q_i}{W \cdot L} - \frac{Q_o}{W \cdot L}\right) \cdot \Delta t \qquad (59)$$

$$Q_o = (h_2 - d)^{5/3} \cdot S^{1/2} \cdot \frac{1}{n} \cdot W \qquad (60)$$

Combining and rearranging the above equations gives a function of continuity,

$$f = -h_2 + h_1 + R + \frac{\sum Q_i}{W \cdot L} \cdot \Delta t - \frac{\left(\frac{h_2 + h_1}{2} - d\right)^{5/3} \cdot S^{1/2}}{n \cdot L} \cdot \Delta t \qquad (61)$$

The Newton–Raphson procedure is used to solve for h_2, which requires differentiation of the above equation.

$$\frac{df}{dh_2} = -1 - \frac{5}{6} \cdot \left(\frac{h_2 - h_1}{2} - d\right)^{2/3} \cdot S^{1/2} \cdot \frac{1}{n \cdot L} \cdot \Delta t \qquad (62)$$

$$h_{2est} = h_1 + 0.5 \Delta R \qquad (63)$$

$$h_{2est}^{new} = h_{2est}^{old} - \frac{f(h_{2est}^{old})}{\frac{df}{dh_2}(h_{2est}^{old})} \qquad (64)$$

$$\left|h_{2est}^{old} - h_{2est}^{new}\right| < \varepsilon \qquad (65)$$

The improvement achieved with each iteration of the Newton–Raphson procedure typically diminishes, and when an improvement increment is below the minimum set increment, ε, then the iteration stops.

Simulation Model Synthesis

Engineering models and methods for estimating urban runoff were presented throughout the previous sections; however, several key techniques that remain unidentified are introduced in this section. Beven provides more details on the range of modeling options for rainfall runoff simulation (see **Chapter 122, Rainfall-runoff Modeling: Introduction, Volume 3** in this series). McPherson and Schneider (1974) articulate several difficulties in modeling urban watersheds, including supply and inflow volumes associated with groundwater pumping and drinking supply reservoirs, supply associated with rainfall at adequate temporal and spatial resolution to match time of concentration, nonconsumptive use patterns by residential, commercial, industrial, and municipal facilities, loss from abstractions such as infiltration, depression storage, interception in the urban environment, and routing through stormsewer networks and surface conveyance systems. It could be contended that the urban hydrological watershed is more complex than the rural watershed due to the layering of these additional issues over the traditional permeable hydrological landscape (Overton and Meadows, 1976).

Nix (1994) categorizes urban stormwater models as simple, simple routing, and complex routing based on varying data input demands and temporal and spatial output options. Simple models without routing of runoff are typically based on empirical relations, and include the Rational Method and TR-55 Curve Number Method. Simple routing, often referred to as hydrologic routing, utilizes continuity principles to move water across space and time, but at larger temporal and spatial scales than hydraulic models. The Linear Reservoir Method or Level

Pool Method is used for simulating the outflow hydrograph based on an inflow hydrograph through a flat-water surface such as a reservoir, while the Muskingum Method is used for simulating the outflow hydrograph based on an inflow hydrograph through a wedge of water such as a river flood wave.

TR-55 is a widely adopted engineering approach based on the Curve Number method from the NRCS (formerly the SCS) used to assess the runoff impacts of watershed change (McCuen, 1998; Chin, 2000). The TR-55 approach provides estimates of effective precipitation, P_e (cm), time to peak discharge, T_p (h), and peak discharge, q_p ($m^3\,s^{-1}$) based on watershed area, A (km^2), measured precipitation, P (cm), the duration of the precipitation event, D (h), time of concentration, t_c (h), and estimated land cover Curve Number values. The CN-based approach is empirically based, and an uncalibrated model intercomparison study in Denver, Colorado and Seattle, Washington (Zarriello, 1998) demonstrated its inability to capture observed runoff as well as mechanistic models. The TR-55 method is derived from empirical studies of 24-h rainfall events in primarily range, forested, and agricultural areas, but has been adapted for storms as short as 6 h and regularly used in simple engineering assessments of urban and suburban development change for estimating hydrological impacts. Curve Number values, presented in Table 7 for various cover types for typical antecedent moisture conditions, are critical for obtaining estimates of long storm duration storage, S, that represents initial abstractions, I_a, of interception and depression storage, and storm event infiltration. When antecedent soil moisture conditions are exceptionally dry or wet, the Curve Number values should be adjusted.

$$S = \frac{2540}{CN} - 25.4 \tag{66}$$

$$I_a = 0.2S \tag{67}$$

$$P_e = \frac{(P - I_a)^2}{(P - I_a) + S} \text{ for } P > 0.2S \tag{68}$$

$$T_p = 0.5 \cdot D + 0.6 \cdot t_c \tag{69}$$

$$q_p = \frac{2.11 \cdot A \cdot P_e}{T_p} \tag{70}$$

Pilgrim and Cordery (1993) provide a review of studies that cast doubt on the application of the Curve Number method, and note that the model predictions are highly sensitive to estimates of the time of concentration and the antecedent soil moisture condition, which are not entered directly but determine the values for model input parameters. Initial abstraction in the TR-55 method is set at 20% of long-term storage, which is likely an overestimate in urban runoff analysis, but has been partially adjusted for with the selected urban and suburban Curve Number values.

The Rational Method was developed for estimating urban peak runoff, q_p ($m^3\,s^{-1}$), based on an assumed uniform intensity precipitation, i ($mm\,h^{-1}$), event across the entire watershed area, A (km^2) and an estimated runoff coefficient, C. Runoff coefficients for urban and suburban areas are provided in Table 8. When the Rational Method is used in design for sizing stormwater conveyance components, estimates of the rainfall intensity are taken from Intensity-duration-frequency (IDF) curves for a given duration and frequency event, which show rainfall intensity decrease with increasing frequency and exponentially decay with increasing duration. The frequency for urban infrastructure design is traditionally specified in local ordinances between 2 and 25 years, most commonly at 10 years, while the duration is often taken as the watershed time of concentration, t_c, to achieve the equilibrium condition of the entire watershed contribution and the maximum peak discharge.

$$q_p = 0.278C \cdot i \cdot A \tag{71}$$

Time of concentration t_c estimates for an urban watershed are obtained from numerous methods, described in detail by Chin (2000), and are most frequently derived by separately analyzing and then summing overland flow travel times, t_i (h), and conveyance elements, such as gutters or stormsewers, and travel times, t_t (h). The kinematic-wave equation is shown below and provides an estimate for the time of concentration for overland flow based on the overland flow path length, L (m), the Manning's roughness factor, n, the design rainfall intensity, i ($mm\,h^{-1}$), and the slope of the overland flow path, S. Manning's equation provides an estimate for conveyance element velocities, which are then divided into flow path length to get the time of concentration for the conveyance element.

$$t_c = \frac{6.92 \cdot L^{0.6} \cdot n^{0.6}}{i^{0.4} \cdot S^{0.3}} \tag{72}$$

The SWMM (Huber and Dickinson, 1992) is a comprehensive open-source urban runoff model developed for the USEPA. SWMM has a wide consortium of users and several private software retailers who offer enhanced graphical user interface options, such as XP Software Inc. In addition to water quality routines, sanitary flows, storage, and treatment options in SWMM, the model offers stormwater flow routing characteristics that are a function of the simulation block selected. The three blocks – the Runoff, Transport, and Extended Transport – provide a range of hydrologic and hydraulic features, which are listed in Table 9. Backwater effects, characterized by the upstream element adjusting momentum terms based on downstream element conditions, are only available in the Extended Transport Block, while the Runoff and Transport Blocks upstream elements simply

Table 7 Runoff curve numbers based on hydrologic soil type (A is well drained and D is poorly drained) for suburban and urban land use for antecedent moisture condition II and initial abstraction equal to 0.2 storage

Land-use type		A	B	C	D
Lawns, parks, golf courses, cemeteries					
Good condition, grass cover >74%		39	61	74	80
Fair condition, grass cover 50–74%		49	69	79	84
Commercial or business area, 85% impervious		89	92	94	95
Industrial districts, 73% impervious		81	88	91	93
Residential					
Lot size	% Impervious				
<0.05 ha	65	77	85	90	92
0.10 ha	38	61	75	83	87
0.13 ha	30	57	72	81	86
0.20 ha	25	54	70	80	85
0.40 ha	20	51	68	79	84
Paved parking lots, roofs, driveways		98	98	98	98
Streets and roads					
Paved with curbs and stormsewers		98	98	98	98
Gravel		76	85	89	91
Dirt		72	82	87	89

Table 8 Typical rational method runoff coefficients for a 2-year to 10-year frequency design

Surface type	Runoff coefficients
Business	
Downtown area	0.70–0.95
Neighborhood area	0.50–0.70
Residential	
Single family Areas	0.30–0.50
Multiunits, detached	0.40–0.60
Multiunits, attached	0.60–0.75
Residential (suburban)	0.25–0.40
Apartment dwelling areas	0.50–0.70
Parks, cemeteries	0.10–0.25
Playgrounds	0.20–0.35
Streets	
Asphalt	0.70–0.95
Concrete	0.80–0.95
Brick	0.70–0.85
Drives and walks	0.75–0.85
Roofs	0.75–0.95
Lawns, sandy soil	
Flat, <2%	0.05–0.10
Average, 2–7%	0.10–0.15
Steep, >7%	0.15–0.20
Lawns, heavy (clay and silt) soil	
Flat, <2%	0.13–0.17
Average, 2–7%	0.18–0.22
Steep, >7%	0.25–0.35

provide inflow for downstream elements. SWMM guidelines recommend that the Transport or Extended Transport Blocks are applied to simulate larger diameter (>762 mm) pipes and trunk sewers, and that the Runoff Block can be used for smaller diameter (<762 mm) pipes and roadside curb and gutter flow in extremely small catchments (Huber and Dickinson, 1992).

Several other comprehensive urban runoff models have been developed, but are less widely used than SWMM. Chow and Yen (1976) evaluated the Illinois Urban Storm Runoff (IUSR) method as well as the Rational Method, Unit Hydrograph Method, Chicago Hydrograph Method, Transport and Road Research Laboratory Method (TRRL), Cincinnati Urban Runoff Model (UCUR), Dorsch Hydrograph Volume Method, and SWMM in their ability to capture volumes and flowrates for several storm events, where SWMM was found to be one of the most capable. Chen and Shubinski (1971) developed an urban stormwater runoff model that routes rainfall excess via the surface runoff system given a preconstructed connectivity matrix. At each rainfall time step, the model accounts for infiltration with Horton's exponential decay function, updates detention storage based on constant values for pervious and impervious areas, and then iteratively solves for continuity between depth and Manning's overland flow from each watershed element, which is then routed to gutter flow. Gutter input is then routed as Manning's concentrated flow by iteratively solving for gutter depth and accumulates as a storm hydrograph, where all gutters join the receiving water. Watt and Kidd (1975) developed and tested an urban stormwater model in Kingston, Ontario, with surface and sewer routing that subdivided the watershed

Table 9 Flow routing characteristics of runoff, transport, and extended transport blocks (Modified from Huber and Dickinson, 1992)

Simulation feature	Runoff block	Transport block	Extended transport block
Flow Routing method	Nonlinear reservoir, cascade of circuits	Kinematic wave, cascade of conduits	Complete continuity and momentum equations, interactive conduit network
Computational expense	Low	Moderate	High
Attenuation of hydrograph peaks	Yes	Yes	Yes
Time displacement of hydrograph peaks	Weak	Yes	Yes
In-conduit storage	Yes	Yes	Yes
Backwater or downstream control effects	No	No, unless as horizontal water surface behind a storage element	Yes
Flow reversal	No	No	Yes
Surcharge	Weak	Weak	Yes
Pressure flow	No	No	Yes
Branching tree network	Yes	Yes	Yes
Looped network	No	No	Yes
Number of preprogrammed conduit shapes	3	16	8
Alternative hydraulic elements (weirs, regulators, pumps)	No	Yes	Yes
Dry weather flow and infiltration generation (base flow)	No	Yes	Yes

by drainage inlets and for each subcatchment land cover was categorized as directly connected impervious area, street-side pervious areas, disconnected impervious areas or backyards, and noncontributing areas. From detailed measurement of subcatchment areas the model first estimates Horton infiltration and allocates depression storage, and then generates surface flow based on hydrograph convolution integrals for 1-min rain interval data. The hydrographs from the multiple subcatchments are time-offset, based on pipe lengths, and routed through sewers with a Manning's velocity equation to generate the watershed cumulative hydrograph.

FUTURE DIRECTIONS IN URBAN RUNOFF

Advances in Model Simulation

Stormwater simulation models, such as the federally supported SWMM (Huber and Dickinson, 1992) and Federal Highway Administration road and gutter computations (AASHTO, 2000) or the private industry Haestad Methods Software suite (e.g. StormCAD, CulvertMaster, PondPack) (Haestad, 2002), have been central to the analysis and design of gutters and curbs, stormwater basins, culverts, drainage inlets and catch-basins, stormsewer networks, and estimation of pollutant loads. A review of urban stormwater models (USEPA, 1997; Wang *et al.*, 2000; Zoppou, 2001) reveals that they range from simple peak discharge rate and total discharge volume methods (e.g. Rational Method and TR-55) to water quality models with complex unsteady wave propagation (e.g. SWMM) or continuous, mixed land use, semidistributed, hydrologic routing (e.g. Hydrologic Simulation Program – Fortran). In general, models that utilized standard engineering design equations are capable of predicting the runoff changes to the system, such as moving from a pasture to an urban lot as illustrated in Table 10.

A new generation of engineering ecology and ecohydrology stormwater models are needed, and might borrow in part from the forest ecosystem models, such as the

Table 10 Runoff differences between a 0.4 ha developed and undeveloped site (Data from Schueler, 1994)

Runoff quantity and quality	Parking lot	Meadow
Curve number	98	58
Runoff coefficient	0.95	0.06
Time of concentration (s)	288	864
Peak discharge 2 year/24 h ($m^3 s^{-1}$)	0.12	0.01
Peak discharge 100 year/toc ($m^3 s^{-1}$)	0.36	0.09
Runoff volume 1in storm (m^3)	97.77	6.18
Runoff velocity 2 year storm ($m s^{-1}$)	2.44	0.55

Regional Hydro-ecologic Simulation System (Band *et al.*, 1991). Several advances in urban stormwater simulation are already established, and provide a basis for the modeling advances in this research. Integration of stormwater models with geographical information system (GIS) data, such as the USEPA BASINS tool kit (Endreny, 2001; USEPA, 2001a), has allowed for several improvements that enable more detailed simulation of infrastructural controls and basic ecosystem processes. Such tools enable rapid evaluation of how variation in the spatial (30-m to 0.1-m pixel side) and radiometric resolution (panchromatic to color-infrared) of the increasingly available remotely sensed land cover GIS products affect simulation of urban watershed soil moisture dynamics and stormwater predictions (Endreny *et al.*, 2003). More detailed and accurate data sets of urban infrastructure, terrain, and land cover (vegetation and paved surfaces) are coming along to advance the stormwater model development. Rauch and Bertrand-Krajewski (2002) have developed REBEKA to provide deterministic and stochastic simulation of complex urban areas, thereby integrating the latest GIS-derived information with engineering algorithms.

Another development in urban modeling that has advanced ecosystem modeling was the creation of a variable source area (VSA) model, traditionally applied to forested areas. VSA-based runoff prediction, which captures the relation between subsurface and surface moisture dynamics, was applied to urban areas by Valeo and Moin (2000) as TOPURBAN, a modification of the TOPMODEL method from Beven and Kirkby (Beven and Kirkby, 1979). TOPURBAN adapted the topographic index to remove impervious surface contributing area (e.g. DCIA) and thereby disconnect it from subsurface discharge, routing it directly to the outlet. Field studies in suburbanizing watersheds with OSTDS have shown that drainage tile leaching predicts saturation more accurately than the topographic index estimates, and further research into urban ecosystem effects are needed.

Multimedia integrated modeling systems (MIMS) provide a framework for simulating the interconnections between stormwater dynamics with vadose zone, groundwater, and receiving water dynamics. MIMS theory can provide a basis for establishing linkages at the common boundary between the different media (Gilliland, 2000), and allow for long-term simulation of storm flow and low flow conditions. Initial developments in this area are being tested in the Neuse River Basin of North Carolina, linking the atmosphere, soils, rivers, and estuary (Peters-Liddard, 2000), but an urban application is not under way.

Ecological Stresses Associated with Urban Runoff

Ecohydrology is loosely defined as the mutual interaction between the hydrological cycle and ecosystems, but has been implemented primarily as a coupled set of climate–soil–vegetation dynamic equations that attempt to replicate soil moisture and plant patterns in space and time (Rodriguez-Iturbe, 2000; Eagleson, 2002). The set of linked equations used to simulate micrometeorological forcing and plant evolution adroitly synthesizes what Harte (2002) identified as disparate Newtonian and Darwinian worldviews of the previously uncoupled engineer and ecologist. To date, the ecohydrological simulations intentionally simplify some areas, by neglecting the activities of bacteria, fungi, and animals (including human management) and the constraints of soil chemistry, to focus on complexities of vegetation form and function. In its next step ecohydrology should address features of the urban environment, by simulating human activities such as stormwater management with the associated chemical constraints, such as road salt toxicity (Wegner and Yaggi, 2001) and the limits on sorption of urban metals (Davis *et al.*, 2003).

Rodriguez-Iturbe (2000; 2003) has identified a major application area for the new field as representing hydrologic control on ecological processes through simulation, where water may be a limiting factor due to scarcity or intermittent and unpredictable appearance. Water often has such a signature in urban environments (Collins *et al.*, 2000; Zhou *et al.*, 2002), making urban applications a natural extension for ecohydrological simulation. In the modeling applications, simulations capture years to decades of soil moisture dynamics, typically at a daily time step, which take on probabilistic patterns defined by the distributions of precipitation, evaporation, soil texture, and root growth observed in nature (Guswa *et al.*, 2002; Porporato *et al.*, 2002). Future work should address how the ecohydrological simulations might represent the shorter hydraulic and hydrologic time step of urban stormwater that determines allocation between runoff and infiltration.

Hart and Finelli (1999) provide a review of several decades of work that establishes how accelerated fluctuations in flow regimes in a stream channel impact dispersal, habitat use, resource acquisition, competition, and predator–prey interactions, arguing that flow is a master variable in stream ecosystems. Booker (2003) used a 3-D computational fluid dynamics (CFD) model, SSIIM, to simulate urban flows and their associated hydraulic forces in two reaches of the upper Tame River, UK to examine whether fish species' maximum sustained swimming speed was exceeded by an overpowering river with excessive shear. Paul and Meyer (2001) identified the amount of impervious surface as a predictor of stream ecological impacts, with replacement of vegetation along riparian corridors with urban structures and impervious cover having greater impacts than development farther removed from the stream.

Finkenbine *et al.* (2000) demonstrated in streams around Vancouver, BC, that even at 5% impervious cover fish survival was impacted, but with in-stream large woody debris and riparian habitat, stream fish communities began to re-equilibrate. The study did not explain the mechanisms for this trend, but noted the establishment of coarser material in urban streams as providing some fish habitat counterbalanced by an absence of large woody debris and fine sediments common in rural reaches. McMahon and Cuffney (2000) were able to use the National Water Quality Assessment (NAWQA) to identify a relationship between intensity of urbanization based on land cover, but not explicitly impervious surface, and biological, chemical, and physical water quality parameters, in a variety of geographic areas. Ecologically based urban hydrology research in Europe, such as that by Krebs and Larsen (1997) and findings from the German-hosted Urban Drainage Modelling conference series, is pioneering the use of sustainability metrics for urban drainage design, and signals new frontiers in stormwater investigations.
