118: Land Use and Land Cover Effects on Runoff Processes: Agricultural Effects

TIMOTHY P BURT[1] AND MICHAEL C SLATTERY[2]

[1]*Department of Geography, University of Durham, Durham, UK*
[2]*Institute of Environmental Studies, Texas Christian University, Fort Worth, TX, US*

The impact of agriculture on runoff processes cannot be underestimated. The greatest impact is usually on soil surface conditions, specifically infiltration. Undisturbed soils have much higher infiltration capacity than soils in agricultural land. Once cultivated, soils become easily compacted as they are laid bare to the elements until the next crop develops a protective cover. Infiltration can fall to levels where infiltration-excess overland flow can occur even in rainfall of modest intensity. Successive rainfall events compact the bare soil further and impermeable crusts often form. Heavy machinery used in agriculture exacerbates soil compaction, particularly at depth, via the development of plough pans. These compacted, dense layers have significantly higher bulk density and lower total soil porosity than the soil directly above or below it and frequently become preferential zones of runoff generation. Temporary saturation of shallow topsoil layers leads to topsoil saturation overland flow that, if connected to the channel network, may become a significant contributor to event response. Linear zones of compaction and reduced hydraulic conductivity that occur as a result of vehicular traffic have similar impacts.

CONTROLS ON STORM RUNOFF GENERATION

Whenever land is cleared for agriculture, the impact on local hydrology is likely to be immediate and obvious. The greatest impact is usually on soil surface conditions: deforestation exposes the soil surface to rainfall, and even where revegetation is rapid, the hydrology of the newly vegetated area, whether grass or shrubs, is very different from that of a mature forest canopy. Even if left to recover naturally, it can be several years before the system recovers to its previous state. Where present, grazing animals will compact the soil surface, which is then in a condition very different from the erstwhile open structure of the undisturbed soil. If the soil is being farmed for arable crops, the soil surface is continually laid bare to the elements, vulnerable until the next crop develops a protective leaf cover. Later improvement to farmland may further alter hydrological condition, for example, through the introduction of ditches or underground drainage. Compared to an area of, say, natural forest, agriculture affects the entire hydrological cycle: the water balance changes because the balance between evaporation and runoff is altered; usually, the land becomes more responsive to rainfall and storm runoff increases. If cultivation ceases, changes in broadly the opposite direction will occur.

The dominant controls of storm runoff generation are climate and soil, with topography as an important secondary variable at the subcatchment scale (Dunne, 1978; Anderson and Burt, 1990). Kirkby (1978) identified the crucial role of soil hydraulic conductivity in relation to rainfall intensity. He recognized domains dominated either by infiltration-excess overland flow, in places where infiltration capacity is low compared to rainfall intensity, or by a combination of subsurface stormflow and saturation-excess overland flow in places where rainfall intensities are low and the soil is relatively permeable. Of course, in some situations, certain soils will straddle the boundary between these two domains. As will be seen later, this will very often occur on farmland when deterioration of soil surface condition results in a much lower infiltration capacity than ought to be the case.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Runoff theories based on the occurrence of infiltration-excess overland flow were championed by Horton (1933, 1945), a hydraulic engineer who worked mainly in the heavily farmed regions of the American Midwest. Horton argued that the soil surface divides rainfall, one part flowing quickly to the stream as overland flow, while the other part infiltrates the soil, where it is stored, eventually draining to the stream or evaporating. Horton (1933) showed that for all soils, infiltration capacity fell during the course of a storm, eventually reaching a constant minimum level. High-intensity rain might produce overland flow immediately, while lower intensity rain would only produce overland flow once the initially high infiltration capacity had declined; low-intensity rainfall might produce no surface runoff at all. The Partial Area model of Betson (1964) remains the best guide to the location of runoff source areas for infiltration-excess overland flow. Horton argued that surface runoff would be widespread across an area, but this can only be the case if both rainfall intensity and infiltration capacity are uniform though space and time. In fact, overland flow is both unsteady and spatially varied since it is supplied by rainfall and depleted by infiltration, neither of which is necessarily constant with respect to time and location (Emmett, 1978). Betson stressed that overland flow is localized, generated from only certain parts of a drainage basin. In contrast to the Variable Source Areas described in the subsequent sections, partial source areas of overland flow appear relatively fixed in location within a given storm event.

Subsurface stormflow may be generated by two mechanisms: by non-Darcian flow through macropores or pipes; and by Darcian flow through the soil matrix. Horton assumed a semi-infinite soil where storage effects were unimportant, but in most soils, the character of the different horizons dictates that hydraulic conductivity declines with depth, often dramatically at a horizon boundary or where there is impermeable bedrock immediately beneath the soil (Note that this decline with depth is not always the case, for example, in areas of blanket peat or glacial till). Once percolating water begins to build within the soil, unless the ground is flat, soil water will begin to drain downslope. In appropriate circumstances, the subsurface response can be rapid enough to generate stormflow (Anderson and Burt, 1990). If soil water storage is limited so that the upper soil horizon becomes saturated, any excess rainfall must pond on the surface and will then produce saturation-excess overland flow; this can occur at rainfall intensities that are much lower than infiltration capacity. Soil saturation will tend to occur in relatively localized zones: in hillslope hollows; at the foot of slopes, especially where the slope profile is concave; and where the soil is thin. However, unlike the source areas for infiltration-excess overland flow, which are relatively fixed during a given storm event, source areas for saturation-excess overland flow can expand during a storm as the areas of soil saturation expand. On this basis, John Hewlett defined his Variable Source Area model, to describe surface runoff generation in areas where soil storage rather than infiltration capacity controls the occurrence of surface runoff. Whilst Hewlett's model was developed in the forested basins of the southern Appalachians, it is equally applicable in nonforested basins too. Note that the source areas for saturation-excess overland flow and subsurface stormflow are essentially identical since the same processes control the occurrence of both types of runoff.

PLOT SCALE: LAND USE AND OVERLAND FLOW ON AGRICULTURAL LAND

To elaborate on Horton's model for partitioning rainfall, when rainfall that has not been intercepted by vegetation reaches the soil surface, it will all infiltrate the soil unless the rainfall intensity exceeds the infiltration rate. In the latter case, only part of the rain infiltrates, part fills small surface depressions, and the remainder, if any, moves across the surface as overland flow. Infiltration rate is defined as the maximum rate at which water can enter into the soil. It is highly variable, depending on rainfall intensity, soil, vegetation, and slope gradient. At any given point, it will vary among storms depending on the soil-moisture content and the changing character of the soil surface, and will decrease during the course of a storm event. Infiltration rate is measured using a ring infiltrometer or a rainfall simulator (Rawls *et al.*, 1993); in neither case is the area of measurement usually very large compared to that of even a small drainage basin, so most reported values are in essence point values.

Given the importance of overland flow for erosion, there have been many studies of infiltration in agricultural soils; the effect of land use on infiltration and surface runoff is immediately apparent. For example, Table 1 shows results from an area of silty-clay loam soils. These soils have a naturally high infiltration capacity, but are easily compacted so that infiltration can fall to a level where infiltration-excess overland flow can occur even in rainfall of modest intensity. Several points are worth making in relation to the results presented in Table 1. Perhaps the most important is that undisturbed soils in woodland have much higher infiltration capacity than soils in agricultural land; intensity of land use correlates broadly and inversely with infiltration capacity. Measurements show that in this area infiltration rate can fall to a very low level if (wet) soils become compacted by mismanagement – by grazing or by the use of heavy machinery at inappropriate times. Bare soil is not necessarily the worst case, although, as will be seen later, the lack of vegetation cover does render the soil very vulnerable to overland flow and erosion. High infiltration rates may occur where tillage or shrinkage cracks have opened up the soil surface.

Table 1 The effect of land use on surface runoff at Slapton, Devon, England

Land use	Rainfall intensity ($mm\,h^{-1}$)	Infiltration rate ($mm\,h^{-1}$)	Surface bulk density ($g\,cm^{-3}$)
Temporary grass	12.5	12.3	0.96
Barley	12.5	11.0	1.08
Rolled, bare soil	12.5	4.0	0.93
Lightly grazed permanent pasture	12.5	5.9	1.12
Heavily grazed permanent pasture	12.5	0.1	1.18
Permanent pasture[a]		9 (range: 3–36)	
Freshly ploughed soil[a]		50	
Woodland soil[a]		180	

Data from Heathwaite *et al.* (1990), Burt *et al.* (1983), Burt and Butcher (1985).
[a]Results obtained using a rainfall simulator except where indicated.

Table 2 Final minimum infiltration rate in relation to soil texture. Based on information contained in Rawls *et al.* (1993)

SCS hydrologic soil group	USDA soil textures included in group	Final infiltration rate ($mm\,h^{-1}$)
A	Sand, loamy sand. Sandy loam	7.6
B	Silt loam, loam	3.8–7.6
C	Sandy clay loam	1.3–3.8
D	Clay loam, silty-clay loam, sandy clay, silty clay, clay	0–1.3

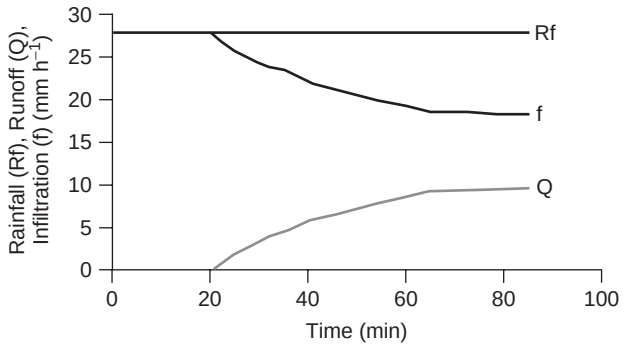

Figure 1 Results from a rainfall simulator experiment for a loess soil near Heidelberg, Germany, showing rainfall (Rf), runoff (Q) and infiltration (f) rates

Table 2 indicates the broad relationship between soil texture and final minimum infiltration rate. The hydrologic soil groups are those defined by the US Soil Conservation Service and the USDA (US Department of Agriculture) soil texture classes normally assigned to each group are indicated. It is clear that fine-grained soils have generally lower infiltration rates, unsurprising given the general link between soil texture and pore size. Whilst the values given can only be broadly correct, they do nevertheless indicate the order of magnitude for soil infiltration rates; the values suggest that, even in temperate regions, rainfall intensities can regularly exceed infiltration rate. It used to be argued that infiltration-excess overland flow was only commonplace in tropical regions, where very high rainfall intensities occur often, or in places where the soil had been mismanaged. However, many field observations over recent decades have shown that infiltration-excess overland flow can be commonplace in very many different circumstances and is by no means the rarity it was once claimed to be.

Figure 1 shows a typical infiltration curve for a loess soil; the results were obtained from a drip-type rainfall simulator (Bowyer-Bower and Burt, 1989). Rainfall intensity was constant throughout the experiment at 27.8 mm per h. No runoff occurs until 20 min after the start of the rainfall; before this point in time the infiltration rate would have been too high for ponding to occur. Once infiltration rate is exceeded, water ponds on the surface; soon after there is overland flow. After approximately 80 min there is equilibrium between rainfall and runoff, infiltration rate having fallen to a final, constant minimum. In this case, the decline in infiltration rate may just not be an effect of the soil becoming wetter, but also because the bare soil surface is compacted and sealed by the impact of raindrops; loess soils are particularly vulnerable in this respect. Imeson and Kwaad (1990, Figure 2) showed how, over the course of a growing season, infiltration rate could fall from an initially very high figure immediately after tillage to almost zero; successive rainfall events compact the bare soil and in between each event an impermeable crust forms. There is a "window of opportunity" for a crust to form while the soil is unprotected by vegetation cover: if the new crop grows quickly and there are few heavy falls of rain, a crust may not form before the soil surface becomes protected by leaf cover (30% cover is usually reckoned to be "safe", although it should be noted that this yardstick is without precise scientific foundation). However, once a crust is present, it may persist until the soil is ploughed again; overland flow can therefore be generated regularly over a large fraction of the crop cycle if a combination of heavy rainfall and poor crop growth prevails early in the growing season. This

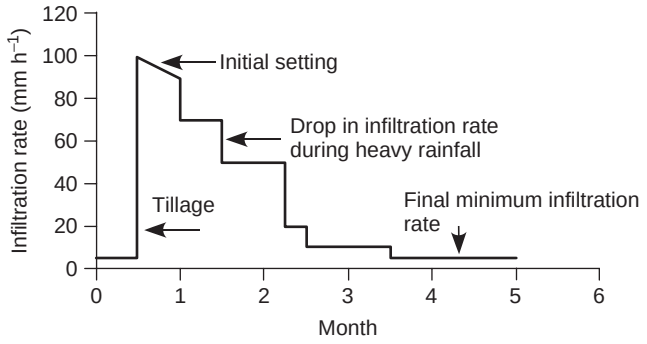

Figure 2 Change in infiltration capacity over a crop cycle for a soil with a tendency to crust (Reproduced from Imeson and Kwaad, 1990 by permission of John Wiley & Sons, Ltd)

shows the need for a new crop to become well established before the wet season and for periods of bare soil to be minimized where possible. Slattery and Burt (1996) showed that the crust can breakdown later on, disturbed by root growth or frost action.

Note that in some countries, frozen soils in agricultural areas can be a factor encouraging overland flow during several months of the year (Harris, 1972). This may be important, not only in relation to the generation of storm runoff, but also in controlling soil-moisture levels during and after the melt season (Granger *et al.*, 1984; Willis *et al.*, 1961). On the other hand, freezing conditions can also break up crusts, so that the infiltration capacity is much higher afterwards (Burt and Slattery, 1996). In some climates, duricrusts or iron pans may form at depth, in some cases limiting infiltration and in others percolation at depth (Goudie, 1985). The effect of compacted layers at depth is further explored in the next section.

TILLAGE IMPACTS AND THE GENERATION OF SATURATION-EXCESS OVERLAND FLOW

In modern agriculture, heavy machines used to pull implements, apply fertilizers, or harvest crops can create yield-limiting soil compaction. Certain tillage implements such as the moldboard plough and the disk harrow compact the soil below their working depth even as they lift and loosen the soil above. Repeated use of these implements at the same depth can form plough pans (often called *tillage pans*), dense zones immediately below the ploughed layer (Figure 3). Plough pans are generally relatively thin (3–6 cm), compacted soil layers having a significantly higher bulk density and a lower total porosity than the soil directly above or below it. Following 10 years of continuous corn tillage on a clay loam soil at Waseca, Minnesota (Bauder *et al.*, 1981), a dense compacted layer was detected

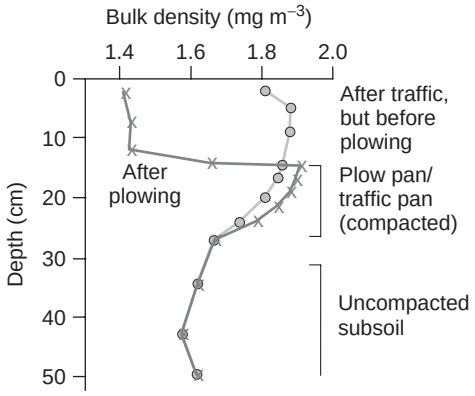

Figure 3 Change in bulk density with soil depth before ploughing (circles) and after ploughing (x's) showing the formation of a combined plough pan and traffic pan at 15–25 cm. The traffic pan is compaction at depth from tires of tractors and other heavy equipment. Bulk densities in excess of 1.8 Mg m^{-3} prevented the penetration of cotton roots in this case (after Voorhees, 1984). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

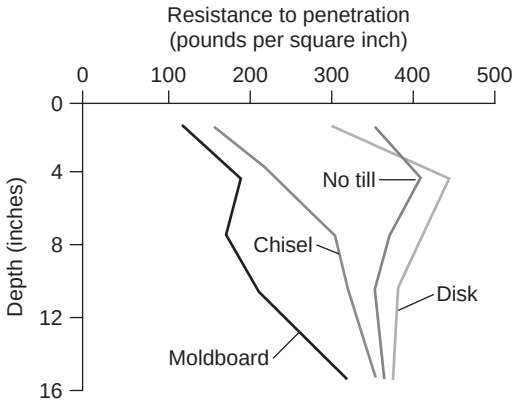

Figure 4 Soil resistance to penetration after 10 years of continuous tillage for four tillage systems (after Bauder *et al.*, 1981). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

just below the depth of tillage (4 inches) on the disk treatment (Figure 4). A cone penetrometer was used to register soil strength, and the greatest force required to penetrate the top 12 inches was measured on the plot that was spring-disked and had no other tillage. Other implements such as chisel ploughs do not press down upon the soil beneath them and thus are useful in breaking up plough pans and stirring the soil with a minimum of compaction.

While tillage pans may not have a significant effect on crop production, and can be alleviated by varying depths of tillage over time or by special tillage operations, they do become preferential zones of runoff generation, specifically as it relates to saturation-excess overland flow. This is

because plough pans are characterized by significantly decreased hydraulic conductivity. On the Texas High Plains, for example, infiltration studies reveal that some soils with a high bulk density plough pan will absorb only 6 cm of moisture in 24 h; similar soils without a plough pan will absorb more than three times the amount in the same period. In these situations, soil saturation begins to buildup above the plough pan; percolating water accumulates above the low-conductivity layer to form a temporarily saturated zone that is not connected to a regional groundwater flow (Figure 5). This situation is referred to as a *perched zone of saturation* (see Burt (1986) for a detailed description of the process mechanisms involved). Bergsma *et al.* (1984) called this *topsoil saturation overland flow*, as shown in Figure 5, where temporary saturation of a shallow topsoil layer occurs above the relatively impermeable pan. In this case, subsurface stormflow can be a significant contributor to event response, especially if it occurs in areas that are well connected to the stream. Saturation-excess overland flow may occur towards the foot of the slope if the subsurface discharge exceeds the transmissivity of the soil above the plough pan.

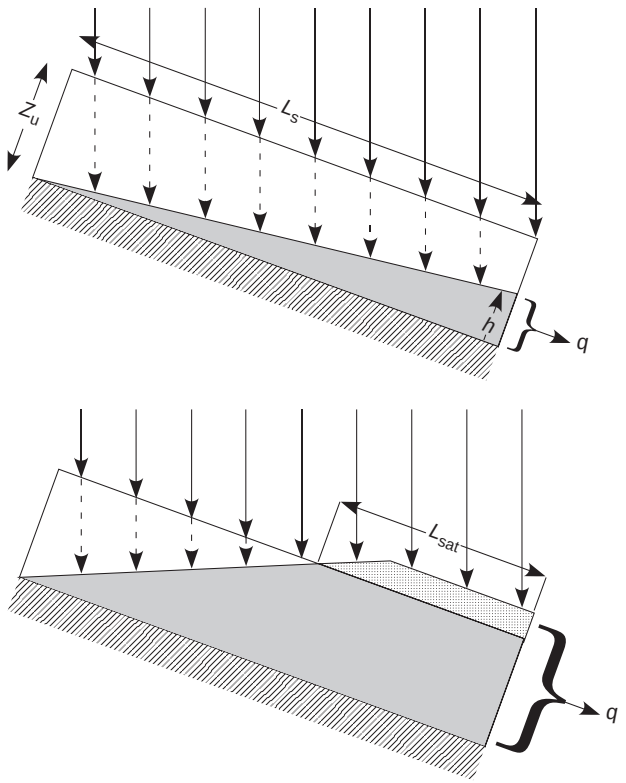

Figure 5 Cross section showing the formation of a perched saturated zone above low-conductivity layer, such as a plough pan, with constant slope and soil thickness. Z_u is soil depth, L_s is slope length, L_{sat} is the length of the zone of soil surface saturation, h is the depth of the saturated wedge, and q is the slope discharge

SCALING UP FROM HILL SLOPES TO CATCHMENTS

While plot studies have significantly enhanced our understanding of runoff generation, it is difficult to extrapolate the results from bounded plots to the scale of the field or catchment. Plots are hydraulically simple compared to the hydrological behavior of watersheds, and they fail to reproduce the complex topography that commonly characterizes both individual fields and whole catchments. Of greater significance, however, is the lack of *connectivity* inherent in bounded plots – that is, the study of runoff generation from a small plot tells us nothing about the delivery of runoff to the stream channel. A basic question central to our conceptualization of how catchments work remains simply this: how are runoff source areas linked to the stream?

In the context of agricultural catchments, features that help link slope and stream include: (i) linear zones of compaction and reduced hydraulic conductivity that occur as a result of vehicular traffic; (ii) convergent topography; and (iii) plough pans. However, it is also important to consider features that interrupt flow paths: these include hedgerows, ponds, and riparian buffer zones. Further discussion on landscape sensitivity in relation to runoff production can be found in Burt (2001).

While rills are generally located on valley-side slopes as a result of the hydraulic shear stress exerted by runoff, they often form along the base of depressions and dry valley bottoms where surface runoff concentrates because of ground surface convergence. These rills have been referred to as *ephemeral gullies, thalweg (or talweg) gullies, and valley-bottom rills* (Boardman, 1988; Poesen and Govers, 1990; Auzet *et al.*, 1993), and are features of many erodible agricultural landscapes, particularly in northwestern Europe, where they have been widely reported. Of course, it is not the agricultural activity *per se* that causes flow convergence in valley bottoms. Rather, it is the tractor wheelings (the compacted lines of soil formed by the passage of vehicles) that generates disproportionate volumes of surface runoff, which then converges in these valley bottoms and scours the soil surface down to the plough pan. Slattery *et al.* (1994), for example, describe an extensive thalweg rill system in a field in north Oxfordshire, UK, supplied with runoff and sediment by a series of "feeder rills" developed along the steeper valley-side slopes that had incised into the soil surface along vehicle wheelings. The importance of wheelings in contributing to runoff has been noted in many areas of the United Kingdom, such as the sandy soils of the West Midlands (Reed, 1983) and the silty soils of the South Downs (Boardman and Favis-Mortlock, 1992). In the North Oxfordshire study, the vehicle wheelings were characterized by very low infiltration levels, $5\,mm\,h^{-1}$ compared to $64\,mm\,h^{-1}$ on the adjacent cultivated surface (Slattery *et al.*, 1994). Wheelings were also shown to be significant zones of runoff generation (and sediment transport) on a

4.5-ha field planted to tobacco on the North Carolina coastal plain (Slattery *et al.*, 1997; Figure 6).

The thalweg rill system described by Slattery *et al.* (1994) developed on cultivated slopes that had been left bare throughout the summer months and drilled in late August with winter wheat. This produced smooth, highly crusted slopes that generated widespread surface runoff often under relatively low-intensity winter rainfall. In this case, runoff from the thalweg rill flowed into adjacent downslope fields but then infiltrated. In other instances, however, runoff from source areas apparently isolated from the stream network can become connected to the main river channel. This raises the complex issue of source-flow path connectivity and challenges current thinking on rainfall-runoff relations, particularly the rather simplistic, mechanistic notions underlying the variable source area and partial area concepts.

Slattery *et al.* (in press) demonstrated direct slope-channel connectivity, and the importance of compaction zones along vehicle tracks, in a study of runoff generation in a 19.4 ha watershed on North Carolina coastal plain cropland. These authors monitored a rill system draining cultivated cotton fields on low-energy slopes <0.003. The main rill, shown in Figure 7, incised along a vehicle track and discharged directly into the main channel, some 100 m from the basin outlet. The study was unusual because the slope runoff was measured during a tropical storm and two hurricanes. The slope and basin hydrographs from the Tropical Storm Arthur are shown in Figure 8. The storm generated 22.9 mm of rain over a period of 14 h, although 9.9 mm fell during a 10-min downpour between 16:48 and 16:57. Runoff was generated within the rill almost instantaneously, reaching a discharge of $28.9\,l\,s^{-1}$ at 16:53, with 4.8 mm of rain having fallen in the three minutes prior to

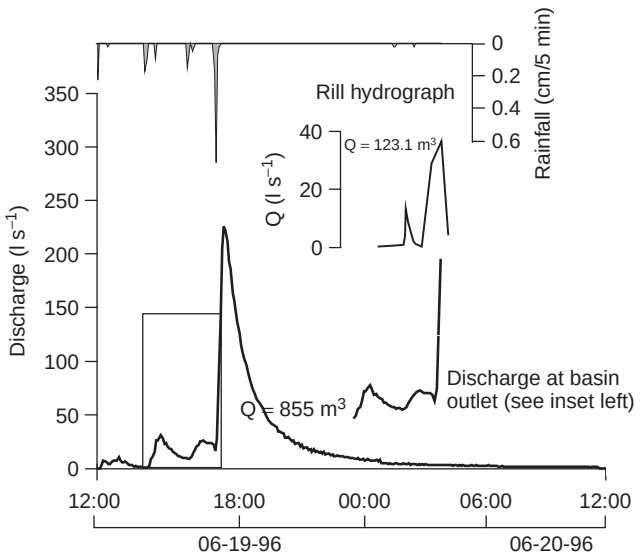

Figure 8 Comparison of hillslope and basin hydrographs during Tropical Storm Arthur in the Clayroot basin, North Carolina (after Slattery *et al.*, in press)

this measurement at a maximum intensity of $96.5\,mm\,h^{-1}$. Flow then quickly broke the banks of the rill channel and no further measurements were possible until the runoff had become reconfined within the rill walls. An estimated peak rill discharge of $44\,l\,s^{-1}$ at 17:08 corresponds to a discharge in the main channel at this time of $179.1\,l\,s^{-1}$ (peaking 7 min later at $224.9\,l\,s^{-1}$). In total, the rill on this field generated $123.1\,m^3$ of runoff, or 14.4% of the storm total for the entire basin. It is noteworthy that this single rill, with a total contributing area of <3% that of the basin area, contributed such a disproportionately large volume of runoff to the total event flow. As noted earlier, Betson (1964) first

formalized this view as the partial area concept, and in rural basins these areas are mainly roads and tracks plus the occasional field where a compacted soil surface causes surface flow. In either case, the total area involved is very often no more than 5% of the basin (Burt and Slattery, 1996).

The work referred to in the preceding section indicates that connectivity in catchments is clearly critical for determining the travel distances of overland flow and hence the amount of flow that exits the slope as channel discharge. If linear features such as roads and vehicle wheelings are fragmented, because of the presence of barriers within the landscape (Burt, 2001), the runoff will infiltrate a short distance downslope, as was the case in the North Oxfordshire thalweg rill example described earlier. Greater connectivity, on the other hand, allows the runoff to travel further and hence become stream discharge. The task then becomes one of elucidating hydrologic connections and disconnections across various scales within complex landscapes (McDonnell, 2003; Burt and Pinay, in press).

119: Land Use and Landcover Effects on Runoff Processes: Forest Harvesting and Road Construction

LA SAMPURNO BRUIJNZEEL

Department of Hydrology and Geo-Environmental Sciences, Vrije Universiteit, Amsterdam, The Netherlands

The hydrologic impacts of various forestry operations are reviewed, notably the effects of thinning, selective harvesting, clear-cutting with and without roads, and removal of understorey or riparian vegetation. Thinning and selective logging have a relatively modest effect on amounts of rainfall reaching the forest floor unless at least 70% of the standing biomass is removed. The effect on soil water and streamflow is smaller still, mostly because of the increased vigor of the remaining vegetation. Removing understorey vegetation produces a similarly small effect. The annual water yield is invariably increased in proportion to the amount of biomass harvested, with the exception of forests subject to high fog incidence or old-growth forest of low vigor. Cutting riparian vegetation produces a larger increase in streamflow (compared to cuts away from the streams) under subhumid conditions and shallow water tables only. The largest seasonal increases in flow after clear-cutting are normally observed at times when water deficits in the undisturbed forest are highest. The gains in streamflow after clear-cutting gradually disappear when regrowth is allowed, the effect lasting longer where soils are deeper and forest regeneration slower. Mechanized harvesting practices and road building both increase stormflow volumes and peak discharges. The relative effect diminishes with storm size in the case of clear-cutting only, but increases in the case of roads only. Similarly, effects of forest cutting per se on stormflows are "diluted" at larger scales, but the effect of the associated road network is not. Various measures are discussed to minimize the adverse hydrologic impacts of timber harvesting operations.

INTRODUCTION

Trees and forests are widely valued for timber and other forest products, for biodiversity, as well as for the general well being most people derive from being in their proximity. It has long been appreciated by both scientists and the general public that a forest cover influences micro climatic and soil conditions and therefore the amount of water flowing from forested areas. In the words of Zon (1927): "Of all the direct influences of the forest, the influence upon the supply of water in streams and upon the regularity of their flow is the most important in human economy". However, with populations rising explosively in some parts of the world, and per capita demands for water, timber, and other forest products increasing in others as living standards continue to improve, the pressure on the world's remaining forests is increasing steadily. In many areas, headwater forests serve as the traditional suppliers of high quality water and there is a widespread belief, particularly in the tropics, that mechanized logging operations or forest removal *automatically* results in increased flooding and massive soil degradation. Although this traditional view of the hydrologic functioning of forest came under (judicious) scrutiny in the early eighties of the last century (Hewlett, 1982; Hamilton and King, 1983; Bruijnzeel, 1986), there is a tendency among the current, more policy-, and socioeconomically oriented generation of forest hydrologic "myth busters" (e.g. Calder, 1999; Calder and Aylward, 2004; Kaimowitz, 2004; *see* **Chapter 187, Land Use Impacts**

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

on Water Resources – Science, Social and Political Factors, Volume 5) to overemphasize the greater water use of forests and to undervalue some of the more positive hydrologic aspects of a well-developed forest cover, such as improved infiltration and moderation of stormflow volumes in all but the most extreme cases, as well as protection against surface erosion and shallow landslides (Bruijnzeel *et al.*, 2004). When discussing the environmental impacts of logging or forest clearing, it is essential to take into account the specific climatic, topographic, and soil conditions in the area under consideration rather than apply blanket generalizations (Bruijnzeel, 2004). Given the current pressure to exploit the world's remaining forests, a sound understanding of the hydrologic functioning of forests (both pristine and "managed" ones) is arguably more important than ever.

This article aims to review the current state-of-knowledge with respect to the ways in which the main forest hydrologic processes are affected by various timber harvesting operations and related activities, such as thinning, selective logging, clear-felling, and road building. In doing so, the principal focus will be on the more humid parts of the world (both temperate and tropical), while paying particular attention to the changes in amounts and timing of streamflow. Hydrologic processes (including runoff generation) under conditions of snow and frost are dealt with in articles **Chapter 162, Hydrology of Snowcovered Basins, Volume 4**, **Chapter 114, Snowmelt Runoff Generation, Volume 3**, and **Chapter 71, Freezing and Thawing Phenomena in Soils, Volume 2**, whereas issues of water quality and biogeochemical cycles are discussed, *interalia*, in article **Chapter 93, Effects of Human Activities on Water Quality, Volume 3**. Before presenting the evidence, the article starts with a definition of terms (forest hydrologic processes, methods of evaluating changes in streamflows, timber harvesting techniques). It concludes with a summary of "best management practices" (BMPs) that are recommended if timber harvesting operations are to be compatible with the maintenance of hydrologic values and high quality water supplies (see Dykstra and Heinrich, 1996; Cassells and Bruijnzeel, 2004).

The Forest Hydrologic Cycle

The principal components of the forest hydrologic cycle are shown in Figure 1. Rainfall (P) is the most important input of water to most forests, with snow added at higher elevations and latitudes (*see* **Chapter 162, Hydrology of Snowcovered Basins, Volume 4**), and so-called "occult" precipitation (fog) in coastal or montane fog belts (*see* **Chapter 38, Fog as a Hydrologic Input, Volume 1**). A small proportion of the precipitation reaches the ground without touching the canopy ("direct" throughfall). Another (usually small) part flows along branches and stems as stemflow (Sf). A considerable portion of the precipitation hitting the canopy evaporates back into the atmosphere during and shortly after the storm (interception loss, Ei), while the remainder reaches the forest floor as crown drip. Because it is impractical to separate direct throughfall and crown drip, the two are usually lumped and simply referred to as *throughfall* (Tf). The sum of throughfall and stemflow is often termed *net precipitation* and normally substantially smaller than P, unless there are significant (and usually unmeasured) contributions by occult precipitation (CW; *see* Bruijnzeel, 2000; **Chapter 38, Fog as a Hydrologic Input, Volume 1**).

If the intensity of net precipitation falling on sloping ground exceeds the capacity of the soil to absorb the water, the excess runs off as "Hortonian" or "infiltration-excess" overland flow (HOF). Given the generally high absorption capacity of the organic-rich topsoil in most forests, this type of flow is rarely observed in undisturbed forest unless there is an unusually dense clayey substrate or an excessive concentration of stemflow. Not all of the water infiltrating into the soil emerges again as streamflow. A considerable part is taken up by the roots of the vegetation and returned to the atmosphere via transpiration (Et). The term evapotranspiration (ET) is often used to indicate the sum of transpiration (evaporation from a dry canopy), interception loss (evaporation from a wet canopy), and evaporation from the litter and soil surface (Es) (*see* **Chapter 42, Transpiration, Volume 1** and **Chapter 43, Evaporation of Intercepted Rainfall, Volume 1**). The latter term is usually small, especially in dense forests where little radiation penetrates to the forest floor; humidity is maintained at high levels and ventilation is limited (*see* **Chapter 39, Surface Radiation Balance, Volume 1** and **Chapter 45, Actual Evaporation, Volume 1**).

If not obstructed by an impermeable layer in the soil, the water not taken up by the vegetation will move to the groundwater table via vertical and lateral downslope percolation and then flow laterally to the nearest stream as groundwater (Figure 1). Alternatively, it may be deflected upon meeting impermeable subsoil or rock. Such laterally draining "throughflow" helps to maintain the typically wet conditions found around headwater streams, thereby accounting for the stream's "baseflow". During rainfall, infiltrated water may take one of several routes to the nearest stream channel, depending on the soil's hydraulic conductivity profile with depth, slope form, and steepness, and the spatial distribution of soil moisture already present (Figure 2). "Saturation overland flow" (SOF) is caused by rain falling onto an already saturated soil, as typically occurring in hillside depressions or on concave footslopes near the stream (Figure 1). More widespread hillside SOF (i.e. outside the riparian zone and depressions) has been observed sometimes during intense rainfall in the

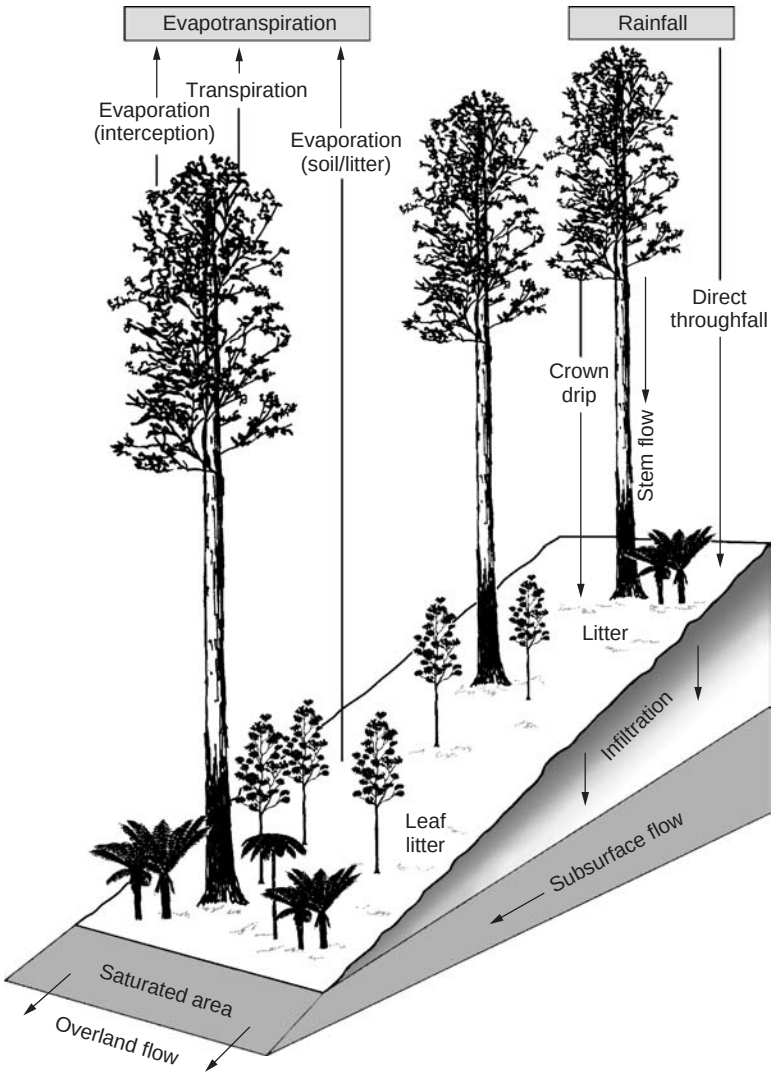

Figure 1 Key hydrological processes on a forested hillslope (after Vertessy *et al.,* 1998)

tropics in places with an impeding layer at shallow depth. Rapid throughflow during storms ("subsurface stormflow", SSF) usually represents a mixture of "old" (i.e. already present in the soil before the rain) and "new" water travelling through "macropores" and "pipes" (*see* **Chapter 111, Rainfall Excess Overland Flow, Volume 3**; **Chapter 112, Subsurface Stormflow, Volume 3**). Because of the contributions by SOF, SSF, and in extreme or disturbed cases also HOF, streamflow usually increases rapidly during rainfall. The increase above baseflow levels is called "stormflow" or "quickflow", whereas the highest discharge is referred to as "peak flow". Peak discharges may be reached during the rainfall event itself or as late as a few days afterwards, depending on catchment size and steepness, soil depth, and water content, and the duration, intensity, and quantity of the rainfall (*see* **Chapter 112, Subsurface Stormflow, Volume 3**). The total amount of streamflow discharged from a catchment area over a certain period of time (usually a month, season, or year) is called *water yield* (expressed in millimeters).

Evaluating Catchment Hydrologic Effects of Forest Disturbance or Removal

Within the limitations imposed by flow measurement techniques, the practical overall influence exerted by forests (or their manipulation) on hydrologic processes is arguably most clearly borne out by a comparison of streamflow amounts from catchment areas with contrasting proportions or types of forest. Forestry activities and natural disturbances both have the potential to more or less seriously alter forest evaporation and infiltration processes, and thus change the amount and timing of streamflow. Because of complications caused by local climatic contrasts (rainfall,

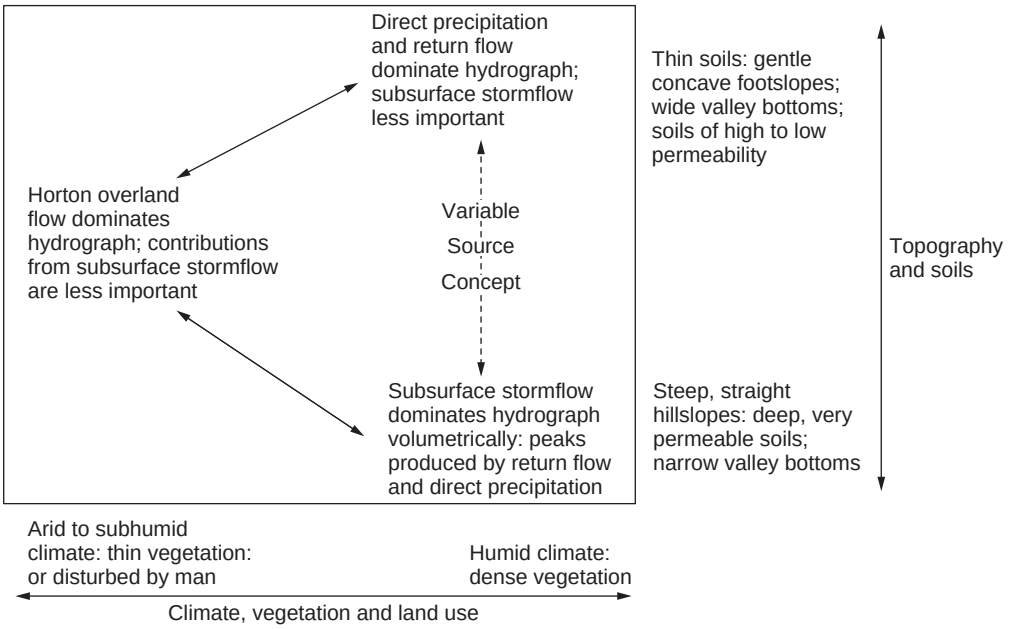

Figure 2 Schematic representation of the occurrence of various streamflow generating processes in relation to their major controls (Reproduced from Dunne, 1978, by permission of John Wiley & Sons Ltd). Note: ''direct precipitation and return flow'' are equivalent to saturation overland flow, *SOF*

exposure to radiation and air streams) and ungauged subterranean transfers of water from one catchment to another, a "direct" comparison of streamflows from catchments with contrasting covers can be problematic. The same applies to a comparison of flows from a single catchment before and after a change in cover. The classic response to such problems has been the "paired catchment experiment" in which the streamflow from two (preferably adjacent) catchments of comparable geology, topography, exposure, and vegetation are expressed in terms of each other (using regression analysis) during a "calibration phase". Once a robust baseline calibration relationship has been obtained, one of the catchments is subjected to manipulation of its cover (e.g. strip cutting or clear-felling) while the other catchment remains undisturbed as the "control" (Figure 3). Throughout this "treatment" phase, streamflow from both catchments continues to be monitored. Any effects of the treatment are evaluated by comparing the actually measured flow totals from the manipulated catchment with the flows that would have occurred if the catchment had remained undisturbed. This is usually achieved by inserting streamflow totals determined for the control catchment into the calibration relationship (Figure 3; Hewlett and Fortson, 1983). Although a more rigorous comparison between catchments is obtained in this way than in the case of a "direct" comparison of flows, the tacit underlying assumption is that differences in leakage between the two catchments remain unchanged with time, regardless of catchment cover status. Also, to avoid unjustified extrapolation of the calibration relationship to accommodate extremes in streamflow during the treatment phase (e.g. because of excessive rainfall or drought), it is imperative for the calibration period to include both wet and dry years. This makes the paired catchment method a time-consuming (typically >5 years) and thus an expensive affair. Moreover, the method is essentially a "black-box" requiring additional process research to reveal the relative importance of different causative factors to explain the observed changes in streamflow. All this, plus the limited resolution afforded by the paired catchment approach (usually more than 20% cover change is required for effects on streamflow to be detectable for small headwater catchments), has led to a general decline in the number of such studies in the last few decades and a gradually increasing emphasis on computer simulations (*see* **Chapter 132, Rainfall-runoff Modeling for Assessing Impacts of Climate and Land Use Change, Volume 3** and **Chapter 121, Intersite Comparisons of Rainfall-runoff Processes, Volume 3**).

Forest Harvesting Techniques

Harvesting of forest products may range from the manual collection of a particular component of the forest (such as fruits, fuelwood, or rattan), usually by forest dwellers or farmers living near the forest, through the removal of litter and topsoil for use as fertilizer or animal bedding, to the mechanized extraction of timber whose impacts are the main focus of this article. The hydrologic effects of the

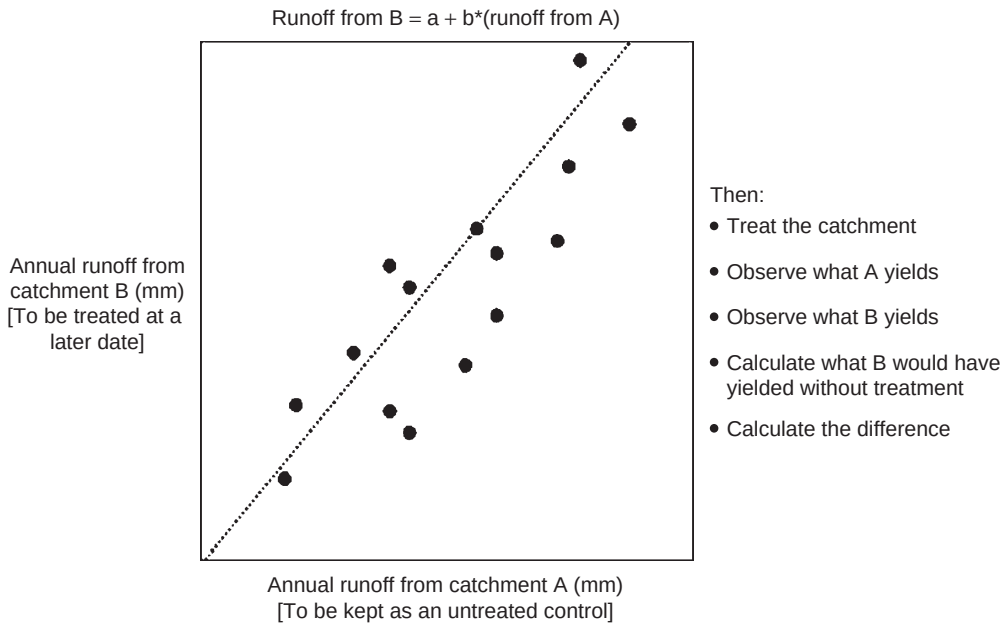

Figure 3 The paired catchment technique to evaluate the effect of land cover change on streamflow. Data shown represent flows as measured during the calibration period; the derived calibration relationship links the flows from the two catchments

various disturbances can be expected to be commensurate with the degree of damage inflicted upon the soil and standing vegetation. Whilst the manual collection of fuelwood is relatively harmless, the repeated removal of litter and topsoil (as widely practiced in South China and neighboring countries) may cause dramatic increases in HOF and surface erosion. Contrary to popular belief, it is the combined protection afforded by understorey vegetation and a well-developed litter layer rather than the main canopy that prevents the soil from being eroded. The erosive power of crown drip often exceeds that of rainfall in the open because of the associated increase in drop sizes, with the largest increases observed for large-leaved trees such as teak (Wiersum, 1985; Hall and Calder, 1993). Several years of uninterrupted litterfall and decomposition are required for the recovery of such a degraded forest floor (Zhou *et al.*, 2001).

Mechanized timber extraction not only opens up the canopy but also causes a number of disturbances to the soil surface. Disturbance occurs particularly during the construction and subsequent use of haulage roads, tractor tracks, and log landings, but also in the form of scars by uprooted and falling trees, especially in steep terrain. It is important to make a distinction between selective logging and clear-felling operations. In the former, damage to the residual vegetation needs to be kept to a minimum to ensure future timber yields, and hence much more of the vegetation is left standing. By contrast, upon clear-cutting, most (if not all) of the forest is felled and removed, with only very steep or wet parts of the terrain being left alone. In addition, logging debris in clear-felling operations may be chopped or "windrowed" by machinery and subsequently burned to gain access for the planting of the new rotation of trees. Up to 80% of the surface in small headwater catchments may be affected by such activities although at larger scales a value of 25 to 33% is more typical (Grip *et al.*, 2004). The (adverse) hydrologic effects of fire are discussed in **Chapter 120, Land Use and Land Cover Effects on Runoff Processes: Fire, Volume 3**.

In the context of selection logging, it has been estimated that for every harvested tree, another tree is killed and a third one damaged beyond recovery. Furthermore, the higher the intensity of the logging, the larger the proportion of the surface temporarily laid bare and greater the damage to the residual vegetation (although the relationship is not linear). In the richly stocked rain forests of Southeast Asia, where timber harvesting intensities of $100-150\,m^3\ ha^{-1}$ are not uncommon, up to 30% of the soil surface may be more or less seriously disturbed. In less intensively exploited forests, soil disturbance is closer to 5–10% (Bruijnzeel, 1992; Bruenig, 1996). Soil compaction by rubber-tyred skidders is much more pronounced than that by tracked vehicles and typically extends to a depth of 15–20 cm. Recovery of saturated hydraulic conductivity values (K*) upon regeneration of the vegetation on former tractor tracks is often slow and may, depending on the intensity of the previous use, require more than 50 years. HOF occurs much more frequently and in larger volumes on such compacted tracks, some of which may effectively

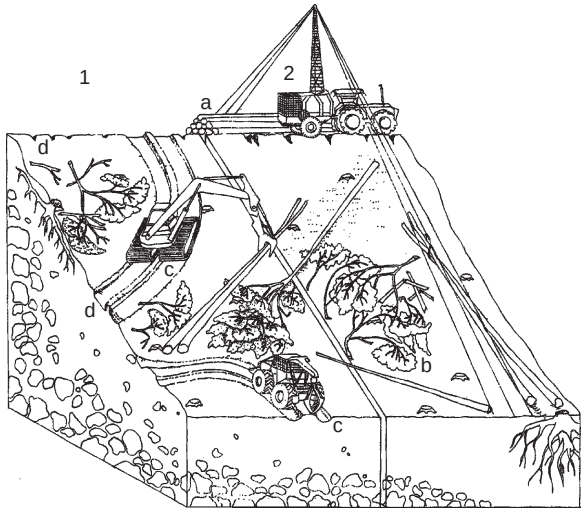

Figure 4 Timber harvesting generally uses heavy machinery such as caterpillars (1) or other tracked or wheeled vehicles; cable crane systems (2) generally have less impact on the soil. (a) Log landing on ridge top, (b) residual slash, (c) soil surface compaction and (d) sheet and rill erosion on tractor tracks (Reproduced from Mackensen *et al.*, 2003 Ambio No. 2, Vol.32, p. 107. by permission of Royal Swedish Academy of Sciences)

act as an extension of the regular drainage network (Grip *et al.*, 2004). Soil impacts during logging may be reduced by the manual skidding of logs on wooden rails in rare cases (e.g. in flat terrain in the tropics where labor costs are low) or by the application of aerial cable yarding techniques (Figure 4). However, because of the high level of damage to the residual vegetation associated with cable yarding, the method is more suitable for use in clear-cut operations. Helicopter-based logging is only rarely economically profitable (Bruenig, 1996; Dykstra and Heinrich, 1996).

HYDROLOGIC EFFECTS OF THINNING AND SELECTIVE LOGGING

In the following paragraphs, the hydrologic effects of (i) various forms of forest management (thinning and selective logging, removal of understorey or riparian vegetation, clear-cutting followed by regrowth or replanting) and (ii) road construction will be reviewed. The effects on the amounts of net precipitation are discussed prior to the effects on soil water, tree water use, and the amounts and timing of streamflow, both on an annual (or seasonal) basis and on an event basis. With a few exceptions, the discussion below is based primarily on experimental rather than simulated results.

Effects of Forest Thinning on Rainfall Interception and Net Precipitation

It has long been recognized that amounts of net precipitation tend to be inversely related to the stocking of a forest, both in the context of thinning or logging operations (Rogerson, 1967; Teklehaimanot *et al.*, 1991; Asdak *et al.*, 1998) and in terms of forest age (Delfs, 1955; Helvey, 1967). In other words, the denser the canopy the smaller the amount of rainfall reaching the forest floor and the greater the amount of rainfall interception. This not only reflects the greater leaf surface area of older stands but also their enhanced aerodynamic roughness (leading to increased atmospheric turbulence and wet canopy evaporation; *see* **Chapter 39, Surface Radiation Balance, Volume 1**). The effect can be substantial. For example, net precipitation in 60-year-old stands of white pine (*Pinus strobus*) in southeastern United States was ca. 220 mm year^{-1} less than in 10-year-old forest, despite the fact that stemflow decreased somewhat with forest age (Helvey, 1967). By contrast, no such decline with age was found for deciduous forests in the same area. Helvey and Patric (1965) concluded from the very similar interception totals derived for 11-year-old oak coppice and 30 and 50-year-old mixed yellow poplar-hickory forests that the younger stand had already acquired comparable leaf biomass and roughness characteristics to the older forests. A rather different picture has been obtained in evergreen mountain ash forests (*Eucalyptus regnans*) in Australia (Figure 5). Here, interception increased rapidly to a value of about 25% of the rainfall during the first 30 years, followed by a gradual decline to about 15% in old-growth forests (marking a difference of about 190 mm year^{-1}). Such changes in interception over time reflect concurrent changes in forest structure: during the first few decades, the regenerating forest consisted of numerous closely spaced trees with little understorey vegetation. In later years, the trees were much more widely spaced, whereas a well-developed understorey had been established as well (Haydon *et al.*, 1996).

Interception by deciduous forests during the dormant season is lower than during the growing season, but

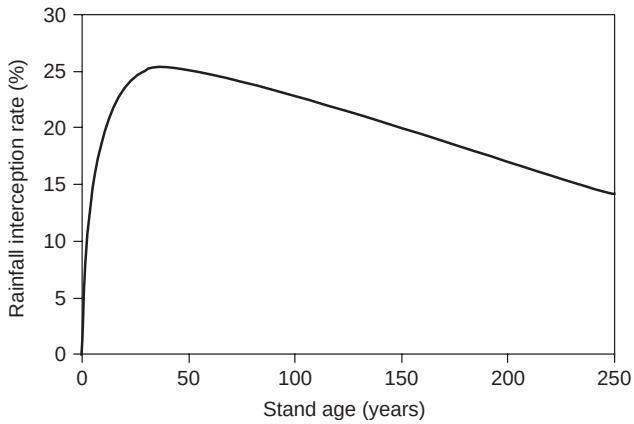

Figure 5 Relationship between mountain ash rainfall interception rate and stand age (Reproduced from Haydon *et al.*, 1996, by permission of Elsevier)

the typically observed increase in throughflow of 5–10% during winter is by no means proportional to the reduction in leaf area that can be up to sixfold (Helvey and Patric, 1965). Likewise, decreases in rainfall interception following forest thinning are often three to four times less than would be expected based on the degree of canopy opening alone. For example, a 50% reduction in basal area of a Douglas fir forest in France resulted in only a 13% reduction in interception (Aussenac *et al.*, 1982), whereas a 13-fold reduction in basal area in a dense Sitka spruce (*Picea sitchensis*) plantation (corresponding to a change in planting interval from 2×2 m to 8×8 m) in the United Kingdom was followed by a less than fourfold reduction in interception (Teklehaimanot *et al.*, 1991). Such findings cannot be explained entirely in terms of the actual decreases in intercepting canopy surface area but must also be ascribed to the gradual decrease in turbulent exchange between the trees and the surrounding air after opening up of the canopy. A strong negative correlation has been reported to exist between the aerodynamic conductance (g_a) of the boundary layer above the forest and the spacing of trees (Teklehaimanot *et al.*, 1991; *see* **Chapter 43, Evaporation of Intercepted Rainfall, Volume 1**).

Results from the humid tropics by and large confirm the above findings. Both Veracion and Lopez (1976) and Florido and Saplaco (1981) found increases in throughfall after thinning 30–50% of (natural) pine forests in the Philippines to be negligible. Significant increases were obtained only after as much as 70% of the trees had been removed. Asdak *et al.* (1998) found rainfall interception in undisturbed and heavily logged lowland rain forest in Indonesia to be 11% and 6% of incident rainfall, respectively. However, because the comparison did not involve the same forest before and after logging, it is not clear whether the reduction in interception primarily reflects the change in canopy cover or the preexisting structural differences between the two stands. Throughfall in tropical rain forests is notoriously variable in space and typically requires large numbers of (roving) gauges to narrow down the standard error of the mean throughfall estimate (Lloyd and Marques-Filho, 1988; *see* **Chapter 43, Evaporation of Intercepted Rainfall, Volume 1**). Elsewhere in Borneo, Chappell *et al.* (2001) reported no significant difference in throughfall beneath undisturbed rain forests and in logging gaps dominated by ca. 10-year-old pioneer vegetation. However, throughfall was significantly reduced in heavily logged-over forests that had been invaded by vines (Chappell *et al.*, 2001).

To summarize, the degree of forest thinning needs to be quite substantial (up to 70% of stand basal area) before a significant increase in net precipitation is achieved.

Effects of Thinning and Selective Logging on Soil Water, Transpiration, and Water Yield

Whilst the effect of thinning on amounts of precipitation reaching the forest floor is thus rather limited, the effect on soil water (and ultimately streamflow) can be expected to be even smaller. If the felled trees are left to decompose *in situ* and protect the soil against the impact of rainfall or crown drip, the slash is bound to intercept part of the gain in throughfall. More importantly, when opening up a stand the penetration of radiation to, and turbulent exchange with, the understorey vegetation and the forest floor are increased, thereby enhancing evaporation. In addition, the roots of the surrounding vegetation will start to compete for the extra moisture supplied by the increased throughfall in the newly created gaps. The magnitude and the duration of such effects will differ between locations, depending on the vigor of over- and understorey vegetation, climatic conditions (including site exposure and rainfall), and the configuration of the cutting (Stogsdill *et al.*, 1992; Parker, 1985; see Figure 6 below).

No change was detected in the streamflow from a deciduous hardwood forest catchment of southeasterly exposure at Coweeta (southeastern US) after a 27% reduction in basal area, and only a 4.3% rise in flows was observed after a 53% selective cut. Also, the removal of the entire understorey (representing 22% of the total basal area) from a 28 ha catchment of northwesterly exposure in the same area produced an equally modest change (Johnson and Kovner, 1956). Apparently, the moisture gained by removing one component of the forest is rapidly taken up by another. Further evidence for this contention comes from

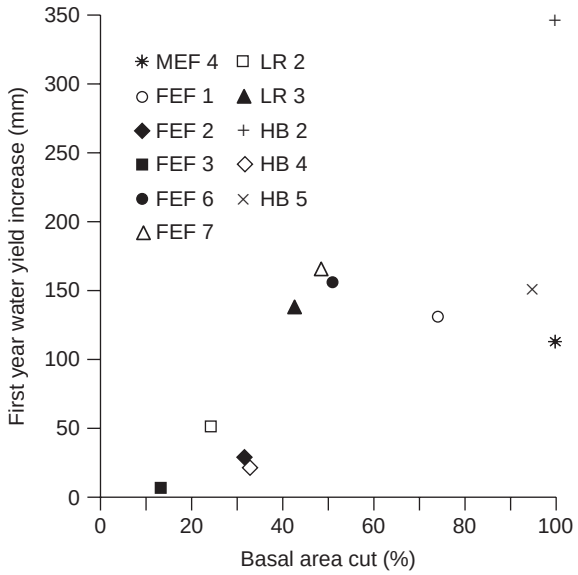

Figure 6 First-year increases in water yield in response to forest cutting in northeastern United States (after Hornbeck *et al.*, 1993, © Elsevier)

the Pacific Northwest of the United States where substantial soil water deficits tend to develop below the Douglas fir forest over the summer. Here, Black *et al.* (1980) observed "remarkably similar" transpiration rates for unthinned stands with little or no undergrowth and thinned stands with a well-developed understorey. In a related study, Kelliher *et al.* (1986) reported that, after removing the undergrowth, transpiration by the Douglas fir trees increased by 30–50%, with the greatest increases being found where undergrowth biomass had been highest. The net effect of the removal of the understorey vegetation on soil water content was insignificant. Whitehead *et al.* (1984) measured tree water uptake rates in two 40-year-old Scots pine (*P. sylvestris*) plantations of similar height, but with a more than fivefold difference in stocking in the northern United Kingdom. Transpiration in the more widely spaced plantation was on an average 67% of that in the denser stand. However, relative transpiration rates *per tree* were 3.3 times higher in the thinned plot, and intermediate in magnitude between the relative increases in average basal sapwood area per tree (2.9 times) and leaf area per tree (4.2 times), compared to the unthinned stand. Therefore, although water uptake by the thinned plantation had not attained prethinning levels yet, the large increases in both leaf and sapwood areas of the remaining trees may be viewed as to represent a tendency toward complete reequilibration following a set of tree physiologic relationships aimed at maximum site utilization and production (Whitehead *et al.*, 1984; *see* **Chapter 42, Transpiration, Volume 1**). Another striking example comes from South Africa where any potentially positive effects on streamflow of three rounds of heavy thinning (46%, 34%, and 50% at age three, five, and eight years) in plantations of *Eucalyptus grandis* were masked entirely by the steady reduction in flows resulting from the vigorous growth of the trees (Lesch and Scott, 1997).

Under wet tropical conditions, Gilmour (1977b) was unable to detect any changes in streamflow after "lightly" logging ($20\,m^3\ ha^{-1}$) a rain forest in northern Queensland, Australia. Although the removal of 33 and 40% of the commercial stocking in a rain forest in Peninsular Malaysia caused increases of 40 and 70% in annual water yield ($100–150\,mm\ year^{-1}$), there was no sign of the expected decline in streamflow gain during subsequent forest recovery (Abdul Rahim and Zulkifli, 1994). This result contradicts the more general experience that evaporation rates associated with young secondary growth in the humid tropics, although initially less than that of the surrounding forest, tend to increase very rapidly and may even exceed water use by old-growth forests within ca. 5 years (Figure 7; see Parker, 1985). Such findings illustrate the limitations of paired catchment studies in the absence of detailed process studies.

The influence of the *position or configuration* of the cutting on the magnitude and duration of any increases

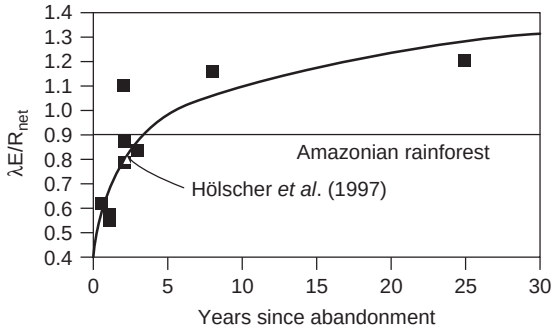

Figure 7 Ratio of energy used for evapotranspiration and net radiation in secondary vegetation as a function of years since abandonment of clearing for sites in eastern Amazonia and northern Thailand (Reproduced from Giambelluca, 2002, by permission of John Wiley & Sons Ltd)

in flow has been investigated in some detail. In eastern United States, the extraction of 24% of the basal area from catchment LR 2 at Leading Ridge (Pennsylvania) caused a nearly twofold larger increase in streamflow than cutting 33% on catchment HB 4 at Hubbard Brook (New Hampshire) or catchment FEF 2 at Fernow Experimental Forest (West Virginia) (Figure 6). The cutting at Leading Ridge consisted of a single block in the lowermost part of the catchment; at Hubbard Book it was effected through a series of strips situated half way up the catchment, while that at Fernow involved harvesting trees from all over the catchment (Hornbeck *et al.*, 1993). Therefore, increases in streamflow associated with strip cutting are smaller than for single blocks. This agrees with the suggestion of increased transpiration by surrounding trees after opening up of the canopy and the limited effect on net precipitation by thinning discussed earlier.

No significant differences in streamflow increases were observed between the cutting *en bloc* of the upper half of a catchment (such as in catchment FEF7 at Fernow, Figure 6) or the lower half (catchment FEF 6 in Figure 6) (Hornbeck *et al.*, 1993). Likewise, elimination of the riparian vegetation at Coweeta (southeastern US) did not produce an increase in water yield above that associated with the removal of an equal area of forest elsewhere in the catchment (Dunford and Fletcher, 1947). A comparable result was obtained for a catchment with similarly deep soils in the summer-rainfall zone of South Africa (Scott and Lesch, 1996), but not for an area in the winter-rainfall zone where streamflow gains after cutting pines and wattle trees in the riparian zone exceeded those associated with the harvesting of pines away from the stream by 30% (Dye and Poulter, 1995). Such contrasting results can be explained in terms of average soil water surplus or deficit, depth to the groundwater table, and slope morphology. Where rainfall is abundant, slopes steep and convex, and the water table is rather deep ($>3\,m$); no major spatial effect is

expected. Conversely, where soil water is scarcer, slopes gentle and concave, and depth to the water table is shallow; a more pronounced effect is possible. This is because trees located closer to the stream will have a better possibility to supplement soil water reserves during dry periods by their more ready access to the water table. Such trees can therefore be expected to maintain higher rates of water uptake than their counterparts away from the stream. These ideas were tested in a modeling experiment conducted for subhumid (MAP 700 mm) conditions, gentle slopes, and high water tables in southeastern Australia by Vertessy *et al.* (2003). Although the simulation aimed to assess the effect of forest planting at different positions in the landscape rather than forest removal, the results may be interpreted in an analogous manner. The predicted effect of tree planting differed markedly, depending on whether planting started at the top of the slope and moved progressively downward, or *vice versa*. The curves shown in Figure 8 suggest that under the prevailing subhumid conditions planting or removing trees in the lower 30% of the catchment would have a much more pronounced effect on flows than the same activity in the uppermost 30%.

Effects of Forest Clear-felling and Regrowth on Annual and Seasonal Water Yield

Well over 100 paired catchment studies have been carried out to date (mostly in the humid temperate zone) to examine the nature and extent of changes in streamflow associated with various forestry operations (mostly clear-felling). The literature on catchment treatment experiments (summarized by Bosch and Hewlett, 1982; Stednick, 1996; Best *et al.*, 2003) allows several generalizations to be made about the direction (increase or decrease) and approximate magnitude of the changes in flow. These are discussed briefly below.

Firstly, increases in total water yield during the first few years after treatment prove roughly proportional to percentage reductions in stand basal area the world over, provided the latter exceed a threshold of 20–25% (Figure 9) and rainfall remains above ca. 800 mm year^{-1} (see Figure 8). The reason for this is that tall forest vegetation evaporates significantly more water than shorter vegetation (such as pioneers in gaps) or a bare surface, partly because of differences in aerodynamic roughness and evaporating surface area and partly because of contrasts in rooting depth (*see* **Chapter 186, Water and Forests, Volume 5**). Because rainfall interception totals are higher in wetter years, the impact of forest clearance (i.e. near-zero interception) on flows also tends to increase with mean annual rainfall (Figure 10). Generally speaking, most of the increase in streamflow will show up in the form of increased baseflows unless the soil surface becomes seriously disturbed over a significant proportion of the catchment.

The database allows a tentative distinction between coniferous and deciduous hardwood forests, suggesting that increases in flow associated with the cutting of conifers are higher than for deciduous hardwoods (ca. 40 vs. 25 mm per 10% change in cover, respectively; Figure 9). The contrast is generally thought to reflect the dense evergreen habit and higher interception exhibited by coniferous forests, compared with deciduous forests that lose their leaves

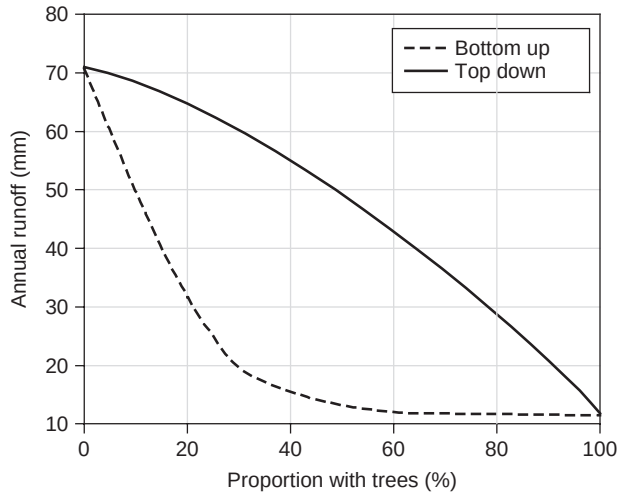

Figure 8 Results from a numerical modeling experiment showing two sets of predictions of annual streamflow after planting trees on a catchment under pasture in central New South Wales, Australia (mean annual rainfall 700 mm). The upper curve (solid line) shows changes in annual flow with forestation starting at the top of the catchment and progressing downslope. The lower curve (dashed line) shows the comparative response when forestation starts at the bottom of the catchment and progresses upslope (Reproduced from Vertessy *et al.*, 2003, by permission of Institute of Foresters of Australia)

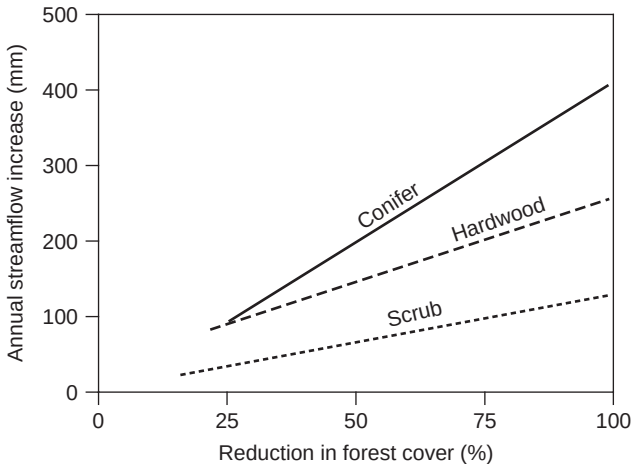

Figure 9 Relationships between reduction in forest cover and increase in annual catchment water yield. The general trend lines show the respective relationships for three types of woody vegetation (adapted from Bosch and Hewlett, 1982, © Elsevier)

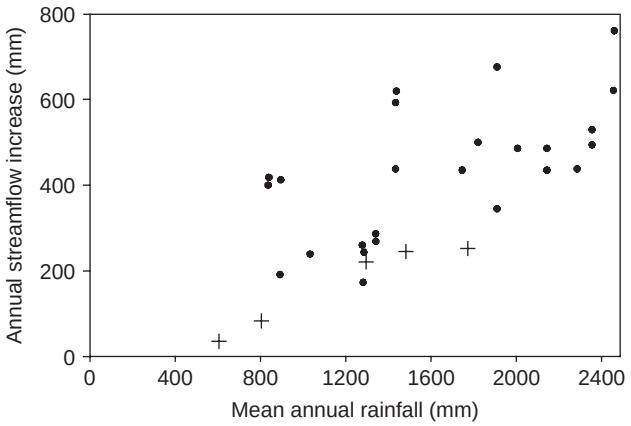

Figure 10 Effect of mean annual rainfall on increases in total water yield caused by total clearance of conifer and scrub vegetation (adapted from Bosch and Hewlett, 1982)

in winter or during an extended dry season. However, the scatter around the two tentative regression lines is large. The effect of the clearing of natural scrub (found in areas with low rainfall) is smaller still (ca. 10 mm per 10% cover change; Figure 9) and again highly dependent on actual rainfall conditions (Figure 10). Stednick (1996) approached the problem of the heterogeneity in results for 95 paired catchment studies from the United States by deriving separate regression equations for geographically homogeneous regions. In doing so, a clearer picture was obtained of the regional variation in yield increases that ranged from ca. 10 mm per 10% cover change in the Rocky Mountains to over 60 mm in the Central Plains. An even larger variation in initial flow increases after clear-felling (ca. 10–80 mm per 10% cover change) has been derived for humid tropical conditions. Partly this must reflect the larger differences in rainfall among different parts of the tropics although the combination of high intensity rainfall and extensive surface disturbance (leading to a larger stormflow component, see below) may also play a role (Bruijnzeel, 2004). One of the few exceptions to the general rule of increased streamflows after forest harvesting is the finding of Ingwersen (1985) that summer flows in a fog-ridden part of the Pacific Northwest of the United States declined instead of increasing after a patch clear-cut operation. The effect disappeared after 5 to 6 years when the regenerating trees had become tall enough again to capture sufficiently large amounts of water from the passing clouds. Another exception relates to the situation in which old-growth forests of low vigor and water use are replaced by young, vigorously growing forest (see Figure 7; Vertessy *et al.*, 2001; Giambelluca, 2002).

Apart from contrasts in rainfall, tree species, and age, part of the observed variability in the change in streamflow after clear-cutting relates to differences in catchment exposure and soil depth. The importance of exposure is illustrated by the difference in first-year streamflow gains after cutting differently exposed deciduous hardwood forest catchments at Coweeta. Flows from southerly exposed catchments increased by about 130 mm year^{-1} but increases from northerly exposed catchments sometimes exceeded 400 mm year^{-1} (Swank *et al.*, 1988). As such, the effect of clearing is inversely proportional to solar radiation inputs. As for the effect of soil depth, Trimble *et al.* (1963), discussing differences in duration of the changes in streamflow following forest clearing in West Virginia, suggested that: "the deeper the soil the longer it takes roots of new growth or the expanding root systems of residual plants to occupy the soil mantle. When the soil mantle is reoccupied, transpiration reaches maximum levels again, and increases in streamflow disappear". However, changes in forest structure (main canopy vs. undergrowth biomass and leaf area) and tree physiology with forest age (such as reduced vigor) may also play a role (see Figure 7; Giambelluca, 2002; Vertessy *et al.*, 2001). The role of soil depth is illustrated further by an examination of the timing of the maximum and minimum increases in flow after forest clearance during the year at Coweeta (Figure 11). Here, the ample rainfall is distributed evenly over the year, and the loamy soils are very deep (up to 6 m) and thus capable of holding large amounts of moisture. Under such conditions, the soil is not fully recharged until early spring (April–May) after which the presence or absence of a forest has little effect on the amount of flow (the soil being at or above field capacity anyway). However, during the summer, the contrast in streamflow from forested and cleared areas increases as the growing season advances. The effect continues well into the winter months (November–January), even though the trees have lost their leaves by then and evaporation is much reduced.

This reflects the development of the much larger soil water deficit during summer below forests that take an additional two months (February–March) to be recharged again by the winter rains (Figure 11). By contrast, in areas with shallow or sandy soils (having less water storage and lower water retention capacity), soil water recharge and depletion patterns alternate much more rapidly and increases in flow after forest clearance follow the pattern of forest water use much more closely (Hornbeck *et al.*, 1970).

The effect of the *timing of the cut* and the importance of controlling regrowth are demonstrated by a comparison of the results obtained for catchments HB2 and HB5 at Hubbard Brook (Figure 6). On catchment HB 2, the forest was clear-cut during the dormant season and regrowth was eliminated by herbicide application the following spring. Together, this caused a first-year increase in water yield of nearly 350 mm. On catchment HB 5, the removal of the trees took nearly a full year, while regrowth was not suppressed. The resulting first-year increase in flow was only ca. 150 mm, or 44% of that observed for catchment HB 2 (Figure 6). In addition, the gain in streamflow had largely disappeared after three years (Hornbeck *et al.*, 1970, 1993). Such contrasting findings again illustrate the effect of vigorously regenerating vegetation on water use and streamflow (see Figure 7; Vertessy *et al.*, 2001). It should be noted, however, that regeneration was particularly vigorous in the example from Hubbard Brook as it took place mainly via sprouting. As demonstrated by comparative work elsewhere in eastern United States, elevated streamflow levels last much longer (two to three times) when regeneration originates from seeds rather than via sprouting (Hornbeck *et al.*, 1993). Also, when a regenerating hardwood forest at Coweeta was cut a second time after 23 years (when streamflow was still ca. 80 mm year^{-1} above that observed for mature forest), the initial increase in water yield was nearly identical to that of the first cut (375 vs. 362 mm). However, the subsequent decline in (extra) water yield was distinctly faster. The difference was attributed to the much more rapid recovery of vegetation biomass during the second regeneration period owing to the greater sprouting potential of even-aged forest. The projected total duration of the second period of increased flows was estimated to be 18 years less than the 35 years associated with the first cut (Swank *et al.*, 1988). Such long durations reflect the time required by the roots to reoccupy the very deep soils at Coweeta compared with the much shallower soil at Hubbard Brook where effects rather last 3 to 9 years (Hornbeck *et al.*, 1993).

Effects of Forest Harvesting and Road Construction on Catchment Response to Rainfall

Part of the increases in annual streamflow totals after forest logging or clear-cutting (Figures 6, 8–11) reflects an increase in catchment response to rainfall (i.e. stormflows). In the absence of compacted surfaces such as roads, tractor tracks, and log landings, storm runoff is normally generated in the wettest parts within the landscape, such as depressions and riparian areas (*see* **Chapter 115, Landscape Element Contributions to Storm Runoff, Volume 3**). Topography permitting (see Figure 2), these runoff-producing areas will be enlarged after forest removal because of the increased amounts of precipitation reaching the ground, and the reduced uptake of water from the soil. Again, the strongest contrasts are expected during the time of the year when the soils are normally driest (see Figure 11; Hewlett, 1982). Also, the wetter soil conditions associated with cleared areas will be more conducive to flow and thus generally more responsive to rainfall. Relative increases in stormflow volumes after forestry operations *with minimum soil disturbance* (e.g. using skyline logging techniques) are largest for small rainfall events (up to three times the predisturbance volumes), intermediate for medium-sized events (+25–50%), but not too different (and lesser than 10–20% increase) for large events (Pearce *et al.*, 1980; Hewlett, 1982). As such, the effect of the presence or absence of a forest cover is inversely related to the size of the rainfall even generating the stormflow (Figure 12). This can be explained in terms of variations in the soil's capacity to store additional rain. Where previous uptake of soil water by the trees has depleted reserves, the storage capacity will be relatively high, but once the soil has become thoroughly wetted by frequent rains, opportunities to absorb large additional amounts of rain will be limited (see Figure 11). Likewise, as rainfall events increase in size, so does the relatively fixed maximum storage capacity of the soil become less influential (Figure 12). In other words, under conditions of extreme rainfall and soil wetness, the

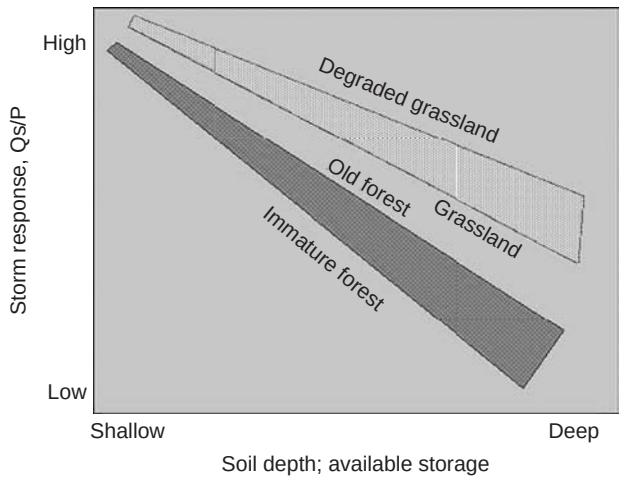

Figure 12 Postulated generalized relationship between catchment storage capacity and stormflow response to rainfall, as affected by vegetation cover (Reproduced from Scott *et al.*, 2004, by permission of Cambridge University Press). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

presence or absence of a forest cover is no longer decisive. Catchment runoff response is then governed primarily by the soil's physical capacity to store and transmit water (Hewlett, 1982; Grip *et al.*, 2004).

Similarly, *peak discharges* immediately downstream of forestry operations are increased temporarily (on an average by 5–50% in the absence of major road effects) as the wetter soil conditions after clearing cause an extension of the drainage network during rainfall. However, such effects on both stormflow volume and peak flows diminish subsequently with the establishment of the new vegetative cover (Hewlett, 1982; Grip *et al.*, 2004).

However, "typical" clear-cut operations involve road construction, mechanized harvesting using wheeled or tracked vehicles, and, in some cases, site preparation (chopping or windrowing and burning of slash) and machine planting (Hewlett and Doss, 1984; Swindel *et al.*, 1983). Under such conditions, soil disturbance can be expected to be much more severe and widespread, and potentially impair the catchment's capacity to absorb rainfall in a more structural manner. The actual effect on stormflow response will depend on the degree of topsoil compaction by machinery, the proportion of the catchment affected, and the degree of connectivity between roads and tracks and the drainage network (Van der Plas and Bruijnzeel, 1993; Jones and Grant, 1996; Grip *et al.*, 2004).

Equally important is the hillslope hydrological setting prior to disturbance, as illustrated by the following example from French Guyana (Figure 13; Grip *et al.*, 2004). Here, stormflow response for a series of small rain forested catchments varied roughly fivefold (7–34% of rainfall), depending on the proportion of the catchment underlain by free-draining or poorly drained soils, and the presence or absence of a marshy valley bottom. After mechanized clear-felling, the strongest *relative* impacts were observed on those catchments having the lowest storm runoff under forested conditions (150–200% increase), and *vice versa*. As such, catchments with free-draining soils proved much more sensitive to disturbance than catchments with impeded drainage and marshy valley bottoms (65–85% increase). This most probably reflects the fact that changes in the surface hydraulic properties of the free-draining soils (notably compaction by machinery) caused a shift in dominant runoff pathways during rainfall, that is, from predominantly vertical percolation under forests to more rapid surface routes (notably HOF) after clearing. By contrast, the soils with impeded drainage already exhibited ample rapid shallow lateral subsurface flow under forested conditions which, although partly displaced upward toward the surface after clearing, had less overall impact on the size of the storm hydrograph (see Gilmour, 1977b). On the other hand, *absolute* annual increases in stormflow totals were greater on the catchments with impeded drainage (310–360 mm) than on free-draining catchments (230–270 mm). However, despite these pronounced initial effects, storm runoff decreased to original values within four to five years for all of the forestry treatments imposed in this experiment (natural regrowth after logging and/or clearing, tree plantation establishment following clearing and burning; Figure 13) although it is pertinent to note that no permanent roads were constructed within the catchments (Grip *et al.*, 2004).

Needless to say, *roads* are usually highly compacted and have very low rainfall intake rates (typically $<15\,\mathrm{mm\,h^{-1}}$) and therefore very high annual runoff coefficients ($>65\%$) (Grip *et al.*, 2004). In addition, road-cut slopes can interrupt downslope-moving subsurface flow which is then converted to more rapid surface flow (Jones and Grant, 1996). As such, the layout of the road system and the proper drainage of road and track surfaces assume great importance if large off-site increases in stormflow are to be avoided (Adams and Andrus, 1990; Dykstra and Heinrich, 1996; see Figure 14 below). Indeed, such increases after forest harvesting in the Pacific Northwest of the United States were shown to be significantly enhanced if more than 10% of the catchment was occupied by roads compared with catchments having only 3–5% of road surface (Harr *et al.*, 1975). Similarly, increases in peak discharges after 25% clear-cutting with roads had the same effect as 100% clear-cuts without roads in the same area, although the underlying hydrologic mechanisms were different (Jones and Grant, 1996). At the same time, the downstream effects of forestry operations on catchment runoff response to rainfall at a larger scale are often thought to be modest to undetectable. This is because any adverse local effects of forest removal on all but the largest stormflow response (see Figure 12) tend to be "diluted" by more modest flows from other areas receiving less rain or being less disturbed (Hewlett, 1982; Bruijnzeel and Bremmer, 1989). However, in a thorough analysis of long-term peak flow records for $60–600\,\mathrm{km^2}$ catchments with logged-over forest in various stages of regeneration (again in the Pacific Northwest), Jones and Grant (1996) concluded that peak discharges had increased by 100% in large basins over the past 50 years versus a 50% increase in small (60–100 ha) basins. These increases were attributed mainly to changes in flow routing because of roads rather than to changes in soil water storage because of vegetation changes (as in some of the experiments discussed above).

Naturally, it is difficult to separate the effect of forest roads on flooding from those of logging in the *case of larger basins* (mostly because the two interventions usually happen more or less simultaneously). La Marche and Lettenmaier (2001), therefore, used a physically based, spatially distributed hydrologic model to explore the relative effects of the two types of disturbance in an extensively logged $150\,\mathrm{km^2}$ catchment (Deschute River, Washington), and in nine subcatchments therein ($2–21\,\mathrm{km^2}$). The model predicted increases in mean annual peak discharge of ca.

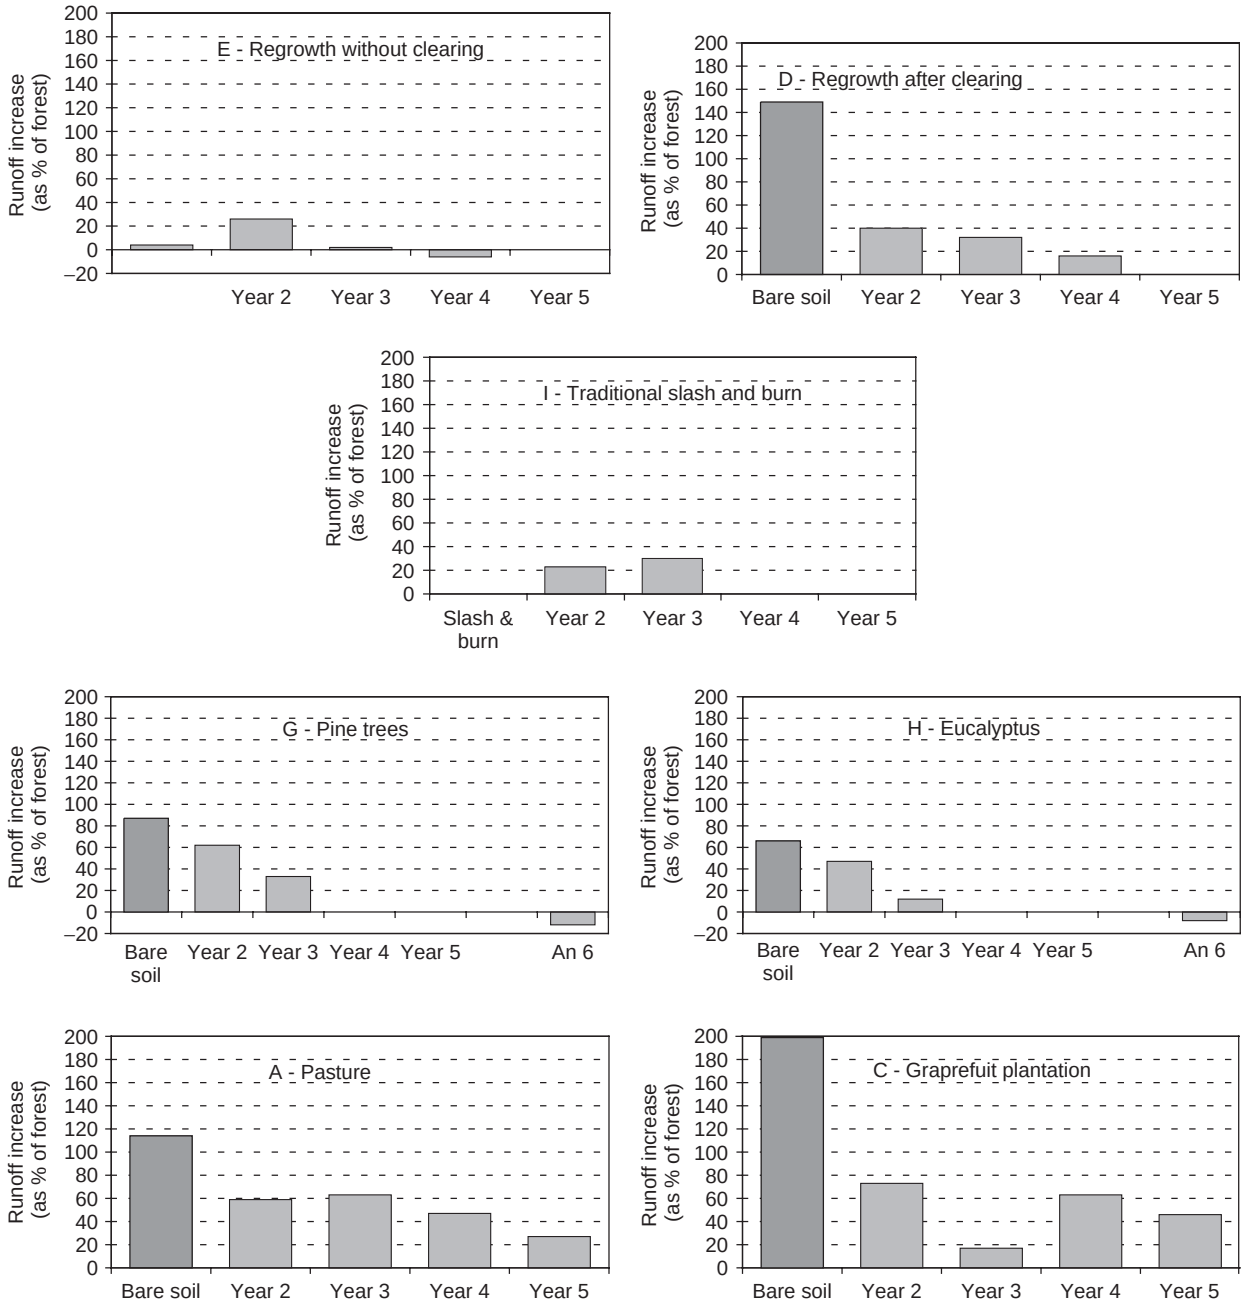

Figure 13 Changes in stormflow with time for the respective treatments within the ECEREX Experiment, French Guyana. Results are expressed as a percentage of corresponding runoff totals under forested conditions. (a) Regrowth following logging, (b) regrowth after logging and land clearing, (c) traditional slash and burn agriculture, (d) conversion to pine plantation, (e) conversion to eucalypt plantation, (f) conversion to pasture, and (g) conversion to grapefruit plantation (adapted from Fritsch, 1993). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

2–10% because of roads alone. These increases were similar to the ones incurred by clear-cutting only. Interestingly, modeled road-only effects were slightly greater (ca. 3–12% increase) for the 10-year-event, whereas those for logging-only decreased with flood return period (i.e. conform the conceptual model of Figure 12). In other words, the effect of roads tends to be exacerbated in larger storms.

In view of these recent findings from the Pacific Northwest, the frequently heard but rarely demonstrated claim that logging tropical forest increases "flood" flows may contain more truth than has been acknowledged by the scientific community (see Hamilton and King, 1983; Bruijnzeel and Bremmer, 1989; Calder and Aylward, 2004), particularly when taking into account that logging operations in the

tropics rarely follow guideline prescriptions (Bruenig, 1996; Cassells and Bruijnzeel, 2004) and rainfall intensities there tend to be much higher than in the Pacific Northwest. It remains to be seen, however, whether the related claim of reductions in dry season flows after logging (due to the seriously hampered water intake capacity of the soil over a large portion of the catchment) in the tropics is as likely. Although such reductions in low flows have been demonstrated in the case of long-term, post-forest land degradation or after widespread urbanization (Bruijnzeel, 2004), regrowth after timber harvesting operations in the tropics is usually prolific and tends to reduce stormflow production from non-road surfaces (see Giambelluca, 2002). Preliminary modeling work has suggested that for dry season baseflows to become seriously reduced, infiltration-excess overland flow would need to be increased from marginal values under undisturbed forest to as much as 30–40% of the rainfall. Further work is needed to settle the debate (see Bruijnzeel *et al.*, 2004).

MINIMIZING ADVERSE HYDROLOGIC IMPACTS OF FORESTRY OPERATIONS

Generally, the more intensive a forestry operation, the more the soil and residual vegetation tend to be damaged. The relationship is not linear, however, and a poorly planned and executed harvest of a relatively small volume of timber may do as much damage as a more carefully executed operation removing twice as much timber. There is ample evidence that the key to minimizing damage to remaining trees and soil is the careful planning, preparation, and execution of any operation. The same holds for limiting the adverse off-site impacts (enhanced peak discharges, stream sedimentation) of, especially, road networks. Without going into detail here, the following measures are generally considered essential for a forestry operation to be successful in terms of minimizing both costs and environmental damage (Adams and Andrus, 1990; Pearce and Hamilton, 1986; Bruijnzeel, 1992; Dykstra and Heinrich, 1996; Bren, 2000):

- Prelogging assessment of potentially unstable (wet depressions, very steep slopes) areas or particularly erodible soil types; delineation of catchment boundaries and drainage lines (including channels that carry water during storms only); evaluation of seasonal distribution of rainfall to identify wettest periods.
- Preplanning of the extraction road and track network in relation to terrain characteristics, the natural drainage network, and type of logging system to be used (tractor/winch lorry/cable yarding/animal traction); keeping to ridges (roads, log landings) and staying away from streams (roads, log landings, and tracks) and steep sections as much as possible.
- Timing of road construction to conform to the period of least rainfall; allowing sufficient time for earthworks to stabilize before intensive use; provide adequate drainage of roads and tracks to prevent accumulation of large volumes of surface runoff that may initiate gully erosion upon being discharged.
- Whenever possible, yard logs uphill rather than downhill (Figure 14); use winch ropes rather than have tractors/skidders clear an approach to every log; directional felling into existing gaps; minimize the number of passes; raise the leading end of logs to keep them from ploughing into the soil; suspend tractor logging during wet periods to avoid excessive soil compaction.

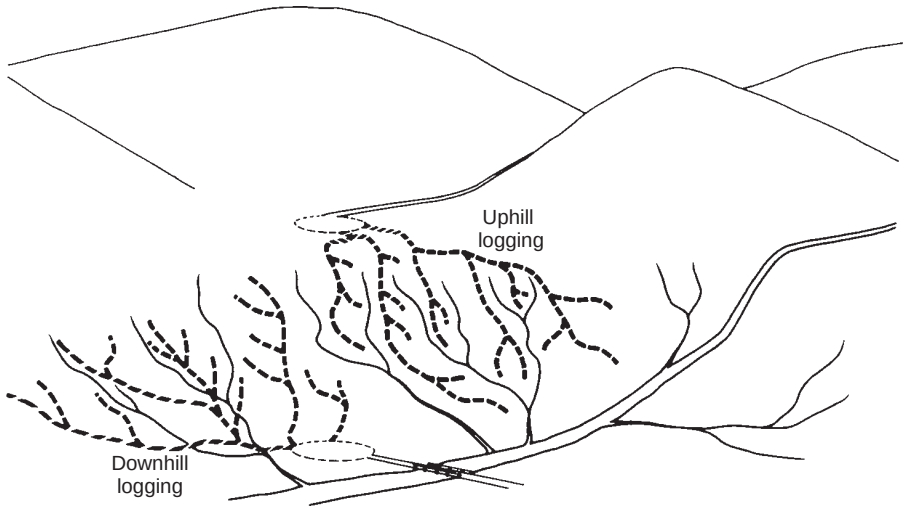

Figure 14 Hypothetical skidder track patterns (dashed lines) for uphill and downhill logging (Reproduced from Gilmour, 1977a, by permission of the Food and Agriculture Organization of the United Nations). Note how uphill logging tends to divert runoff and sediment away from streams, in contrast with the flow convergence promoted by downhill extraction

- Maintain streamside buffer strips to trap runoff and sediment generated upslope and to provide shade to the aquatic ecosystem; recommended widths will vary between terrains, but should be at least 10–20 m on either side and not only cover major streams but also ephemeral channels and other runoff generating areas where possible.
- Postlogging treatment of skidder tracks (removal of temporary stream crossings, construction of cross drains on critical tracts) and log landings (breaking up/reseeding); road maintenance; reseeding of roadside earth works.

Comprehensive sets of guidelines that include most or all of the above aspects have been developed in a number of countries. Their application in northern Australia in an area experiencing some of the world's most erosive rainfall intensities, has been shown to be highly effective in meeting the objectives of minimum extra costs and minimum environmental impacts, both on-site and downstream (Gilmour, 1977a; Cassells *et al.*, 1984). Naturally, to be truly effective, the various measures listed above should be applied with a rigor that matches the intensity of local rainfall and steepness of terrain. In many cases, this is easier said than done, as the forestry industry tends to resist change, being guided by short-term economic gains rather than long-term considerations of environmental sustainability. However, with the introduction of educational programmes, combined with the application of a realistic penalty structure and, more recently, the introduction of timber certification schemes, major improvements in harvesting practices have been achieved in a number of areas (Cassells *et al.*, 1984; Bruenig, 1996; Cassells and Bruijnzeel, 2004).

120: Land Use and Land Cover Effects on Runoff Processes: Fire

CHARLES H LUCE

Rocky Mountain Research Station, Boise, ID, US

Fire dramatically alters hydrologic processes in many regions of the world. Individual fires reduce vegetation and change soil characteristics, sometimes producing dramatic runoff events in the years shortly after a fire. The greatest determinant of the effect of fire on runoff generation is the severity of the fire, which relates to the frequency of fires and other climatic and vegetation characteristics. Severe fires can produce hydrophobic soils or increase risk of soil surface sealing, reducing infiltration rates. Measurements of the spatial pattern of water repellent soils are useful for estimating potential runoff from postfire storms. The most severe events occur during convective storms, so the spatial extent of individual postfire floods is generally limited in extent. Recovery of water repellent soils is relatively rapid, with significant reductions occurring within a few years. Longer-term changes to hydrology are related to the reduced evapotranspiration caused by loss of vegetation biomass. In forests, changes to annual water balances may last decades.

INTRODUCTION

In some parts of the world, fire is an important natural disturbance to landscapes. Its very nature can cause substantial changes in hydrological processes in an area, as it consumes vegetation biomass and sometimes affects the soil characteristics directly. One of the most spectacular hydrologic results of fire is the combination of water repellent soils followed by thunderstorms, which can create locally severe flooding and erosion (e.g. Klock and Helvey, 1976; DeBano, 1981; Swanson 1981; Moody and Martin, 2001; Istanbulluoglu *et al.*, 2002; Miller *et al.*, 2003). Effects of fire on vegetation, soil, and hydrologic processes can be extraordinarily variable, ranging from nearly no noticeable effect to extreme flood events with results such as those shown in Figure 1. The degree of effect depends on the severity of the fire, or how hot and long it burned, and the spatial extent and patchiness of high severity fire. While there are clear deterministic influences on fire behavior, such as fuel amount and condition, air temperature, humidity, and wind, it can be treated stochastically, and in this sense, fire can be thought of as a weather phenomenon itself. Like other hydrologically relevant weather parameters, fire can be considered both from the perspective of regime, with return frequency and severity metrics, and as an event. Fire regime is essentially the climatic context of fire, and just as it would be somewhat nonsensical to discuss flooding processes without mentioning the aridity of the landscape, so it is that fire regime is an important concept for fire effects. This article first discusses fire regimes and their relationship to hydrology and expectation for fire events, followed by a discussion of the hydrologic responses that might be expected from a given fire event.

FIRE REGIMES AND HYDROLOGY

Metrics for fire regimes relate to the frequency with which fire visits an area and what it tends to do to dominant vegetation in the area. The effects of fire can range from minor damage to the dominant vegetation to stand replacement, where all vegetation in the area is consumed (Hessburg and Agee, 2003). Where there is a strong tendency for one type of outcome versus the other, the severity can be classified as "nonlethal" or as "stand replacing." Where the nature of effects tends to change from fire to fire, the severity is classified as "mixed," and a spatially patchy vegetation structure can result. Within

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

Figure 1 Mouth of Wren Creek in the Boise National Forest, Idaho. The watershed burned in 1994, and a severe thunderstorm passed over the basin in the summer of 1995, initiating a hyperconcentrated flow event in this and neighboring streams. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

a given vegetation community type (e.g. shrub steppe, or forest), severity tends to go hand in hand with frequency. Very frequent regimes, with mean fire intervals less than 25 years, tend to have little fuel to consume with each event, and frequent kills of small trees do not allow for creation of complex vegetation canopies that can act as ladders from ground fuels to the dominant vegetation species. Conversely, very infrequent regimes allow time for buildup of significant fuels and complex canopies, and crown fires are more common in areas where fires occur less frequently.

Fire regimes have a profound influence on vegetation characteristics, so knowledge of the relationship between plant species and the kinds of fire regimes that they tend to occur with can provide some information about the nature of fires one might expect. Frequency and severity of disturbance can be important in the determination of species (Franklin and Dyrness, 1973), which in turn can affect the probability, severity, and continuity of successive fires. Fire-adapted plant species have strategies to either avoid impacts from flames or to quickly capitalize on freshly burned sites. Trees with thick bark (e.g. Ponderosa Pine, *Pinus ponderosa*) are common in locations with frequent low severity burns, where the bark protects the cambium from the effects of a quickly moving ground fire, and the height of the tree keeps the crown from catching fire. Trees with serrotinous cones (e.g. lodgpole pine, *Pinus contorta*, or Jack pine, *Pinus banksiana*) are more common in locations with rare but severe fires that cover large areas, as the serrotinous cones release seeds into a nutrient rich environment with little competition from more distant seed sources. Invasive fire-adapted grass species (e.g. Cheatgrass, *Bromus tectorum*) can set up a frequent fire regime that prevents regeneration of deeper-rooted native shrub species (Young and Evan, 1985; Billings, 1994).

One of the effects of fire on runoff generation processes may occur where shifts in fire regime force changes in plant communities that affect soil properties and the hydrologic cycle. Fire regime is a function not only of vegetation assemblages but also of the climate. Fire both drives and is driven by vegetation changes in response to climate change. A variety of stratigraphic evidence has shown that substantial variations in precipitation and temperature can occur on long timescales, producing periods of shifting fire regimes and vegetation within an area (Meyer and Pierce, 2003; Whitlock *et al.*, 2003).

Within arid forests and rangelands, physiological adaptations to seasonal aridity are obviously important in determining relative success and spatial distribution of species within the landscape. The ecohydrological optimality principles (*see* **Chapter 12, Co-evolution of Climate, Soil and Vegetation, Volume 1**; **Chapter 101, Ecosystem Processes, Volume 3**; and **Chapter 103, Terrestrial Ecosystems, Volume 3**) that apply well to more humid landscapes (Eagleson, 2002) could potentially represent arid and semiarid landscapes better if fire disturbance, essentially a hydroclimatology phenomenon itself, was included in the conceptualization.

HYDROLOGY AFTER FIRE EVENTS

The effects of an individual fire event on hydrologic processes are tied primarily to the loss of vegetation, loss of organic matter at the soil surface, and the chemico-physical changes to shallow soil horizons that lead to water repellency. The degree of effect is greatly affected by the characteristics of the fire and the fuels it is burning through. Rate and duration of energy releases are key characteristics, and are affected by fuel size and moisture distributions, the amount of fuel available to the fire, volatility of the fuels, and weather (temperature, humidity, wind speed) at the time of burning (Albini *et al.*, 1996). The patchiness of the resulting burn is also important to runoff generation and is tied to continuity and availability of fuels. Effects on soil organic matter and water repellency are less common and depend on soil and vegetation characteristics. One of the primary differences between purposefully set "prescribed" fires and wildfire is that the decision about when to set the fire allows for some degree of control of many of the important factors, including weather, fuel moisture, and soil moisture, which allows for some control on the degree of disturbance to the soil.

Water Repellency

One of the most commonly cited effects of fire on runoff generation processes is the formation of a water repellent layer in the soil, sometimes termed *hydrophobicity* (e.g. DeBano, 1981, 2000). Water repellency is a condition where soil not only loses its usual capillary draw on water, but actually resists entry of water into the soil (*see* **Chapter 68, Water Movement in Hydrophobic Soils, Volume 2**). This condition increases the amount of infiltration excess overland flow (*see* **Chapter 111, Rainfall Excess Overland Flow, Volume 3**). Water repellency occurs naturally in some soils, but seems to be increased in severity, strength, degree, persistence, and continuity by fire (DeBano, 2000). Typically, water repellency occurs in locations with severe heating of the soil surface.

Postfire water repellency is hypothesized to occur by translocation of waxes and other organic compounds with hydrophobic properties from upper layers of the soil and organic matter into lower layers by vaporization where temperatures are high at the surface and condensation on soil particles lower in the soil profile where temperatures are cooler (DeBano *et al.*, 1976). As one might expect, sufficient temperature and duration of heating are necessary for the formation of water repellent layers, and there is some indication that vegetation type affects the formation of water repellent soils (Doerr *et al.*, 2000). The effectiveness of the hypothesized coating process is dependent on the amount of material to be coated, and there is some effect of soil specific surface, generally as measured by grain size. Coarse soils tend to be more susceptible to water repellency than fine grained (DeBano, 1981).

Water repellency is sensitive to soil moisture, and the soil does not impede water movement once wetted (Imeson *et al.*, 1992; Doerr *et al.*, 2000). The requirement for low soil moistures tends to make water repellency a dry season phenomenon, with little effect on runoff generation during snowmelt. Typically, the concern is intense precipitation events during the summer months leading to brief, severe flash flood events. Once the wettable surface layers are wetted, water repellent soils can yield substantial runoff as an infiltration excess process. Over the course of a storm, the infiltration capacity of the soil tends to increase, at least during early times; this is in direct contrast to normally wettable soils that see a decrease in infiltration capacity during a storm (Imeson *et al.*, 1992). After being wetted, soils can become water repellent again if dried.

There are three timescales fundamental to the degree of water repellency, the time for wetting during a storm event (minutes to hours), the variations due to annual wetting and drying, and a longer-term decay of water repellency. While there are a number of examinations of the shortest timescale (e.g. Imeson *et al.*, 1992), and a fairly well known wetting and drying relationship, the longer-term persistence of fire-induced water repellency is not well understood. A water repellent layer may break down due to microbial activity, dissolution during wetting and drying, or physical disturbances like freeze thaw, bioturbation, and soil creep. Severe erosion events (often in the form of rilling) induced by water repellency are a key process for removal of water repellent layers and result in a spatial organization of water repellent and nonrepellent soils, where the upslope interrill patches are repellent but the rills are nonrepellent. There are few published observations of the persistence of water repellency. Dyrness (1976) observed water repellency in a burned area six years after the fire. Personal observations have shown extensive water repellency still existing seven years after severe fire under a subalpine fir stand, and spotty repellency 25 years after a prescribed fire in a coastal Douglas-fir stand. I have also seen extensive water repellency under a subalpine fir stand that had no fire in the last 200 years, but there is no certainty that the repellency originated with a fire in this stand. The erosion mechanism, mentioned above, seems to be the fastest mechanism for removing large areas of water repellent soils. A clearer picture of processes and timescales for recovery from fire-induced water repellency is needed to better understand long-term risks of flooding posed by fires (Doerr and Moody, 2004).

While substantial study has gone into research on water repellency at point and plot scales, an understanding of how it contributes to runoff generation even in small catchments is largely unexplored (Shakesby *et al.*, 2000; Doerr

and Moody, 2004). Most of the research on water repellency has focused on methods for measuring the "strength" of the water repellency (Letey *et al.*, 2000). Such measures include water contact angles, head needed to penetrate, or water drop penetration times. At scales of one to a few meters, the tendency of water repellent soils to form preferential flow paths or fingers of wetting has been noted (Imeson *et al.*, 1992; Ritsema and Dekker, 2000). Conceptually, this idealization can apply at larger scales as well, where topology and runoff–runon relationships must be considered (Shakesby *et al.*, 2000; Doerr and Moody, 2004). This conceptualization would argue that if we were interested in the potential for runoff production from a watershed during intense storm events, we would want to measure the fractional area that is water repellent. This approach has seen some success in estimating location of gully initiation sites (Istanbulluoglu *et al.*, 2002).

Soil Surface Sealing

Surface sealing is another frequently suggested mechanism for reductions in infiltration capacity and increases in overland flow (*see* **Chapter 111, Rainfall Excess Overland Flow, Volume 3**) following fire (e.g. Rowe, 1948; Swanson, 1981; Benavides-Solorio and MacDonald, 2001; Meyer and Pierce, 2003). Surface sealing has not received as thorough a treatment for postfire periods as it has in the literature addressing agricultural and severely disturbed soils (e.g. Mohammed and Kohl, 1987; Bosch and Onstad, 1988; Luce, 1997). Surface sealing occurs when raindrop impact and rapid wetting break up soil aggregates, effectively reducing the surface grain size and hydraulic conductivity, and potentially forming a crust. Erosion initiated with the loss of the protective surface organics can also cause relocation of surface fines into macropores, reducing their capacity to move water into deeper layers quickly. Luce (1997) noted reductions in hydraulic conductivity in excess of 70%. The degree of reduction depends on clay content and type, the kinetic energy of the precipitation, and the duration of exposure. Soils with high clay content (nondispersive clays) and high organic matter content tend to have stronger aggregates (Kemper and Koch, 1966). Reduced surface hydraulic conductivity can lead to the initiation of infiltration excess (Horton) overland flow during rainfall events with intensities greater than the hydraulic conductivity. Organic matter reductions are patchy, with organic matter consumption generally related to local burn conditions. If soils in a watershed are susceptible to surface sealing, the hillslope scale runoff generation will depend on the degree of surface sealing, and the proportion of the hillslope and downslope continuity of patches where the organic matter is completely consumed.

Vegetation Loss

The effects of vegetation canopy loss are similar to other land use effects such as forest harvest or rangeland chaining (*see* **Chapter 119, Land Use and Landcover Effects on Runoff Processes: Forest Harvesting and Road Construction, Volume 3**). These effects include reductions in evapotranspiration, reduced interception of liquid and solid precipitation, and increased snowmelt rates during periods of solar dominated melt (e.g. Reifsnyder and Lull, 1965; Harr, 1976; Waring and Schlesinger, 1985 and *see* **Chapter 42, Transpiration, Volume 1**, **Chapter 43, Evaporation of Intercepted Rainfall, Volume 1**, **Chapter 39, Surface Radiation Balance, Volume 1**). Reductions in evapotranspiration and interception generally lead to higher soil moistures (Johnston, 1970; Klock and Helvey, 1976) and greater annual water yields (Megahan, 1983; Troendle and King, 1985; Kuczera, 1987; Watson *et al.*, 1999). The result is greater low flow generation during summer, with springs active higher in watersheds, and more opportunity for production of peak flows (Harr, 1976; Campbell and Morris, 1988). Reduced shading by canopy can substantially increase snowmelt rates leading to increased peak flows in snowmelt-dominated systems (*see* **Chapter 160, Energy Balance and Thermophysical Processes in Snowpacks, Volume 4**). Although we understand that standing dead trees can inhibit turbulent exchange between the snowpack and the atmosphere, the strength of the effect of wildfire on turbulent heat transfers is less well researched. Reductions in organic matter on the soil surface accompanying other vegetation loss primarily yield a reduction in water interception, which can be important during brief precipitation events. While some effect of vegetation loss on runoff generation is expected for almost every fire, the degree of the effects listed is greatly determined by the degree of vegetation loss. A crown fire may remove branches and needles from a tree, where a ground fire may result in patchy mortality and gradual dying of leaves and needles.

Scale of Effects

Although fire creates soil and vegetation conditions that are more conducive to severe hydrologic behavior and rapid runoff forming processes, the more catastrophic postfire runoff events also require substantial precipitation or snowmelt events. There are generally some limitations on the spatial and temporal scales of extreme events (*see* **Chapter 1, On the Fundamentals of Hydrological Sciences, Volume 1**). Although we have seen large fires (e.g. greater than 20 000 ha) in some parts of the world in recent years, it is not uncommon for severe hydrologic events to be confined to a small portion of the fire, even to a small portion of the severely burned areas, suggesting that the characteristic patch scale of intense

precipitation and rapid snowmelt events is generally smaller than that of large wildfires (Miller *et al.*, 2003). The fact that these events tend to be limited in their scale is of great consequence to fish, which have evolved migratory life histories and metapopulation strategies to cope with fire related disturbances (Dunham *et al.*, 2003; Rieman *et al.*, 2003).

Flash flood events and related hyperconcentrated flows are partially constrained in scale by the size of the thunderstorm causing the event. Infiltration excess runoff generation processes require that a threshold precipitation intensity be exceeded in order for runoff to occur, and intense precipitation from thunderstorms cover a limited extent. Consequently, it is not uncommon to have only a few small patches within a burned area, typically less than 20 square kilometers each, affected by severe runoff processes (Moody and Martin, 2001; Miller *et al.*, 2003). This dependence on area is not a new concept, as evidenced by a long and prolific literature on the subject of spatial scaling for design precipitation events (e.g. Rodriguez-Iturbe and Mejia, 1974; Rodriguez-Iturbe, 1986; Sivapalan and Blöschl, 1998; Seed *et al.*, 1999 as a small sample). In most engineering applications, the areal reduction factor (ARF) approach has been used. The ARF relates a decrease in storm intensity to the size of the basin. To examine the change in probability of an event of particular intensity and duration as a function of the area under consideration, storm-centered ARFs are needed. Statistics for both storm-centered and basin-centered ARFs can be developed from radar precipitation images of a series of storms. The size of individual basins affected by hyperconcentrated flows is effectively governed by tributary junctions with larger stream channels, with major deposition occurring when what constitutes a major event to a tributary is insignificant to the receiving channel.

Debris flows related to rapid snowmelt characteristically have larger patch dimensions (Miller *et al.*, 2003). Rapid snowmelt generally occurs in concert with large synoptic scale precipitation events covering patches a few hundred kilometers in extent, and in practicality, rapid snowmelt is constrained in scale by elevation. Rapid snowmelt is driven by the high winds during these events and occurs only where air temperatures over a snowpack are above freezing, in one major storm, the elevation range was less than 500 m (Miller *et al.*, 2003). The severe landslide events related to it are further constrained by the land slope, and the final extent of related debris flows is constrained by channel slope, which generally restricts them to headwater basins.

Less dramatic changes to subsurface flow runoff generation processes caused by loss of vegetation or changes in vegetation density are probably effectively constrained by elevation as well. Most measurements of changes in annual water yield only show differences in humid climates. In the interior west of the United States, changes have been seen in mixed conifer and subalpine vegetation types, with little to no change occurring in montane systems at lower elevations (e.g. compare Troendle and King, 1985 to Megahan, 1983).

SUMMARY

Fire is fundamentally intertwined with hydrology. Its occurrence is controlled by seasonal and longer timescale hydroclimatology, and it greatly affects hydrologic processes through its controls on vegetation and soil conditions.

Fire regime presents some expectation for the nature of fire events that might occur in an area. Specifically, some idea of the degree to which vegetation will be removed, the degree to which the soil might be altered, and the patchiness of those effects are tied to the fire regime. Fire regimes also control the type and density of vegetation present in an area.

After a fire, the potentially most destructive runoff generation process is infiltration excess runoff generation, which is influenced by the fractional area with water repellent soils and by the degree to which surface sealing occurs. Observations of these quantities in burned areas are largely missing. In addition, we can expect a greater amount of subsurface flow contribution to streams because of reduced interception and evapotranspiration. The magnitude of these effects is largely controlled by the severity and heterogeneity of the burn, with large homogeneous severe burns having the greatest potential for severe runoff events.

Although postfire runoff generation processes can be spectacular in their magnitude and results, they seem to be generally limited in the areal extent of their effect. This characteristic is critical to the evolved ecology of aquatic ecosystems in response to natural disturbances.

121: Intersite Comparisons of Rainfall-runoff Processes

JULIA JONES

Department of Geosciences, Oregon State University, Corvallis, OR, US

This article argues that despite the limitations of rainfall-runoff data, there are compelling reasons for hydrologists to conduct many more intersite comparisons of rainfall-runoff data. Inferences about hydrologic processes are drawn from an unnecessarily narrow subset of temporal scales, spatial scales, and geographic conditions given the range of data available. In intersite comparison of rainfall-runoff data, we face the same challenge as hydrologic modelers, namely: how can we discriminate among alternative mechanistic explanations for any given rainfall-runoff (or runoff-runoff) dataset? This article (1) provides a justification for additional intersite comparisons given the history and lessons learned from rainfall-runoff and related studies, (2) demonstrates how intersite comparison helps discriminate among alternative hydrologic mechanisms, and (3) outlines steps involved in conducting intersite comparative analysis with a particular focus on analysis of primary data. The article argues that the best approach to intersite hydrology is (re)analysis of original data, which allows us to (1) expand the sample size to include data not yet analyzed and replicate hypothesis tests; (2) ask new questions, even of old data, posed by the current context for hydrology; (3) make new comparisons among records not formerly juxtaposed; (4) use novel statistical approaches to reveal hitherto obscure features of the data, and (5) use ancillary data to refine hypothesis tests about hydrologic mechanisms. The article provides suggestions for the steps involved in intersite comparison including (!) identifying a question, (2) developing a study design, (3) selecting, accessing, and merging datasets, and (4) choosing statistics for comparison of rainfall and runoff data. The endeavor of intersite comparison of rainfall and runoff data is analogous and complementary to the parallel quest for methods of parameter identification and model structure selection in hydrologic modeling.

OBJECTIVE AND SCOPE OF THIS ARTICLE

Of the tools available to hydrologic science – process studies, modeling, and analysis of rainfall-runoff data – data analysis has taken a far back seat over the past few decades. Reasons for this neglect are varied, but many hydrologists are deeply disparaging of the potential for new insights from rainfall-runoff data. A common view is that it is impossible to gain insights about hydrologic mechanisms from rainfall-runoff data because they are inevitably limited to a black-box form of analysis.

This study takes the opposite view, namely, that a great deal can be learned from intersite comparison of rainfall-runoff data. Our inferences about hydrologic processes are drawn from an unnecessarily narrow subset of temporal scales, spatial scales, and geographic conditions, given the range of data available. A distressingly large number of publications simply repeat or challenge the results of a few primary analyses, without exploring unexamined datasets.

In analysis of rainfall-runoff data, we face the same problem as that faced by hydrologic modelers. Hydrologic modelers have great difficulty in identifying the correct parameters from among the very large set of parameters that can optimize any given rainfall and/or runoff dataset applied to a given model structure (Beven, 2000). Moreover, hydrologic modelers must find some means of discriminating among alternative model structures, other than optimizing models to fit rainfall and/or runoff datasets. In intersite comparison of rainfall-runoff data, we face the same challenge, namely: **how can we discriminate among alternative**

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

mechanistic explanations for any given rainfall-runoff (or runoff–runoff) dataset?

The creative analysis of multiple rainfall-runoff records can help test hypotheses about hydrological processes. This optimism is based on the following observations:

1. *A great many rainfall-runoff datasets have never been examined*. Even in datasets that have been analyzed, there exist time periods and temporal resolutions that have never been examined. Because many bitter controversies in interpretation of hydrologic processes hinge upon hypotheses tested using very small samples, replicating these hypothesis tests with enlarged samples of basins and time periods is an obvious first step toward constructing hydrologic theory from analysis of observed data.
2. *New questions can be asked of rainfall-runoff records*, even those that have been analyzed to answer old questions. Old questions that have dominated the analysis of rainfall-runoff data include (i) (forest harvest) treatment effects, (ii) tests of unit hydrograph, and (iii) flood and water yield forecasting. New questions include tests for (i) trends related to climate and/or vegetation and (ii) scaling of rainfall and runoff in space and time. Prediction of runoff in ungaged basins is an ongoing question.
3. *New comparisons may be made among records not previously compared*. The most common intersite comparison has been of runoff in small, treated-control basin pairs within a site. However, many opportunities exist for other kinds of comparisons. For example, (i) two or more control basins can be compared to reveal the influence of some factor that differs between them, (ii) a small basin may be compared to a larger basin that contains it to reveal the effect of spatial scale and routing, or (iii) two or more large basins may be compared to reveal the influences of factors that differ between them. It may even be possible to compare (iv) two basins in very different, distantly spaced sites, to infer the progression of some external forcing, such as climate change.
4. *New forms of statistical analyses may reveal new aspects of rainfall-runoff data*. Intersite comparisons of rainfall-runoff data have been limited to a few statistical methods, which provide limited insights into the patterns of rainfall and runoff. Linear regression, such as of runoff at a treated versus a control basin, has dominated analyses in the past. However, many other statistical techniques such as analysis of variance, autocorrelation methods, cross-correlations, and even spectral analysis or wavelets, can reveal hitherto unknown aspects of rainfall-runoff relationships among sites.
5. *Ancillary datasets are now available to reveal processes operating inside instrumented basins.* With improved computer technology and Internet access, rainfall and runoff data can be readily accessed and merged with rainfall-runoff data. Examples of ancillary data include historical climate data, digital elevation data, maps of geology, soils, and vegetation, and process studies and experiments. In combination with greater computer power and the ready availability of multiple statistical analysis tools, this information can be used to stratify and subdivide rainfall records to more precisely test hypotheses about the hydrologic mechanisms operating in instrumented basins of all sizes and types.

Intersite comparison of rainfall-runoff data involves **analysis of primary datasets, using new data, new questions, novel comparisons, novel statistical approaches, and ancillary datasets to discriminate among alternative mechanistic hypotheses about hydrologic processes**. Records from all gaged basins are relevant, irrespective of basin size, climate type, ecosystem or vegetation type, continent, time period, or length of record. Until recently, primary analyses of rainfall-runoff data have attempted to draw inferences on the basis of the behavior of streamflow, precipitation, or runoff ratios using a single basin at one site, or a single paired basin. *Intersite hydrology comparison studies enlarge this perspective to include multiple basins within a site or across sites, or multiple paired-basin experiments within a site, or across sites.*

The objective of this article is to describe intersite analyses of rainfall-runoff processes, and evaluate their potential and limitations for contributing to basic advances in hydrology. The article consists of

- justification for additional intersite comparisons given the history and lessons learned from rainfall-runoff and related studies
- how intersite comparison helps discriminate among alternative hydrologic mechanisms, and
- an outline of steps involved in conducting intersite comparative analysis with a particular focus on analysis of primary data.

JUSTIFICATION FOR INTERSITE COMPARISON STUDIES

Analysis of primary rainfall and runoff data is by far the most practical and promising approach to intersite comparisons aimed at elucidating fundamental hydrologic processes. Analysis of primary data is necessary because to date, analyses of rainfall-runoff data have not produced accepted generalizations or theory. On the contrary, rainfall-runoff studies, as well as reviews and metaanalyzes of these studies, have left a great many questions and controversies about mechanisms that control runoff.

Some authors have approached intersite comparison by conducting literature reviews or summarizing findings

(e.g. Robinson *et al.*, 2003). A somewhat more formal, but still qualitative, approach involves tabulating streamflow studies. These approaches to intersite comparison are weak because they are qualitative, and rely upon the original authors' assessments of whether findings were significant, independent of sample size or the type of test used. Such approaches also may lead to incorrect synthesis, particularly when they involve many studies with small sample sizes (e.g. short hydrologic records).

Metanalysis overcomes some of the limitations of reviews or summary tables, but it is still limited to answering the questions posed by the original authors. Metanalysis is a quantitative approach to synthesizing results from multiple studies (Gurevich and Hedges, 2001). In metanalysis, studies that share common methodologies – usually an experimental treatment – are compared, so that collective results are not confounded by differences in approaches. Metanalysis techniques estimate the average effect of some treatment across a range of studies, determine whether that average effect is significantly different from zero, and examine whether differences in effects can be attributed to certain characteristics of studies. The "average effect of the treatment" is a measure of the difference between treated and control sample units (e.g. instrumented watersheds) and may be a simple difference or a log-transformed difference (Gurevich and Hedges, 2001). These differences may be weighted to account for differences in sample sizes.

Reviews, summaries, and metanalysis of hydrologic data have focused on predicting the effects of forestry treatments on water yield, flooding, and nutrient/sediment fluxes, although many other questions could potentially be examined. For example, Hibbert (1967) examined the relationship between annual water yield responses and forestry treatments, and concluded that water yield was inversely related to forest cover, although responses to forestry treatments were highly variable and unpredictable. Bosch and Hewlett (1982) expanded Hibbert (1967) study, collecting data on the maximum increase in water yield in the first five years following reduction of forest cover from 94 paired watershed experiments around the world. They concluded that streamflow increases were weakly positively related to the proportion of forest cover removed, and the strength of the relationship between percent forest removed and annual streamflow increase was greatest for conifers, followed by hardwood and scrub vegetation. Bosch and Hewlett (1982) also noted that annual streamflow response was positively related to mean annual precipitation, at least for the sample of watersheds with conifers. The inverse relationship between forest cover and water yield from these studies gave rise to a large set of studies examining the potential for water yield augmentation from forestry treatments. These studies (e.g. Harr, 1983) revealed that short-term water yield increases were not preserved as forests regenerated, and, furthermore, streamflow surpluses often occurred in wet seasons when downstream users did not need additional water. More recent reviews, such as Stednick (1996), also have evaluated the effects of forestry treatments on water yield. More recently, metaanalyzes have examined water yield and flooding consequences of reforestation. For example, based on a metanalysis of 28 small basin studies across Europe, Robinson *et al.* (2003) concluded that reforestation was unlikely to have much effect on floods or lowflows, except where conifer plantations were established on poorly drained soils.

Many intersite comparisons in the form of reviews, summaries, or metaanalyzes have addressed the relationships of rainfall-runoff processes to nutrient and sediment. Binkley and Brown (1993) extended the metanalysis approach to examine the effect of forestry treatments on stream temperature, dissolved oxygen, nitrate, and suspended sediment based on studies in the United States. They concluded that "best management practices" were able to mitigate undesirable changes in most of these properties, except for occasional large storm event-related sediment pulses. Martin *et al.* (1984) and Hornbeck *et al.* (1997) summarized and evaluated the implications of forestry treatments for water quality with a focus on the eastern United States. Binkley *et al.* (2004) summarized the nitrogen and phosphorus concentrations of streams draining forests in the United States, but found no factors that explained the variation among sites.

Reviews, summaries, and metanalysis are an inadequate approach to intersite hydrology comparison in many instances. Reviews are limited to repeating the conclusions drawn by the authors, which may be limited or biased, depending on the experimental design, sample size, and analysis. Frequently, experiments combined in a review or summary have small sample sizes, which lack the power to detect treatment effects. Thus, a summary or evaluation of a set of experiments may provide misleading conclusions biased toward no detected effect (see discussions in Hedges and Olkin, 1985). Although metanalysis is quantitative, and does not rely upon the conclusions of the original authors (Gurevich and Hedges 2001), it is still a weak form of synthesis because it is limited to estimates of effects determined by the original authors of the studies.

HOW INTERSITE COMPARISON HELPS DISCRIMINATE AMONG ALTERNATIVE HYDROLOGIC MECHANISMS

The essence of an intersite comparison is that it examines primary rainfall and/or runoff data to determine the difference, or change, between two or more datasets, at two or more time periods, in order to elucidate hydrologic processes. The best-understood example of this approach is paired-basin forest harvest treatment experiments, in which the ratio of the runoff at the treated and control

basin is compared between the pretreatment and the treated period to infer how the treatment (removal or replacement of vegetation) has affected runoff. *In this article, intersite comparisons encompass all analyses in which rainfall and/or runoff is compared among any two or more sites or two or more time periods, with an aim to inferring hydrologic mechanisms.*

Intersite comparison, when it involves analysis of primary data, can be a useful tool for discriminating among alternative process explanations for observed rainfall-runoff relationships. Analysis of primary rainfall-runoff data can overcome many of the deficiencies of secondary analyses such as literature review and metaanalyzes. Analysis of original data allows us to

- expand the sample size to include data not yet analyzed and replicate hypothesis tests;
- ask new questions, even of old data, posed by the current context for hydrology;
- make new comparisons among records not formerly juxtaposed;
- use novel statistical approaches to reveal hitherto obscure features of the data; and
- use ancillary data to refine hypothesis tests about hydrologic mechanisms.

Replicating Hypothesis Tests and Expanding Sample Size

Intersite comparison studies can expand the sample size of records tested for certain hydrologic responses, and thereby replicate hypotheses tested in earlier studies. Our inferences about hydrologic processes are drawn from an unnecessarily narrow subset of temporal scales, spatial scales, and geographic conditions, given the range of data available (Figure 1).

A vast amount of rainfall and runoff data have been collected, but never analyzed (Figure 1). Rainfall and runoff data have been collected for centuries to aid in predictions of water yield, flooding, and other hydrological properties. Over the past century, and particularly the past 50 years, streamflow gaging technology has permitted the acquisition of continuous records with very fine temporal resolution (5 or 15 minutes). Sites with streamflow gaging have proliferated and number in the millions, with more than 1.5 million sites gaged historically by the United States Geological Survey alone. Continued developments in computer database technology and informatics have permitted data to be digitized and stored for ready access. Many rainfall and runoff records, especially those managed by government agencies, are now publicly available on the Internet.

The fact that rainfall and runoff records are held by a variety of agencies may partly explain why some records have never been analyzed. Streamflow and precipitation have been monitored systematically in basins in the United States and abroad since the early to mid twentieth century. In the United States, such monitoring has occurred under the auspices of individual states, the US Forest Service, the US Geological Survey, the USDA Agricultural Research Service, and state agencies. In the United Kingdom, monitoring is conducted under the auspices of the Center for Ecology and Hydrology. In Australia, monitoring is conducted by the water resources branch of the CSIRO, Forestry Tasmania, and state and municipal agencies. In Japan, streamflow monitoring is conducted by the Forestry and Forest Products Research Institute and Japanese universities. All countries have some form of streamflow monitoring, although record length, quality, and availability vary.

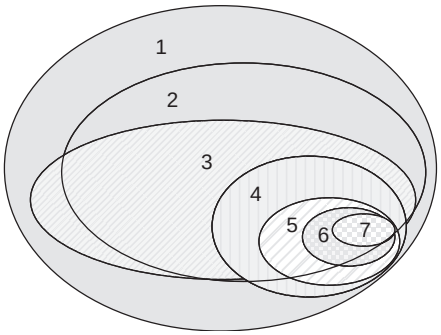

Figure 1 Most inferences from data about hydrologic processes are drawn from an unnecessarily narrow subset of temporal scales, spatial scales, and geographic conditions, given the range of data available. A distressingly large number of publications simply repeat (or challenge) the results of a few primary analyses without exploring unexamined datasets. Only a small fraction of the published studies in hydrology (1) utilize any measured streamflow data (2) (boxes not to scale). The majority of these studies are based on data from small basins (3) despite the enormous numbers of gaged large basins. Of the small, instrumented basins whose records are noted in any publication (3), only a fraction have been analyzed (4), so that many basin records remain unexamined. Few of these studies involve analysis of data at finer than annual time steps (5), and only a fraction of studies utilize records longer than a decade (6), so very few studies examine daily data over long periods comparable to most hydrologic modeling efforts (7). Apart from analyses of instantaneous peak flows, virtually no studies have compared streamflow data among sites at finer than daily time steps. Thus, there are at least four opportunities for intersite comparisons involving hypothesis testing and expanded data use: (a) using data to verify modeling and process studies, which have not involved measured data; (b) analyzing large basin records that have never been looked at; (c) analyzing small basin records that have never been looked at; and (d) extending the time periods, or increasing the temporal resolution (e.g. from annual to daily, daily to hourly) of analyses for basins whose records have been examined. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Also, intersite comparisons may be made more difficult by the fact that agency jurisdiction and consequent objectives and study designs in monitored basins vary with basin size. Small basins are more likely to be instrumented for research and forest or agricultural land use management, whereas large basins are more likely to be instrumented for water management and supply assessment objectives. In the United States, most basins monitored for research purposes by federal agencies (USFS of the USDA, NCRS of USDA, USGS research branch) are small, usually $<1\,km^2$, usually with a single land owner and one dominant vegetation type. In contrast, basins monitored for water supply and flood control purposes may drain areas up to millions of square kilometers and typically encompass multiple land uses and vegetation types.

Intersite comparisons could replicate a number of hypotheses that have been advanced about hydrologic responses, mostly based on experiments designed to test the effect of vegetation removal on runoff. These hypotheses are based on analyses conducted from records using a small number of basins, limited record length, basins of only one – usually small – size, and only one temporal resolution – usually annual runoff (Figure 1). Several key hypotheses merit replicated testing, including statements (from Hibbert, 1967; Bosch and Hewlett, 1982; Jones and Grant, 1996; Beschta *et al.*, 2000) that the hydrologic response to vegetation treatment is positively related to

- the amount of vegetation removed;
- the amount of precipitation;
- the evergreen-ness of the vegetation;

and negatively related to

- the amount of runoff;
- the size of the basin.

Analyses of primary rainfall and runoff data using more sites, longer records, and finer temporal resolutions of data could replicate tests of these hypotheses, and resolve contradictions among them. Reviews (e.g. Hibbert, 1967, Bosch and Hewlett, 1982) have included many small paired-basin records in the initial posttreatment period. However, the primary data from many of these small, paired basins have not been reanalyzed, although much of these data are now available through the Internet *(see* e.g. the Clim-DB, Hydro-DB website **`http://www.fsl.orst.edu/climhy/`**). Moreover, the primary records from other small basin sites that were not part of paired-basin experiments, recently established paired-basin experiments, and a great many large basins monitored for flood control and water yield have not been analyzed (Figure 1). In cases where streamflow and climate records are continually expanding, new trends may emerge from examination of longer records. The treated-control relationships in small paired-basin experiments summarized by Bosch and Hewlett (1982) could be reanalyzed using longer records to ascertain how vegetation succession alters water yield over time. Examination of finer resolution data may help discriminate multiple scales of pattern indicative of several interacting hydrologic mechanisms. For example, Jones and Post (2004) showed that basins with similar hydrologic response to forest harvest at the annual streamflow resolution had very different day-to-day patterns of hydrologic response. Continuous records of streamflow or precipitation that may have been analyzed at one temporal resolution (such as annual or monthly) can be resampled at finer resolutions (such as storm, daily, or hourly) to seek evidence for hydrologic processes that are not detectable at monthly or annual time scales.

Posing and Answering New Questions

Often, intersite hydrology involves asking new questions about old data. Typically, streamflow monitoring studies were established for reasons that are no longer principal motivating factors for research or management. For example, an original objective for many USGS instrumented basins included establishing flood frequency curves for designing downstream engineering structures such as dams or bridges. However, in many cases, the construction of engineering works has been completed, while upstream land use may have changed the flood frequency distributions. Also, many USFS sites established paired watershed experiments to determine how water quantity would be affected by forest harvest treatments. However, forest harvest and road building practices have changed and no longer resemble the treatments imposed in the experiments.

Changing contexts have created important new questions about rainfall-runoff processes. New areas of concern include considerations of climate change, scaling, and the ongoing challenge of prediction in ungaged basins. For example, we can ask how the rainfall-runoff relationship has changed over time, and interpret those findings to infer changes in climate and vegetation. Also, we can examine how the rainfall-runoff relationship varies with spatial scale to understand how perturbations propagate in streamflow networks. We can combine these two general questions to determine how the rainfall-runoff relationship varies as a function of basin scale and the temporal resolution of the data to help scale up our understanding of hydrologic processes to that of global climate models. We can also ask how the geography of basins influences the rainfall-runoff relationship based on intersite comparisons, and perhaps derive principles on which to base predictions of runoff in ungaged basins.

Making Novel Intersite Comparisons

A key component of intersite comparison of rainfall and runoff involves the choices of basins to compare. Intersite hydrology involves comparisons of rainfall and runoff

Table 1 Novel comparisons among basins represent new experimental designs for intersite comparison to test a variety of hydrologic mechanisms influencing rainfall-runoff relationships. Examples are based on runoff data, but could be extended to rainfall/runoff ratios in cases where both rainfall and runoff data exist for all the sites

Compare	To	Study question	Hydrologic interpretation
Runoff at treated basin (vegetation removal, roads)	Runoff at control basin	Was there a detectable effect of an experimental treatment?	Water balance altered by vegetation removal and/or roads routing water
Runoff at treated basin, by time period since treatment	Runoff at control basin, by time period since treatment	How did the treatment effect change over time?	Water balance affected by vegetation recovery or other covarying factors
Runoff at treated basin, by season	Runoff at control basin, by season	How did the treatment effect vary by season?	Water balance affected by seasonal variation in wetness, temperature, and/or other factors
Runoff at treated, by event size	Runoff at control, by event size	How did the treatment effect vary by the size of the runoff event?	Water balance affected by antecedent wetness, precipitation, snow, and/or other factors
Runoff at multiple treated basins, by time since most recent pretreatment disturbance	Runoff at multiple control basins, by time since most recent pretreatment disturbance	How did the treatment effect differ among basin pairs according to the time since most recent pretreatment disturbance?	Water balance affected by changes in vegetation structure and species composition over succession
Runoff at small basin	Runoff at large basin containing the small basin	How does runoff vary with basin scale?	Hydrograph affected by routing of water in network and/or differences in vegetation type and cover and/or roads small to large
Runoff at basin in climate type a	Runoff at basin in climate type b	How does runoff vary with climate?	Water balance affected by differences in timing of moisture, freezing
Runoff at basin in vegetation type a (or land use type a)	Runoff at basin in vegetation type b (or land use type b)	How does runoff vary with vegetation type (or land use)?	Water balance affected by differences in timing, amount of transpiration, evaporation, interception

among basins according to the differences in those basins, whether differences arise from "controlled" or inadvertent experiments, or geographical differences. It involves examining flow regimes and responses to treatment across divergent vegetation, hydrologic systems. Intersite comparison studies could make important contributions to inferring the importance of various hydrologic processes by examining novel pairings of basins that have not been compared before (Table 1). Obvious comparisons involve (i) multiple neighboring or nearby basins, and (ii) nested basins.

Multiple small, neighboring, or nearby basins are a logical choice for intersite comparisons. Small basins are instrumented at many United States Forest Service-sponsored experimental forests (e.g. Andrews, Caspar Creek, Coweeta, Fernow, and Hubbard Brook Experimental Forests) as well as United States Department of Agriculture Agricultural Research Service sites (e.g. Reynolds Creek, Walnut Gulch). When multiple basins are instrumented in a single site, they allow examination of environmental variation and treatment effects on streamflow. Some sites have implemented one or more "paired watershed experiments" in which a small control and one or more small treated (usually adjacent) basins are monitored over some pretreatment period, and then a treatment, such as vegetation removal, is imposed on one basin, and the monitoring of both the treated and control basin is continued for some posttreatment period. Bosch and Hewlett (1982) identified nearly 100 such treated/control basin pairs in several dozen locations with experiments involving modification of forest, shrub, and grassland vegetation.

Multiple large basins also could be compared using intersite analysis. Large basins generally are instrumented for flood and water yield forecasting. Large paired-basin experiments do not exist because of the difficulty of implementing a treatment over a large area and because of the lack of large basins in a "control" state. However, neighboring or nearby large basins with contrasting vegetation histories can be considered as parts of inadvertent experiments (*see* e.g. Jones and Grant, 1996; Thomas and Megahan, 1998). Nested basin comparisons are possible when small, instrumented basins occur inside large, instrumented basins (see e.g. the Andrews Forest, Hubbard Brook, Coweeta). Nested basins allow the testing of scaling relationships (Gupta and Waymire, 1998).

Table 2 Novel statistical approaches, multiple sites, and longer records permit asking novel questions in intersite comparisons of rainfall and runoff data

Questions	Number of Variables	Sites	Periods	Analysis tool	Illustrative citations
1. What is the mean value of rainfall, runoff?	One	One	One	Mean	Post *et al.* (1998)
2. What is the variation in rainfall, runoff?	One	One	One	Variance, standard deviation, coefficient of variation	Post and Jones (2001)
3. What is the shape of the distribution of rainfall, runoff?	One	One	One	Mean, variance, and higher moments; quantiles	Gupta and Waymire (1989)
4. How has the mean value of rainfall, runoff varied over time?	One	One	Two or more	Means	Andreassian *et al.* (2003)
5. How is rainfall, runoff related to itself over time?	One	One	Two or more	Time-series methods: autocorrelation, spectral analysis, wavelets	Kirchner *et al.* (2000) Lafrenière and Sharp (2003) Tague and Grant (2004)
6. How is runoff (rainfall) related across sites?	One	Two or more	One	Linear regression	Hibbert (1967), Bosch and Hewlett (1982), Andreassian (2004)
7. How does the shape of the rainfall or runoff distribution change across sites or time?	One	Two or more	One or more	Statistical self-similarity; quantiles	Gupta and Waymire (1993, 1998), Andreassian *et al.* (2003)
8. How does the rainfall or runoff relationship between two sites change over time?	One	Two	Two or more	Linear regression for each time period; anova by time period	Jones and Grant (1996), Thomas and Megahan (1998), Beschta *et al.* (2000), Jones (2000), Jones and Post (2004)
9. How is rainfall related to runoff?	Two	One	One	Rainfall-runoff ratio	Post and Jones (2001), Kokkonen *et al.* (2004)
10. How is rainfall related to runoff at a site over time?	Two	One	Two or more	Cross-correlation; cross-spectral, cross-wavelet	Post and Jones (2001), Lafrenière and Sharp (2003)

Novel Statistical Approaches Reveal Hitherto Unquantified Aspects of Data

Most of the published analyses of rainfall and runoff data are based on a narrow set of statistical tools. Linear regression has been widely used. However, other techniques, including time-series analysis, autocorrelation, and cross-correlation approaches have the potential to reveal aspects of rainfall and runoff data that could be compared among sites, and lend themselves to interpretations of physical or biological processes (Table 2).

New Ancillary Data to Refine Hypotheses

Counter to the assertion that rainfall-runoff data are a "dead end" for determining hydrologic processes, this article contends that intersite comparisons of rainfall and runoff data can shed light on the hydrologic processes operating within the basin. While such interpretations are not definitive, rainfall, runoff, and ancillary data can be used to narrow the range of possible interpretations of hydrologic mechanisms operating at a given site for a given time period. In so doing, researchers are engaged in a process analogous to that conducted by hydrologic modelers in selecting the appropriate model structure and identifying correct parameters.

Intersite comparisons involve drawing inferences about the water balance – revealing or inferring the processes inside the black box. The water balance is the basic theoretical tool for the interpretation of analyses of rainfall-runoff data (Figure 2). Any analysis of rainfall and runoff confronts the difficulty of discriminating which of the large number of terms in the water balance explain the hydrologic processes at a site under a given set of conditions (Figure 2a).

Intersite comparisons can make progress by utilizing ancillary data to narrow down the number of possible terms in the water balance that could be operating under certain conditions, thereby reducing the number of possible mechanistic interpretations (Jones and Post, 2004). If certain moisture, temperature, or eco-physiological conditions are

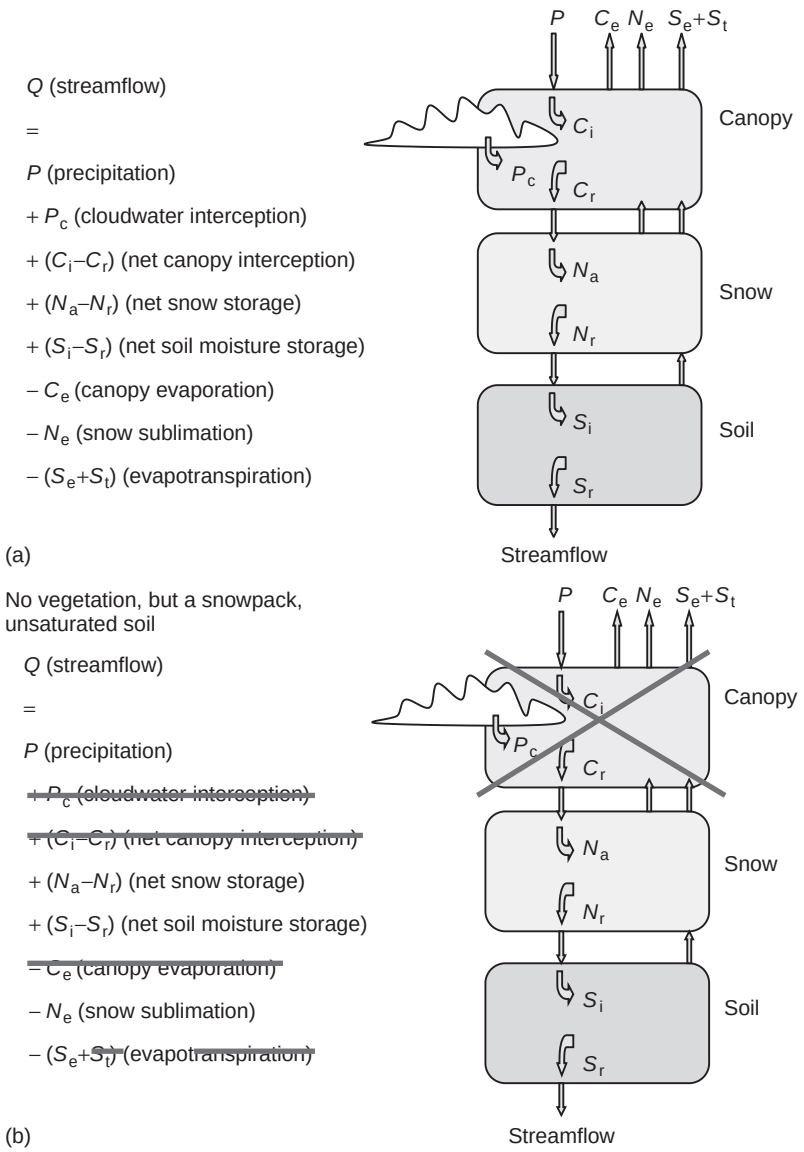

Figure 2 An approach to simplifying the number of possible hydrologic processes that can explain rainfall-runoff data involves partitioning data into subsets, each of which can be argued to involve a subset of terms in the water balance. Thus, the complete water balance for a given site (a) can be simplified into a set of water balances for conditions when (b) vegetation is absent, or (c) both vegetation and snowpack are absent, or (d) snowpack is absent and soils are near-saturated, or (e) vegetation is not actively transpiring, snowpack is absent, and soils are near-saturated. Analyses of rainfall-runoff relationships for each of these subsets of data can help bracket the range of values for the terms in the water balance. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

met, key terms can be effectively removed from consideration in the water balance for a given place or time period (Figure 2b–2e). For example, if vegetation is absent, soils are unsaturated, and a snowpack is present, any observed change in streamflow relative to precipitation must involve snow and soil moisture storage only (Figure 2b). If, in addition, no snowpack is present, the water balance can be simplified to consider only the effects of the soil moisture storage (Figure 2c). Alternatively, when vegetation is present, but snow is absent, and if the soil is saturated, then the water balance is regulated by interception, evaporation, and transpiration processes in the vegetation canopy (Figure 2d). To further simplify the water balance, it may be possible to identify periods when vegetation is not actively transpiring, and the water balance can be reduced to the interception and evaporation terms (Figure 2e).

This kind of approach can guide intersite comparison studies, because data are collected on related climate variables in addition to precipitation and streamflow at most

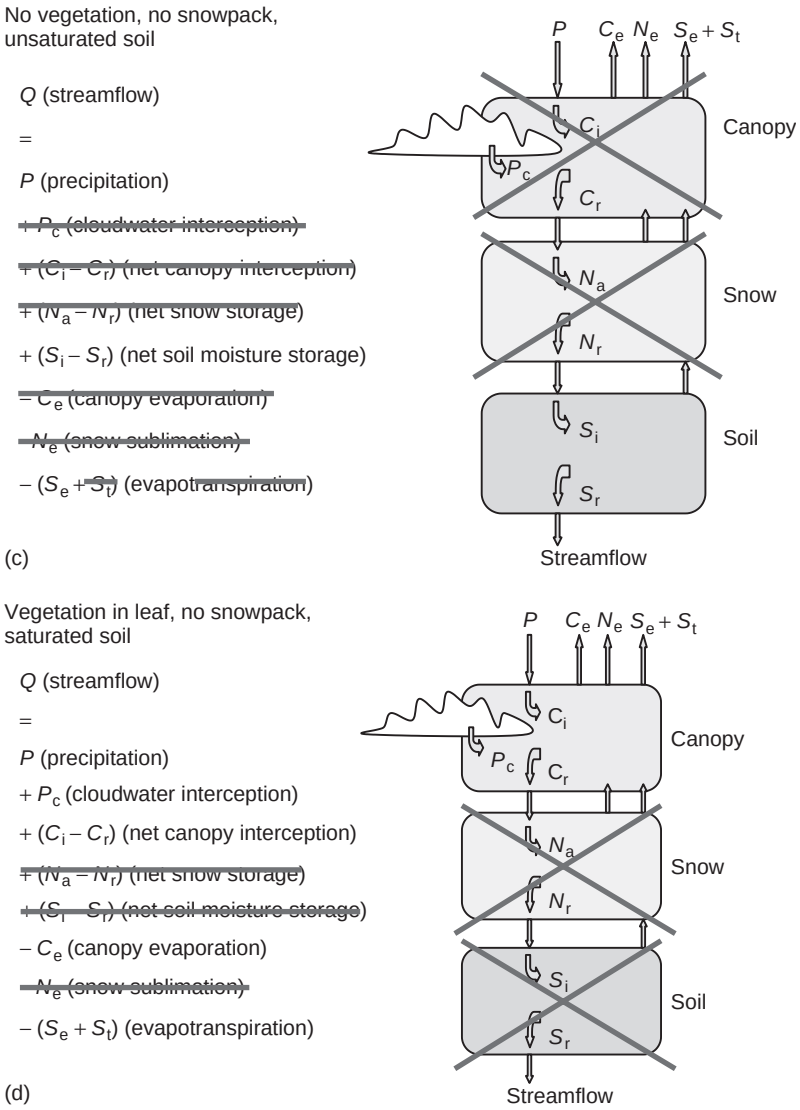

Figure 2 (*continued*)

instrumented sites (see the Reynolds Creek dataset publications for an excellent example, described in Slaughter *et al.*, 2001; Pierson *et al.*, 2001). Instrumented variables differ among sites, and, over time, within a site, depending upon the objectives for the site and whether the data have been or are being utilized for research and/or management.

AN OUTLINE OF STEPS INVOLVED IN CONDUCTING INTERSITE COMPARATIVE ANALYSIS

The steps involved in conducting an intersite comparison are

- identifying a question;
- developing a study design;
- selecting, accessing, and merging datasets; and
- choosing statistics for comparison of rainfall and runoff data.

Identifying a Question

Many questions are possible for intersite comparisons (Tables 1 and 2). The list below (and Tables 1 and 2) contains questions that hydrologists can answer using intersite comparison. Answers to these questions would represent important contributions to the current state of knowledge in hydrology.

1. *Are basins unique, or are there consistent types of behavior among basins?*

Intersite comparisons among multiple instrumented basins may reveal consistent groupings of basin behavior. If

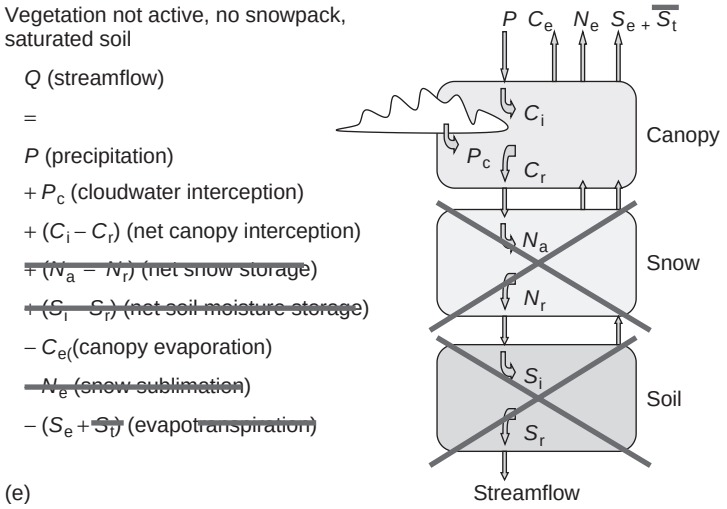

Figure 2 (*continued*)

consistent types of rainfall-runoff behavior can be identified for groups of instrumented basins, a classification system may be developed, which could facilitate the prediction of runoff from ungaged basins (see the IAHS PUB initiative).

2. *What factors (climate, vegetation, subsurface properties, land use history) explain similarities and differences in streamflow among basins?*

Intersite comparisons can involve *post hoc* superexperiments, in which rainfall-runoff responses associated with one factor (such as vegetation) can be examined while controlling for other factors (such as climate, land use history). Understanding, and separating, the roles of climate, vegetation, and other factors will help elucidate hydrologic mechanisms that account for streamflow in ungaged basins.

3. *Can streamflow be predicted in ungaged basins based on a priori knowledge?*

Records from multiple instrumented basins could be examined in such a way as to test models for predicting streamflow in ungaged basins.

4. *Are precipitation, streamflow, or rainfall-runoff relationships changing over time?*

Rainfall-runoff relationships are the basis for predictions of water yield and flooding and other practically relevant aspects of hydrology. Intersite comparison of long-term rainfall-runoff records can reveal changes in these relationships, and, potentially, the factors that cause the changes.

5. *How does the variability of streamflow and rainfall change with time scale – diurnal, storm, seasonal, or the time scales of vegetation succession and climate change?*

Existing records of streamflow and precipitation have high temporal resolution, potentially revealing processes occurring at multiple time scales. However, most published analyses of these records have dealt with annual or mean annual data. Intersite analyses of these records may reveal hydrologic processes that produce streamflow responses at diurnal or storm time scales, while other analyses may reveal processes operating at the time scales of vegetation succession and climate change.

6. *Are changes over time in streamflow occurring in response to vegetation change, climate change, or other drivers?*

Intersite comparisons can involve examination of changes in basins whose vegetation and climate history is well documented, potentially revealing responses to vegetation, climate change, natural and anthropogenic disturbances, and their influences on streamflow.

7. *Do basins respond differently to similar perturbations or treatments? If so, what accounts for differential responses?*

Intersite comparisons can investigate the causes of divergent streamflow responses to similar treatments (such as vegetation removal). For example, the presence of snow, soil depth and texture, and the seasonality of vegetation water use; all may produce different responses to the same treatment in different basins.

8. *Do basins respond predictably to perturbations or treatments?*

Very few of the existing long-term rainfall/runoff records are regularly used for testing hydrological models. Yet, the lengths of these records, the detailed associated knowledge about these basins, and the differences among them provide many opportunities for testing hydrologic model predictions.

9. *Are streamflow responses to perturbations or treatments linear or nonlinear? Are there thresholds of response?*

Intersite analysis of rainfall-runoff records offers the opportunity to seek nonlinear responses, or thresholds, in hydrologic system behavior.

Developing a Study Design

The second step in an intersite hydrology comparison is to establish an experimental design. The experimental design involves identifying a comparison that appropriately tests the study question (Table 1). It also involves selecting the number of basins, variables, and time periods for the analysis (Table 2). In an intersite comparative analysis of primary rainfall and runoff, data are included from a sample of basins selected because the hydrologic processes are expected to differ among these basins in a predictable fashion. Study basins may be selected to replicate the effects of a given treatment (deliberate or inadvertent), or to examine rainfall or runoff relationships across a gradient of conditions.

A number of decisions are made in designing any intersite comparison. These include the following:

1. Choosing the study basins.
2. Choosing a temporal resolution.
3. Stratifying data by time period, season/climatic conditions, event size, or other factors.

The study basins should be chosen so as to allow testing of the question of interest, usually by selecting basins that differ from one another according to the factor of interest (whether or not this difference was the result of a human-imposed treatment) (Table 1). The temporal resolution of the data (ranging from 15 minutes to annual or decadal) also should be chosen so as to permit testing of the question of interest. For example, questions involving the timing and routing of runoff (e.g. flooding) focus on the time scale of individual storms (peak discharges, storm hydrographs), whereas questions involving the amounts of water in various components of the water balance may focus on hourly, daily, or annual data. Because the influence of hydrologic mechanisms varies according to the conditions, it can be quite important to stratify data by time period (e.g. age of vegetation, or time since treatment), by season or climatic conditions (e.g. subzero vs warm temperatures, wet vs dry conditions), by event size (e.g. amount of precipitation or runoff), or other factors.

Selecting, Accessing, and Merging Datasets

Selecting, accessing, and merging datasets is the third step in an intersite comparison. Data availability poses some restrictions on the types of intersite hydrology comparisons that can be made (Figure 3). Streamflow, precipitation, temperature, snow, vegetation, geology, topography, and other records are all pertinent to intersite comparisons. Each form of data has its own advantages and weaknesses.

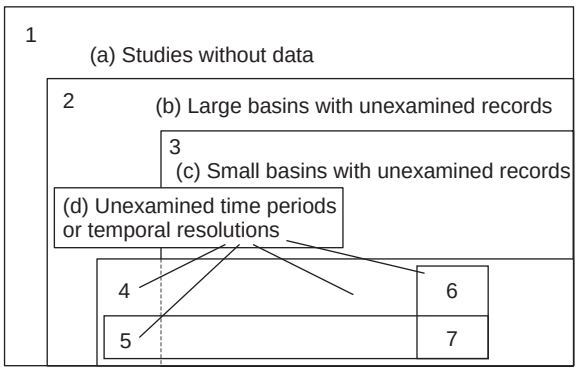

Figure 3 Data availability poses some restrictions on the types of intersite hydrology comparisons that can be made (ellipses not to scale). Many basins have streamflow records (1), but only some have been digitized (2). Ancillary data on precipitation and temperature, not all of which is digitized, are available only for some basins (3). Of the total number of gaged basins, only a few involve treated/control pairs, and not all of these records are digitized (4). Ancillary data on vegetation, snow, and other ecological factors is available for only a subset of basins, whether they are treated-control pairs or not (5). Online datasets that involve streamflow, precipitation, temperature, and ancillary data on vegetation, snow, and other ecological factors are only a small fraction of the total data, and these are limited to daily time resolutions (6). A very few sites have online data available at finer than daily time steps (7)

Streamflow measurements vary in accuracy and precision, and these differences among sites determine the minimum change that can be detected in an intersite comparison of runoff data. In small basins, streamflow is measured using flumes or weirs with controlled cross sections, so stage height observations are readily converted to discharge. The greatest uncertainty, however, is associated with the largest flows for which measurements are most difficult to obtain. In large basins, discharge is calculated on the basis of the measured stage height on a known cross section; changes in the cross section associated with flooding add additional uncertainty to discharge estimates from large basins. Streamflow records typically are continuous, so, if the original charts are saved, or the record is digitized, it is possible to capture streamflow patterns at very fine temporal resolutions, including small diurnal fluctuations (*see* e.g. **`www.fsl.orst.edu.lter/data/hydrology`**). The weir, flume, or cross section determines the ability of the streamflow record to capture small variations in discharge. For example, trapezoidal flumes typically cannot capture very small fluctuations as well as V-notch weirs. Thus, the minimum detectable change in a given streamflow record is smallest for records collected in small basins using V-notch

weirs, and largest for records collected in large basins where cross sections change frequently.

Precipitation and air temperature records are also typically available from sites adjacent or near to streamflow gages, but it is challenging to match point measurements of precipitation with area measurements of streamflow. Capturing the spatial variability of precipitation (or air temperature) is problematic, particularly for large basins, and especially for particular time periods in the past. Most small basin streamflow studies involve one or more precipitation and air temperature gages. When multiple precipitation (air temperature) gages are present, it is possible to spatially interpolate precipitation or temperature over the basin (Daly *et al.*, 2002; Smith, 2002). Maps of interpolated precipitation can be found at **http://www.ocs.orst.edu/prism/**, and illustrative maps of temperature interpolations can be found at **http://www.ocs.orst.edu/pub/smithjw/hja/**).

Accurate representation of precipitation is more difficult in large compared to small basins, and this difficulty is compounded by the fact that precipitation gages in large basins are maintained by different agencies than those that manage streamflow data collection. Thus, for example, in the United States, the US Geological Survey manages streamflow data collection from large basins, but state climate services or the National Oceanic and Atmospheric Administration manage precipitation records.

In an intersite comparison study, it is generally possible to match fine-resolution temporal streamflow data with precipitation data at the small basin scale, because these records usually were collected as part of the same monitoring effort. However, at the large basin scale (above 1 km^2), it may not be possible to match historical streamflow with precipitation at temporal resolutions finer than monthly, particularly if spatial heterogeneity is important. Obtaining historical precipitation data for periods of record that match gaged periods in large basins can be a significant challenge. Nevertheless, historical climate records have been compiled at the national scale in some cases (*see* e.g. for the United States, **http://cdiac.esd.ornl.gov/epubs/ndp019/ndp019.html**). Temporal resolution of precipitation and air temperature data at the small basin scale is usually high, and may even match that of streamflow (e.g. 15-minute data). However, obtaining spatially interpolated historical – or even current – precipitation and air temperature data at temporal resolutions finer than monthly may be difficult for many large basin sites (*see* **http://www.ncgc.nrcs.usda.gov/branch/gdb/products/climate/data/index.html**).

Other data, such as vegetation cover and type, soils, geology, and land use history may be critical for interpreting intersite hydrology comparisons. However, these data are much less likely than streamflow or climate data to be available or tabulated in a format that is easily interpreted. Some good examples of vegetation, soils, and other spatial datasets linked to streamflow and precipitation can be seen at long-term ecological research (LTER) sites (**www.lternet.edu**), especially those that were originally experimental forests, in the United States. Even if they are available, vegetation, soils, and land use history data are very unlikely to have been collected in a consistent framework across multiple sites, increasing the difficulty of making use of such data in an intersite hydrology comparison. When conducting an intersite hydrology comparison, it is usually necessary to contact researchers or managers at individual sites for help in obtaining and interpreting this sort of data.

Intersite hydrology comparisons are limited by the availability of data (Figure 3). Efforts are underway to systematically collect and provide hydrologic data (see hydrodb website, **http://www.fsl.orst.edu/hydrodb/**). However, hydrologic data may still be in original analog formats, or not yet publicly available, at many sites of interest for intersite hydrology studies. Researchers will need to seek out data of interest from these individual sites, and they will also need to support and participate in efforts to make such data publicly available.

Intersite comparisons require that hydrologic data be collected using comparable measurement methods, units, and data records. Relative to other kinds of comparative studies, such as vegetation or stream chemistry, intersite hydrology and climate studies are made easier by the fact that streamflow data collection methods are largely standardized and common units (e.g. cfs, cms) are used. Both precipitation and streamflow data are typically collected at 15-minute or finer resolution, and are tabulated at daily, monthly, and annual resolution.

An intersite hydrology comparison also may require overlapping records, but certain intersite hydrology comparisons may not. Runoff ratios require overlapping precipitation and streamflow periods of record, and intersite comparisons of runoff ratios probably should be made controlling for climate by using a common period of record. Paired-basin experiments require the collection of simultaneous records at treated and control basins. Intersite comparisons looking for trends over time due to climate change also require simultaneous records. On the other hand, intersite hydrology comparisons of paired-basin experiments need not have records from the same time periods, since the questions of interest relate to the periods before and after imposition of a treatment.

The lengths of record available limit the scope of what can be determined from an intersite hydrology comparison (Figure 3). Short records (i.e. a few years) lend themselves to calculations of metrics, such as runoff ratios, which may be compared to other sites, or examined to compare

hydrologic processes at finer than annual temporal resolutions such as seasonal, storm, or daily time scales. In contrast, long records allow examination of changes over time in metrics, such as runoff ratios, that may be related to longer-term processes, including vegetation succession, disturbance, or climate change.

The numbers of sites with records of hydrology, climate, and environmental variables also limit the scope of what can be learned from intersite hydrology comparisons (Figure 3). There is no complete listing of small monitored basins, or of small paired-basin experiments. Only a couple of dozen small basins ($<1\,km^2$) exist in the United States where streamflow and precipitation data have been consistently monitored for periods of several decades and where good records exist describing vegetation cover, soils, and landscape history (see `http://www.fsl.orst.edu/hydrodb/`). Bosch and Hewlett (1982) noted a total of 26 sites in 16 states in the United States where small paired-basin experiments had been conducted, but many of these records are not available in digital form. On the other hand, hundreds of large basins (10^1 to $10^6\,km^2$) have long-term streamflow records collected by the USGS. However, these sites may not have matching precipitation records, and they do not have compiled records of vegetation cover, soils, or landscape history.

Choosing Statistics for Comparison of Rainfall and Runoff Data

Lots of ink and breath have been expended in statistical controversies in hydrology. Some argue that discussion of statistical methods distracts from the essential questions. However, statistical approaches force researchers to clearly articulate the questions and hypotheses they are testing. Many statistical techniques are now available (Table 2). As in any statistical analysis, the analysts must keep in mind that if data are not independent, or if data are not normally distributed, certain statistical findings will be biased. Thus, tests of autocorrelation, and data transformations, are an important component of intersite comparisons.

The statistics used may be measures of single variables, or they may be measures involving two or more variables. Statistics that are useful for intersite comparisons include means, variances, general linear models (regression and analysis of variance), autocorrelation methods (including spectral analysis and wavelets), and cross-correlation methods (Table 2). Single-variable measures include means, variability (e.g. standard deviation), distributions or measures of distribution shape, or measures of autocorrelation. Bivariate measures include linear regression, analysis of variance, rainfall-runoff ratios, and cross-correlation.

Single-variable Analysis – Comparison of Means

Mean daily (or monthly, or annual) streamflow may be compared across a range of sites in an intersite hydrology study (Table 2). For example, Post *et al.* (1998) compared mean annual precipitation and mean annual runoff across sites. This kind of comparison of long-term averages can reveal differences in climate, or which types of vegetation use larger or smaller proportions of water input as precipitation. Post *et al.* (1998) showed that rainfall-runoff ratios were similar across four forested sites with strongly contrasting climates.

Single-variable Analysis – Comparison of Variance or Variation

A second single-variable approach to comparison involves measures of variability (Table 2). Standard deviations, standard errors, or coefficients of variation (standard deviation divided by the mean) of streamflow can be evaluated to compare variability among sites or time periods. For example, Post and Jones (2001) conducted an intersite comparison based on the coefficients of variation of daily, monthly, and annual streamflow at small, forested basins in the United States. They replicated the common finding of decreased variability with increasing temporal aggregation, noting that streamflow variability was much higher at daily timescales than at seasonal or annual time scales, at four sites with temperate deciduous, temperate conifer, and tropical forest. More interestingly, from the point of view of intersite comparison, Post and Jones (2001) showed that the greatest variability in rainfall and runoff varied among sites for any give time scale: variability at the daily time scale was greatest at eastern United States temperate forest sites in mesic climates, variability at the seasonal time scale was greatest at western United States conifer forest sites in xeric (Mediterranean) climates, and annual variability was greatest at tropical forest sites in hurricane-affected Puerto Rico.

Single-variable Analysis – Comparison of Higher Moments of Distributions or Quantiles

A third single-variable approach involves creating and comparing measures of the shapes of distributions of precipitation, streamflow or rainfall-runoff ratios (Table 2). For example, Andreassian *et al.* (2003) created measures of the proportions of the daily streamflow distributions that fell above or below certain benchmarks (e.g. flood flows, low flows, base flows) and compared how these proportions changed over time for a number of small, forested basins. This kind of comparison can be used to detect changes over time, or cross-site differences, in low flows, high flows, or other parts of the flow frequency distribution. Andreassian *et al.* (2003) showed that flow frequency distributions had remained relatively constant at a recently reforested basin in Ohio, USA (Coshocton) and a burnt shrubland basin in southern France (Real Collobrier), but low flows and baseflow had shifted downwards over time at an old-growth basin in Oregon, USA (Andrews WS 2). Gupta and

Waymire (1998) used the moments of the distributions of rainfall and runoff to test for self-similarity across a set of basins arranged in increasing size.

Single-variable Analysis – Comparison of Autocorrelation

A fourth single-variable approach involves measures of how streamflow or rainfall are related to themselves over time (Table 2). Measures of autocorrelation can be used to characterize and compare streamflow, precipitation, or rainfall/runoff ratios among sites at various time scales, which can then be compared across sites or time periods. For example, Post and Jones (2001) conducted an intersite comparison based on the autocorrelation coefficients for a range of lags using both daily and monthly streamflow at four forested sites. They were able to detect differences among sites in the seasonal and daily timescales rainfall-runoff relationships that were linked to differences in climate and vegetation. Tague and Grant (2004) applied autocorrelation analysis to streamflow records from two large basins in Oregon, showing how the seasonality of flows differed between two basins with contrasting geology.

Single-variable Analysis – Comparison of Spectra or Wavelets

More complex single-variable approaches to intersite comparison of rainfall and runoff data involve the use of spectral analysis or wavelets (Table 2). Kirchner *et al.* (2000) constructed log–log plots of the spectral power of rainfall, streamflow, and stream chloride concentrations in catchments in Plynlimon (Wales), and showed that the plot of spectral power of chloride concentration was fractal (had a positive slope). Lafrenière and Sharp (2003) used wavelet analysis of streamflow from glacially controlled lakes to infer and separate the influences of snowmelt from rainfall on discharge.

Bivariate Analysis – Comparison Using Linear Regression

Linear regression has been widely used to compare two sites over two or more time periods (Table 2). The slope of a regression line comparing e.g. runoff at site 1 versus site 2 (y/x) is a ratio that can be compared across sites or time periods. The earliest studies of paired-basin experiments used a regression of streamflow at the treated (y-axis) versus the control (x-axis) to characterize the treatment effect. Beschta *et al.* (2000) used linear regression to reexamine data from the small basins in Jones and Grant (1996). Jones and Grant (1996) used regression analysis to examine the ratio of change in peak discharge versus change in cumulative area harvested in large (60 to 600 km^2) basins, as a way to detect whether forest harvest was associated with changes in peak discharges. Thomas and Megahan (1998) used analysis of covariance to reexamine data from large basins in Jones and Grant (1996).

Bivariate Analysis – Comparison Using Analysis of Variance

Analysis of variance has been less widely used than linear regression, but it also can be used to compare two sites over two or more time periods (Table 2). The ratio of e.g. runoff at site 1 versus site 2 can be tested for significant changes by time period using ANOVA. A more useful ratio is the log-transformed ratio, i.e. $\ln(y/x)$, which is equivalent to the difference of the log-transformed values, i.e. $\ln(y) - \ln(x)$. Eberhardt and Thomas (1991) recommend that the log-transformed ratio be used in analysis of streamflow from paired-basin experiments. For example, Jones and Grant (1996) and Jones (2000) used the log-transformed ratio of streamflows at the treated versus the control basins as a dependent variable in an analysis of paired-basin treatment effects on peak discharges. Using this ratio, they were able to show how peak discharges changed in the treated versus the control in small paired-basin experiments over 5-year periods after forest harvest (Jones and Grant, 1996; Jones, 2000). Jones and Post (2004) used this ratio to calculate how daily flows changed in the treated versus the control basins in small paired-basin experiments over 5-year periods after forest harvest.

Bivariate Analysis – Comparison Using Rainfall-runoff Ratios

Rainfall-runoff ratios are a second form of ratio that has been widely used in intersite comparisons, but only at certain time scales (Table 2). This kind of comparison allows examination of the fraction of water released from the basin relative to precipitation inputs, over time or among sites. For example, Post and Jones (2001) used mean annual runoff ratios (streamflow divided by precipitation) as a basis for comparison across sites. Annual runoff ratios also can be used as dependent variables in more complex analyses involving ratios. For example, Post and Jones (2001) conducted an intersite comparison based on the slopes of annual rainfall-runoff regressions across sites for a group of small, forested basin sites. Using annual runoff ratios in long (up to 50 year) records, they were able to show that forested basins respond to interannual variation in precipitation by taking up more or less water, and water use was similarly responsive to interannual variations in precipitation for all four forest types (Post and Jones, 2001).

As these examples illustrate that ratios of streamflow in treated versus control basins are the most commonly used measures for assessing treatment effects in paired-basin experiments. However, ratios also have the potential to be used for comparisons among basins that have not been subjected to formal treatments, but whose behavior may be diverging as the result of inadvertent treatments (e.g. Table 1). Inadvertent treatments in such "out of control" basins may include forest mortality from disease or disturbances like windthrow or fire, climate change, or

changes in species composition and leaf area associated with forest growth and succession. The potential for learning about rainfall-runoff relationships by applying standard treated/control comparison methods to pairs of control basins (which may actually be "out of control") deserves further exploration.

Runoff ratios have potential uses that have not been explored. For example, an intersite comparison could examine the change over time in the runoff ratio (e.g. Kokkonen *et al.*, 2004), and compare this measure across basins. Or, runoff ratios could be calculated for finer than annual time periods, such as seasons or even days. This latter approach resembles the calculations involved in water balance estimates.

Bivariate Analysis – Comparison Using Cross-correlation

The cross-correlation is a form of the rainfall-runoff ratio that takes into account the temporal lag between precipitation input and streamflow output in a basin, or the lag in rainfall or runoff between one basin and another (Table 2). Cross-correlations of rainfall versus runoff at a basin estimate the lags involved between input and output in a given basin, while cross-correlations of runoff (or precipitation) across sites can be used to determine the delays in transmission of a pulse of rainfall or runoff through a stream network. For example, Post and Jones (2001) used cross-correlation of daily and monthly precipitation versus streamflow as a measure for comparing across small, forested basins. Streamflow responses to precipitation lasted for only a day or two at deciduous forest sites with mesic climates and shallow soils, but they persisted for almost two weeks at conifer sites with a Mediterranean climate and deep soils. Bond *et al.* (2002) correlated hourly sapflow with streamflow at various lags to compare across two adjacent small basins with old-growth and young conifer forest (Andrews, Oregon, US). They were able to show that diurnal variations in streamflow were most pronounced and occurred within a few hours of maximum sapflow in the early summer, but, by late summer, the relationship had diminished and the lag between maximum sapflow and streamflow had lengthened to eight hours. Moore (2003) correlated hourly precipitation, soil moisture, sapflow, and streamflow at various lags to extend this comparison of two, small, adjacent forested basins. She showed that diurnal streamflow variations were related to soil moisture, sapflow, and vapor pressure. However, strong lagged relationships were apparent during only one of several periods in three successive summers. Tague and Grant (2004) used cross-correlation of streamflow in two, large, adjacent basins to demonstrate how contrasting geology produced consistent lags in runoff at the basin whose geology permitted longer storage and slower transmission of water.

SUMMARY

Despite the limitations of rainfall-runoff data, there are compelling reasons for hydrologists to conduct many more intersite comparisons of rainfall-runoff data. Studies of rainfall-runoff processes in hydrology have generated many important predictions. Our inferences about hydrologic processes are drawn from an unnecessarily narrow subset of temporal scales, spatial scales, and geographic conditions, given the range of data available. Too many publications simply repeat (or challenge) the hypotheses inferred from a few analyses of primary data, without exploring unexamined datasets. However, verification of these hypotheses depends on replicating them using rainfall and streamflow records from locations and time periods not included in the original studies. Many thousands of basin-years of data from a wide variety of ecosystems, climate types, and basin sizes have been collected, and much of these data are now available on the Internet. However, only a fraction of these data have been analyzed. Existing published analyses of these records do not address all of the questions of current interest to hydrologists and researchers from related disciplines, including climate science, geomorphology, and ecology. New questions, novel combinations of basins, new statistical approaches, and ancillary data can all be used to more carefully test important hypotheses regarding hydrologic mechanisms operating inside basins. The endeavor of intersite comparison is analogous and complementary to the parallel quest for methods of parameter identification and model structure selection in hydrologic modeling.

Acknowledgment

This work has been supported by grants to the H.J. Andrews Long-term Ecological Research program, and for Intersite Hydrology comparisons, from the Long-term Studies program of the National Science Foundation, and by a Bullard Fellowship at Harvard Forest. Younes Alila provided helpful comments on a draft of this manuscript.

PART 11

Rainfall-runoff Modeling

122: Rainfall-runoff Modeling: Introduction

KEITH J BEVEN

Department of Environmental Science, and Lancaster Environment Center, Lancaster University, Lancaster, UK

This section provides an introduction to the theme of rainfall-runoff modeling in hydrology. It provides a summary of the purposes of rainfall-runoff modeling; a classification of rainfall-runoff models; a brief account of process descriptions in rainfall-runoff models; and a short history of rainfall-runoff modeling. It also discusses the problem of model choice from the wide range of possibilities available, and the important question of model calibration using different types of observational data before considering the prediction of the effects of future change (when no observations are possible). Finally, a guide is given to the future of rainfall-runoff modeling. Reference to the other sections in this article are given throughout, as well as to relevant available texts.

INTRODUCTION

The Many Purposes of Rainfall-runoff Modeling

No introduction to the range of rainfall-runoff modeling techniques can be presented without considering the purposes for which the modeling is carried out. All modeling involves some form of extrapolation in either time or space, but different modeling techniques are appropriate for different hydrological problems. At the end of this article, there are reviews of modeling for flood forecasting (both in real time and for predicting flood frequencies), for flood inundation modeling, for integrated basin management, and for the prediction of the effects of change. There are also sections that present different types of modeling methodologies in more technical detail.

It has to be recognized straight away that, despite the very real demand for good quantitative rainfall-runoff predictions for these very practical problems, the degree to which current models can satisfy that demand is limited. Much of hydrology measurement technique is constrained, since so much of what is interesting in the hydrological response of a catchment to rainfall takes place beneath the ground surface. The development and application of models is, therefore, also limited by the available measurement techniques. The result is that it remains very difficult to predict the hydrological response of any arbitrary catchment area based on mapped information about the local topography, soils, and land use alone. This "prediction of ungauged catchments" problem is still essentially unsolved (*see* **Chapter 133, Rainfall-runoff Modeling of Ungauged Catchments, Volume 3**). Thus, there is still a considerable body of modeling work that depends on local *calibration* of models using measured rainfall inputs, and comparing observed and predicted discharges with a view to improving the predictions. In the past it had been considered sufficient to find some "optimal" model to make predictions. Today, the uncertainties inherent in the measured inputs to the model, model definition, and model calibration are more widely recognized, and techniques of assessing uncertainties in the predictions are being developed (*see* **Chapter 130, Fuzzy Sets in Rainfall/Runoff Modeling, Volume 3** and **Chapter 131, Model Calibration and Uncertainty Estimation, Volume 3**).

Part of this uncertainty arises from the model definition itself. There are now very many different models in hydrology, representing variants on several different lines of development or families of models of different degrees of complexity (see Section "A classification of rainfall-runoff models"). They all remain, however, simplifications of what we perceive as the real complexity of hydrological processes. One of the major questions that arises in rainfall-runoff modeling is how best to approximate the perceived complexity of the real catchments. Ironically, perhaps, making models more complex to take account of some of the perceived complexities does not necessarily lead to

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

more precise and less uncertain predictions. This is because adding complexity in general, introduces more parameter values that are not easily measured directly or calibrated on the basis of indirect information. More complex models, therefore, in general have more degrees of freedom in representing the catchment, and this might result in greater uncertainty in prediction. Thus, there is a problem of trying to achieve the right balance between model complexity and prediction uncertainty in situations that might have different types of data available for model calibration or evaluation.

It must be stressed that this is an ongoing research area in hydrology. This is reflected in the sections on recent modeling approaches, including fuzzy modeling techniques, "top–down" approaches to modeling and the assessment of uncertainties in model calibration and model predictions. These new approaches have been developed out of a recognition of some of the difficulties and limitations of modeling all the hydrological processes in any specific catchment area; difficulties that become important when trying to predict hydrological responses under more extreme (wet or dry) conditions than measured before, or trying to predict the hydrological impacts of future change in land management or climate inputs to inform policy and management decisions. A view on the future of rainfall-runoff modeling is expressed below in "Predicting the effects of change" and a guide to further reading in "The future of rainfall-runoff modeling".

A Classification of Rainfall-runoff Models

There are a variety of different ways of classifying rainfall-runoff models (see e.g. Clarke, 1973; Wheater *et al.*, 1993), but the most fundamental distinction that is usually made is between *lumped* models and *distributed* models. Lumped models deal with a catchment as a single unit, attempting to relate precipitation inputs to discharge outputs without any consideration of the spatial patterns of the processes and characteristics within the catchment. Distributed models attempt to take account of the spatial patterns of hydrological response within a catchment area.

Rainfall-runoff modeling started with lumped models back in the nineteenth century with the "*rational method*" that related discharge (usually peak discharge) directly to a measure of rainfall inputs, catchment area, and a runoff coefficient (see Beven, 2001b). The runoff coefficient served the purpose of what would now be called a model *parameter* that could be varied to reflect local conditions in particular applications. The difficulty in applying the rational method was therefore a difficulty of deciding on a value for the runoff coefficient. This was a particular difficulty in this prototype model because this parameter would vary not only from one catchment to another but also with the magnitude of an event and the state of the catchment prior to an event (the *antecedent conditions*).

In the twentieth century, therefore, more complex lumped models were developed to reflect the perceptions of different hydrologists about the processes of hydrological responses to rainfall. One of the most important developments was that of the *unitgraph* (now called the *unit hydrograph*) that attempted to predict the time distribution of discharge as well as the peak. The unitgraph represented the time distribution of one unit of *effective* or *excess* rainfall. The effective rainfall was that part of the total rainfall inputs that contributed to the storm hydrograph for an event (though it is known that in many catchments much of the hydrograph is made up of water that was stored in the catchment prior to an event, and which is displaced out of storage during the event). There was still a runoff coefficient problem in predicting how much of the rainfall would become effective rainfall for a given magnitude event and antecedent conditions, on an event-by-event basis. The unit hydrograph is a *linear* approximation, which means that once a unit hydrograph has been determined for a catchment area, different effective rainfalls will be predicted as having the same time distribution, but with a simple linear scaling of the magnitudes. The linear approximation then produces the result that two units of *effective* rainfall (rather than the total input) will produce twice as much discharge.

The linear assumption of the unit hydrograph has been much criticized in the past, but has served rainfall-runoff modelers quite well. Similar principles are still used in *transfer function* models today (*see* **Chapter 128, Rainfall-runoff modeling: Transfer Function Models, Volume 3**). The greater problem is that of estimating how much of the total input to a catchment should form the effective rainfall. The effect of antecedent conditions on the effective rainfall is very much a nonlinear problem. Twice as much rainfall with the same antecedent conditions will generally produce more than twice the discharge, while the same rainfall under dry antecedent conditions will produce much less runoff than under wet antecedent conditions. This nonlinearity problem was partly solved by the introduction of continuous simulation models, particularly as digital computers started to become more widely available in the 1960s. One of the earliest lumped continuous simulation models was the Stanford Watershed Model, developed by Norman Crawford and Ray Linsley at Stanford University in 1962 (for a fuller history see Section "A short history of rainfall-runoff modeling" and Beven, 2001b). This structure still survives, with many added components, in the HSPF (Hydrologic Simulation Package Fortran) package now distributed by the US Environmental Protection Agency. It is an example of a lumped explicit soil moisture accounting (ESMA) model in that it has several storage elements to represent different hydrological processes and storages (interception, upper soil moisture, lower soil moisture, groundwater etc.). The fluxes between these stores are

controlled by a variety of different parameters. Application of the model, therefore, requires that these parameters be estimated or calibrated for each application area. The temporal changes in the antecedent conditions are taken into account by continuously calculating the changes in storage in the model, but at the expense of introducing a considerable number of parameter values (more than 30 in some versions of the Stanford Watershed Model).

This type of model can be made more distributed by applying it to different subcatchments and then routing the subcatchment outputs to the point of interest using a river routing component. This allows the spatial patterns of inputs to be taken into account, at least at the subcatchment level. This might be important where there are strong spatial patterns in inputs resulting from strong changes in rainfall with elevation, or the seasonal patterns of snowmelt as a function of elevation, aspect, snow accumulation, and so on. The only problem with such a strategy is that each subcatchment then requires its own set of parameter values to be estimated or calibrated.

A similar problem applies to fully distributed models which attempt to make predictions of the response of all the elements in a spatial discretization of a catchment area. The elements might be based on a square grid discretization (an approach that has become common with the widespread availability of raster digital elevation data) or more irregular elements or *control volumes*. Each element can have its own inputs and parameter values. The more complex models also involve multiple layers in the vertical to predict fluxes in three dimensions. Thus, these models can have literally hundreds or thousands of parameter values that must be defined to run the model. Even so, these models cannot reflect all the perceived complexity of the hydrological processes. In particular, they still require some parameterization of the variability in soil water, runoff, and evapotranspiration fluxes at the sub-element scale. Beven (1989) has therefore, suggested that even the most distributed hydrological models are still effectively lumped representations at the element scale. The *representative elementary watershed* approach to distributed modeling, described in (**Chapter 13, Pattern, Process and Function: Elements of a Unified Theory of Hydrology at the Catchment Scale, Volume 1** and **Chapter 127, Rainfall-runoff Modeling: Distributed Models, Volume 3**), is an attempt to deal directly with this issue in a physically rigorous way.

A final classification of rainfall-runoff models is into models that are *deterministic* and models that are *stochastic* in their predictions. A deterministic model will, with a given input sequence, produce a single prediction of all its output variables. The majority of model applications in hydrology are still run deterministically, even though the uncertainties associated with such predictions are now widely appreciated. A stochastic model allows for uncertainty in the inputs or parameterizations or outputs, such that a given input sequence will produce an uncertain prediction of the output variables. Unfortunately it can be very difficult to separate out the effects of the various sources of uncertainty that contribute to the prediction process, particularly for this type of nonlinear system. There is, therefore, no agreement about what approach should be used in assessing predictive uncertainty. Those methods that have a good theoretical base often have restrictive assumptions that are difficult to justify in real applications. Other methods are not so restrictive in their assumptions, but do not have such a strong basis in theory. These issues are discussed further in (*see* **Chapter 130, Fuzzy Sets in Rainfall/Runoff Modeling, Volume 3** and **Chapter 131, Model Calibration and Uncertainty Estimation, Volume 3**).

Process Descriptions in Rainfall-runoff Models

It is important to recognize the difference between the perceived complexity of water flow pathways in a catchment and the relatively simplistic models that are used to predict water fluxes and stream discharges. The hydrologist can appreciate the complexity of the real processes in a qualitative way (the *perceptual* model); it is much more difficult to represent that complexity in a quantitative mathematical description (the *formal* or *conceptual* model). Thus, any rainfall-runoff model must be necessarily only an approximate representation of the real processes. This is perhaps easiest to appreciate for lumped catchment models, though these can still make useful predictions if the only variable of real interest is the discharge hydrograph. The same consideration also applies, however, to even the most distributed rainfall-runoff model, since they can only approximate the responses at the sub-control volume scale. Thus, all process descriptions in rainfall-runoff models rely on some parameterization of the sub-control volume complexities and heterogeneities.

In all models, it is necessary to maintain mass continuity. Water, as represented by the model, should not be gained or lost. Theoretically, this should also be the case for continuity of energy and momentum as well, so that hydrological models could claim to preserve the second law of thermodynamics. Unfortunately, this is much more difficult to ensure, with energy and momentum losses being accounted for implicitly by model parameters such as resistance coefficients (but *see* **Chapter 127, Rainfall-runoff Modeling: Distributed Models, Volume 3**). What is often not realized, however, is that even for mass continuity, the water balance kept by the model may not be the same as that kept by a real catchment or control volume. This is because there are components of the real mass balance that cannot easily be measured accurately, especially as integral fluxes over an area. This is particularly true of precipitation inputs over a catchment when rain falls from locally intensive convective cells or

snow accumulation is affected by wind redistribution. It is also true of evapotranspiration fluxes from heterogeneous vegetation covers on hillslopes. This is not to suggest that models should not maintain mass continuity (although some models include multipliers to adjust the input rainfalls or potential evapotranspiration rates as parameters), only that these physical laws must be viewed as theoretical capacities of the system that might be difficult to verify by measurement (see discussion in Beven, 2002a).

In many conceptual models, the representation of processes at the control volume scale is expressed in terms of some function relating flux to storage in the control volume. Most lumped catchment models are of this type, including the ESMA models. Many routing models, such as the unit hydrograph, can also be interpreted as a sequence of storage elements in series or in parallel. These storage elements can have storage-flux relationships that are either linear or nonlinear. With one or two exceptions, these relationships are not based on secure theoretical reasoning, but on subjective choices that seem to give the right type of behavior. A linear store has often been used, for example, to represent the recession curve from a catchment area. The equation of a linear storage gives a recession curve for which discharge declines exponentially with time. There is no physical reason to suggest that the recession of the integral drainage fluxes of all sources of subsurface flow in the catchment or control volume should have the form of a linear store (except under some the very limiting assumptions: *see* **Chapter 126, Modeling Recession Curves and Low Streamflows, Volume 3**) but the form appears to work for many cases.

But not for all cases: other nonlinear storage elements seem to be more appropriate for some catchments. Some models have used first order or second order hyperbolic functions in time (see e.g. Tallaksen, 1995; Lamb and Beven, 1997, for a recent discussion of the different forms that result from different assumptions about the subsurface flow domain). The important point to take from these different parameterizations is that we do not have the investigative measurement techniques necessary to be secure about what form these relationships should take, given that we know that the sub-control volume processes are subject to considerable complexity, except by seeing which functions might be appropriate in reproducing the discharges at the catchment outlet (where we can take a measurement). It then follows that different types of function might be appropriate for different catchments or control volumes within a catchment. This does not only apply to subsurface drainage but also to any other hydrological flux within a control volume. Any subjective choice of function to represent the fluxes at the control volume scale can usually only be calibrated and corroborated by comparison with measured discharges in this way.

The subjective nature of model design was recognized early in the history of computer-based rainfall-runoff modeling. It did not seem to be really scientific. There was then a conscious attempt to make model definition more objective by representing the processes by the physical "laws" used to describe those processes. The seminal paper describing such an approach was the "blueprint for a physically based digitally simulated model" of Freeze and Harlan (1969). Very briefly, they showed how a model could be developed using the Richards' equation (based on Darcy's law) for partially saturated subsurface fluxes and the St. Venant equations for depth-integrated surface fluxes. These equations could be coupled though appropriate boundary conditions. The equations are both nonlinear partial differential with boundary conditions that vary in space and time as hydraulic potentials and therefore infiltration rates, seepage faces, and other features of the system change dynamically. There are no general analytical solutions to these equations; therefore, the model must be based on approximate numerical solution algorithms (originally finite difference methods but now more usually finite element or finite volume techniques). This requires that the system be discretized into a large number of control volumes to represent the dynamic distributed responses and the way in which the fluxes will vary in response to patterns of hydraulic potentials on the hillslopes and in the stream network.

Following the Freeze and Harlan blueprint, the model description is objectively based on physical principles. It does not, however, entirely eliminate the subjective element in model definition. This is because the characteristics of all the control volumes representing the catchment must be defined in terms of appropriate parameter values before the model can be run. In principle, these parameters have physical meaning (they include, for example, hydraulic conductivity and porosity of the soil, and the roughness coefficient for channel flow). But we have no techniques that will allow the values of those parameters to be measured at the control volume scale. Small-scale measures of hydraulic conductivity, for example, reveal that there may be small-scale variability of orders of magnitude within a control volume, especially for soils containing macropore structures. This then implies that there will be sub-control volume variability in the hydraulic gradients and velocities of flow in the soil. Because of the highly nonlinear relationships between unsaturated hydraulic conductivity and flow rate, this then implies that the small-scale physics (as represented here by Darcy's law so that flux per unit area is assumed to be directly proportional hydraulic gradient and local unsaturated hydraulic conductivity) should not be used at the control volume scale. In a heterogeneous domain, the same form of relationship cannot represent the nonlinear variability of local velocities at the control volume scale except in the special

(and unrealistic) case of a soil with spatially homogeneous characteristics.

Darcy's law is still being used, however, in nearly all rainfall-runoff models based on the Freeze and Harlan blueprint, because without detailed knowledge of the small-scale heterogeneity in soil structure and characteristics, it is difficult to develop an adequate alternative description. The continued use of Darcy's law to represent control volume fluxes, therefore, depends on an implicit (and subjective) assumption that it is an adequate approximation to the integral fluxes at the control volume scale. Physically, this is much easier to justify for flows in the saturated zone than in the unsaturated zone. Similar considerations apply to the representation of surface flows because of the way in which velocities and depths can vary rapidly across a hillslope (especially if covered with short vegetation) or in the variable cross-sections of the channel network. In all these cases, effective values of the model parameters will be required at the control volume scale, but these effective values cannot easily be measured and their physical basis has been undermined by the effects of the sub-control volume nonlinearities. These laws are now just one possible choice for a sub-control volume parameterization, awaiting the development of something more realistic. For a modern interpretation of the Freeze and Harlan blueprint, however, (*see* **Chapter 127, Rainfall-runoff Modeling: Distributed Models, Volume 3**).

In addition, the Freeze and Harlan blueprint is not complete (Beven, 2002b). There are processes that were not included in the original description, including preferential flows in the soil and on the surface. Other processes might also be important, such as surface crusting, the concentration of rainfalls reaching the soil surface as a result of the structure of the vegetation canopy, and the separation of different parts of the saturated flow domain due to fracturing of the bedrock or small-scale undulations in the bedrock surface. There are many field studies that attest to the perception of such processes as important in different catchments, but the development of generally acceptable descriptions of such processes has proven to be very difficult. It is, for example, extremely difficult to obtain adequate descriptions of the bedrock surface or soil structure even in research catchments. Some models have added preferential flow components or depth variations in surface flow within their sub-control volume parameterizations, but the effective parameter values will be difficult to estimate.

The difficulty of applying this type of model, even with intensive field measurements to try and determine model parameter values, is attested by the continuing story of modeling the R5 catchment at Chickasha, Ohio, by Keith League and his coworkers. Their original model was based on the perception that the stream hydrograph was the result of a Hortonian infiltration excess runoff process. They made several attempts to predict the stream hydrographs using a model based on this concept and with more and more detailed information about the spatial patterns of local infiltration characteristics in the catchment. The measurement scale was, however, still smaller than the model control volume scale. None of these attempts was considered entirely successful (see League and Kyriakidis, 1997) and the story is now continuing with a new approach based on coupled surface and subsurface modeling (van der Kwaak and League, 2001). Similar problems have been encountered in trying to represent distributed field measurements of soil water contents or water table levels in other studies (e.g. Lamb *et al.*, 1998; Anderton *et al.*, 2002). It should be noted, however, that such comparisons are also subject to scale problems since local water content measurements and even local water table measurements in shallow soils might not be directly equivalent to the variable of the same name predicted by the model at the control volume scale.

There is one additional important consideration in the formulation of process representations of rainfall-runoff models. In many field natural and artificial tracer experiments, based, for example on the variations in concentrations of the environmental isotopes of oxygen and hydrogen in the water molecule, it has been shown that much of the storm hydrograph is made up of water that was stored in the catchment prior to an event, and not the rainfall that fell in that event. The stored water is being displaced into the stream by the incoming water. A model that is predicting only discharge does not necessarily need to take this into account, but it might be an indication that the process descriptions being used in a model are not appropriate (for example, if a model is based on an infiltration excess runoff description but the tracer data indicate a high proportion of pre-event water in the hydrograph). It does become important if predictions of water quality are required, since the pre-event water and the event water might have quite different quality characteristics (though it has to be remembered that the event water might interact geochemically with the vegetation and soil before reaching the stream even if it does contribute to the storm hydrograph). In research studies, it has proven very difficult to achieve adequate simulations of both runoff and some quality characteristics, even for conservative tracers such as the oxygen and hydrogen isotopes. This is, at least in part, because the effective storage volumes for the prediction of fluxes might be quite different to the effective storage volumes for the prediction of concentrations, and neither might relate easily to the storages that can actually be measured (locally) in the soil profile. Thus, additional model parameterizations and additional effective parameter values, will be required for the prediction of concentrations in addition to fluxes.

A Short History of Rainfall-runoff Modeling

The nineteenth century origins of rainfall-runoff model in the rational method were noted in the Section "A classification of rainfall-runoff models". The rational method, in its very simple equation,

$$Q_p = CAP \tag{1}$$

where Q_p is peak discharge, P is the volume of input precipitation over the catchment area A in a defined time period, and C is a runoff coefficient parameter, already has all the elements of a rainfall-runoff model and, indeed, the method is still in use today. The problem in its application, and the reason why we need more complex methods, lies in the parameter C. C cannot be treated as a constant for a catchment area, but will vary from event to event. It must incorporate the effects of the space and time variability in antecedent conditions, precipitation inputs and surface and subsurface runoff generation and the effects of routing of that runoff to the catchment outlet or where predictions are required.

There was obvious scope, therefore, in later developments of rainfall-runoff models to separate out the processes of runoff generation from runoff routing. This was first done in the 1920s by C. N. Ross in Australia when he used the idea of zones of different travel time to the outlet in a catchment to allow for different runoff coefficients in different zones. The runoff generation in each zone could then be delayed by the appropriate travel time and summed to produce a total discharge. A similar approach was used by Zoch and Clark in the United States, and by Richards (1944) in the United Kingdom in one of the very first books on rainfall-runoff modeling. The approach is dependent on the assumption that the routing times do not change for different events. It is, therefore, equivalent to a linear *transfer function* for the predicted runoff generation. Sherman (1932) took this idea and proposed that the transfer function could be represented as a time distribution for routing runoff from a catchment area without any direct link to the areas involved. He called the transfer function the *unitgraph*, now more commonly referred to as the *unit hydrograph*. The unit hydrograph approach to runoff routing is still widely used, and can be treated within a general linear transfer function methodology (*see* **Chapter 128, Rainfall-runoff modeling: Transfer Function Models, Volume 3**).

There remained the (nonlinear) question of how much of the input rainfalls would be available as effective rainfall to create the output hydrograph from a catchment. At the same time as Sherman proposed the unitgraph, Robert Horton (1933) came up with a model of runoff generation that has since been very widely applied. He proposed that the storm hydrograph, in excess of a baseflow component, was predominantly made up of surface overland flow in excess of the local infiltration capacity of the soil. He provided a function to describe the infiltration capacity of the soil, with two parameters to be identified for each soil type, though he viewed this function as very much a representation of the surface controls on infiltration, rather than a control resulting from flow through the bulk soil as it is represented using the Richards' equation in most process based models today. The combination of Horton's and Sherman's ideas then provided one of the first models to predict the full storm hydrograph and has been very widely used. It has also been widely modified with different types of runoff generation function, such as the US Soil Conservation Service method that has its origins in the analysis of runoff data from plots and small catchment areas and does not explicitly assume an infiltration excess mechanism (see the summary of this and other methods in Beven, 2001b).

We now know, of course, that runoff generation is more complicated than that (see the Section below on "Process descriptions in rainfall-runoff models"), that surface runoff can be generated by saturation excess as well as infiltration excess mechanisms and that in many environments much of the storm hydrograph is made up of water that was stored in the catchment prior to an event and which is then displaced out of subsurface storage by the input rainfalls. Thus, particularly as digital computers allowed more complex calculations to be made, there were new models developed that tried to take more explicit account of the various storages in a catchment and their responses to rainfalls. These ESMA models, referred to in the Section "A classification of rainfall-runoff models" have been very widely used and many different variants can be found. In the 1960s and 1970s there were probably nearly as many ESMA models as there were hydrological modelers. All of them had parameters of the functions controlling the fluxes between the storage elements that had to be calibrated for a particular catchment, although they varied in the number of parameters to be calibrated. They all worked, more or less, because given a historical period of rainfall and discharge data the parameters could be varied until a good or atleast acceptable fit was obtained between observed and predicted discharges.

This calibration was either carried out manually, with a visual evaluation of how well the model was fitting the data (this was how the Stanford Watershed Model was calibrated) or by an automatic optimization method, using a quantitative measure of model performance, such as the sum of the squared errors between observed and predicted discharges during the calibration period. The manual method had the advantage of using "hydrological reasoning" and the experience of the modeler to improve the model performance (though this is difficult in practice once more than 4 or 5 parameters are being varied); the automatic optimization method has the advantage of objectivity (at least once the quantitative criterion of performance has been chosen). But, using either technique it was often difficult

to decide whether one model or parameter set was really better than another.

At the end of the 1960s, an alternative approach was proposed with a view to avoiding some of these problems by making the representation of the processes as "physically based" as possible as in the Freeze and Harlan (1969) blueprint for a physically based distributed description of surface and subsurface flow processes in time and space. Although, with even the best computers available in the early 1970s, only very approximate (and indeed inaccurate) solutions of these equations could be achieved there were many perceived advantages of this family of models and they have continued to be developed and applied to the present day. The best known current example of such a model is the Système Hydrologique Européen (SHE) which is now available in a number of different versions. The advantages of such models included the potential to apply the models using only measured (rather than calibrated) parameters, the ability to take account of spatial variability of inputs and catchment characteristics in their correct spatial context; the ability to make spatially distributed predictions of water fluxes that could then be used as the basis for other predictions of sediment and contaminant transport. All of these advantages appeared to make the model applications more realistic and more objective.

Unfortunately, for a number of reasons, it has proven difficult to take full advantage of these attractive features of the Freeze and Harlan distributed model blueprint. It is now more widely appreciated that the equations of these models, when applied at the model grid scale, are still only very approximate representations of the actual processes. Thus, it is still generally necessary to resort to some form of calibration to apply these models in real catchments. There are very few applications reported in the literature where results based only on measured and directly estimated parameter values are reported and these results have generally not been that accurate for predictions of either discharge or internal state variables such as water table levels or soil moisture storage. For internal state variables, there is, in fact, a problem in making such a comparison, since the local measurements are themselves generally at a much smaller scale to the element scale used in the distributed model.

These difficulties, however, do not take away the demand for predictions that are distributed in space, so there has also been a family of models that have attempted to take account of the spatial heterogeneity in catchment areas, but in a parsimonious way (that is, with only a small number of parameters). This type of model represents the variability in responses by some statistical distribution function of characteristics within the area of the catchment rather than making spatially distributed predictions directly. In some cases, these models have been constructed so that the predictions can still be mapped back into their correct spatial context and compared with spatial observations. Because of the simplifications made, however, the spatial predictions are expected to be much more approximate than for the fully distributed models. The best known examples of this type of model are the Probability Distributed Model (PDM) in which a distribution function of storage capacities is based on a purely statistical distribution with parameters to be determined by calibration; and TOPMODEL in which a distribution function of an index of hydrological similarity is based on an analysis of catchment topography. In the latter case, the similarity assumptions mean that predictions only need to be made for representative values of the topographic index, but knowing the pattern of the topographic index allows the predictions to be mapped back into space (see Beven, 2001b, for a full description of this and other distribution function models).

The Problem of Model Choice

Given this wide variety of different rainfall-runoff models available, there is a real problem of model choice for the practitioner in any practical application. Beven (2001b) summarizes a number of criteria on which to base model choice.

- Is a particular model readily available, or could it be made available if the investment of time and money appeared to be worthwhile?
- Does the model predict all the variables required for a particular aims of a project?
- Are the assumptions of the model likely to be limiting given what is known about the nature of the hydrological responses at a site?
- Can all the inputs required by the model (flow domain, boundary and initial conditions, model parameters) be provided within the time and cost constraints of the project?

More correctly these are criteria for model rejection, and it is all too common that all the available models could be rejected on the basis of one or more of these criteria. This is clearly not very helpful in practical applications, so some compromise may have to be reached. It is important, however, that the user be aware of what compromises are being made so that the associated uncertainties can, as far as possible, be evaluated.

The Problem of Model Calibration

Nearly, all model applications require some form of model calibration to identify the model parameter values appropriate to a site. This is because we do not have the techniques that would allow the direct measurement or independent estimation of parameter values at the scale required by the model (i.e. the control volume scale for a distributed model

or the catchment scale for a lumped model). There is no general agreement, however, about how best to approach the model calibration problem. This is because the calibration problem is associated with many different sources of error that cannot be easily separated. There is the error associated with the model structure, in that even the best model structures available are only an approximate representation of the actual processes. There are the errors associated with the definition of the subsurface flow domain and its boundary conditions. There are the errors associated with the specification of the initial storages within the flow domain. There are the errors associated with the measurements of the input precipitation (and other forcing variables) to the model, and their spatial and temporal variability. There are the errors associated with measurements of the discharges (and other internal variables) with which the predictions of the model will be compared. Normally, there is no way of estimating any of these different sources of error independently. We can evaluate how well a particular model predicts the observed discharges, given the specified inputs, but we do not know what is the real source of the modeling error.

In many rainfall-runoff modeling situations, this then makes it quite difficult to use the theories of parameter inference that have been well developed in statistics. These theories require that the structure of the different sources of error be defined, so that the probability or likelihood function of predicting a particular observation, given the model, can be assessed. The form of the likelihood function depends on the assumptions that are made about the nature of the errors. It is possible to lump all sources of error into a single "modeling" error, assume a particular structure for that total error, and use the statistical approach. This is an objective approach in that the validity of the assumptions about the modeling error can be tested in comparison with the actual modeling results to see if those assumptions are justified, at least approximately.

Some progress has been made in using this type of approach, particularly in real time forecasting of river flows when predictions are only required for a few time steps into the future (e.g. Young, 2002; Krzysztofowicz and Kelly, 2000). However, for the case of longer time rainfall-runoff simulations, using nonlinear distributed models, it is far more difficult to justify simple structures for the errors in space and time, especially in the face of potential errors in both the inputs and available model structures. Thus, some alternative approaches have been developed, generally based on Monte Carlo simulation in which very large numbers of model runs are made using random choices of inputs and/or parameter sets and compared with the available observations. Those models that perform well in this evaluation are then kept for use in prediction. However, this approach also cannot separate out the different sources of error and does not have the same firm theoretical basis for model evaluation as is the case where strong assumptions can be made about the nature of the errors in statistical inference.

What is important in modern model calibration, however, is that some attempt should be made to evaluate the uncertainty in the model predictions. It is no longer sufficient to find an optimal model and make a single deterministic prediction of the rainfall-runoff response. There is then too much chance of being wrong in prediction. The problem of model calibration and uncertainty estimation is discussed further in (**Chapter 131, Model Calibration and Uncertainty Estimation, Volume 3**).

Predicting the Effects of Change

One of the most interesting problems in rainfall-runoff modeling is predicting the impacts of future change (*see* **Chapter 132, Rainfall-runoff Modeling for Assessing Impacts of Climate and Land Use Change, Volume 3**). This might be change in land management strategies or change in climate as inferred from the global predictions reported by the International Panel on Climate Change (IPCC, 2001; *see* `www.ipcc.ch`). In both cases, it may not only be changes in runoff and subsurface storage that are of interest, but also other variables that depend on runoff such as sediment production, nutrient export, plant water stress, and so on. In addition, it may be changes in the extreme hydrological responses (floods and droughts) that may be of most interest to water managers. The interesting thing about such prediction problems is that there are no data available from the future for recalibration of the hydrological model.

Prediction of the effects of change for a particular catchment is, therefore, essentially an extrapolation problem; extrapolation from what can be learned about the catchment responses today into some future scenario. This can be difficult because there will certainly be additional uncertainties involved, but it may be very difficult to estimate the magnitude of those uncertainties. For example, the various global model outputs reported by the IPCC usually provide estimates of the change in monthly rainfalls to be expected later in the twenty-first century as a result of changes in atmospheric composition. Since these models take so long to run even on the best of today's supercomputers, such predictions are not associated with any direct estimates of uncertainty (though different global models from different modeling groups currently produce quite widely differing predictions). Thus, it is impossible to associate any probability estimate with these scenarios. In addition, to model the impact of change on the hydrological extremes, it will be necessary to interpret these predicted mean monthly changes into changes in the distributions of rainfalls (and other climate variables) when it is not clear if the relationships seen between atmospheric and ocean circulation patterns and rainfall extremes in a region today

will be the same under a changed climate. Many different scenarios could be envisaged for how these relationships might change, but again it will be impossible to associate an uncertainty measure with a potential scenario. Similar considerations hold for potential changes in land management that might have more to do, for example, with future agricultural subsidy policies than with the impacts of climate change.

Thus, we know that predictions of future change will be uncertain but cannot easily quantify that uncertainty. About the only strategy that can be taken in this situation is to assess the uncertainty in the predictions of a model under current conditions and then run different future scenarios with that model taking account of similar input and parameter uncertainty assumptions. Any relative possibility estimate for different scenarios will be necessarily subjective, but such a procedure will give the most realistic assessment of the potential future hydrological responses. The implication, however, is that it will be very important to continue monitoring catchments into the future so that as the responses change they can be used to revise and update the scenario predictions.

The Future of Rainfall-runoff Modeling

New computer technologies seem likely to change the way that rainfall-runoff models are constructed and used as components of large-scale integrated modeling frameworks for environmental management. In particular, the possibility of using large-scale (the GRID; *see* **www.gridcomputing.com**; **www.gridforum.org**; **www.globus.org**) computer networking to link together distributed database and computational engines means that it will be possible to couple together models of many more different environmental systems across disciplinary boundaries and across national administrative boundaries. This is, in fact, already possible and is already happening on a limited basis as demonstrated, for example, in the regional water resources models under construction in Denmark or the national models for environmental management being used in the Netherlands. In Japan, the very large-scale "Earth Simulator" is aiming to implement global scale models (see Earth Simulator Center, 2003; see **www.es.jamstec.go.jp/esc/eng/ES/index.html**).

There is then, however, a real question raised about how this type of interdisciplinary model might be best implemented. In the past, comprehensive modeling systems have been constructed as large complex computer programmes. These programmes were intended to be general, but have proven to be expensive to develop, difficult to maintain and difficult to apply because of their data demands and needs for parameter identification. With GRID computing technology, it will be possible to continue in the same vein, but with more coupled processes and finer spatial and temporal resolutions for the predictions. It is not clear, however, whether this will result in a real improvement in model accuracy and use because the problems inherent in the current generation of distributed environmental models do not necessarily easily go away with improvements in space and time resolutions of the component models.

We can distinguish two different (albeit overlapping) types of models here in terms of constraints. In the first, the accuracy of solutions is still constrained by computational resources; in the second model accuracy is primarily a result of lack of knowledge of appropriate process representations and boundary conditions. In the first type of models, real advances may still be possible as computational constraints are relaxed. In atmospheric modeling, for example, there is still scope for improvements of the representation of local convection and rainfall forecasts, in the representation of sub-grid spatial variability of energy fluxes, and in the representation of topography by finer grid scales. Ultimately, however, this type of model will be constrained by the need to know finer and finer detail of boundary conditions and parameter values, as is already the case in the second type of model. An example of this second type is classical distributed hydrological models.

New developments in environmental modeling will allow a new approach to be taken to this problem based on scale-dependent model objects, databases, and spatial objects in practical applications to specific places. One of the most exciting benefits of the possibilities provided by the GRID in environmental modeling is the potential to implement models available from different institutions as a process of *learning about specific places*. It will be possible, in fact, to have models of all places of interest. However, as argued by Beven (2000, 2001a, 2002b, 2004), as a result of scale, nonlinearity, and incommensurability issues, the representation of place will be inherently uncertain so that this learning process should be implemented *within an uncertainty estimation framework*.

Sites of interest for a particular prediction can be implemented as *active objects*, seeking information across the GRID to achieve a specified purpose, and using the power of parallel computing resources to estimate the uncertainty associated with the predictions as constrained by *site-specific observations*, including those accessed over the GRID in real time. Initially model results, based perhaps on only GIS databases and limited local information, may be relatively uncertain but experience in monitoring and auditing of predictions will gradually improve the representation of sites and boundary conditions. It is this learning process that will be critical in the development of a new generation of environmental models that are geared toward the management of specific places, rather than general process representations.

That is not to say that models of places will not require process representations, but there is a real research question about how detailed a process representation is necessary to

be useful in predicting the dominant modes of response of a system, given the uncertainties inherent in representing the processes in places that are all unique. This appropriate complexity issue has become obscured by the desire to build more and more scientific understanding into models, including physical, chemical, and biological components. This desire is perfectly understandable, it is a way of demonstrating that we do understand the science of the environment, but it results in models that have lots of parameter values that cannot be easily measured or estimated in applications to real places. There is always a certain underlying principle in science, that as we add more understanding and eliminate empiricisms, then the application of scientific principles should become simpler and more robust. This does not seem to have been the experience in the practical application of environmental models.

Events such as the river flooding in the UK in 2000, 2002 and 2004 and the consequences of the 2001 fires in the US, have demonstrated the need for a new generation of systems for environmental forecasting. The subtle (and sometimes not so subtle) coupling between atmospheric forcing, catchment response, river runoff, and transport processes requires the dynamical coupling of many components to capture these subtleties. Components would be a representation of the regional atmosphere and the terrestrial surface and subsurface hydrology that would interact through different boundary conditions. Built on the fluxes within those models air and water pollutant transport models and biogeochemical models could be implemented locally within the regional-scale domain. Each component would be able to assimilate data transmitted from field sites and assess the uncertainty in the predictions. The components would share 4-D/5-D visualization tools with appropriate interactive user interfaces. Users will be able to access the current data, visualize predictions for particular locations and play what-if scenario games over different timescales. The structure of the system would be such as to facilitate and even stimulate improvements to the representation of different components and the constraint of predictive uncertainty by field data collection and data assimilation. The potential capabilities of the GRID underlie all these components, though much could already be achieved using the Web technology of today. Examples of steps toward this type of integrated system (albeit essentially raster based) include the US Inter-Agency Object Modeling System (OMS), (*see* **Chapter 129, Rainfall-runoff Modeling for Integrated Basin Management, Volume 3**).

Such an integrated system should operate both in real time, assimilating data and boundary conditions from larger scale models, and displaying the "current state of the environment", as well as providing the potential to update model predictions into the future under different scenarios. Initiatives such as the European Union Water Framework Directive (see **www.europa.eu.int/comm/environment/water-framework/index-en.html**; **www.defra.gov.uk/environment/water/wfd**) are increasing demands for predictions of this type about the *responses of specific locations to change* in a way that integrates hydrological and ecological considerations in management. The system would need to be powerful enough to be used for assessing *uncertainties in model predictions and the consequent risks of potential outcomes*. It should also be able to be used off-line for "what-if" management purposes or decision support including developing strategies for risk-based sustainable management in the context of climate and other changes. This will include the evaluation of management of subsystems including for licensing of airborne emissions and effluents to water courses; strategies for remediation of contaminated land, rivers and estuaries, and so on.

An essential element of this strategy will be the need, as far as possible, to "future proof" the model and database systems used; avoiding, for example, a strict raster based approach or a commitment to one particular modeling framework. The key will need to be flexibility. Raster databases will continue to be driven by remote sensing imaging inputs to the modeling process, and, in some cases, by convenient numerical solution schemes for partial differential equations. However, it is often inappropriate to force an environmental problem into a raster straightjacket. Treating places as flexible active objects might be one way around this future proofing problem. Defining the spatial domain of a prediction problem would allow that place, as an active object, to search on the GRID for appropriate methods and data for resolving that problem, and also for appropriate methods and data for providing the boundary conditions for the problem (which might then involve other modeling or data extrapolation techniques).

There are some interesting implications of such an approach. One is that the variety of modeling methods available across the GRID to solve a prediction problem might be able to be compared more readily, leading to better understanding of issues of appropriate model complexity for different modeling problems. This will especially be the case if, as part of the learning process, simulations are saved to be compared with later observations of the real outcome. This use of "post-audit" analysis has been rarely used in environmental modeling, but has been instructive in the field of groundwater modeling (Konikow and Bredehoeft, 1992; Anderson and Woessner, 1992) and is routine in atmospheric modeling in the evaluation of forecast skill (although the evaluation of global climate model predictions still requires an element of compromise at the regional level).

To be useful, however, the process of model application will require the definition of a self-coding system attached to places to record and retrieve the methods that have been applied to (or by) that place in the past so that they can be easily reviewed and evaluated by the user. There is then

a further interesting question that arises as to how far the place, once defined for a problem, can learn about itself from the data and model predictions available; using methods such as fuzzy classification or genetic programming as tools to extrapolate data from that and other sites to develop predictive methods of appropriate complexity to the problem at hand within the limitations of the uncertainties implied by the data available. This approach has been advocated, for example, by the proponents of "hydroinformatics" (e.g. Abbott, 1991).

The learning framework that underlies this framework is best suited to systems that are not changing. In that way new data should allow a refinement of the feasible model representations and reduction in the predictive uncertainty. Many of the predictions required of environmental systems, however, involve questions of current or future change under different scenarios. Such predictions will be even more uncertain than the simulation of current conditions, but there has been very limited work on estimating the uncertainties of potential outcomes in future scenario simulations, and less on the conditioning of those predictions as monitoring of changing conditions changes. Continued monitoring and recursive data assimilation, in this framework then becomes a tool for following drift in system response (within the limitations of data uncertainties.

Perhaps a theme can be identified in running through this discussion of environmental models of everywhere: the focus on data. Data will be required to characterize places, to drive model predictions, to evaluate the results of model predictions, to reject some models previously considered feasible, and to monitor changes in system response. Once all places are represented within the flexible GRID-based system envisaged, the data may assume a greater importance than model structures as a means to refine the representation of each place within a learning framework. The result may be a new way of looking at environmental modeling that transcends the traditional goal of incorporating all our understanding of the complexity of coupled environmental systems into a single mathematical framework with a multitude of parameters that cannot easily be identified for any particular place (Beven, 2003, 2004).

Further Information

There have been a number of reviews of rainfall-runoff models published in the last decade. For more details, the reader is referred to Singh (1995); Abbott and Refsgaard (1996); and Beven (2001b). Concise descriptions of particular models can be found in Singh (1995) and Singh and Frevert (2002a,b). Extensive discussions of the model calibration problem can be found in Anderson and Bates (2001).

123: Rainfall-runoff Models for Real-time Forecasting

EZIO TODINI

Department of Earth and Geo-Environmental Sciences, University of Bologna, Bologna, Italy

This article describes the use of rainfall-runoff models within the frame of real-time flood forecasting and warning. After assessing the requirements of real-time flood forecasting systems, some of the more well known ones available for operational purposes are briefly mentioned. The different types of rainfall-runoff models used in practice are then presented, within the framework set on the one hand by the operational system requirements, and on the other hand by the historical evolution of research and development in the fields of hydrological and meteorological forecasting. After discussing the problems of real-time updating and of the assessment of the predictive uncertainty, two example applications are illustrated. The article concludes with a description of current and future research themes for extending the forecasting lead time, assessing forecasting uncertainty, and appropriately communicating it to the end users.

INTRODUCTION

Definition of Real-time Flood Forecasting Systems

Real-time flood forecasting systems are tools aimed at reducing the uncertainty on the evolution of future events thus allowing decision makers to take the most effective decisions under uncertainty (Raiffa and Schlaifer, 1961; Todini, 1999). This means that, to be operational, flood forecasting systems are not only required to be timely and sufficiently accurate within predetermined time horizons but should also provide a usable quantification of the forecasting uncertainty.

The following example (Figure 1), relevant to the decision of issuing a flood warning, can demonstrate why a flood forecast without a measure of its uncertainty can be of no value and sometimes even dangerous. In the example, if the water level in the channel rises above the dykes, damages will occur with costs increasing with the dot–dashed line. The forecast says that the expected value will stay below the top of the dyke, which seems to imply that the expected damage costs will be zero and no action should then be taken. Unfortunately, because of the forecasting uncertainty always embedded in a forecast (depicted in Figure 1 as a probability density function with mean on the forecasted value), one can immediately notice that the expected damage (the integral of the product of the density times the cost) is not null and the most appropriate decision may then be totally different.

Uncertainty increases with the forecasting horizon, which is a function of the time required to implement the flood protection measures. The forecasting horizon is a characteristic of each individual problem and may vary from a few hours needed to safeguard a small village to more than four days, as it is required to protect the city of Canton, given that the dykes of the Bei Jiang river must be blown with dynamite after evacuating 2 million inhabitants from their villages in the water detention areas to the surrounding hills.

Whenever the forecasting horizon required for the implementation of the flood management interventions is sufficiently short, when compared to the characteristic response time of the river, one should use hydraulic routing models to compute downstream discharge and/or level forecasts from the upstream measured ones, given that the hydraulic models tend to be more accurate than the hydrologic rainfall-runoff models. Unfortunately, in most situations the lead time provided by the hydraulic models is insufficient to allow for the implementation of the protection measures. In these cases, the use of rainfall-runoff models is inevitable. If the forecasting chain starts from

the measured rainfall that is to be used as input to a rainfall-runoff model, one gains forecasting lead time as a function of delays, mostly because of soil storage filling and surface waters' travel time, but inevitably introduces additional errors and uncertainty because of the simplifications of the processes' representation and the parameterizations typical of the hydrological rainfall-runoff models. Finally, when the time horizon gained using the measured rainfall is still insufficient, as in small steep or urban catchments or more generally when the required lead time is very large compared to the characteristic space–time dimensions of the phenomena, one must resort to use RADAR-based nowcasting (0–6 h) (MUSIC, 2001, **http://www.geomin.unibo.it/orgv/hydro/music/**) or quantitative precipitation forecasts (QPF) provided by numerical weather prediction (NWP) models (1–4 days) (EFFS, 2003, **http://effs.wldelft.nl**). Inevitably, the level of uncertainty increases greatly, and overcoming this problem currently represents the frontier of research efforts (see Section on "The HEPEX Project").

The assessment of the problem relevant to the estimation of a measure of uncertainty to be provided to the decision makers, which would incorporate all the different sources of uncertainty, has been analyzed in detail (Krzysztofowicz, 1999), and a Bayesian combination approach has been proposed. Although very rewarding from a speculative point of view, its practical implementation (Krzysztofowicz and Kelly, 2000; Krzysztofowicz and Herr, 2001; Krzysztofowicz, 2001) is still under evaluation.

Operational Systems

One must acknowledge that a wide gap still exists today between operational flood forecasting and research in the related field. Most people working in operational flood forecasting still perceive the forecast as a "deterministic" value to be compared to a threshold in order to select the most appropriate decision. They tend to look for simple packages with extremely simple solutions that would fit into their way of thinking. On the other hand, researchers tend to overparameterize the models, to overfit the data, and to produce extremely complex outputs or pieces of information instead of trying to integrate the complexity of the uncertainty estimation into some simple decision rule to be easily understood by the decision makers.

In this context, it is easy to find operational systems that, in reality, never worked properly because of their complexity while some very simple approaches, although unsatisfactory from the scientific point of view, have been fully understood and properly used by decision makers.

Nonetheless, the definition of a real-time flood forecasting system as a tool for reducing the uncertainty in the future events implies that all the components included in the system must be (i) robust, since a forecast must be provided, (ii) sufficiently accurate, (iii) adaptive, and (iv) capable of providing, at each step in time, an overall measure of uncertainty. Moreover, the operational system must run round the clock, accept inputs arising from several sources generally stored in different databases, detect incoming data errors, and rebuild the missing data. As one can imagine, from the schematic representation of one of the commercially available real-time flood forecasting systems (Figure 2), this can be quite a sophisticated and complex piece of software that must guarantee its continuous operation to the user.

As can be seen from Figure 2, the European Flood Forecasting Operational Real Time System (EFFORTS), is a complex real-time flood forecasting system that incorporates automatic data validation, sampling, and reconstruction; stochastic extrapolation of rainfall and upstream inflows; rainfall-runoff modeling and 1-D flood routing; stochastic assessment of uncertainty using the Mutually Interactive State and Parameter (MISP) estimation algorithm of Todini (1978).

As a matter of fact, the number of existing operational real-time flood forecasting systems is not too large and, moreover, not many of these systems can be taken as representative of a specific approach, this is why this article will only briefly mention the most widely known commercial packages. Several operational systems are now available starting from the historical ALERT system based upon the Sacramento model, widely used in the United States, since the end of the 1970s, to the Flood Works (FW) developed by Wallingford Software (**http://www.wallingfordsoftware.com/products/rivers/**) and based on the Real Time Flood Forecasting System (RFFS) (**http://www.nwl.ac.uk/ih/www/research/mfloodfore.html**) developed at CEH, to the SMHI Real-time Flood Forecasting system based on the HBV model (Bergström, 1976, 1992, 1995), to the more

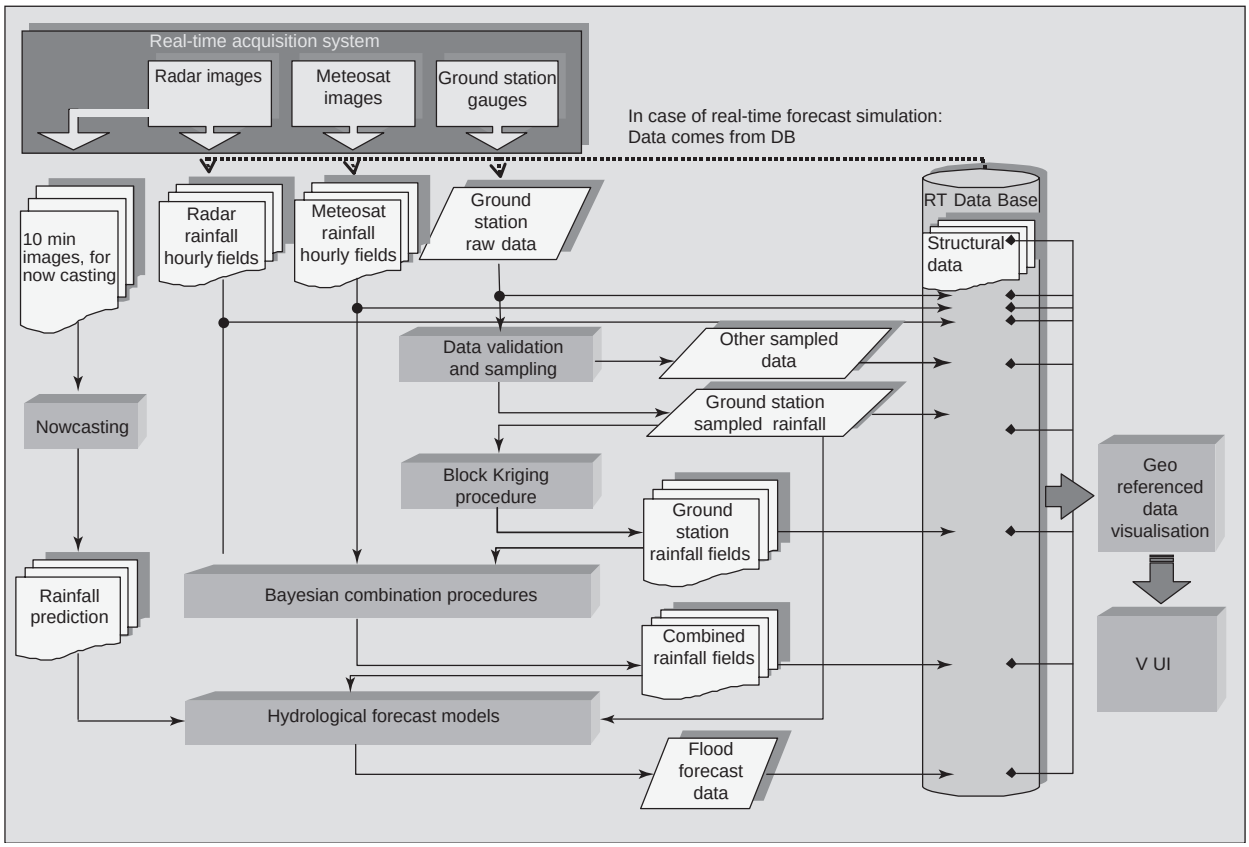

Figure 2 Schematic representation of EFFORTS an operational real-time flood forecasting system (by permission of PROGEA (Protezione e Gestione Ambientale) Srl). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

recent MIKE FLOODWATCH (DHI, 2000a), which couples the NAM model (DHI, 2000c) with MIKE 11 FF (DHI, 2000b) into an operational GIS-based flood forecasting system, and to EFFORTS in its two GIS-based versions, the first one based on the ARNO model (Todini, 1996; 2002a) and the second one based on the TOPKAPI (Todini and Ciarapica, 2002; Liu and Todini, 2002). Last, but not least, a shell for incorporating alternative real-time flood forecasting models and in particular, LISFLOOD (De Roo *et al.*, 1998; 2000), although not yet fully operational, is currently under development at Delft Hydraulics within the framework of project EFFS.

RAINFALL-RUNOFF MODELS FOR REAL-TIME FLOOD FORECASTING

It is not easy to generalize a typology for the rainfall-runoff models used for real-time flood forecasting because the choice of the model heavily depends on the scale of the catchment, the rapidity of the phenomena, and the required forecasting lead time. As can be easily understood, one thing is to deal with real-time forecasting in some small flashing catchment or alternatively in very large catchments such as those of the Po, the Rhine, the Danube, the Mississippi, or the Yangtze rivers.

In addition, there are two lines of thought in the development of rainfall-runoff models for flood forecasting. The first one, mostly originated by the continuous flow of available data generally collected round the clock, places more emphasis on measurements and develops extremely simple statistical or parametric models, the parameters of which may be estimated and continuously updated by means of observations. The second line of thought, still recognizing the importance of the available data, believes that the highly nonlinear behavior of the rainfall-runoff processes may not be fully learned from the limited set of data used for calibration (the learning set) and must be introduced as *a priori* knowledge into the models in order to reduce uncertainty and improve the reproduction of the phenomena beyond the range of observations (Kitanidis and Brass, 1980a,b; Brath and Rosso, 1993).

The consequence to this dichotomy is that one can find all sorts of operational systems that range from extremely simplified models, possibly recalibrated in real-time, to systems based on extremely complex rainfall-runoff models. In addition, real-time flood forecasting models developers

still discuss the use of event type models as opposed to continuous type explicit soil moisture accounting (ESMA) models.

During recent decades, most of the operational flood forecasting systems based on rainfall-runoff models were developed using continuous type ESMA models (WMO, 1975; Todini, 1988; Franchini and Pacciani, 1991). The main reason for this is because ESMA-type models are capable of continuously updating the soil moisture conditions on the basis of the water balance equation. The major limit to the use of simple linear models lies in the fact that they do not correctly represent the nonlinear threshold-type soil behavior and the split of rainfall into infiltration and surface runoff. Similarly, the event type models, not performing a continuous mass balance computation, must be initialized with actual soil moisture conditions, which heavily condition the forecasts in real time and can hardly be measured at a catchment scale. From the original ESMA models developed in the 1960s and early 1970s (WMO, 1975) needing an exaggerated number of parameters (generally more than 20), new types of models were developed in the 1980s needing only three to six parameters but fully representing the dynamics of saturated areas, which was recognized as a main cause of runoff generation in large floods. This result originates from the finding that, for the purposes of flood forecasting, the most important effect that models must represent is the overall soil filling and depletion mechanisms and the resulting variation in the extension of the basin saturated areas; in fact, when large portions of the basin reach saturation the rainfall that falls over these areas has a direct effect on the flood magnitude without being attenuated by the soil's absorption capacity. These concepts have spawned the new ESMA-type models, such as for instance the PDM model (Moore and Clarke,1981; Moore, 1985) or the Arno model (Todini, 1996; 2002a) that have been widely used and extensively described in the literature. In general, these models have been developed as semidistributed models, although the problem of their adaptation to ungauged subcatchments has not yet been properly resolved.

More recently, deterministic spatially distributed rainfall-runoff models have been used more widely. Apart from the recent availability of GIS tools and more powerful computers, there are several reasons for this tendency. The main reason lies in the fact that the physical meaning of processes and relevant parameters can only be preserved at small scales, while this physicality is lost when the processes are aggregated at subcatchment or catchment scales. On the basis of equations representing the storage and the movement of water in the soil and on the surface, these models are potentially easier to calibrate by relating the values for their physically meaningful parameters to additional information provided in the form of Digital Elevation Maps, Soil Maps, and Land Use Maps. These models, which attempt to represent more realistically the different processes at scales finer than the subcatchment, account for the spatial distribution of rainfall (now available at pixels of between 1×1 km and 10×10 km from RADAR images or in terms of QPF from NWP models) and are better equipped to address the problem of extrapolating the parameter values to the ungauged subcatchments, a problem for which a proper solution has not yet been found.

All these potential properties, combined to the increased efficiency of computers, has given rise to a number of fully distributed rainfall-runoff models, some of which have been (while others are in the process of being) incorporated into real-time flood forecasting systems.

Black-box Models

Black-box models have a long history in hydrology. In 1932, Sherman introduced the concept of the unit hydrograph based on the principle of superposition of effects. Even though it had not yet been formalized at that stage, the superposition principle involved many assumptions: a basin, under the effects of rainfall-runoff transformation, should behave like a linear, dynamic, time invariant causative system. This unit hydrograph definition nevertheless excited the interest of hydrologists who by then were able to provide not just an estimate of the peak discharge as with the rational method but also the behavior of flood flows under the action of rainfall with a more or less complex pattern.

Yet, the unit hydrograph method presented a certain number of problems that were solved using more or less subjective methods like

- the separation of surface runoff from base flow;
- the determination of "effective" rainfall, namely, that portion of the rainfall that is not lost via evaporation and transpiration and does not filter down through the soil; and
- the actual derivation of the unit hydrograph from the available data.

The leap in quality only came about in the 1950s when hydrologists mastered systems theory techniques. They realized that the unit hydrograph was merely the response of a linear, dynamic, time invariant, causative system and that the use of techniques such as Z transforms and Laplace or Fourier transforms enabled them to derive this response from an analysis of the system's input and output data.

This was the period in which "conceptual" models came into being. The derivation of the unit hydrograph based on sampled input and output data, known as the *inverse problem*, was still a complex problem both because of the less than perfectly linear behavior of the basin system and also because of gross errors in the measurement of input and output quantities. To overcome these problems, hydrologists found that the forms of the unit hydrograph

could be obtained as the solutions of differential equations describing the temporal behavior of simple systems, such as a linear reservoir or a cascade of linear reservoirs, for example, the Nash model (Nash, 1958, 1960). The unit hydrograph thus came to be expressed as a function of a few parameters that could be estimated using statistical techniques: moments, cumulants, regressions, maximum likelihood, and so on, thereby permitting regionalization and extension to basins without measurements by regressing the parameters obtained as a function of the physiographic characteristics of the basin. A plethora of these models gave rise to an incredible variety of solutions: a cascade of linear reservoirs, linear channels, linear channels and reservoirs, nonlinear reservoirs (Prasad, 1967), and so on.

On the other hand, the derivation of the form of the unit hydrograph by means of transforms based on observed data still presented enormous difficulties as far as its application to real cases was concerned: in a classic article, Rao and Delleur (1971) highlighted the extent of the effects induced, on a unit hydrograph estimate made using Fourier transforms, by errors of measurement on input and output data. Only after the works of Wiener (1949) and Tikhonov (1963a,b) and the introduction at the estimation stage, of elementary physical concepts, such as mass balance or as regularity and nonnegativity of unit hydrograph ordinates (Eagleson *et al.*, 1965; Natale and Todini, 1976a,b; Bree, 1978; Bruen and Dooge, 1984) were realistic and reliable unit hydrograph estimates obtained.

At the same time, research into nonlinear systems led to representations based either on Volterra integrals of an order greater than the first, or by means of projections based on orthogonal polynomials (Amorocho and Orlob, 1961) or based on piecewise linearizations (Todini and Wallis, 1977; Todini, 2002b) aimed at reproducing the sharp soil saturation effect.

Box and Jenkins (1970) provided hydrologists with new instruments for expressing unit hydrographs in a discretized form by means of autoregressive exogenous variables models (ARX) or autoregressive moving average models (ARMA) (Clarke, 1973; Ubertini, 1982), and analogies with existing conceptual models were pointed out by Spolia and Chander (1974). In subsequent developments of the applications by means of the techniques pioneered by Box and Jenkins there was, however, a loss of "physicality" in the models (particularly when using ARIMA and Intervention Analysis models) in favor of mere mathematical and system identification techniques. The loss of physicality is even more accentuated with the new Artificial Neural Network (ANN) approaches, which can be viewed as nonlinear analogues of the transfer function models. This can turn into poor forecasts when the events are larger than the one experienced in the training set (Cameron *et al.*, 2002).

Although research is very active in this domain as, for instance, Shamseldin (1997) and Dawson and Wilby (2001), who provide an interesting review on application of ANN to rainfall-runoff modeling, very few examples of existing operational systems are presently based on ANN (Garcìa-Bartual, 2002). More recently, a Data Based Mechanistic (DBM) modeling approach was introduced by Young (2002), which, although deriving the model structure and the parameter values from the input and output data by means of system engineering identification and parameter estimation techniques, attempts to go beyond the black-box concept by selecting those (not necessarily linear) model structures that are considered physically meaningful (Young, 2001, 2002). Adaptive DBM models were used as the basis for an operational flood forecasting system for the river Nith in Scotland (see Lees *et al.*, 1994). Although, the DBM modeling approach recognizes the importance of the physical coherence of the identified model structure, it derives it from the observations, thus disregarding *de facto* the results of at least 50 years of research efforts aimed at specifying the hydrological physical mechanisms that generate floods. This might cause problems in forecasting beyond the range of observations that are available in calibrating a DBM model, or where those data are highly uncertain in times of flood, but the ease of implementing these models in an adaptive form may mitigate against this. A full application of the Bayes principle would suggest that all possible *a priori* knowledge (in this case our knowledge on the hydrological processes and possibly on the parameter values as well as past observations) should be combined with the current observations to obtain less uncertain *a posteriori* forecasts, but it remains a research question as to how best to do so.

The ESMA-type Models

In the 1960s, new types of hydrological cycle models were introduced. In an attempt to achieve a better physical interpretation of the phenomena, experts tried to represent the behavior, at basin level, of each individual component in the hydrological cycle by using a group of interconnected conceptual elements, each of which represent the response of a particular subsystem. The need for this kind of approach was due to newly emerging requirements implying the extension of hydrological models to continuous simulation on larger catchments by overcoming the complexity and subjectivity of the separation of surface and base flows and of the derivation of the effective rainfall.

A large number of these models were developed: Dawdy and O'Donnell (1965), the Stanford Watershed Model IV (Crawford and Linsley, 1966), the Sacramento (Burnash *et al.*, 1973), the SSARR (Rockwood, 1982), the Tank (Sugawara, 1967, 1995), and so on, which represented in different ways the response mechanism of the various phenomena and the interconnections between the various subsystems, and which at that time were regarded as the very best that could be achieved with models. Figure 3

shows a block diagram of the different processes generally represented in the ESMA models.

In theory, the parameters of these models, such as the storage coefficients, roughness coefficients, or the different thresholds, could be somehow set in relation to the physiographic quantities of the basins. In reality, when the parameter estimates are made on the basis of objective functions to be minimized (e.g. the sum of squared deviations), groups of unrealistic parameters are obtained which incorporate both data measurement errors and the errors present in the structure of the model itself; in addition the observability conditions are not always guaranteed, particularly for multiple input–output hydrological models, as pointed out by Sorooshian and Gupta (1983) and by Singh and Woolhiser (2002). ESMA-type models have given rise to several real-time flood forecasting systems. In particular, among them four specific models have to be recalled, since they have given rise to operational real-time systems. The first one is the National Weather Service-River Forecast System (NWS-RFS) also known as the Sacramento model (Burnash *et al.*, 1973). The NWS-RFS was used as the basis of the ALERT flood forecasting

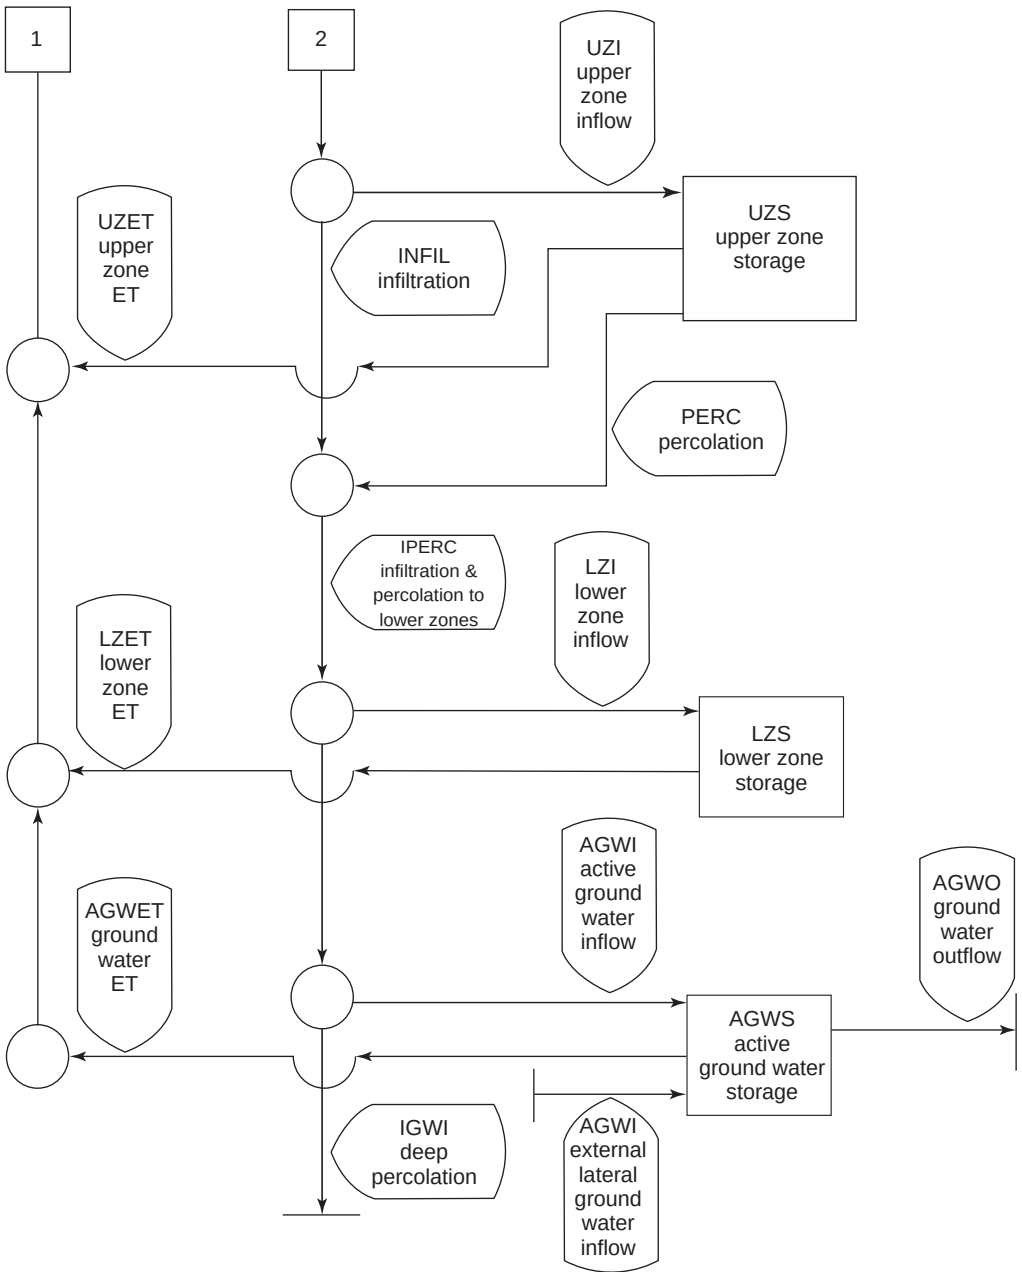

Figure 3 A schematic representation of storages and processes in an ESMA-type model

system, which is widely used in the United States, and for the development of several flood forecasting systems around the world, such as for example, the forecasting systems of the Hindus (WMO/UNDP, 1980) and the Nile in Sudan (Elzeim and Adam, 1996). A second model, the SSAR (Rockwood, 1982) is operationally used for flood forecasting in the Mekong (Tanaka, 1999). Another widely used model, the HBV (Bergström, 1976, 1992, 1995), which is part of the Swedish SMHI flood forecasting system, has found several applications in many countries and in particular, in the North European countries. Last but not least is the NAM model (Nielsen and Hansen, 1973; DHI, 2000c), which is included as the rainfall-runoff model in the MIKE FLOODWATCH software package (DHI, 2000a), which is becoming more and more widely used throughout the world.

The Variable Contributing Area Models

A new generation of ESMA-type models, the variable contributing area models, appeared around the end of the 1970s with the work of Zhao (1977) which originated the Xinanjiang model used in China for forecasting floods on the Xinanjiang river. More or less at the same time, and quite independently, Moore and Clarke (1981) (see also Moore, 1985), proposed the Probability Distribution Moisture (PDM) model, while Juemou *et al.* (1987) developed the Synthesized Constrained Linear Systems model (SCLS) by combining the Xinanjiang soil water production function with the Constrained Linear Systems (CLS) model (Natale and Todini, 1976a,b; Todini and Wallis, 1977; Todini, 2002b). Few years later, by modifying the Xinanjiang soil water production function, Todini (1996, 2002a) developed the ARNO model, from which Wood *et al.* (1992) derived the VIC by increasing the number of soil layers (Liang *et al.*, 1996a,b). All these models were developed as lumped semidistributed models on the assumption of a spatially variable storage capacity for infiltration at the soil surface: namely, all the precipitation enters the soil and surface runoff is originated by saturation of the first soil layer.

The core of these models is a two-parameter curve representing the relation between the total volume of water stored in the soil and the extension of the saturated areas. Unfortunately, the parameterization of this curve, as well as that of the other processes represented (drainage, percolation, groundwater flow, etc.) is based on empirical parameters to be estimated from the data. Beven and Kirkby, (1979) originated a more physically meaningful lumped model by following an alternative approach to derive a similar relation. They originated the TOPMODEL on the assumption that the accumulation of soil moisture can be approximated by successive steady states of the water table originating in a first layer of soil. On this basis, they derived a new relation between the volume of water stored in the soil and the extent of areas at saturation on the basis of physically meaningful parameters.

All these models, generally combined with simplified hydrological overland flow and channel routing components, have been transformed into semidistributed models and are used for the setting up of operational real-time flood forecasting systems. For instance, after the applications of the original Xinanjiang system, most real-time flood forecasting systems in China have been modeled using the SCLS, which recently came out first in a Chinese nationwide competition.

In the United Kingdom, the Center for Ecology and Hydrology combined the use of the PDM model and RADAR rainfall data producing the RFFS, 2005, (**`http://www.nwl.ac.uk/ih/www/research/mfloodfore.html`**), which constitutes the core of the FW system, a generic software package oriented to real-time flood forecasting developed by Wallingford Software, 2005 (**`http://www.wallingfordsoftware.com/products/rivers/`**). In Italy, the ARNO model, which incorporates linear parabolic routing on the catchment slopes and in the channels, has been used for many years as the core of the EFFORTS. The system, originally developed for the Fuchun river in China (ET&P, 1992), was successively applied to the Danube in Germany as well as to several Italian rivers.

The Distributed Models

The lack of any real "physical" connection between lumped models and reality, which emerged in the work of Wooding (1965a,b; 1966) and Woolhiser and Liggett (1967) where kinematic models were used for the study of small urban basins, prompted Freeze and Harlan (1969) to propose, albeit only as a future project, the creation of a mathematical model based on distributed physical knowledge of the phenomena by means of the numerical integration of the various systems of differential equations describing surface flow, flow in unsaturated soils, and flow in water tables, matching the solutions of a subsystem with the boundary conditions of another. Unfortunately, the applications, not the least because of the limited computational resources available at that time, were directed only at small, almost impermeable mountain basins and were designed to evaluate flow in the catchment-closing section without highlighting the characteristics peculiar to this type of approach.

The need to evaluate the effects of modifications to the hydrological cycle engendered by changing agricultural practices and more generally by anthropogenic intervention prompted several research institutes such as the Danish Hydraulic Institute (DK), the Institute of Hydrology at Wallingford (UK), and SOGREAH (F) to return to Freeze and Harlan's proposal, and to produce a model that expressed the various phenomena by integrating the differential equations with partial derivatives that express the continuity of mass and momentum

in reciprocal compliance with the exchanged boundary conditions (Abbott *et al.*, 1986a,b).

The result of these efforts, the SHE (Système Hydrologique Européen), now available in two versions, the MIKE-SHE of DHI (Refsgaard and Storm, 1995) and the SHETRAN of the University of Newcastle upon Tyne (Ewen *et al.*, 2000), is a powerful and interesting tool that has opened the interest to distributed modeling at the catchment scale.

With the recent advances in remote sensing, geographic information system, and computer technology, together with the natural evolution of research in hydrologic modeling, physically based distributed hydrologic models with simple and parsimonious parameterizations, such as WATFLOOD (Kouwen, 2000), DHSVM (Wigmosta *et al.*, 1994), TOPKAPI model (Todini, 1995b; Todini and Ciarapica, 2002; Liu and Todini, 2002), FEWS NET Stream flow Model (Verdin and Klaver, 2002), LISFLOOD (De Roo *et al.*, 1998, 2000), tRIBS (Vivoni, 2003), and InHM (van der Kwaak and Loague, 2001) were developed in recent years and represent interesting alternatives to MIKE-SHE and SHETRAN, which cannot yet be incorporated into real-time flood forecasting systems because of their computational time requirements.

Although interesting from a scientific point of view, not all the above-mentioned models are used in practice for real-time flood forecasting. Presently, only the TOPKAPI model can be considered fully operational, as it has been incorporated into the EFFORTS within the frame of project MUSIC and is operationally active on the Arno, the Reno, and nine additional smaller rivers in Italy. Another model, LISFLOOD FF is under development and test within the frame of project EFFS, but cannot yet be considered as an operational tool, while MIKE-SHE will be probably incorporated into a real-time flood forecasting system within the frame of a recently EC-funded project FLOODRELIEF.

REAL-TIME ADJUSTMENT OF RAINFALL-RUNOFF MODELS

The Different Types of Real-time Adjustment

The need for on-line adjustments in real-time flood forecasting models was underlined at the WMO Simulated Real-Time Intercomparison of Hydrological Models workshop (WMO, 1992), which was held at the University of British Columbia.

When real-time flood forecasting is performed using a nonstructural model, for instance, a "data-driven model", namely, a model for which the structure is not imposed *a priori* but identified from the observations, it is common practice to perform at the same time both the hydrological model and noise model identification, as well as the estimation of their relevant parameter values. As a matter of fact, real-time updating of state variables and parameter values is an essential feature that allows the models to more closely reproduce the observations. Recursive estimation algorithms are used that are generally based upon Kalman filter-type algorithms or other similar on-line estimation techniques. For instance, Lees *et al.* (1994) developed an adaptive flood warning scheme for the river Nith at Dumfries where they used a stochastic time-variable parameter (TVP) estimation algorithm (Young, 1984).

The problem is definitely more complex when using "structural models" (Kendall and Stuart, 1967), namely those models, such as for instance, the ESMA or the physically meaningful distributed models, for which a (generally complex) model structure has been hypothesized. In this case, apart from bluntly matching the latest model output to the most recent observations, there are basically three known procedures for adjusting forecasts in real time.

The first procedure is to correct the observed input to the model, given its large uncertainty (for instance, areal precipitation) and rerun the model until there is a reasonable match between model output and observed runoff (Bergström, 1976). Although several objections may be raised to this method, its rationale is to modify the state variables (the different water storages present in the model such as soil moisture storage content, groundwater content, etc.) in order to allow the hydrological model to be consistent with the observed output. Unfortunately, the method has a limited validity, which is restricted to reservoir type models.

The second procedure is to modify the parameters of the model by means of a real-time recalibration approach. This can be performed either limiting it to the transfer function relevant to the generally linear routing component of the model, or by recalibrating in real time all the model parameters, as proposed by Georgakakos for the SACRAMENTO model, by means of an Extended Kalman Filter (Georgakakos, 1986a,b). Following the results of the WMO (1992) Simulated Real-Time Intercomparison of Hydrological Models, this approach should not be recommended, not only because of the computational requirements of implementing such complex nonlinear Kalman Filters but chiefly because it often leads to highly unstable parameter estimates with a consequent increase in flood forecasting uncertainty.

The third procedure, based upon the development of a noise model, can be approached either by identifying the structural model parameter values and the noise model at the same time or by identifying the noise model conditionally to a given structural model and its parameter values. Owing to the complex nonlinear and/or threshold-type structures of the hydrological models and the parameter estimation difficulties expressed above, the conditional noise model approach is presently more widely used.

The noise model, conditional to the chosen model structure and parameter values, which implies the derivation

of the hydrological model residuals for a long historical record, can be achieved in several ways, ranging from ARMA and ANN models to Nearest Neighbour techniques (Brath *et al.*, 2002). More recently, Bayesian approaches have been increasingly used. They are based either upon the application of Kalman Filters, containing both the observed and the modeled flows in the state vector (EFFORTS, 2005, **http://www.progea.net**) or, as in the case of the hydrological processor introduced by Krzysztofowicz (1999), on a regression between observed and modeled flows after transforming them into a Standard Normal space using the Normal Quantile Transform (Van der Waerden, 1952, 1953; Kelly and Krzysztofowicz, 1997).

As an example of the effect of the noise model, Figure 4 shows graphically the reduction of uncertainty, obtainable by means of a two-dimensional Kalman Filter on the observed and modeled flows using the MISP algorithm (Todini, 1978). In Figure 4, the white histogram represents the forecasting standard error when the QPF from a NWP model is used for extrapolating the discharge forecast up to 12 h in advance at the Casalecchio gauging station on the Reno river (as further discussed in the Section on "Input uncertainty"), for which it is difficult to reliably provide more than 4–5 h in advance forecasts because of the relatively short catchment concentration time. One can see in Figure 4 (white histogram) that the standard error of the hydrological model remains unchanged around $50\,m^3\,s^{-1}$ up to 4 h of advance, while it reaches $100\,m^3\,s^{-1}$ when the forecast is issued 12 h in advance. The black histogram shows the reduction of the forecasting standard error when MISP is used. It is easy to verify, as one could expect, that the advantage provided by the noise model is much larger in the first few hours and tends to vanish with the increasing forecasting lead time.

The Kalman Filter

Given its importance in real-time updating of rainfall-runoff models, it was felt essential to provide in this section the basic elements of the Kalman Filter, while a more extensive derivation can be found in Jazwinski (1970) or Gelb (1974).

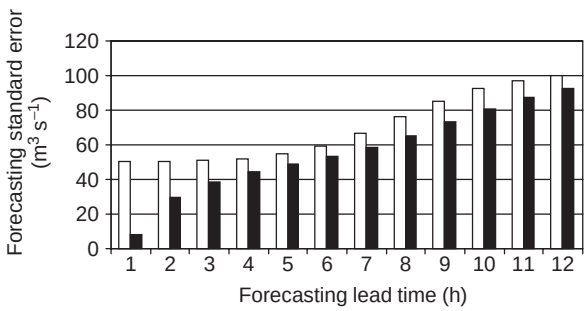

Figure 4 Reduction of forecasting uncertainty at Casalecchio on the river Reno using MISP up to 12 h in advance. Without MISP (white histogram), with MISP (black histogram)

The Kalman Filter (KF) (Kalman, 1960; Kalman and Bucy, 1961) is the recursive extension of the Wiener Filter (Wiener, 1949) to linear (or locally linearized in time) stationary as well as nonstationary processes. Its original derivation descends from the classical state-space formulation of dynamic systems in its time discretized form:

$$\mathbf{x}_t = \mathbf{\Phi}_{t-1,t}\mathbf{x}_{t-1} + \mathbf{\Gamma}_t\boldsymbol{\eta}_t$$

known as the "model" or "system" equation (1)

and

$$\mathbf{z}_t = \mathbf{H}_t\mathbf{x}_t + \boldsymbol{\varepsilon}_t \quad \text{known as the "measurement" equation} \tag{2}$$

where $\mathbf{x}_t[n, 1]$ is the state vector, namely, the vector containing all the n state variables used to represent the dynamic system; $\mathbf{\Phi}_{t-1,t}[n, n]$ is the state transition matrix that may vary at each step in time; $\boldsymbol{\eta}_t[p \le n, 1]$ is an unknown random Gaussian time independent process, with mean $\overline{\boldsymbol{\eta}}_t$ and covariance matrix $\mathbf{Q}_t$, used to represent the model error, while matrix $\mathbf{\Gamma}_t[n, p]$ is an appropriate matrix to relate the dimensions; $\mathbf{z}_t[m \le n, 1]$ is the measurement vector, namely, the vector containing the m observations and matrix $\mathbf{H}_t[m, n]$ is an appropriate matrix to relate the dimensions; $\boldsymbol{\varepsilon}_t[m, 1]$ is the measurement error, represented as a random Gaussian time independent process with mean $\overline{\boldsymbol{\varepsilon}}_t$ and covariance matrix $\mathbf{R}_t$, which is taken as being also independent from the model error $\boldsymbol{\eta}_t$.

For the sake of simplicity, following the original derivation by Kalman (1960) the "control" term has been omitted from the model equation, while a measurement error term has been added. The Kalman Filter aims at finding $\hat{\mathbf{x}}_{t|t}$, the unbiased minimum variance estimate of the unknown state $\mathbf{x}_t$, together with its error covariance matrix $\mathbf{P}_{t|t}$, conditional to the knowledge of an unbiased *a priori* state estimate $\hat{\mathbf{x}}_{t|t-1}$, together with its covariance matrix $\mathbf{P}_{t|t-1}$ (which fully represent the stochastic process because of the hypothesis of Gaussian errors), and the latest noise-corrupted measurements $\mathbf{z}_t$ together with its measurement error statistics (again mean and covariance are sufficient due to the Gaussian hypothesis). This estimate is obtained using the following equations, a neat derivation of which can be found in Gelb (1974).

At each step in time, the estimates of the state and of the error covariance are extrapolated from the previous step:

$$\hat{\mathbf{x}}_{t|t-1} = \mathbf{\Phi}_{t|t-1}\hat{\mathbf{x}}_{t-1|t-1} + \mathbf{\Gamma}_t\overline{\boldsymbol{\eta}}_t$$

state extrapolation (3)

$$\mathbf{P}_{t|t-1} = \mathbf{\Phi}_{t|t-1}\mathbf{P}_{t|t-1}\mathbf{\Phi}_{t|t-1}^T + \mathbf{\Gamma}_t\mathbf{Q}_t\mathbf{\Gamma}_t^T$$

error covariance extrapolation (4)

Then the following quantities are estimated:

$$\boldsymbol{v}_t = \mathbf{z}_t - \overline{\boldsymbol{\varepsilon}}_t - \mathbf{H}_t \hat{\mathbf{x}}_{t|t-1}$$

known as the *Innovation* (5)

$$\mathbf{K}_t = \mathbf{P}_{t|t-1}\mathbf{H}_t^T (\mathbf{H}_t \mathbf{P}_{t|t-1}\mathbf{H}_t^T + \mathbf{R}_t)^{-1}$$

known as the *Kalman Gain* (6)

Finally the *a priori* estimates can be updated to include the latest measurements:

$$\hat{\mathbf{x}}_{t|t} = \hat{\mathbf{x}}_{t|t-1} + \mathbf{K}_t \boldsymbol{v}_t$$

state update (7)

$$\mathbf{P}_{t|t} = (\mathbf{I} - \mathbf{K}_t \mathbf{H}_t)\mathbf{P}_{t|t-1}$$

error covariance update (8)

With respect to the Wiener Filter, the advantage of the Kalman Filter lies in the fact that optimality (in terms of unbiasedness and minimum variance) is recursively imposed at each step in time as opposed to the batch form required by the Wiener Filter. This also allows the nonlinear process dynamics to be locally linearized in time to produce what is known as the *Extended Kalman Filter* (*EKF*) (Jazwinski, 1970).

The basic problem in applying the KF is that the optimality conditions only hold when the state transition matrix $\boldsymbol{\Phi}_{t-1,t}$, together with the model and measurement error statistics ($\overline{\boldsymbol{\eta}}_t$, $\mathbf{Q}_t$, $\overline{\boldsymbol{\varepsilon}}_t$, $\mathbf{R}_t$) are fully known. Mehra (1970) provided a solution to the problem of estimating the unknown error statistics by imposing the time independence of the innovation, a condition associated with the KF optimality. The estimation of the state transition matrix parameters (generally known as the *hyper-parameters*) proved to be a far more complex problem. Several approaches can be found in the literature for solving the nonlinear estimation problem originated by the simultaneous estimation of both state and parameter values, ranging from developing the KF in the parameter space (Mayne, 1965; Sage and Husa, 1969) to the use of the Extended Kalman Filter on a state vector enlarged with the parameters (Jazwinski, 1970) or from the use of Maximum Likelihood (ML) (Gupta and Mehra, 1974; Cooper and Wood, 1982a,b; Wood and O'Connell, 1985) to the method of moments (Wojcik, 1993) and to full Bayesian approaches (Mantovan *et al.*, 1999). Following the Instrumental Variables (IV) approach (Kendall and Stuart, 1967; Young, 1974; Young and Whitehead, 1977), Todini realized that the posterior state estimate $\hat{\mathbf{x}}_{t|t}$, is the best possible IV, being totally independent from measurement noise and a minimum variance estimator of the true unknown state due to optimality of the KF. Accordingly, he developed the Mutually Interactive State Parameter (MISP) estimation technique by using two mutually conditional KFs: one in the space of the state conditional to the previous step parameter estimates and one in the space of the parameters conditional to the previous and the last updated state estimates (Todini, 1978). MISP was recently found by Mantovan *et al.* (1999) to be superior to the method of moments and very close to ML but much less demanding in computer time, while a full Bayesian approach, requiring the use of the Gibbs sampler (Gelfand and Smith, 1990; Carter and Khon, 1994) to produce the posterior distributions, had to be abandoned because of its exaggerated computer time requirements.

Several examples of application of Kalman Filters in hydraulic and hydrological applications can be found in Chao-Lin (1978), while specific applications to rainfall-runoff models can be found in Hino (1973), Szollosy-Nagy (1976) for on-line estimation of linear transfer function models, in Todini and Wallis (1978) for on-line state and parameter estimation of a threshold-type multiple input single output ARX model, and in Georgakakos (1986a,b) for the on-line update of the Sacramento model parameters using an EKF.

Recent developments in Kalman Filtering aim at overcoming the EKF limitations because of error Gaussianity requirements and model equation linearization. These new developments include the Particle Filter (PF) (Salmond *et al.*, 1993), the Ensemble Kalman Filter (EnKF) (Evensen, 1994, 2003) presently used for assimilating data in large nonlinear ocean and atmospheric models, and its simplification known as the *Unscented Kalman Filter* (*UKF*) (Julier and Uhlmann, 1997; Wan and van der Merwe, 2000).

Before concluding this section, it is worthwhile pointing out that the KF being a "filter" is not a "predictor". Therefore, it is an excellent tool for assimilating observations and calibrating state and parameter values, but rapidly becomes very poor when used for "forecasting" at future times, when observations are no longer available. In addition, it cannot be directly used for assessing what will be defined as "forecasting uncertainty", unless a "pseudo measurement" is available at future times, as described in the Section on "The definition of forecasting uncertainty". Unfortunately, these problems have been overlooked for many years in real-time flood forecasting.

ASSESSMENT OF FORECASTING UNCERTAINTY

The Definition of Forecasting Uncertainty

As pointed out in the introduction, one of the most relevant aspects of real-time flood forecasting is to allow better decision making under uncertainty. Krzysztofowicz, (1999) points out that "*Rational decision making (for flood warning, navigation, or reservoir systems) requires that the total uncertainty about a hydrologic predictand (such as river*

stage, discharge, or runoff volume) be quantified in terms of a probability distribution, conditional on all available information and knowledge" and that *"Hydrologic knowledge is typically embodied in a deterministic catchment model*."

These statements very clearly underline two aspects usually not clearly understood.

The first one is that the objective of forecasting is to provide the description of *the uncertainty of the future values of water stage, discharge, runoff volume, and so on, and not the uncertainty of predictions generated by the hydrological forecasting models.*

The second one is that this uncertainty, generally expressed in terms of *probability density* (or probability distribution) *function, must be "conditional" upon the forecasting model prediction, which is now seen as the available, although uncertain, knowledge of the future*. In other words, the forecasting model prediction is now taken as an *error affected pseudo measurement* of future values of water stage, discharge, runoff volume, and so on.

If, at a given river cross section of interest, variable y_t represents the observations of our "hydrologic predictand" (water stage, discharge, runoff volume, etc.) while $\hat{y}_t$ is the corresponding hydrological model output, the scope of uncertainty assessment can be defined as the estimation of the following conditional probability density:

$$f\{y_{t^*+i\Delta t} \,|\hat{\mathbf{y}}_{t^*+i\Delta t}, \mathbf{y}_{t^*}\} \tag{9}$$

where $y_{t^*+i\Delta t}$ represents the unknown future value of the predictand some $i\Delta t$ time steps after the present time, t^*; $\mathbf{y}_{t^*}$ represents the vector of all available observations of the predictand up to the present time, while $\hat{\mathbf{y}}_{t^*+i\Delta t}$ represents the vector of all the hydrological model forecasts available up to the required forecasting horizon.

Unfortunately, instead of the conditional probability density given in equation (9), it is common practice to provide the following probability density:

$$f\left\{\hat{y}_{t^*+i\Delta t} \,\middle|\hat{\mathbf{y}}_{t^*+(i-1)\Delta t}, \mathbf{y}_{t^*}\right\} \tag{10}$$

namely, the uncertainty of our forecast, which is not the proper uncertainty measure to be used in the decision making process.

Going back to the preference given by many hydrologists to the use of structural rainfall-runoff models (ESMA or physically meaningful distributed models), it must be noted that when the observations end, and the models are run in predictive mode, the nonstructural models will forecast future values by projecting (extrapolating) in the future the latest state estimate. Given that there are no more measurements to be used to "filter" these extrapolations (namely to reduce their variance) at each step in time, they will tend more or less rapidly to degrade as a function of the state transition probabilities. On the contrary, if one uses the structural modeling approach combined with a Bayesian processor, one can initially extend the structural model predictions beyond the measured record because of the concentration time of the catchment and/or to the availability of QPF. The structural model predictions can thus be taken as uncertain measures of the flows that are expected to occur and used to derive their probability density, or at least their expected value and variance, conditional upon the model predictions, by means of Bayesian or Kalman filtering techniques, which inevitably leads to a reduction of forecasting uncertainty.

Unfortunately, most of the existing operational real-time flood forecasting systems do not incorporate such a measure of uncertainty and the few operational real-time flood forecasting systems that provide, together with the forecast, a measure of uncertainty are essentially based upon a stationary measure of uncertainty derived from the analysis of performances on past historical data. This stationary measure is sometimes updated in real-time by means of a Kalman filter (see the Section on "The Kalman filter"), or similar recursive tools, in order to incorporate some information on the most recent performances but the final result is not always satisfactory.

With respect to the sources of uncertainty, as described by (Krzysztofowicz, 1999), they can be categorized as operational, hydrologic, and input. Excluding operational uncertainty, such as the one caused by erroneous or missing data, human processing errors, unpredictable interventions and so on, total uncertainty in real-time flood forecasting, which deals with forecasting horizons ranging from a few hours to a few days in advance, can be schematized as the combination of (i) hydrological uncertainty and (ii) input uncertainty.

Hydrological Uncertainty

Uncertainties definitely arise from imperfections of the hydrological model: its structure and relations, incorrect values of model parameters, incorrect estimates of other inputs taken as deterministic, errors in measurements of physical quantities, and so on. All these uncertainties are incorporated into what is referred to as the hydrological uncertainty.

Extensive research has been carried out on parameter estimation and on the assessment of parameter uncertainty. Examples are the Generalised Likelihood Uncertainty Estimation (GLUE) due to Beven and Binley (1992), NLFIT by Kuczera (1994), the more recent Bayesian Recursive Estimation (BaRE) algorithm introduced by Thiemann *et al.* (2001), or the Shuffled Complex Evolution Metropolis (SCEM-UA) by Vrugt *et al.* (2003).

Unfortunately, these approaches, although useful tools for estimating parameters and describing parameter uncertainty given a specific model, do not entirely represent the forecasting uncertainty since they neglect or treat implicitly

many other sources of uncertainty, such as the measurement and the areal precipitation estimate uncertainty or the uncertainty due to the choice of the model. Moreover, marginalizing with respect to all the possible sources seems presently an overwhelming task that makes the approach hardly usable to assess the *predictive uncertainty* of the predictand of interest (described by the probability density of equation 9). When observations are no more available, the only practical possibility to describe the predictive uncertainty is to use the presently selected model with a fixed set of parameter values (a given value or the last updated one) as well as all the other uncertainty sources, except the rainfall forecast, taken as deterministic. In other words, the forecast will necessarily be *conditional upon the chosen model structure, the parameter values as well as to all other error sources except the precipitation forecasts*. This conditional uncertainty, the *hydrological uncertainty*, can thus be more simply ascertained by using the chosen model with fixed parameter values and by comparing the observed and predicted values in the historical record using the observed rainfall as input. Krzysztofowicz (1999), Krzysztofowicz and Herr (2001) provide a technique based upon a Bayesian combination of a Markov model of water levels with a regression model relating the future levels with the predicted as well as the last observed ones. The approach, which is applied to data transformed in a Gaussian space via Normal Quantile Transform (Van der Waerden, 1952, 1953; Kelly and Krzysztofowicz, 1997), allows in the end to generate the conditional density of equation (9).

After assessing the *input uncertainty*, it is then possible to obtain the predictive uncertainty by combining in Bayesian sense, the input, and the hydrological uncertainty (Krzysztofowicz, 2001).

Input Uncertainty

Input uncertainty encompasses all exogenous variables and internal states (initial conditions) whose values vary from one forecast time to the next; they exclude parameters whose values remain fixed for a given river basin. Input uncertainty includes the uncertainty of the inputs causing the most significant effects on the forecasts (within the relatively short forecasting horizon), such as the future rainfall forecasts, while disregarding inputs generating minor effects over the forecasting horizon, such as evapotranspiration, the effect of which is appreciable in terms of its integral over longer periods of time.

Kelly and Krzysztofowicz (2000) provide a simple probabilistic approach based upon a two-component Weibull distribution in order to account for the probability of no future rainfall as an alternative to Monte Carlo approaches (Lardet and Obled, 1994). Nonetheless, a large amount of research work is still needed, taking into account the quality of the presently available quantitative precipitation forecasts (QPF) arising from Nowcasting or from numerical weather prediction (NWP) models.

In their work, Kelly and Krzysztofowicz (2000) and Krzysztofowicz and Herr (2001) assume that a probabilistic quantitative precipitation forecast (PQPF) is available and that it is actually representative of the precipitation uncertainty.

Unfortunately, because of several reasons among which the fact that the amount of precipitated water is not a state variable in NWP models (with the consequence that they cannot be updated in the models by means of precipitation observations) the QPFs have not yet reached the accuracy needed for issuing reliable flood forecasts when directly introduced as inputs to rainfall-runoff models. Moreover, as it was clearly shown in project EFFS the PQPFs originating from the NWP ensemble forecasts tend to be highly biased, therefore providing a very poor and distorted representation of future precipitation input uncertainty to be used within the proposed Bayesian processor.

Research is presently concentrated at finding more realistic alternatives to the direct use of NWP ensembles as inputs to flood forecasting models (see Section on "The HEPEX Project").

As an alternative to the direct coupling proposed by Georgakakos (1989), within the frame of the EU Funded Flood Forecasting Research Project AFORISM project (A Comprehensive Forecasting System for Flood Risk Mitigation and Control) (Todini, 1995a), an approach for linking a Limited Area Meteorological models (LAMs) to real-time flood forecasting models was introduced, which was then set up and tested under the EU funded TELFLOOD Project (Todini and Cerlini, 1999). The technique uses a Bayesian combination of an ensemble of past measured precipitation traces, conditional to the latest ground measurements of rainfall, derived with a phase-space approach known as the *Nearest Neighbour technique* (Yakowitz, 1987; Yakowitz and Karlsson, 1987; Todini, 1999), with the LAM forecasts that are taken as biased and noise-corrupted measures of future precipitation. The procedure was tested on nine flood events observed on the Reno river at Casalecchio (1051 km^2), which were chosen as to represent various rain and flood typologies.

The QPF forecasts from 1 to 24 h in advance were used as input to a rainfall-runoff model of the Reno river and the computed bias and standard deviation of errors of forecast are shown in Figure 5.

Using the Nearest Neighbours technique, 50 rainfall series of 24 h were drawn from the past observed values. Again, the bias and standard deviation of errors of forecast were computed and are shown in Figure 6.

From Figure 6, it is possible to notice that after a few hours with virtually no bias and a more or less constant standard deviation of errors of about 50 $m^3 s^{-1}$, which measures the uncertainty due to the rainfall-runoff model, the standard deviation rapidly reaches the value of 160 $m^3 s^{-1}$. Although of poor quality, the synthetically

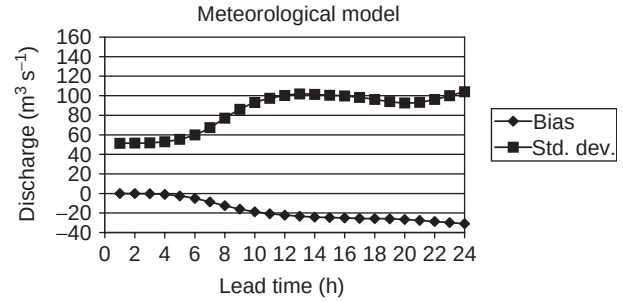

Figure 5 Bias and standard deviation of discharge forecasting errors for the Reno river at Casalecchio using LAM QPFs

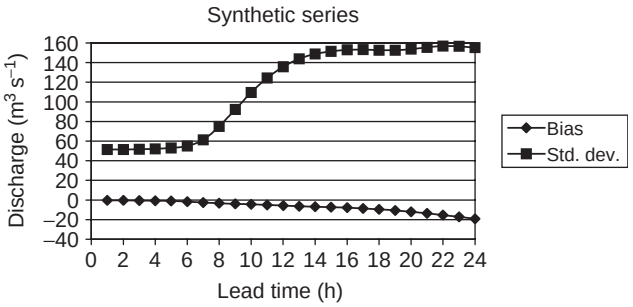

Figure 6 Bias and standard deviation of discharge forecasting errors for the Reno river at Casalecchio using the Nearest Neighbour rainfall forecasted scenario

generated scenarios, which can be considered as our "*a priori* best guess", can now be corrected using the QPF provided by the NWP model, taken as an "imperfect measure" of future rainfall.

Following the Bayesian approach described in Berger (1980) under the assumption of Gaussian errors, a correction scheme, typical of a Kalman filter (see Section "The Kalman filter") can be set up.

Given z_1 and z_2, two different measures of the unknown quantity x both affected by errors, namely:

$$z_1 = x + \varepsilon_1 \qquad z_2 = x + \varepsilon_2 \tag{11}$$

where: $\varepsilon_1 \cong N\{\mu_1, \sigma_1^2\}$, $\varepsilon_2 \cong N\{\mu_2, \sigma_2^2\}$ are mutually independent, namely:

$$E\{(\varepsilon_1 - \mu_1)(\varepsilon_2 - \mu_2)\} = 0 \tag{12}$$

A Bayesian combination of the two measures starts by defining a posterior estimate $\hat{x}$, as a linear combination of the two measures (minus their respective measurement bias):

$$\hat{x} = k_1(z_1 - \mu_1) + k_2(z_2 - \mu_2) \tag{13}$$

The two weights, k_1 and k_2 can be found by imposing that $\hat{x}$ must be unbiased and minimum variance, which implies that $\tilde{x} = \hat{x} - x$, the estimation error, must fulfill the following requirements: $E\{\tilde{x}\} = 0$ and $E\{\tilde{x}^2\} = Min$.

The first condition gives: $k = k_2 = 1 - k_1$, while the minimization of the error variance, provides:

$$k = \frac{\sigma_1^2}{\sigma_1^2 + \sigma_2^2} \tag{14}$$

This coefficient, also known as the *Kalman gain*, is then used in equation (1) to give:

$$\begin{aligned}\hat{x} &= \left(1 - \frac{\sigma_1^2}{\sigma_1^2 + \sigma_2^2}\right)(z_1 - \mu_1) + \frac{\sigma_1^2}{\sigma_1^2 + \sigma_2^2}(z_2 - \mu_2) \\ &= \frac{\sigma_2^2}{\sigma_1^2 + \sigma_2^2}(z_1 - \mu_1) + \frac{\sigma_1^2}{\sigma_1^2 + \sigma_2^2}(z_2 - \mu_2)\end{aligned} \tag{15}$$

As can be easily verified, the posterior estimate $\hat{x}$ is unbiased and its variance:

$$\begin{aligned}E\{\tilde{x}^2\} &= \left(1 - \frac{\sigma_1^2}{\sigma_1^2 + \sigma_2^2}\right)^2 \sigma_1^2 + \left(\frac{\sigma_1^2}{\sigma_1^2 + \sigma_2^2}\right)^2 \sigma_2^2 \\ &= \left(\frac{\sigma_2^2}{\sigma_1^2 + \sigma_2^2}\right)^2 \sigma_1^2 + \left(\frac{\sigma_1^2}{\sigma_1^2 + \sigma_2^2}\right)^2 \sigma_2^2 \\ &= \sigma_1^2\sigma_2^2 \frac{\sigma_1^2 + \sigma_2^2}{(\sigma_1^2 + \sigma_2^2)^2} = \frac{\sigma_1^2\sigma_2^2}{\sigma_1^2 + \sigma_2^2} = \left(\frac{1}{\sigma_1^2} + \frac{1}{\sigma_2^2}\right)^{-1}\end{aligned} \tag{16}$$

is definitely smaller than the single variances σ_1^2 and σ_2^2 of the two original measures.

By taking each member of the discharge ensemble generated by the Nearest Neighbor approach as measurement z_1 and the discharge obtained by using the QPF provided by the NWP model as measurement z_2, the Bayesian approach can be used after estimating μ_2 and σ_2 by means of historical data.

The results of the experiment on the Reno river were quite encouraging. Figure 7 shows that the bias, present

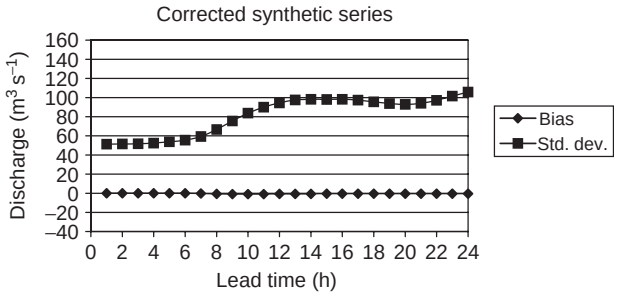

Figure 7 Bias and standard deviation of discharge forecasting errors for the Reno river at Casalecchio after the Bayesian correction

in the generated precipitation traces, has been totally eliminated, while the standard deviation of errors is being reduced at lags larger than three hours, while no improvement is obtained at lags up to three hours because of the relatively better quality of the *a priori* Nearest Neighbor forecasts on a short-term basis.

These encouraging results, together with the results obtained by Obled *et al.* (2002) and Obled and Djerboua (2001) using meteorological pressure fields for sorting the analogues, can be viewed as the starting point for estimating an improved input uncertainty, to be used within Bayesian integration techniques, such as the one proposed by Krzysztofowicz (1999, 2001), as described in the Section on "Examples of real-time flood forecasting systems". This approach seems realistically possible given the large amount of available weather reanalyses produced by most of the Meteorological Forecasting Centers, such as he NCEP-NCAR (Kalnay *et al.*, 1996) or the ECMWF.

Communicating Forecasting Uncertainty to the Users

A major problem associated with the use of predictive probability densities, instead of deterministic forecasts, is how to communicate understandable information to the stakeholders (the authorities responsible for taking decisions in real-time) as well as to the general public.

At present, there is ample evidence that the performance of several flood warning systems is rather poor. The information that they are designed to disseminate fails to reach a large part of the target audience, and the people who make up this audience are not satisfied with the service that they receive. This poor performance is a function of a weak link in the chain that connects the flood forecast with the person who is designated to obtain this information: the flood manager and particularly the public at large risk from the flooding that is being forecasted. Without comparable strength in this dissemination link in the chain, the performance of the whole system is degraded. The advancement of the accuracy of flood forecasting, and better targeting of the dissemination of ensuing message, is not for the benefit of the forecasters but for the public (Penning-Rowsell and Tunstall, 1997). As pointed out by several authors (Penning-Rowsell and Fordham, 1994; Handmer and Penning-Rowsell, 1990; Parker and Fordham, 1996), a flood warning system can be conceptualized as the combination of a flood forecasting subsystem (the technological part) and a flood warning dissemination subsystem (the social part), interlinked by a feedback arrangement. The messages that are generated by the technological part of the system, also and hopefully in terms of predictive probabilities, must be converted into simple and understandable messages, not necessarily the same, to the flood managers and to the public. While extensive research is still needed in this context in collaboration with sociologists and flood managers, a number of potential approaches are delineated in the sequel.

The Bayesian Approach

The more natural approach to incorporate flood forecasting uncertainty into a simple decision scheme, as evaluated in the MUSIC project, is the classical Bayesian utility function approach.

Traditionally, flood alert thresholds are computed in a preliminary planning phase and compared to water stage or discharge forecasts taken as "deterministic", implicitly assuming that they are not affected by forecasting errors. This is a reasonably good approach when the forecast is extremely reliable. Nevertheless, when the forecast is highly uncertain, particularly when using QPF to extend the forecasting horizon, the approach may give rise to too many false alarms as well as missed alarms. It is therefore reasonable to incorporate the forecasting uncertainty into the decision scheme.

With reference to the flood warning problem of Figure 1, the following utility functions shown in Figure 8 can be defined to represent (i) the perception of losses that could occur if a warning is not appropriately issued $g_{na}(y)$; (ii) the cost of implementation of the measures taken as a consequence of an alert, plus the losses, in the case of dykes being overtopped, assumed smaller than in case of no alert $g_a(y)$. By means of the probability density of future water stages (or discharges) conditional on the hydrological model forecasts given by equation (9), it is possible to estimate at each step in time the expected value of both costs and choose to issue an alert if, within an established horizon, the inequality of equation (17) holds.

$$\int_0^{+\infty} g_a(y_{t^*+i\Delta t})\, f\{y_{t^*+i\Delta t}|\hat{\mathbf{y}}_{t^*+i\Delta t}, \mathbf{y}_{t^*}\}\, \mathrm{d}y_{t^*+i\Delta t} \leq \int_0^{+\infty} g_{na}(y_{t^*+i\Delta t})\, f\{y_{t^*+i\Delta t}|\hat{\mathbf{y}}_{t^*+i\Delta t}, \mathbf{y}_{t^*}\}\, \mathrm{d}y_{t^*+i\Delta t} \tag{17}$$

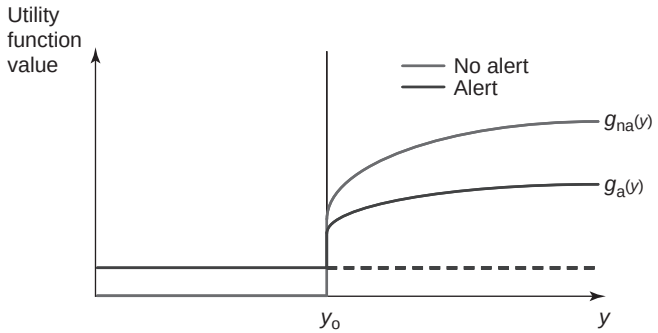

Figure 8 Utility functions for the dyke overtopping decision scheme. y_0 water stage (or discharge) at which overtopping occurs; $g_{na}(y)$ losses in case of no alert; $g_a(y)$ losses in case of alert. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

In this approach, it is not necessary to develop extremely correct estimates of the different cost utility functions. The technique is more sensitive to the actual overtopping thresholds (that can be established reasonably well on the basis of hydraulic analyses) than to the shape of the cost functions, that can be adjusted in order to maximizing the desired success rate by simulating the decision mechanism over the historical record.

The Alert Decision Support Matrix

The major aims in communicating flood forecasting to the stakeholders are clarity and simplicity. People in charge of decisions during flood events are not necessarily technical people; therefore efforts have to be made to convert probability densities into meaningful decision tables or support matrices. Within the frame of project MUSIC, the University of Newcastle upon Tyne developed a framework for converting flood forecasting uncertainty into alert decision support matrices similar to the one shown in the following Table 1.

The proposed methodology requires the preliminary definition, during a planning phase, of a number of alert levels (blue, yellow and red) corresponding to bankfull (blue), inundation of property (yellow), and potential loss of life (red). The decision to take (or not to take) action is derived as a function of (i) the alert level, (ii) the likelihood of the event, and (iii) the reliability of the forecast. The likelihood of the event is defined as a function of the probability of exceedence (Very low, Low, Medium, High, Very high) of each specific alert level, while the reliability (Very low, Low, Medium, High, Very high) of the forecast is defined in terms of its coefficient of variation (CV).

The rationale for this approach is that on the one hand it becomes more essential to take the right decision when the Red level is reached and that on the other hand one has to be more careful when the uncertainty of the forecast is low. The results are synthesized into three simple decision support matrices (one for each alert level) similar to the ones shown below, where A stands for "action" and NA for "no action".

The Development of Conditional Precipitation Thresholds for Early Flood Warning

Another aspect, currently under investigation, is the possibility of deriving precipitation thresholds, conditional on soil moisture, to be used as a simple basis for early warning. Today, in several countries early flood warning is based on unconditional precipitation thresholds such as: if 50 mm of rainfall is forecasted for the next 24 h, a warning must be issued. It is obvious that the effects of 50 mm of rain in 24 h are quite different if they fall over a dry or a saturated catchment. Bearing in mind that the weak link in real-time flood forecasting systems is not the technical component but rather the communication to the stakeholders, it would certainly be useful to provide them with extremely simple but sound and robust procedures based on rainfall thresholds, conditional to the initial soil moisture status; these thresholds can in fact be easily understood and used by nontechnical people.

In order to incorporate this information into a simple decision support scheme for flood warning authorities, extensive Monte Carlo simulations (10 000 years) are needed using synthetic rainfall generators and rainfall-runoff models.

Table 1 An example of flood decision support matrices

	Likelihood					
Reliability	Blue	Very low	Low	Medium	High	Very high
	Very low	NA	NA	NA	NA	NA
	Low	NA	NA	NA	NA	NA
	Medium	NA	NA	NA	NA	A
	High	NA	NA	A	A	A
	Very high	NA	NA	A	A	A
	Likelihood					
Reliability	Yellow	Very low	Low	Medium	High	Very high
	Very low	NA	NA	NA	NA	NA
	Low	NA	NA	NA	NA	NA
	Medium	NA	NA	A	A	A
	H	NA	A	A	A	A
	Very high	NA	A	A	A	A
	Likelihood					
Reliability	Red	Very low	Low	Medium	High	Very high
	Very low	NA	NA	NA	NA	NA
	Low	NA	NA	NA	A	A
	Medium	NA	A	A	A	A
	High	A	A	A	A	A
	Very high	A	A	A	A	A

The basic idea is in fact to define a critical level threshold at a specific cross section of a river: for instance, the level can be of 0.50 m (or 1.00 m to be conservative) below the top of the levee. From that level, one can estimate the corresponding maximum flood discharge and, via stochastic simulation, it is possible to derive, for a number of alternative soil humidity classes, cumulated rainfall threshold values on increasing length time horizons. Only if the forecasted rainfall cumulated in time overtops one of the corresponding threshold values a warning is then issued. A first attempt was produced by DIIAR (2002) for the case of the Arno river in Italy, by using a lumped rainfall-runoff model based on the USDA-CN concept.

Libralon (2002) developed a decision theory oriented approach by combining a Neyman-Scott stochastic model to the lumped version of TOPKAPI. From the joint probability densities of discharge and rainfall conditional to the initial status of the soil moisture, two probability densities were derived. The first one is the density of rainfall that does not produce a discharge (or a water level) overtopping the threshold, while the second one is the density of rainfall that does produce a discharge (or a water level) overtopping the threshold (Figure 9).

It is then possible to determine a rainfall threshold by maximizing the probability of issuing correct forecasts, or, better, by minimizing a Bayesian utility function as described in the Section on "The Bayesian approach". This becomes clear when a threshold value is introduced in Figure 10: the two densities give rise to the four probabilities, namely the probability of issuing a true alert (TT), of issuing a false alert (TF), of not issuing a true alert (FT), and of not issuing a false alert (FF). The rainfall threshold can be defined as the one that maximizes the two probabilities of success, namely TT and FF. In the work

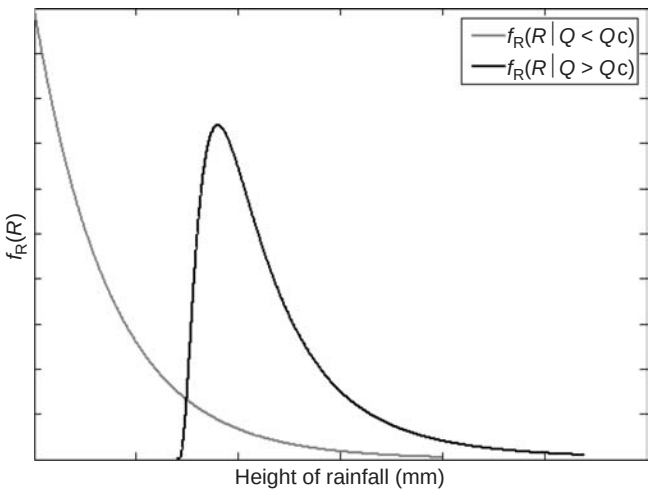

Figure 9 The probability densities of cumulated rainfall conditional to the overtopping of a discharge (or water stage) threshold

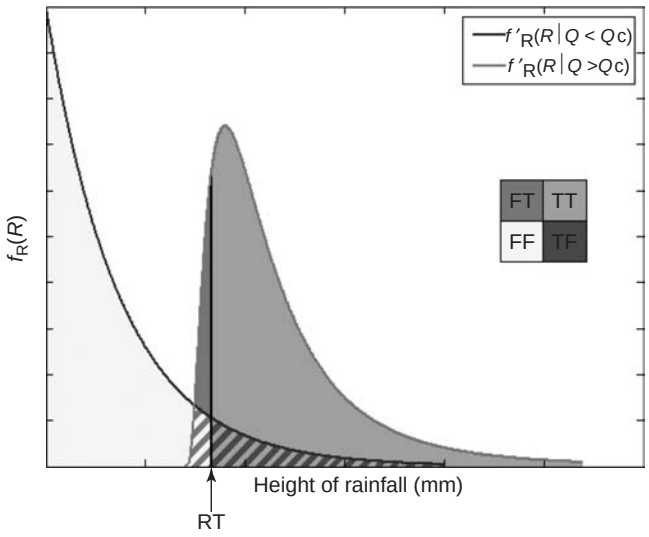

Figure 10 The four probabilities of alert: TT correctly issued alert; FF correctly nonissued alert; FT missed alert; TF wrongly issued alert. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

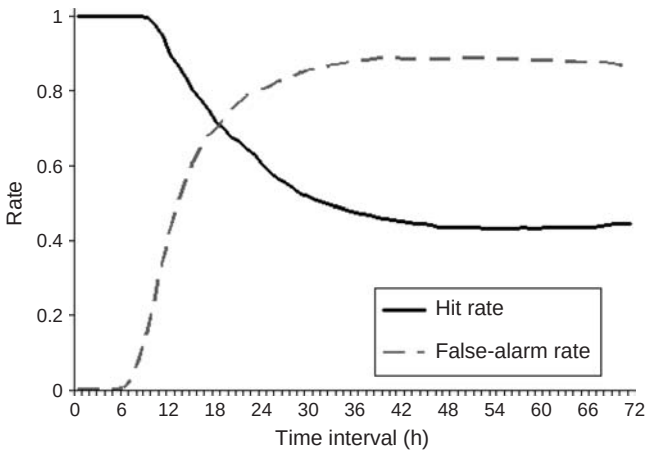

Figure 11 The Hit Rate (percent of successfully forecasted threshold overtopping) and the False Alarm Rate (percent of false alerts) for the Sieve river, a tributary of the Arno river, at Fornacina

of Libralon, the threshold was more generally defined as the one that minimizes the expected value of a Bayesian utility function that will trade off between the reduction of damages because of successful warnings and the actual cost of actions descending from activating the warning and a psychological cost expressing the loss of credibility generated by a large number of false alarms. The results, so far obtained on the assumption of error free rainfall forecasts, show a very high rate of success. Figure 11 shows the results obtained for the Sieve river, a steep and rather small tributary of the Arno river (ca. 800 km^2 of catchment area) on which it is very difficult to issue a reliable forecast for

more than 3–4 h in advance. As can be seen, the hit rate remains practically equal to 100% up to 9 h in advance, with only 10% of false alarms.

The present limitation in the use of the rainfall thresholds approach lies in the implicit assumption that the forecasted rainfall totals are not affected by errors. Current research is thus investigating the possibility of incorporating the rainfall forecasting uncertainty in the estimation of the expected damage curves to be minimized.

EXAMPLES OF REAL-TIME FLOOD FORECASTING SYSTEMS

The Upper Po River Flood Forecasting System

The first example relates to the Piemonte Region operational flood forecasting system developed for the upper Po catchment closed at the exit of the Piedmont Region (Figure 12).

The system was developed on the basis of MIKE FLOODWATCH (DHI, 2000a), which couples the NAM hydrological model (Nielsen and Hansen, 1973; DHI, 2000c) with MIKE 11 FF (DHI, 2000b) into an operational GIS-based flood forecasting system (Figure 13).

On the basis of approximately 300 rainfall real-time reporting raingauges, in order to catch the spatial variability of the meteorological forcing, the upper Po catchment was divided into 187 subcatchments with an average area of 200 km^2, for each of which a NAM model was calibrated.

Forecasts at several river sections are issued in a qualitative mode up to 48 h ahead using the hydrological model coupled with QPF provided by a limited area meteorological model and, in a quantitative management mode up to 6–12 h in advance using the observed rainfall and water levels.

Figure 14 shows the results of such operational forecasts at the cross section of Torino (catchment area of 5362 km^2 and concentration time of ca. 24 h) during the flood event of October 13–16, 2000. Five days of heavy rainfall hit the northern part of the Piemonte region with an average

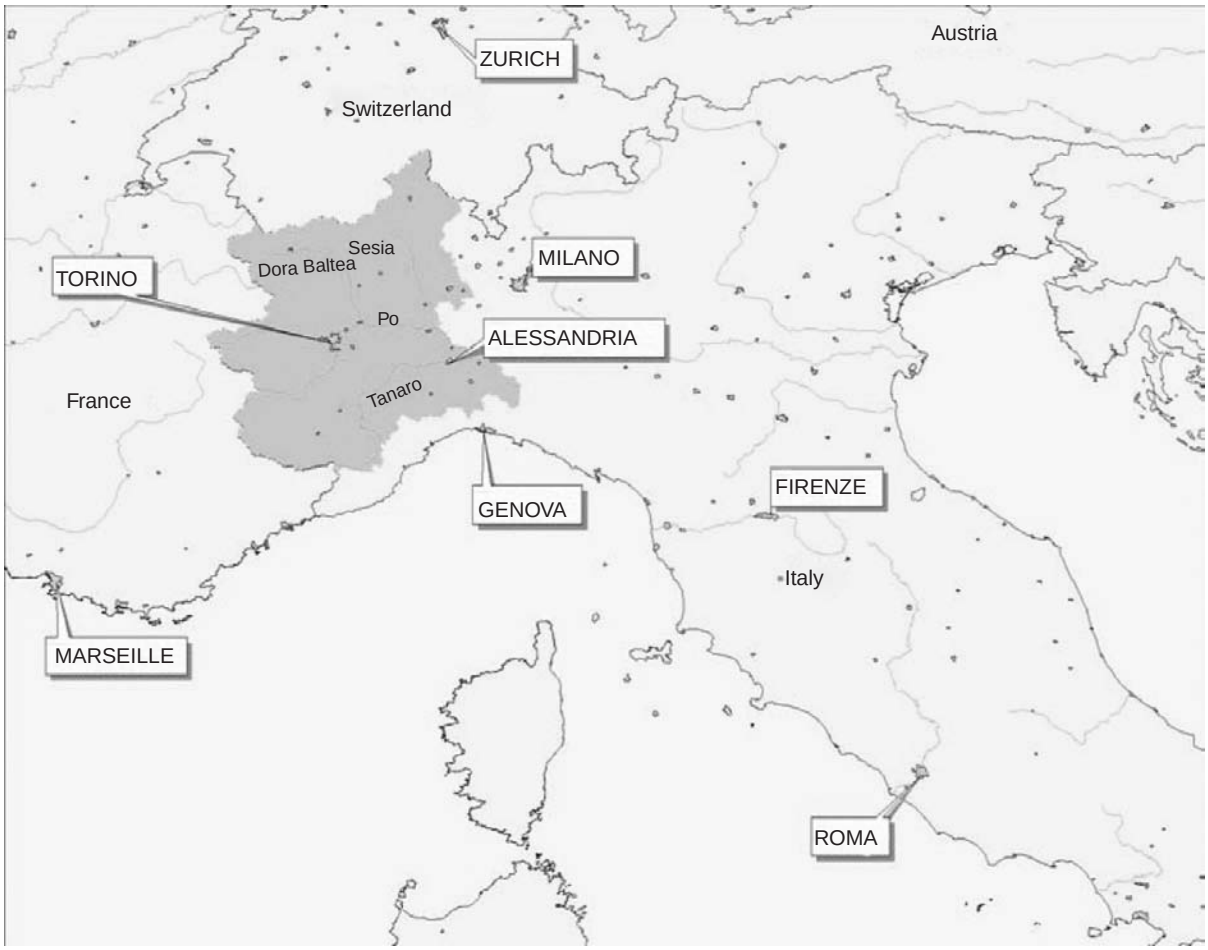

Figure 12 The Piemonte region in Italy (Courtesy of ARPA Piemonte). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

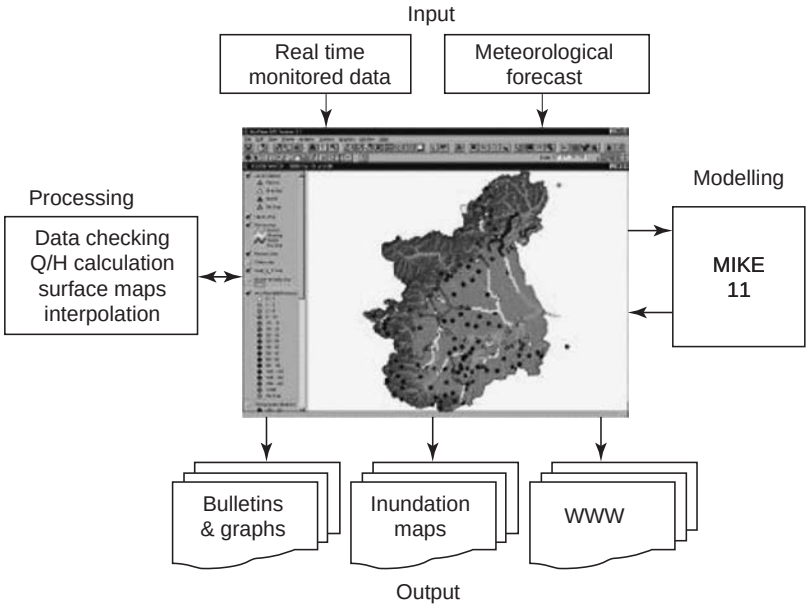

Figure 13 Schematic representation of MIKE FLOODWATCH applied to the Po river in the Piemonte Region (Courtesy of DHI Water & Environment). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

total rainfall larger than 300 mm, with peaks of 700 mm, producing large flood waves in most of the river network (Rabuffetti and Barbero, 2005).

It can be observed that forecasts up to 12 h in advance are quite reliable, particularly in the rising limb, and can be successfully used to trigger the warning level (grey) and the alarm level (black).

The Reno River Flood Forecasting System

The second example relates to the Reno river flood forecasting system operational at the Emilia-Romagna Hydro-Meteorological Service. The system, developed using the EFFORTS package within the frame of the EU funded project MUSIC, is relevant to the Reno river whose drainage basin has a total surface area of 4930 km^2, more than half of which pertains to the mountain basin.

Figure 15 shows the catchment and its subcatchments, while the available observation network is summarized in the following Table 2.

As shown in Table 2, in addition to the availability of a meteorological RADAR, METEOSAT-based rainfall estimates are available through the Institute of Atmospheric Sciences and Climate (ISAC-CNR). As described in MUSIC Deliverable 9.1 (**`http://www.geomin.unibo.it/orgv/hydro/music/`**), the distributed version of TOPKAPI (Todini, 1995b; Todini and Ciarapica, 2002; Liu and Todini, 2002) was the hydrological model used for the Reno catchment.

The model was developed at 1 × 1 km scale on the basis of three available maps: a digital elevation map (Figure 16), a map of soil types (Figure 17 and Table 3), and a land use map (Figure 18 and Table 4).

Table 2 The different measurement systems available on the Reno river

Measurement station type	Numerosity
Telemetering thermometers	15
Telemetering raingauges	47
Telemetering stage gauges	28
Rating curves	12
Radar	1
Satellite	1

As shown in Figure 19 for the upper Reno closed at the gauging station of Casalecchio di Reno, the operational forecasting system, which runs around the clock, is continuously fed not only by all the telemetering gauges (point measurements) but also by the RADAR measurements (fine mesh) as well as by the METEOSAT-based rainfall estimates (coarser mesh). An innovative Block–Kriging/Bayesian Combination of the three measurement systems aimed at producing an unbiased minimum variance estimator for rainfall (Todini, 2001; Mazzetti and Todini, 2002) was developed within the frame of project MUSIC and integrated into the EFFORTS system. At each time step, the system checks the availability of the different measurements and integrates the ones that are available to produce an estimate of rainfall over each model pixel.

In order to extrapolate flood forecasts in the future, the system uses the QPF generated by NWP whenever available, while a combination of the meteorological forecast

with an analogue-based technique is presently under test. Future precipitation is obtained by combining the QPF generated by a limited area model with 50 series of precipitation derived from past observations with a technique similar to the one proposed by Obled *et al.* (2002) and Obled and Djerboua (2001). The technique aims at finding the closest analogues in terms of geopotential fields at 500 hPa (which was shown to provide the best results) over a wide spatial domain conditioning the weather conditions over the catchment in the following hours (Figure 20).

The treatment of uncertainty follows the Krzysztofowicz (1999) approach. The deterministic model forecasted flows are converted into a Gaussian space via the Normal Quantile Transform and are used to produce the probability density of the future values of discharge conditional on the hydrological forecasts. Figure 21 shows an example of successive 6 h in advance forecasts compared to the

Table 4 The nine classes of land use in the Reno river catchment

n	Land use	Percentage
1	Continuous urban, industrial and business areas, roads, and railways, airports, rock, basins	1.38
2	Discontinuous urban, dumps, green urban areas, sports/recreation areas	3.31
3	Extraction area, apamoors and shrubs, evolving vegetation, sparse vegetation	5.53
4	Crops: farm, heterogeneous, annual/permanent, nonirrigated seed	63.17
5	Vineyards	0.08
6	Fruit orchards	0.46
7	Meadows, natural pasture	1.84
8	Woods: broadleaf, conifer, mixed, beaches	23.64
9	Watercourses, inland swamps, lagoons	0.61

observed discharge values (unknown at the time of forecast) together with quantiles corresponding to plus or minus two standard deviations of errors in the Normal space. Although the example refers to one of the largest events recorded in the Reno river in the latest years (November 6–7, 2000), it can be noted how the observed value falls always well inside the uncertainty band and that the band results as being asymmetric and nonstationary in time.

FUTURE DEVELOPMENTS

The HEPEX Project

A new international project, the Hydrological Ensemble Prediction Experiment (HEPEX, 2004) (**http://www.ecmwf.int/newsevents/meetings/workshops/2004/HEPEX/index.html**) was recently initiated, which aims at bringing the international hydrological and meteorological communities together to demonstrate how to produce reliable hydrological ensemble forecasts that can be used with confidence by the emergency management and water resources sectors to make decisions that have important consequences for the economy, public health, and safety.

The main scientific theme of HEPEX will be how hydrologic forecast uncertainty can reliably be quantified at each step of the forecast process and then communicated to and applied by the end users. Reliable quantification of forecast uncertainty is the key science issue that gives the program a unique and important role that at the present is not fulfilled by any existing hydrological prediction related program.

Similar to meteorological ensemble predictions, HEPEX will study the possibility of issuing hydrologic ensemble prediction by integrating many sources of uncertain information and accounting for how hydrologic processes would behave in response to it. Because hydrological models are imperfect and because of limitations in representing important sources of uncertainty, it is expected that hydrological ensemble forecasts will contain complex biases that must be removed to meet user requirements for reliable ensemble forecast information.

Data assimilation is required in hydrological ensemble prediction to process available observations to produce the best possible probabilistic estimates of initial hydrological conditions. These estimates must include ensemble members as well as probabilistic distributions of individual state variables. The ensemble members must represent the appropriate joint variable structure, both among state variables at a given location and spatially of equally likely possible initial states.

The relevance of HEPEX lies in its aim of giving an answer to most hydrologic modeling issues discussed in this article, such as:

- How can meteorological forecasting uncertainty be accounted for in hydrological forecasts?
- What are the sources of uncertainty in hydrological models?
- What are the implications of hydrological models being imperfect representations of real hydrological systems?
- How can uncertainties in hydrological models, model parameters, and hydrological initial conditions be represented in hydrological ensemble prediction?
- How can forecasting uncertainty be communicated to the users and how it can be used for improving decisions?

CONCLUSIONS

In this chapter, the description of rainfall-runoff models used in real-time flood forecasting has been placed into the perspective of the more complex problem of the effectiveness of the forecasts. The problem of real-time flood forecasting is, in fact, only partly dependent on the correct choice of the most appropriate rainfall-runoff model, although these models constitute the essential core of most of the existing operational systems. The effectiveness of the flood warnings and the success of the flood management decisions depend mostly upon the capability of a forecasting system to provide simple messages (e.g. “issue the warning” or “do not issue the warning”), which must be derived on the basis of a correct use of the predictive probabilities, to be assessed and estimated by combining all the possible uncertainties involved. Starting from an *a priory* subjective guess of these probabilities, it is then possible to revise them as a function of all the uncertain information gathered (such as input precipitation data) or generated via a model (such as the rainfall-runoff model) using a Bayesian integration technique, in order to obtain a posterior predictive probability density. This density, which is the best technical information one can provide, must then be used to produce simple messages by minimizing the expected value of a utility function (or several for the different purposes) associated to the scope of the required decision to be taken.

Given the importance of the objective at stake, extensive research is still needed in this domain, aiming at reducing flood damages and related casualties by improving the overall efficiency of the flood forecasting systems.

124: Flood Routing and Inundation Prediction

PAUL D BATES

School of Geographical Sciences, University of Bristol, Bristol, UK

This contribution considers the methods available to hydrologists to simulate flow routing and inundation in natural channels. Whilst the fluid dynamics of free surface flow in rivers and over floodplains may be complex, the methods available to treat such problems range widely in complexity from simple empirical models to full solutions of three-dimensional Navier–Stokes equations with sophisticated representations of flow turbulence. These methods are reviewed in detail, followed by a consideration of their requirements for topography, friction, initial condition, boundary condition, and validation data. In particular, the contribution discusses how these needs are being met increasingly using remote sensing techniques. Lastly, the contribution considers techniques to evaluate uncertainties in flow modeling.

THE NEED FOR FLOW ROUTING AND INUNDATION MODELS

Stream channel hydraulic process may need to be represented in rainfall-runoff models for two main reasons. First, flow routing may be required to translate runoff that has arrived in a stream channel to some point of interest further down the stream network. Second, models may be required to translate a predicted point hydrograph, as produced by a rainfall-runoff model, into predictions of practical interest to catchment managers and civil protection authorities. These may include predictions of flood depth and extent, flow velocity, and possible defence failure. In both cases, the hydrologist draws on, and contributes to, the body of research into open channel flows, discussed in detail elsewhere in this volume (*see* **Chapter 135, Open Channel Flow – Introduction, Volume 4**; **Chapter 136, Hydrodynamic Considerations, Volume 4**; **Chapter 137, Uniform Flow, Volume 4**; **Chapter 138, Unsteady Flow, Volume 4**; and **Chapter 141, Computer Modeling of Overbank Flows, Volume 4**). For basin scale hydrologic forecasting and most flood prediction problems the hydrologist is generally concerned with flow routing and inundation prediction over relatively long river reaches or whole river basins of the order of $10^1 - 10^3$ km or more, and this strongly influences the types of hydraulic model adopted. Moreover, at large basin scales the travel time of flood waves within the channel system may become the dominant process in hydrological forecasting.

For real-time forecasting problems (see e.g. Young, 2002; Brath *et al.*, 2002) computational speed is a key requirement and this leads hydrologists to favor models based on simple wave equations or approximations to these. The same constraint also holds for assessments of predictive uncertainty (see e.g. Aronica *et al.*, 1998) where Monte Carlo analysis of model response to parameter variations may be required, thus resulting in a need to compute many different realizations with the same model. However, for design and planning studies where there is no requirement to minimize computational costs, two and three-dimensional hydraulic models may be applied, even when large domains are under consideration. For example, Sauvaget *et al.* (2000) report the application of a finite element solution of the two-dimensional Shallow Water equations to a 15-km reach of the Dordogne-Isle confluence plain to produce an optimum design for flood relief culverts. Sauvaget *et al.* use a very detailed unstructured grid consisting of 60 000 elements ranging in size from 2 m in the culverts to 150 m on flat floodplain areas. This leads to a single model simulation taking 10 days on a UNIX workstation.

This section will first consider the hydraulics of flood waves in both simple and compound channels in order to identify the processes operating at particular space and time scales and which define our current perceptual model of open channel flow. It will then examine the range of models adopted for both flow routing and inundation prediction in

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

hydrology and the ways in which these models make simplifying assumptions according to our best understanding of process dominance. The article concludes by examining data sources for inundation prediction models, and in particular the ways in which remotely sensed data are beginning to affect modeling opportunities, before finally considering uncertainties and uncertainty handling in such schemes.

FLOOD WAVE HYDRAULICS

Floods can be thought of as a long, low amplitude wave passing through a compound channel of complex geometry. In the very largest basins, such waves may be up to $\sim 10^3$ km in length or greater but with an amplitude of only $\sim 10^1$ m, and may take several months to traverse the whole system. Flood waves are translated downstream with speed or celerity, c (LT^{-1}), and attenuated by frictional losses and floodplain storage such that in downstream sections the hydrograph is flattened out (see Figure 1). Wave speeds can be shown (see NERC, 1975) to vary with discharge such that maximum wave speed occurs at approximately two-thirds bankfull capacity (Knight and Shiono, 1996). Typical observed values for c reported by NERC (1975) and Bates *et al.* (1998) for UK rivers are in the ranges 0.5 to 1.8 ms^{-1} and 0.3 to 0.67 ms^{-1} respectively.

Below the scale of the flood wave itself, other significant in-channel process can be identified, each with a characteristic length scale. These include shear layers forming at the junction between the main flow and slower moving "dead zones" at the scale of the channel platform (Hankin *et al.*, 2002), secondary circulations at the scale of the channel cross section (Bridge and Gabel, 1992; Nezu *et al.*, 1993), and turbulent eddies ranging from heterogeneous structures at the scale of roughness elements and obstructions on the bed (Ashworth *et al.*, 1996; McLelland *et al.*, 1999; Shvidchenko and Pender, 2001) down through the turbulent energy cascade (Hervouet and Van Haren, 1996) to the

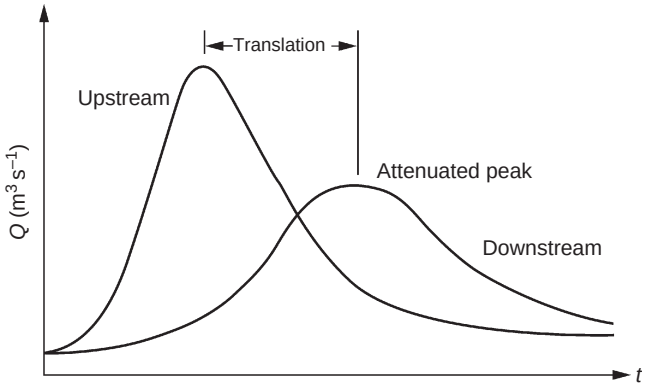

Figure 1 Translation and attenuation of a flood wave between two gauging stations

Kolmogorov length scale, η (L), where turbulent kinetic energy is finally dissipated. In typical channel flows, these very smallest eddies may be only $\sim 10^{-2}$ mm across (Hervouet and Van Haren, 1996) and are highly transient. All these scales may be fully described with the Navier–Stokes equation (Schlichting, 1979):

$$\rho \frac{D\mathbf{u}}{Dt} = -\nabla p + \mu \nabla^2 \mathbf{u} + F \tag{1}$$

where ρ is the fluid density (with dimensions ML^{-3}); $\mathbf{u}$ is the velocity vector (LT^{-1}); t is the time (T), p is the pressure ($ML^{-1}T^{-2}$); μ is the viscosity ($ML^{-1}T^{-2}$) and F is the set of terms (e.g. gravity, coriolis, and friction) to be included in the specification of a particular problem.

When equation (1) is combined with the equation of continuity:

$$\nabla \cdot \mathbf{u} = 0 \tag{2}$$

one obtains a system of equations that can be solved to yield the three-dimensional velocity vector $\mathbf{u} = (u\ v\ w)$; where u, v, and w are the three components of $\mathbf{u}$ in the x, y, and z directions respectively, and pressure, p, for a given point in time and space.

Solution of equations (1) and (2) over a suitably refined grid (i.e. $\Delta x \ll \eta$) using a suitably small time step can, in theory, simultaneously simulate all flow features described above. However, for typical flood wave flows (i.e. unsteady, nonuniform flows of high Reynolds number in a complex geometry), the direct numerical simulation of the Navier–Stokes equations is computationally prohibitive. Hydrologists have therefore sought to isolate from this complex assemblage those processes that are central to the problem of flood routing and inundation prediction in order to build appropriate models.

A starting point for such approximations is to consider the forces acting on the flow. For fluvial flood-routing problems the dominant driving and resisting forces are clearly gravity and friction. This realization led in the eighteenth and nineteenth centuries to the development of resistance laws for steady open channel flow by Chezy, Manning, and Darcy–Weisbach amongst others (see Chanson, 1999, pp. 72–91 for a discussion). However, to describe unsteady flows requires development of equations of motion based on principles of mass and momentum conservation for which the critical decision is the number of dimensions in which significant flow field variation occurs. Clearly, for the hydrologist concerned with calculating the translation and attenuation of a flood wave over long river reaches, significant variations in the flow field occur dominantly in the streamwise direction. Hence, despite known three-dimensional processes, channel flows are often considered as one-dimensional in the streamwise direction and variations in velocity in the vertical and cross-stream directions

may be neglected. For many channel flood-routing applications, this is a reasonable approximation, however, Knight and Shiono (1996) suggest that when flow exceeds bankfull capacity and begins to spread over adjacent low-lying floodplains, a series of two- and three-dimensional processes are initiated which may be important in some circumstances.

One such process is momentum exchange between fast moving water in the channel and slower moving water on the floodplain (Knight and Shiono, 1996). This momentum exchange occurs across the shear layer created at the interface between channel and floodplain which is manifest (see Figure 2) as a series of vortices with vertically aligned axes (Sellin, 1964; Fukuoka and Fujita, 1989; Shiono and Knight, 1991). Knight and Shiono (1996) draw attention to the three-dimensional structure of this interface zone, whilst Ervine and Baird (1982) conclude that failure to account for the resulting momentum exchange can lead to errors of up to ±25% in the discharge calculated using uniform flow formulae. Further vigorous momentum exchange occurs during out-of-bank flow in meandering compound channels (see Sellin and Willetts, 1996 for a discussion). Here, water spills from the downstream apex of channel bends and flows over meander loops before interacting with channel flow in the next meander (see Figure 3). These three-dimensional interactions modify secondary circulations within the channel and represent an additional energy loss in the near channel area. Floodplain flows beyond the meander belt will not be subject to such energy losses and this region may provide a route for rapid flow conveyance. The impact of these additional energy losses and storage of water on the floodplain leads to a reduction in wave speed for out-of-bank flows (see Figure 4). Minimum wave speeds occur at a particular shallow overbank stage when the interaction between main channel and floodplain is at its greatest (Knight and Shiono, 1996), before slowly increasing again as the whole floodplain and valley floor begins to behave as a single channel unit.

Flow in the floodplain itself is clearly a two-dimensional process, given that flows may be several kilometers in horizontal extent but only a few meters deep, and many inundation prediction studies make the assumption that the variation in vertical velocity is negligible compared to variation in the horizontal. Such shallow water flows over low-lying topography are characterized by rapid extension and retreat of the inundation front over considerable distances, potentially with distinct processes occurring during the wetting and drying phases (see Nicholas and Mitchell, 2003). Correct treatment of this moving boundary problem is, therefore, important both to capture adequately the shallow water energy losses (which may be high due to large relative roughness) and because flood extent is a common prediction requirement from hydraulic codes. Flow interactions with microtopography (see Walling *et al.*,

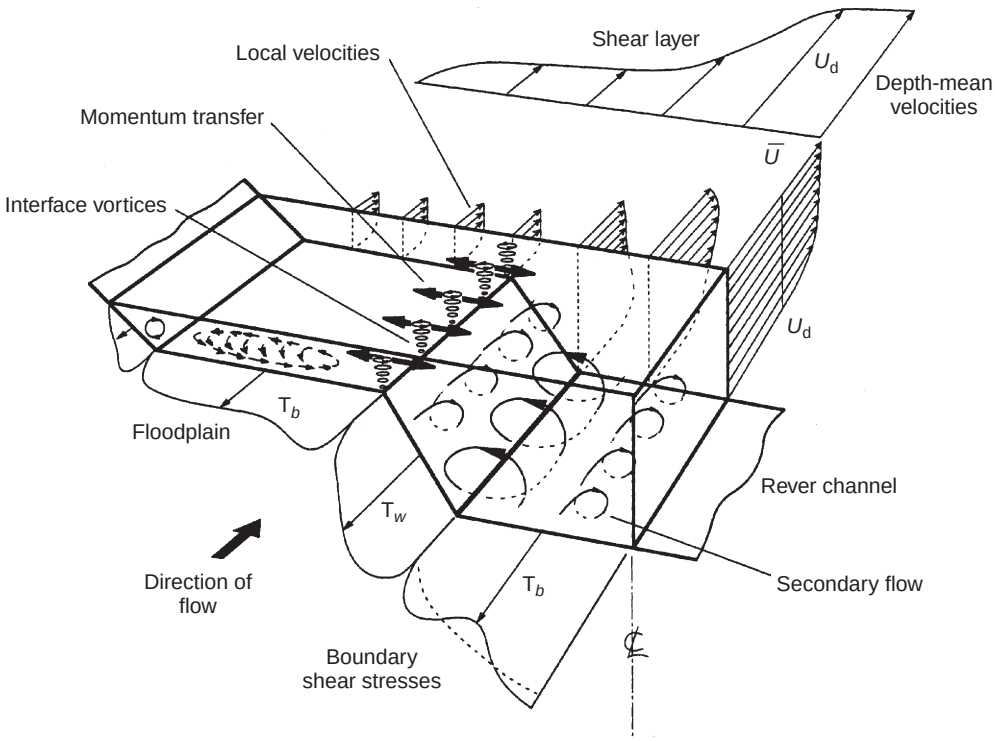

Figure 2 Hydraulic processes associated with overbank flow in a straight compound channel (after Shiono and Knight, 1991, © Cambridge University Press)

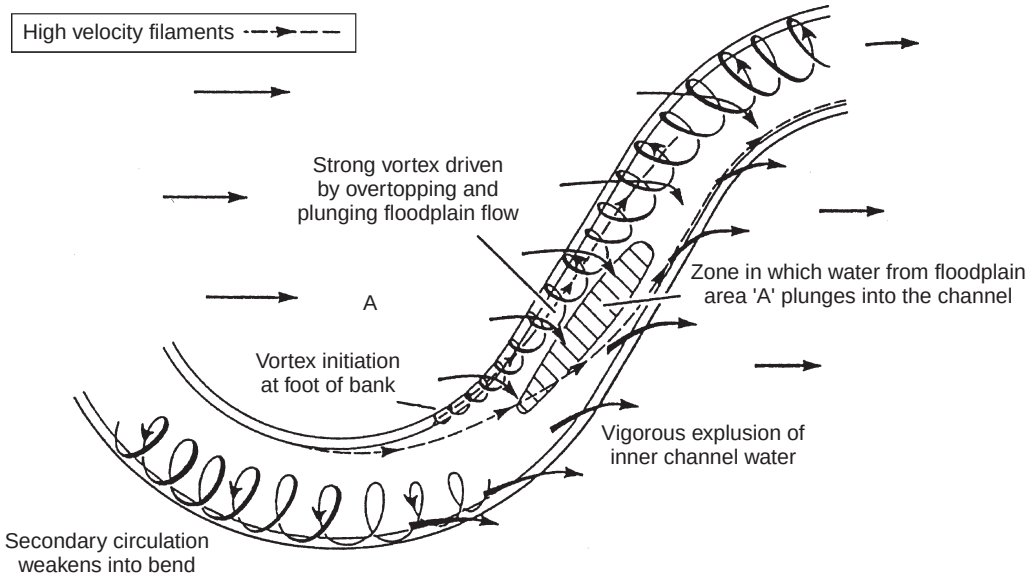

Figure 3 Representation of principal flow structures occurring during overbank flow in a meandering compound channel (after Sellin and Willetts, 1996, © John Wiley & Sons Ltd)

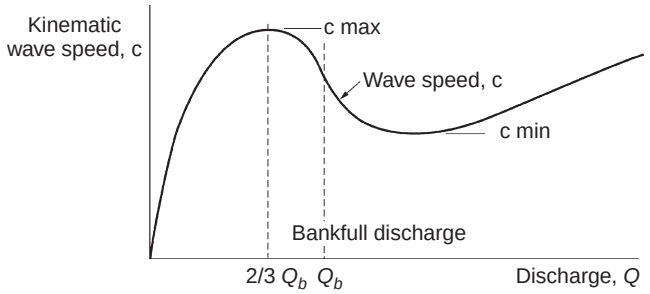

Figure 4 Typical kinematic wave speed versus discharge curve for a compound channel (after Knight and Shiono, 1996, © John Wiley & Sons Ltd)

1986), vegetation (Lopez and Garcia, 2001) and structures (Meselhe *et al.*, 2000) may all be important thereby giving a complex modeling problem. In particular, where the floodplain acts as a route for flow conveyance rather than just as storage, energy losses are dominated by vegetative resistance. In particular, hedges and walls may have a large impact on the effective floodplain roughness. Yet, despite a small number of pioneering studies (see e.g. Kouwen, 1988; Nepf, 1999; Ghisalberti and Nepf, 2002; Wilson and Horritt, 2002), the interaction between plant form, plant biomechanics, energy loss, and turbulence generation is at present relatively poorly understood. Moreover, most flood-routing models assume that the channel bed is fixed over the course of the event, and for very large floods this may not be the case as embankment failure or geomorphic change may considerably affect the propagation of the flood wave.

Lastly, whilst typical hydraulic models do not consider water exchanges with the surrounding catchment, for whole catchment modeling or flood inundation simulation over long river reaches such exchanges may, at particular times, become important (e.g. Stewart *et al.*, 1999; Woessner, 2000). Such processes include direct precipitation or runoff to the floodplain surface (e.g. Mertes, 1997), evapo-transpiration losses, so-called bank-storage effects (Pinder and Sauer, 1971; Squillace, 1996) resulting from interactions between the river water and alluvial groundwater contained within the hyporheic zone (Stanford and Ward, 1988; Castro and Hornberger, 1991; Wroblicky *et al.*, 1998), subsurface contributions to the floodplain groundwater from adjacent hillslopes (e.g Bates *et al.*, 2000; Burt *et al.*, 2002) and flows along preferential flow paths, such as relict channel gravels, within the floodplain alluvium (e.g. Haycock and Burt, 1993; Poole *et al.*, 2002). Over particular reaches and in particular environments, integration of some or all of these processes with flood-routing models may be required and necessitate complex modeling structures (e.g. Stewart *et al.*, 1999; Kohane and Welz, 1994).

In summary, it is common to assume that in-channel routing may be treated as a one-dimensional flow in the streamwise direction, and this is the approach taken in most industry standard hydraulic models (see Havnø *et al.*, 1994), for example, HEC-RAS (**http://www.scisoftware.com/environmental_software/product_info.php?products_id=182**); MIKE11 (**http://www.dhisoftware.com/mike11/**); ISIS Flow (**http://www.wallingfordsoftware.com/products/isis/**); SOBEK (**http://www.sobek.nl/**). For out-of-bank flows, such consensus does not yet exist, and the choice

of model is best considered as being dependent on scale and user needs. Clearly, floodplain flow is at least a two-dimensional processes, yet it is also known that in particular zones, such as the channel-floodplain interface, flow is strongly three-dimensional. A working assumption has evolved (see e.g. Feldhaus *et al.*, 1992; Bates *et al.*, 1992; Bates *et al.*, 1998) that reach scale flows are best treated with two-dimensional methods, whilst for shorter sections or applications such as sediment transfer to overbank sections, where the details of the channel-floodplain momentum transfer are clearly critical, a three-dimensional approach may be more appropriate. Such working assumptions are, however, provisional and waiting to be refined on the basis of better data or understanding.

FLOW ROUTING IN RAINFALL-RUNOFF MODELS

In rainfall-runoff modeling applied to relatively large river basins it is often necessary to model explicitly the translation and attenuation of a flood wave downstream through the channel network. As discussed above, for in-channel flows a consensus exists that one-dimensional models are an appropriate tool for such problems and to achieve this a number of empirical and physically based methods are available. These can be broadly classified as: (i) empirical or nonstorage models; (ii) full and simplified solutions of the one-dimensional St. Venant equations, and (iii) hydrological storage models. For flood-routing problems where flow is in an out-of-bank condition a number of methods exist which attempt to predict the additional energy losses and mass transfers in a way that can be incorporated in one-dimensional codes (Knight and Shiono, 1996, pp. 155–159; De Roo *et al.*, 2001). In the future, it may also be possible to integrate recently developed simplified two-dimensional codes (see e.g. Bates and De Roo, 2000) with hydrologic models. Such schemes have already been used to represent river-floodplain reaches up to 60 km in length and may allow simultaneous simulation of flood routing and inundation prediction at the whole catchment scale.

Empirical or Nonstorage Flood-routing Models

At the most basic level, flood-routing predictions may be achieved by building regression models to predict stage or discharge at a particular point on the river network based on observed stage or discharge at some upstream point (see Fread, 1984, p. 439). For example, Shaw (1983, p. 379) includes an example (see Figure 5) showing good correlation between 35 flood peaks recorded over a five-year period at two gauging stations 345 km apart on the River Irrawaddy, Burma. Such simple linear relationships may work well under certain circumstances, but like all regression models they are not easy to extrapolate to conditions beyond those for which training data are available. For example, Shaw (1983) points out that floods of the same peak flow but different volume may show very different routing behavior as they move downstream through a river network. Recently, this type of approach has been revisited in a more sophisticated way using Transfer Function models (e.g. Young, 1986; Lees *et al.*, 1994; Young, 2002; Young, **Chapter 128, Rainfall-runoff modeling: Transfer Function Models, Volume 3**) to relate upstream and downstream levels. These consist of linear and nonlinear functions that are the discrete-time equivalents of differential equations and describe the temporal behavior only at selected spatial nodes within the catchment system. For example, Lees *et al.* (1994) describe a model to forecast flood levels in sections of the River Nith, Dumfries, UK, based only on upstream levels measured up to 5 h ahead and a general noise term as part of an adaptive real-time flood warning scheme. The overall system achieved mean prediction accuracy in terms of peak stage of 0.08 m rmse over nine large flood events. Such models can also be combined with distributed models to yield distributed predictions, as demonstrated by Romanowicz and Beven (1998) for the case of flood inundation forecasting. However, where the system will be used to undertake environmental design or forecast the effects of change then distributed, physically based models have an advantage. These are described in the following section.

Full and Simplified Solutions of the One-dimensional St. Venant Equation

As outlined previously, in-channel flood routing is often assumed to be a one-dimensional shallow water flow in the streamwise direction (e.g. Fread, 1984; Samuels, 1990;

Fread, 1993; Singh, 1996). Equations for one-dimensional channel flow can be derived by considering mass and momentum conservation between two cross sections Δx apart. This yields the well-known one-dimensional St. Venant or shallow water equations:

Conservation of momentum

$$\frac{\partial Q}{\partial t} + \frac{\partial (Q^2/A)}{\partial x} + gA\left(\frac{\partial h}{\partial x} + S_f - S_o\right) = 0 \qquad (3)$$

where Q is the flow discharge ($L^3\,T^{-1}$); A is the flow cross-section area (L^2), g is the gravitational acceleration (LT^{-2}), S_f is the friction slope (LL^{-1}) and S_o is the channel bed slope (LL^{-1}).

Conservation of mass

$$\frac{\partial Q}{\partial x} + \frac{\partial A}{\partial t} = q \qquad (4)$$

where q is the lateral inflow or outflow per unit length ($L^2\,T^{-1}$).

Equations (3) and (4) have no exact analytical solution, but with appropriate boundary and initial conditions they can be solved using numerical techniques (e.g. Preissmann, 1961; Abbott and Ionescu, 1967) to yield estimates of Q and h in both space and time. The river reach in one-dimensional St. Venant models is discretized as a series of irregularly spaced cross sections (see Figure 6). Boundary conditions consist of specifying the scalar velocity, u (LT^{-1}) and h at each inflow or outflow boundary. In practice, however, measurements of u are rarely available from river gauging stations and we generally have only h. This can be used with an approximate rating curve and cross-sectional survey to give values of Q and A from which u can be derived. This rating curve can be measured, or derived from some uniform flow formulae such as the Manning equation, if the appropriate roughness coefficient is given. In this case uniform flow represents an additional approximation that implies the water surface is parallel to the bed slope. This is not the case for a full dynamic wave, where the water-surface slope should be steeper than the bed slope on the rising limb of the hydrograph, and less steep on the falling limb. Thus, it is important to be very clear what assumptions and approximations are being made in any particular boundary condition specification. For critical flow where the Froude number, $F_r = u/\sqrt{gh}$, exceeds 1 where u is a scalar velocity (LT^{-1}), waves cannot propagate upstream within the domain and no downstream boundary condition need therefore be prescribed. These equations form the basis of most standard commercial hydraulic modeling softwares such as HEC-RAS (**http://www.scisoftware.com/environmental_software/product_info.php?products_id=182**); MIKE11 (**http://www.dhisoftware.com/mike11/**); ISIS Flow (**http://www.wallingfordsoftware.com/products/isis/**); and SOBEK (**http://www.sobek.nl/**) and assume (NERC, 1975; Beven, 2001) that:

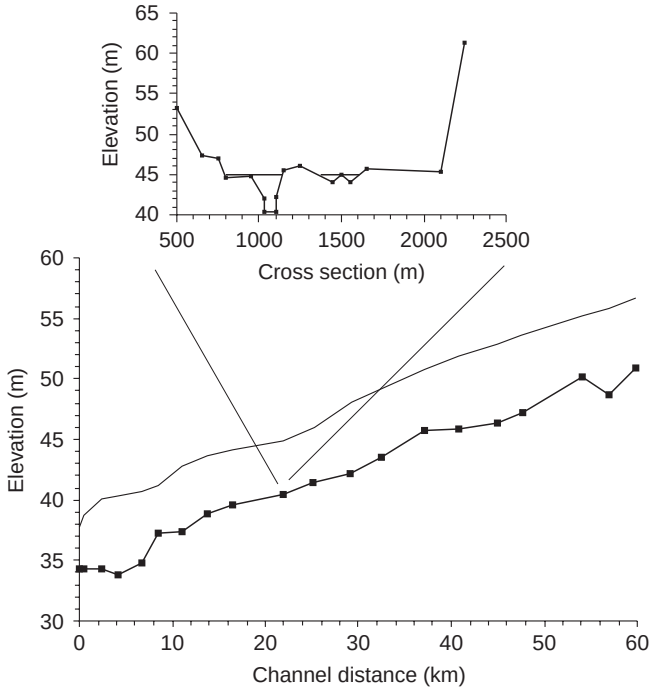

Figure 6 A typical discretization from a one-dimensional hydraulic model, in this case the HEC-RAS scheme applied to a 60-km reach of the River Severn in the United Kingdom by Horritt and Bates (2002) © Elsevier. Shown are the bed elevation profile with model cross-section locations marked by squares and a typical simulated water free surface profile. A sample cross section is also shown

- the flow can be adequately represented by the average flow velocity and average flow depth at any cross section;
- the water-surface slope varies gradually downstream so that pressure distribution in the vertical can be assumed hydrostatic;
- the water is incompressible and of constant temperature and density;
- the friction slope may be estimated using one of the standard uniform flow formulae.

Despite recent advances in computer power that allow the full dynamic flood wave contained in equations (3) and (4) to be solved with relative ease, there are many situations where this complexity is not required. Simplification of the full St. Venant equations may therefore be possible and can be achieved merely by neglecting particular terms in equation (3) to yield an approximate solution to the full equation. The two main classes of approximate solution are the kinematic and diffusion forms of equation (3).

The kinematic model was first described by Lighthill and Whitham (1955) and its use in hydrology has recently

been comprehensively reviewed by Singh (2001). The model assumes that the first three right-hand-side terms in equation (3) are small compared to the fourth term and the momentum equation can be simplified to:

$$S_f - S_o = 0 \tag{5}$$

This implies that the momentum of an unsteady flow is equivalent to that of a steady uniform flow as described by the Chezy or Manning equations where discharge is a single valued function of depth and the water surface is always parallel to the bed (Fread, 1984). If velocity, **u**, is evaluated using the Manning equation, the kinematic wave speed, c_k (LT^{-1}) in a wide, rectangular channel will be (Graf and Altinakar, 1998, pp. 274–275):

$$c_k = \frac{5}{3}\mathbf{u} \tag{6}$$

The kinematic approximation to the full one-dimensional St. Venant equations has three important limitations which arise from the assumption that the water slope is always parallel to the bed:

1. In channels of uniform geometry the kinematic model can simulate wave translation only and not the attenuation effect, such that although the shape of a kinematic wave may change as it propagates through a reach, its peak discharge will not. In variable geometry, however, both the peak and wave shape will change.
2. Hysteresis in the discharge-stage relationship cannot be represented.
3. Similarly, the effect of disturbances can only propagate in a downslope direction (Beven, 2001) and the kinematic model cannot, therefore, predict backwater effects in subcritical flows.

All the above three effects require the water and bed slope be nonparallel, and limitation 3 also means that for a kinematic flood-routing model the bed slope must be everywhere negative and a downstream boundary condition is not required. However, despite these constraints, kinematic equations form the basis of many flood-routing codes (see Singh, 1996; Bates and De Roo, 2000; Cameron *et al.*, 2002; Cooper *et al.*, 2002). This is not only because of their computational efficiency but also because Lighthill and Whitham (1955) have shown for the subcritical flow with $F_r < 1$, as is typical of most floods, that dynamic waves decay exponentially and kinematic waves come to dominate.

The diffusion form of the St. Venant equations is based on the assumption that only the inertia terms, $\partial Q/\partial t + \partial(Q^2/A)/\partial x$, in equation (3) are insignificant and thus the momentum equation can be approximated as:

$$\frac{\partial h}{\partial x} + S_f - S_o = 0 \tag{7}$$

Inclusion of the water-surface slope term, $\partial h/\partial x$, allows the model, unlike the kinematic approximation, to describe the flood wave attenuation effect as described in the Section on "Flood wave hydraulics". Attenuation can be thought of as a diffusion process, hence giving the model its name (see Figure 7). It also follows that the diffusion model can deal with stage-discharge hysteresis, nonnegative slopes, and backwater effects and also that numerical solution of the equations (4) and (7) require specification of a downstream boundary condition. Diffusion wave models are also widely utilized in hydrology (Moussa, 1997; Horritt and Bates, 2001a) and continue to be the subject of development research (see Cappelaere, 1997; Moussa and Bocquillon, 2001). However, Fread (1984) notes that inclusion of the additional inertia terms to derive a full dynamic wave model actually adds relatively little to the computational burden over solution of the diffusion wave equation. Moreover, comparison of different wave routing approximations for channel flow by Horritt and Bates (2001a) showed that the computational cost of a kinematic solution was an order of magnitude less than an alternative diffusion wave model. There may therefore be relatively little advantage, in terms of either flow physics or computational cost, in using the diffusion wave approximation over a full dynamic wave.

Fread (1984), Ponce *et al.* (1978), Vieira (1983), Moussa and Bocquillon (1996), Graf and Altinakar (1998, pp. 280–281), and Singh (2001) all discuss the range of validity for kinematic, diffusion, and full dynamic wave equations for flood routing. Singh (2001) argues that in a channel flow, all wave types exist at any given position, with their relative significance changing with the changing nature of the flow as characterized by the Froude number, F_r.

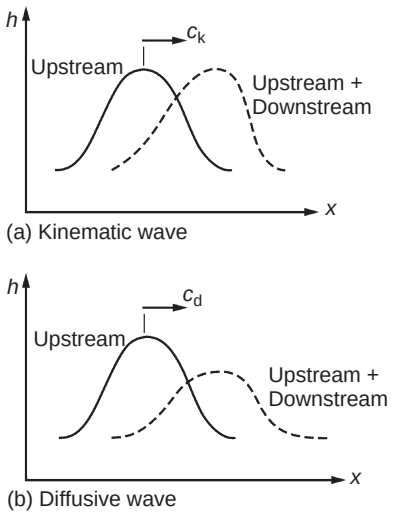

Figure 7 Translation and attenuation of a flood wave under different hydraulic approximations (after Graf and Altinakar, 1998) where c_k is the speed of a kinematic wave and c_d is the speed of a diffusive wave

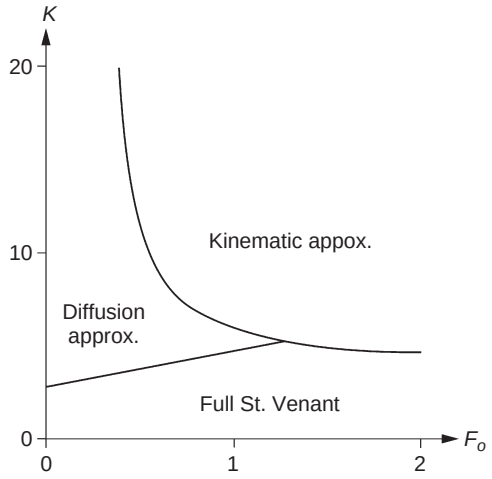

Figure 8 Ranges of validity of approximations to the one-dimensional full St. Venant equations in terms of the dimensionless Froude (F_o) and kinematic wave (K) numbers (after Vieira, 1983, © Elsevier)

Vieira (1983) presents a similar analysis in terms of the dimensionless Froude and kinematic wave numbers (see Figure 8), whilst Ponce *et al.* (1978) conclude that bottom slope and wave shape determine the range of applicability. The consensus of these studies (Graf and Altinakar, 1998) is that for typical flood flows where $F_r < 1$ the kinematic approximation holds, but on very low angle slopes where $F_r \ll 1$ a flood must be approximated as a diffusion wave as backwater effects become significant. Moreover, Beven (2001, p. 116) argues that uncertainty over effective parameter values and boundary conditions may mean that simplified models may even be useful under a wider range of conditions than this. It may thus not be possible to conclusively discriminate that a more complex treatment of the wave physics gives better performance, particularly if the model is calibrated. For a full discussion of these studies the reader is referred to Singh (2001, pp. 682–685).

Hydrological Storage Models

Even greater simplification of equations (3) and (4) can be achieved by replacing the momentum equation with an arbitrary functional relationship that describes storage in a reach as a function of its inflow and outflow. This is often referred to as hydrological storage flood routing, and a complete background to such methods is given by Shaw (1983, pp. 386–391). Hydrological storage models treat the river reach in question as a "black box" (NERC, 1975), and assume that the geometry and frictional resistance are too complex to be modeled in detail. The first step in implementing such a procedure is to replace the mass conservation equation (4) with:

$$\frac{\mathrm{d}S}{\mathrm{d}t} = I - O \tag{8}$$

where S is the storage within a river reach (L^3), I is the inflow to the reach ($L^3\,T^{-1}$) and O is the outflow ($L^3\,T^{-1}$).

The momentum equation (3) is then replaced with a relationship which expresses storage as a linear function of the inflow I, outflow O, and one or more parameters which are specific to the river reach being studied. A general form of this relationship is given (Fread, 1984) as:

$$S = K[\lambda I + (1-\lambda)O] \tag{9}$$

where K is a travel time constant (T) and λ is a dimensionless weighting parameter indicating the relative importance of I and O in determining the storage S within the reach. λ has lower and upper limits of 0 and 0.5, and typical values in the range 0.2 to 0.4 (Shaw, 1983, p. 388).

Similar to the kinematic wave equation, all hydrological routing models are limited (Fread, 1984) to applications where there is unique relationship between depth and discharge. Thus, they cannot consider backwater effects or "looped" depth-discharge rating curves. The earliest hydrological storage routing method was proposed by McCarthy (1938) and is termed *the Muskingum method*. This considers flow routing through a reach between time $t = 1$ and $t = 2$. Using this notation, equation (8) is first recast in centered finite difference form:

$$\frac{S_2 - S_1}{\Delta t} = \frac{I_1 + I_2}{2} - \frac{O_1 + O_2}{2} \tag{10}$$

where the subscripts refer to the time. Equation (9) is then substituted into equation (10) and rearranged to give an equation in terms of the desired unknown, namely outflow from the reach at $t = 2$.

$$O_2 = C_a I_2 + C_b I_1 + C_c O_1 \tag{11}$$

with

$$C_a = \frac{\Delta t + 2K\lambda}{\Delta t + 2K - 2K\lambda} \tag{12}$$

$$C_b = \frac{\Delta t - 2K\lambda}{\Delta t + 2K - 2K\lambda} \tag{13}$$

$$C_c = \frac{-\Delta t + 2K - 2K\lambda}{\Delta t + 2K - 2K\lambda} \tag{14}$$

As $\sum C = 1$, the outflow from the reach at the end of a time step is a weighted sum of the starting inflow, the starting outflow, and the ending inflow. Young (1986) points out that this is now a Transfer Function model (see the Section on "Empirical or nonstorage flood-routing models" and Young, **Chapter 128, Rainfall-runoff modeling: Transfer Function Models, Volume 3**), but not a good one as it does not include a time delay. The Muskingum method can therefore be viewed as just one structure in a general

class of autoregressive moving average (ARMA) models (Beven and Wood, 1993, p. 103).

To implement the Muskingum method the coefficients K and λ must be calibrated based on observed values of I and O. The methods can thus only be applied between gauging stations and only the average flood wave shape is reflected in the fitted routing parameters (Fread, 1984). Moreover, best-fit Muskingum parameters will often have an impulse response with nonphysical negative ordinates unless the reach is split down into the right number of subreaches to get a time delay compatible with the time step used (Young, 1986).

An improvement on the Muskingum method which removes the need for calibration of K and λ was proposed by Cunge (1969) who showed that K was approximately equal to the travel time of the flood wave through the reach:

$$K = \frac{\Delta x}{c_k} \tag{15}$$

Where x is the reach length and c_k is the kinematic wave speed. Given equation (15), Cunge then derived an expression for λ based on channel properties:

$$\lambda = 0.5\left[\frac{1 - q_o}{c_k S_o \Delta x}\right] \tag{16}$$

where q_o is a unit width reference discharge ($L^2\,T^{-1}$) obtained by dividing the mean peak discharge by the mean channel width.

While the Muskingum–Cunge method does not require observed inflow and outflow hydrographs to establish the routing coefficients, Fread (1984) notes that best results are obtained if the wave speed is determined from actual flow data and the criticism of Young (1986) still applies. Despite these limitations, the Muskingum–Cunge scheme is still frequently used for both flood routing (Barry and Bajracharya, 1995; Tang *et al.*, 1999a,b; Franchini *et al.*, 1999; Litrico, 2001) and catchment modeling (Koussis *et al.*, 1998; Takeuchi *et al.*, 1999; Lange *et al.*, 1999; Coe *et al.*, 2002) problems.

Flood Routing for Overbank Flows

Whilst it has been demonstrated that for overbank flows the one-dimensional flow field assumption breaks down, for many long reach flood-routing problems use of higher dimensional hydraulic codes may be both computationally prohibitive and unnecessary. This is particularly so if the additional distributed predictions generated by the higher order code are not required for the application in hand. However given, we are often interested in routing relatively large flood events, overbank flow is likely to be encountered. Here, hydrologists have three main options. First, one can assume that the additional approximations involved in continuing to treat out-of-bank flow as if it were one-dimensional are small compared to other uncertainties (for a discussion see Ali and Goodwin, 2002). Second, one can attempt to correct one-dimensional flow routing methods to account for the additional energy losses and/or mass transfers. Lastly, one can use a simplified two-dimensional code that incorporates some, but not all, of the additional processes known to occur during overbank flow.

Horritt and Bates (2002) demonstrate for simulation of a flood event over a 60-km reach of the River Severn, UK, that one-dimensional, simplified two-dimensional, and full two-dimensional models perform equally well in simulating flow routing and inundation extent given uncertainties over inflow, topography, and validation data. This suggests that although gross assumptions are made regarding the flow physics incorporated in a one-dimensional model applied to out-of-bank flows, the additional energy losses can be compensated for using a calibrated effective friction coefficient.

The second class of approaches are reviewed by Knight and Shiono (1996, pp. 155–159) and are based on subdividing the channel in the streamwise direction and then calculating the conveyance in each section using uniform flow formulae. The subarea conveyances are then summed to give the total conveyance. Knight and Shiono (1996) identify three main variations on the channel division method which aim to simulate the channel-floodplain interaction more exactly. These are: (i) modification of the subarea wetted perimeters (Wormleaton *et al.*, 1982); (ii) calculation of discharge adjustment factors for each subarea based on a "coherence" concept (Ackers, 1993), and (iii) quantification of the apparent shear stresses on the subarea division lines (Knight and Hamed, 1984). However, these methods have been developed to estimate the depth-discharge rating curve at particular cross sections and are yet to be incorporated in standard flood-routing models. One exception here is the LISFLOOD-FF model of De Roo *et al.* (2001). Here, a correction of the Manning roughness value is applied to simulate the momentum exchange, which occurs across the shear layer between main channel and floodplain flows.

Lastly, recent advances in higher order modeling have led to the development of simplified two-dimensional codes (see e.g. Bladé *et al.*, 1994; Estrela and Quintas, 1994; Bechteler *et al.*, 1994; Romanowicz *et al.*, 1996; Bates and De Roo, 2000; Venere and Clausse, 2002; Dhondia and Stelling, 2002) that, because of their computational efficiency, may potentially be applied to long reach flood-routing problems. Such models typically treat in-channel flow with some form of the one-dimensional St. Venant equations, but treat floodplain flows as two-dimensional using a storage cell concept first described by Cunge *et al.* (1980). Here the floodplain is discretized as a series of regions, with flows between regions calculated using analytical uniform flow formulae such as the Manning equation.

Initially, this approach was implemented in standard one-dimensional river routing packages such as ISIS (Wicks *et al.*, in press) by defining the storage cells as large polygonal areas (surface areas of $\sim 10^0 - 10^1\,\mathrm{km}^2$) representing discrete flooding compartments (e.g. polders, storage basins etc.) that are subjectively identified by the user. Recent developments in topographic data capture have, however, allowed high (cell size $\sim 10^0$ m) resolution Digital Elevation Models (DEMs) of floodplain areas to be produced (see the Section on "Data sources for inundation models and model data assimilation"). This has allowed storage cells to be discretized as a high-resolution grid, for example, the LISFLOOD-FP raster flood-routing model of Bates and De Roo (2000). LISFLOOD-FP treats in-channel flow using either kinematic (equations 4 and 5) or diffusion (equations 4 and 7) wave routing. Floodplain flows are similarly described in terms of continuity and mass flux equations, discretized over a grid of square cells, which allows the model to represent two-dimensional dynamic flow fields on the floodplain. Flow between two cells is assumed simply to be a function of the free surface height difference between those cells (Estrela and Quintas, 1994):

$$Q_x^{i,j} = \frac{h_{\mathrm{flow}}^{5/3}}{n}\left(\frac{h^{i-1,j} - h^{i,j}}{\Delta x}\right)^{1/2} \Delta y \qquad (17)$$

Water depths in each cell are then updated at each time step based on the sum of the fluxes over the four faces of the cell.

$$\frac{\mathrm{d}h^{i,j}}{\mathrm{d}t} = \frac{Q_x^{i-1,j} - Q_x^{i,j} + Q_y^{i,j-1} - Q_y^{i,j}}{\Delta x \Delta y} \qquad (18)$$

where $h^{i,j}$ is the water free surface height at the node (i, j), Δx and Δy are the cell dimensions, n is the effective grid scale Manning's friction coefficient ($\mathrm{L}^{1/3}\mathrm{T}^{-1}$) for the floodplain, and Q_x and Q_y describe the volumetric flow rates between floodplain cells. Q_y is defined analogously to equation (6). The flow depth, h_{flow}, represents the depth through which water can flow between two cells, and is defined as the difference between the highest water free surface in the two cells and the highest bed elevation (this definition has been found to give sensible results for both wetting cells and for flows linking floodplain and channel cells.) This approach is similar to diffusive wave propagation, but differs marginally due to the decoupling of the x- and y-components of the flow. Whilst this approach does not accurately represent diffusive wave propagation, it is computationally simple and has been shown to give very similar results to a more accurate finite difference discretization of the diffusive wave equation (Horritt and Bates, 2001a).

Equation (17) is also used to calculate flows between floodplain and channel cells, allowing floodplain cell depths to be updated using equation (18) in response to flow from the channel. These flows are also used as the source term, q, in the channel flow submodel (see equation 4), effecting the linkage of channel and floodplain flows. Thus, only mass transfer between channel and floodplain is represented, and this is assumed to be dependent only on relative water-surface elevations. Whilst this neglects effects such as channel-floodplain momentum transfer and the effects of advection and secondary circulation on mass transfer, it is the simplest approach to the coupling problem and should reproduce the dominant behavior of the real system.

The channel in the LISFLOOD-FP model occupies no floodplain pixels, but instead represents an extra flow path between pixels lying over the channel. Thus floodplain pixels lying over the channel have two water depths associated with them: one for the channel and one for the floodplain itself. This new scheme (referred to as the *Near Channel Floodplain Storage,* or NCFS model by Horritt and Bates, 2001b) has proved more suitable for situations where large floodplain grid spacings are used in conjunction with a narrow (width $< \Delta x$) channel since channel width and raster grid size are decoupled. Since the NCFS scheme will also calculate floodplain flows between cells occupied by the channel, extra flow routing in near channel regions will also be represented.

Such cellular approaches are capable of high-resolution application to relatively long river reaches up $\sim 10^2$ km in length and may provide an alternative to one-dimensional codes for channel routing in rainfall-runoff models. One such application is described by Coe *et al.* (2002) who model the whole of the Amazon basin using a regular grid of resolution 9 km with Muskingham–Cunge routing in-channel and floodplain flow treated using a storage cell approach. Similarly, the LISFLOOD-FP storage cell code has been successfully used to model flow routing along a 60-km reach of the River Severn in the United Kingdom (see Horritt and Bates, 2002) and a 35-km reach of the River Meuse in The Netherlands (see De Roo *et al.*, 2003 and Figure 9).

INUNDATION PREDICTION MODELS

In addition to modeling the downstream translation and attenuation of a flood wave, hydrologists may also be required to predict distributed hydraulic quantities, such as inundation extent, for use by catchment managers and civil protection authorities. Potentially this may be a difficult problem, as it requires prediction of the extension and retreat of a flow over large and relatively flat areas. Small errors in predicted water-surface elevation may result in large errors in the position of the predicted inundation front, and comparison of hydraulic models to inundation extent data may therefore be a sensitive test of their abilities. This task requires not only accurate floodplain topographic data but also models capable of treating dynamic wetting and

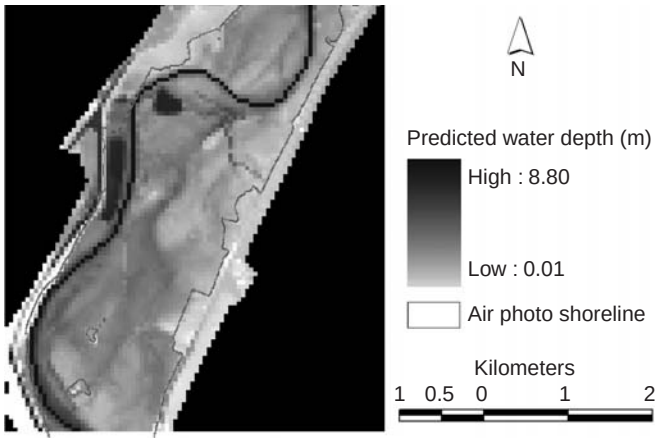

Figure 9 Predicted water depths and inundation extent simulated using the LISFLOOD-FP two-dimensional storage cell model applied at 50 m resolution to a 35 km river-floodplain reach of the River Meuse, The Netherlands over 20 days of a 1 in 63-year recurrence interval flood event that occurred in January 1995. Observed flow at the gauging station from the 19 January onwards is used as a model boundary condition and predicted inundation is compared to that observed by aerial photography taken on 27 January. The model correctly classifies as wet or dry 85% of pixels in the above image. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

drying in a numerically stable fashion (see Lynch and Gray, 1980 for a discussion).

Whilst floodplain flow is clearly a two-dimensional phenomena (as the flow paths cannot be predicted *a priori*, see Nicholas and Mitchell, 2003), overbank flow can still be treated using one-dimensional models as noted in the Section on "Flood routing for overbank flows". Such codes predict water depth at each model cross section at each time step, and it is then a relatively simple matter to calculate the predicted inundation extent by reprojecting the predicted water-surface elevations onto a DEM (see e.g. Puech and Raclot, 2002). The success of this procedure therefore depends strongly on the quality of the DEM, but with the advent of high-resolution, high-accuracy topographic data capture techniques (see the Section on "Data sources for inundation models and model data assimilation") this is becoming less of a problem. For example, Werner (2001) demonstrates a simple GIS method to generate inundation extent and depth maps from the predictions of a standard one-dimensional code. Similarly, Horritt and Bates (2002) show that with such an interpolation step in place, the performance of a one-dimensional code in predicting inundation extent for a 60-km reach of the River Severn, UK, was indistinguishable from the performance of two-dimensional storage cell and full two-dimensional models.

The success of such interpolation methods indicates that in certain situations one may not even need a model at all to predict inundation extent. Given gauged water-surface elevations along a reach, or water-surface elevations predicted on the basis of flood frequency analysis, one can perform a similar interpolation to that used by Werner (2001). This approximates the flood wave as a plane (or series of planes) which are intersected with the DEM to give extent and depth predictions. Bates and De Roo (2000) compared this method to two-dimensional storage cell and full two-dimensional hydraulic models for a 35-km reach of the River Meuse, The Netherlands and found that in certain situations the planar approximation performed almost as well as hydraulic modeling. In this application, the methods were used to simulate the January 1995 event ($Q_{\text{peak}} = \sim 2700\,\text{m}^3\,\text{s}^{-1}$, 1 in 63-year recurrence interval) and validated by comparison to air photo imagery of flood extent taken at around the time of maximum flooding. For regions close to gauging stations where the recorded water level was used as a height control, the planar approximation achieved accuracy of 81% pixels correctly predicted as wet or dry, compared to 85% for a two-dimensional storage cell model. Away from the gauging station, the planar approximation performed less well, and using a hydraulic model produced a better result in all circumstances examined, even if at times this difference was marginal. Clearly, the planar approximation will work well for reaches that are short compared to the wavelength of the flood and where there are good gauged data to constrain the position of the plane. Even in these circumstances, however, lack of mass conservation will mean that the areas that are not hydraulically connected to the channel are predicted as flooded. Nevertheless, this may be a useful method under some circumstances, and provides a benchmark level of performance that all hydraulic models should exceed to be considered skillful.

Despite the potential success of planar and one-dimensional models, a general solution to the problem of predicting flood inundation extent requires a model with a dimensionality to match our perceptual understanding of the flow physics. As discussed previously, this requires at least a two-dimensional code (see Figure 10). Numerous classes of two-dimensional approaches have been developed, and these include storage cell codes, full solutions of the two-dimensional St. Venant or shallow water equations (Gee *et al.*, 1990; Feldhaus *et al.*, 1992; Bates *et al.*, 1998; Nicholas and Mitchell, 2003) and simplified shallow water models (see e.g. Molinaro *et al.*, 1994) where certain terms, such as inertia, are omitted from the controlling equations. The two-dimensional St. Venant equations are derived from the full three-dimensional Navier–Stokes equations (1 and 2) by first averaging each dependent variable in time to yield the Reynolds Averaged Navier–Stokes or (RANS) equations and then integrating over the flow depth (see Bates and Anderson, 2001, pp. 328–332 for a discussion). Reynolds averaging leads to the introduction of

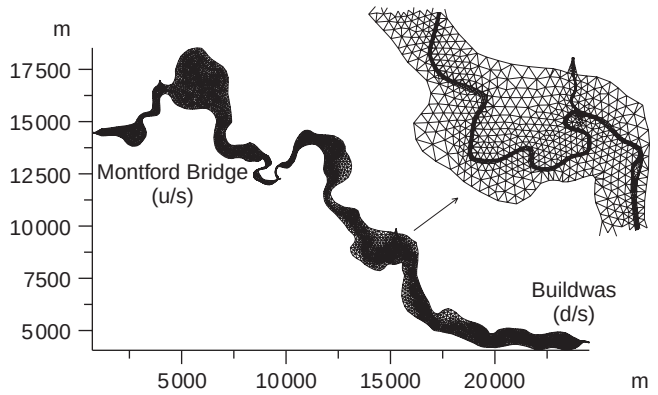

Figure 10 Two-dimensional unstructured mesh discretization constructed for a typical reach scale river-floodplain application. In this case the mesh was constructed by Horritt and Bates (2002) for use with the TELEMAC-2D finite element solution of the two-dimensional shallow water equations for the 60-km reach of the River Severn, UK, shown in Figure 6

new terms representing the shear stress on the mean flow due to turbulence. These so-called Reynolds stresses may be given, for example, as:

$$\bar{\tau}_{xz} = -\rho(\bar{u'}\bar{v'}) \tag{19}$$

where $\bar{\tau}_{xz}$ is the Reynolds stress in the $x - z$ plane.

As these depend on the instantaneous velocity fluctuations, their existence is a problem for a time-averaged model as these values are unknown. To close the RANS equations we need to provide values for the Reynolds stresses by introducing some model of turbulence. A variety of schemes for these are available but the most simple are those based on the Boussinesq approximation and this approach is therefore favored in flood inundation codes given the typical scale of the computational domain. This method treats turbulent momentum transfer in a similar manner to the approach adopted for viscous forces, as both can be thought of as shear stresses. Here a turbulent viscosity coefficient μ_t, is introduced with dimensions similar to the molecular viscosity μ. The overall fluid shear stress, τ ($ML^{-1}T^{-2}$) including molecular and turbulent components then becomes:

$$\tau = (\mu + \mu_t)\frac{d\bar{u}}{dy} \tag{20}$$

As with molecular viscosity, for convenience μ_t is often expressed in kinematic form, v_t, with dimensions (L^2T^{-1}). Simple models of turbulence, such as the zero equation, mixing length, one equation and k-ε (two equation) schemes, merely attempt to provide a value for v_t. The two-dimensional St. Venant may then be given in nonconservative form as:

Continuity equation

$$\frac{\partial h}{\partial t} + \vec{u_d} \cdot \overrightarrow{grad}\,(h) + h\,div(\vec{u_d}) = 0 \tag{21}$$

Momentum equations

$$\frac{\partial u_d}{\partial t} + \vec{u_d} \cdot \overrightarrow{grad}\,(u_d) + g\frac{\partial h}{\partial x} - div(v_t \cdot \overrightarrow{grad}\,(u_d)) = S_x - g\frac{\partial Z_f}{\partial x} \tag{22}$$

$$\frac{\partial v_d}{\partial t} + \vec{u_d} \cdot \overrightarrow{grad}\,(v_d) + g\frac{\partial h}{\partial y} - div(v_t \cdot \overrightarrow{grad}\,(v_d)) = S_y - g\frac{\partial Z_f}{\partial y} \tag{23}$$

where u_d, v_d are the depth-averaged and time-averaged velocity components (with dimensions LT^{-1}) in the x and y Cartesian directions (L); Z_f is the bed elevation (L); v_t is the kinematic turbulent viscosity (L^2T^{-1}) and S_x, S_y are the source terms (friction, coriolis force, and wind stress).

Given appropriate boundary and initial conditions, equations (21) to (23) can then be solved numerically to obtain predictions of the water depth, h, and the two components of the depth-averaged velocity, u_d and v_d.

Both storage cell and numerical models can be discretized using structured (Bates and De Roo, 2000; Nicholas and Walling, 1997; Nicholas and Mitchell, 2003) or unstructured grids (Sen, 2002; Hervouet and Van Haren, 1996), and more complex schemes even allow the grid to deform to follow the moving inundation front through time (Lynch and Gray, 1980; Kawahara and Umetsu, 1986; Benkhaldoun and Monthe, 1994). Fixed grid approaches require additional algorithms to treat spurious mass and momentum conservation effects that occur in partially wet cells at the flow field boundary (King and Roig, 1988; Leclerc *et al.*, 1990; Defina *et al.*, 1994; Ip *et al.*, 1998; Tchamen and Kawahita, 1998; Bates and Hervouet, 1999; Defina, 2000). Given the computational cost of remeshing and potential problems in maintaining numerical stability, to date fixed grid approaches have been preferred. This also has the advantage that it allows use of a more resolved spatial discretization and thus a greater degree of topographic complexity to be included in the model. This is clearly critical, as topography is a major control on the inundation process.

Lastly, for relatively short river-floodplain reaches (<5 km) three-dimensional approaches may be used. Here either the three-dimensional RANS equations or the three-dimensional shallow water equations (Hervouet and Van Haren, 1996, p. 191) are solved for a structured or unstructured grid using either finite difference, finite element or finite volume techniques. Correct grid spacing

in the vertical is typically obtained through the σ-transform (see Hervouet and Van Haren, 1996, p. 206) to give a normalized thickness of vertical layers irrespective of bottom topographic variations. One such application is reported by Stoesser *et al.* (2003) who report the application of a three-dimensional RANS model to a 3.5 km channel-floodplain reach of the River Rhine in Southwest Germany. The governing equations were solved for a general three-dimensional geometry, discretized by the finite volume method on curvilinear coordinates. The study used a relatively high-resolution mesh of 1 98 144 cells comprising $258 \times 64 \times 12$ cells in the streamwise, cross-streamwise, and vertical directions respectively (Figure 11), giving an approximate cell size of 13 m by 3 m by 0.5 m. The model successfully reproduced reach scale floodplain velocity observations determined from dye tracing experiments taken during a 1 in 100-year recurrence interval flow with discharge of $\sim 3600\,m^3\,s^{-1}$ and water levels for an independent verification event when discharge equaled $\sim 2400\,m^3\,s^{-1}$. The study provided evidence of the computational feasibility of a three-dimensional approach for river reaches of this scale for steady-state flows and demonstrated the range of hydraulic quantities that can be calculated (see Figure 12). Three-dimensional approaches may suffer from stability problems during dynamic flows as cell height-length ratios become highly distorted as water depth h approaches zero. Solution of this problem requires deformation of the three-dimensional mesh that may be computationally prohibitive.

Higher order turbulence modeling approaches for three-dimensional flow in compound channels have also been attempted and include algebraic stress (Shao *et al.*, 2003) and Large Eddy Simulation (Thomas and Williams, 1995; Bradbrook *et al.*, 2000) schemes. However these approaches incur large computational costs and have yet to be applied to anything other than experimental channels of regular geometry. Full field-scale models of complex natural geometry will no doubt become possible in the future, but may be over-specified for the problem in hand given the quality of the available validation data.

DATA SOURCES FOR INUNDATION MODELS AND MODEL DATA ASSIMILATION

The above discussion has made clear the variety of models available for flow routing and inundation prediction. Choice of model has been shown to depend on the scale of the problem, the computational resources available and the needs of the user. However, any model is only as good as the data used to parameterize, calibrate, and validate it, and in this section the data sources available for flow routing and inundation models are discussed along with the methods available to assimilate these data into hydraulic models. The data required by any hydraulic model

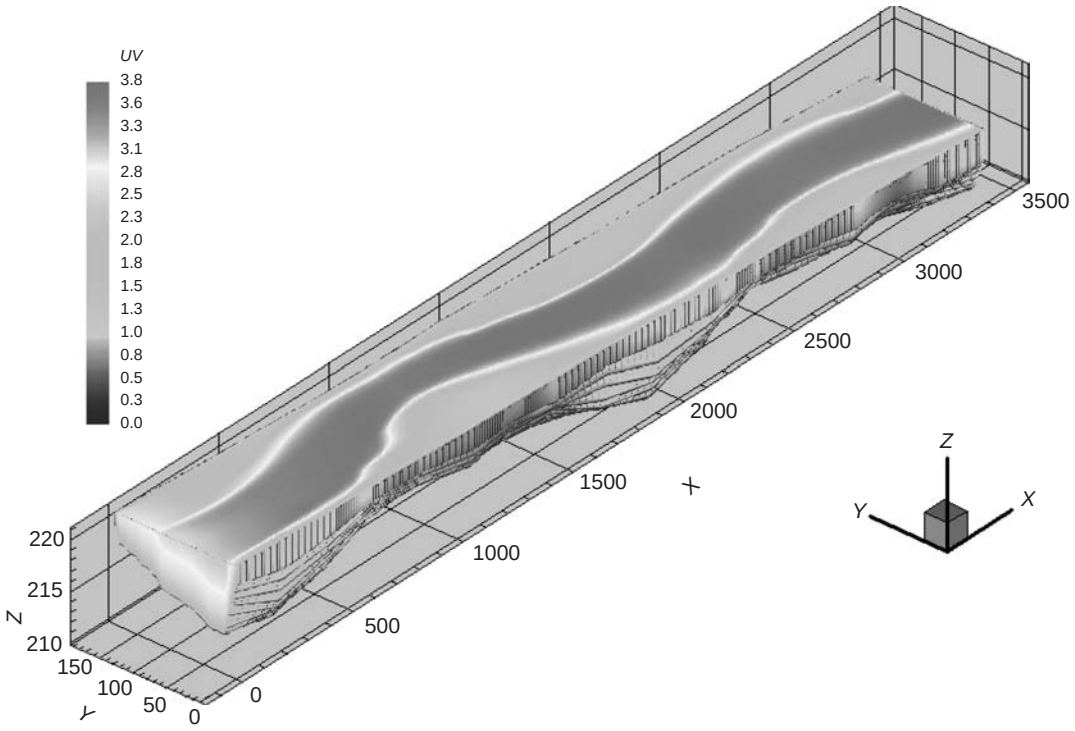

Figure 12 Scalar product of u and v velocities in ms^{-1} predicted by Stoesser *et al.* (2003) for the 3.5-km reach of the River Rhine shown in Figure 11 using a three-dimensional solution of the full Navier–Stokes equations with k-ε turbulence closure. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

are principally: (i) boundary condition data; (ii) initial condition data; (iii) topography data; (iv) friction data; and (v) hydraulic data for use in model validation.

Boundary Condition Data

Boundary condition specification in hydraulic models consists of assigning values for each dependent variable at each boundary node at each time step. Hence, for a two-dimensional model this would consist of values for the water depth, h, and the two components of the depth-averaged velocity vector, u_d and v_d. Typically, values for u_d and v_d are unavailable, and a rating curve is used to convert gauged stage values into discharge, Q, which in conjunction with a surveyed cross section can be used to calculate the velocity. If the rating curve was derived using the assumption of locally uniform flow at the boundary (i.e. with a uniform flow relationship such as the Manning equation) this introduces a further approximation into the model. For kinematic treatments and super-critical flows where $F_r > 1$ the absence of backwater effects means that the downstream boundary condition is unnecessary. Boundary condition data can also be taken from design floods calculated on the basis of flood frequency data or from the output of a rainfall-runoff model. Along the lateral boundary, exchanges with the adjacent catchment or floodplain (variable q in equation 4) are either set to zero, parameterized using data on average lateral inflow rates from previous floods for the given reach, or assumed proportional to the upstream inflow rate (e.g. O'Donnell, 1985).

Initial Condition Data

Initial conditions for a hydraulic model consist of values for each model dependent variable at each computational node at time $t = 0$. In practice, these will be incompletely known, if at all, and some additional assumptions will therefore be necessary. For steady-state simulations any reasonable guess at the initial conditions is usually sufficient, as the simulation can be run until the solution is in equilibrium with the boundary conditions and the initial conditions have ceased to have an influence. However, for dynamic simulations this will not be the case and whilst care can be taken to make the initial conditions as realistic as possible, a "spin up" period during which model performance is impaired will always exist. For example, initial conditions for a flood simulation in a compound channel are often taken as the water depths and flow velocities predicted by a steady-state simulation with inflow and outflow boundary conditions at the same value as those used to commence the dynamic run. Whilst most natural system are rarely in steady state, careful selection of simulation periods to

coincide their start with near steady-state conditions can minimize the impact of this assumption.

Topography Data

A conclusion that can be drawn from the studies discussed above is that the key data set for flow routing and inundation modeling is topography. High-resolution, high-accuracy topographic data are essential to shallow water flooding simulations over low slope floodplains with complex microtopography, and such data sets are increasingly available from a variety of remotely mounted sensors. Traditionally, hydraulic models have been parameterized using ground survey of cross sections perpendicular to the channel at spacings of between 100 and 1000 m. Such data are accurate to within a few millimeters in both the horizontal and vertical, and integrate well with one-dimensional hydraulic models. However, ground survey data are expensive and time consuming to collect and of relatively low spatial resolution. Moreover, topographic data available on national survey maps tends to be of low accuracy with poor spatial resolution in floodplain areas. For example, in the United Kingdom, nationally available contour data are only recorded at 5-m spacing to height accuracy of ± 1.25 m, and for a hydraulic modeling study of a typical river reach Marks and Bates (2000) report finding only three contours and 40 unmaintained spot heights within a $\sim 6\,km^2$ floodplain area. When converted into a DEM such data lead to relatively low levels of inundation prediction accuracy in hydraulic models (see Wilson and Atkinson, in press).

Considerable potential therefore exists for more automated, broad-area mapping of topography from satellite, and more importantly airborne platforms. Three techniques which currently show reasonable potential for flood modeling are aerial stereo-photogrammetry (Baltsavias, 1999; Lane, 2000; Westaway *et al.*, 2003), airborne laser altimetry or LiDAR (Krabill *et al.*, 1984; Gomes Pereira and Wicherson, 1999) and airborne Synthetic Aperture Radar (SAR) interferometry (Hodgson *et al.*, 2003). Radar interferometry from sensors mounted on space-borne platforms, and in particular the Shuttle Radar Topography Mission (SRTM) data (Rabus *et al.*, 2003), may also in the future provide a viable topographic data source for hydraulic modeling in large, remote river basin where the flood amplitude is large compared to the topographic data error. The characteristics of these instruments relevant to flood inundation modeling are compared in Table 1.

LiDAR in particular has attracted much recent attention in the hydraulic modeling literature (Marks and Bates, 2000; Bates *et al.*, 2003; French, 2003; Charlton *et al.*, 2003). Major LiDAR data collection programmes are underway in a number of countries, including The Netherlands and the United Kingdom, where so far approximately 20% of the land surface area in England and Wales has been surveyed. In the United Kingdom, helicopter-based

Table 1 Characteristics of remotely sensed topographic data relevant to flood inundation modeling

Type	Typical sensor altitude	Spatial resolution	Vertical accuracy	Survey rate	Approximate relative cost per km^2
Airborne stereo-photogrammetry	~1000 m	User defined, only partially automated	5–20-cm rmse depending on photo scale	Depends on the point spacing	1
Airborne laser altimetry (LiDAR)	~1000 m	~2 m	10–30-cm rmse	~50 km^2 per day	~0.1
Airborne synthetic aperture radar interferometry	~6000 m	~5 m	0.3–3.0-m rmse	~500 km^2 per day	~0.01
Satellite synthetic aperture radar interferometry (ERS, RADARSAT, ENVISAT, etc.)	~800 km	12–25 m	2–10-m rmse	Global repeat coverage every 24–35 days depending on the satellite	–
SRTM	~230 km	30 m	~5-m rmse ~2-m rmse pixel-to-pixel variations	Data collected over an 11-day Space Shuttle mission in February 2000 targeting 80% of earth's land mass (between 60°N and 56°S). Acquired at a rate of ~10.6 M km^2 per day	~0.0003

LiDAR survey is also beginning to be used to monitor in detail (~0.3-m spatial resolution) along critical topographic features such as flood defences, levees, and embankments. LiDAR systems operate by emitting pulses of laser energy at very high frequency (~5–33 KHz) and measuring the time taken for these to be returned from the surface to the sensor. Global Positioning System data and an onboard Inertial Navigation System are used to determine the location of the aircraft in space and hence the surface elevation. As the laser pulse travels to the surface, it spreads out to give a footprint of $\sim 0.1\,m^2$ for typical operating altitude of ~800 m. On striking a vegetated surface, part of the laser energy will be returned from the top of the canopy and part will penetrate to the ground. Hence, an energy source emitted as a pulse will be returned as a waveform, with the first point on the waveform representing the top of the canopy and the last point (hopefully) representing the ground surface. The last returns can then be used to generate a high resolution "bare earth" DEM (see Figure 13).

In general, all the above sensors only monitor topography above the water surface. Subsurface bathymetry is also important and can be monitored by either traditional ground survey at low water, boat surveys or for large water bodies, sidescan sonar (e.g. Howe *et al.*, 2001). Bathymetric and topographic data then require careful "stitching" together to create a single terrain model.

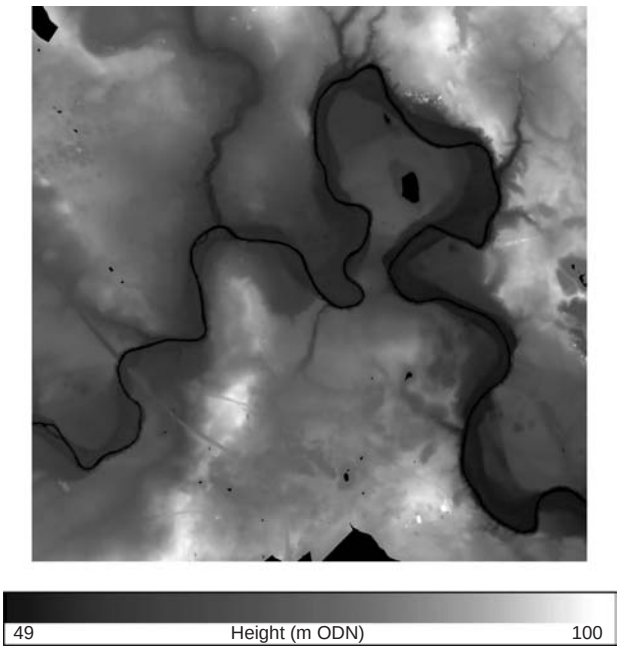

Figure 13 Digital Elevation Model at 10-m resolution derived from LiDAR data for a 6×6 km region of the River Severn floodplain in the United Kingdom using the processing algorithm of Cobby *et al.* (2003)

Friction Data

Friction is usually the only unconstrained parameter in a hydraulic model. Two- and three-dimensional codes, which use a zero-equation turbulence closure may additionally require specification of an "eddy viscosity" parameter which describes the transport of momentum within the flow by turbulent dispersion; however, this prerequisite disappears for most higher order turbulence models of practical interest. Hydraulic resistance is a lumped term that represents the sum of a number of effects: skin friction, form drag, and the impact of acceleration and deceleration of the flow. These combine to give a lumped energy loss coefficient, which in hydraulics is usually expressed in terms of resistance coefficients such as Manning's n and Chezy's C, and are derived from uniform flow theory. This assumes that the rate of energy dissipation for nonuniform flows is the same as it would be for uniform flow at the same water- surface (friction) slope. The precise effects represented by the friction coefficient for a particular model depend on the model's dimensionality and resolution. Thus, the extent to which form drag is represented depends on how the channel cross-sectional shape, meanders, pool-riffle sequences (see Beven and Carling, 1992) and long profile are incorporated into the model discretization. For example, a one-dimensional code will not include frictional losses due to channel meandering in the same way as a two-dimensional code. In the one-dimensional code, these frictional losses need to be incorporated into the hydraulic resistance term. Similarly, a high-resolution discretization will represent explicitly a greater proportion of the form drag component than a low-resolution discretization using the same model. Complex questions of scaling and dimensionality hence arise which may be somewhat difficult to disentangle.

Certain components of the hydraulic resistance are, however, more tractable. In particular, skin friction for in-channel flows is a strong function of bed material grain size, and a number of relationships exist which express the resistance coefficient in terms of the bed material median grain size, D_{50} (e.g. Hey, 1979). Equally, on floodplain sections where conveyance rather than storage processes dominate the drag due to vegetation is likely to form the bulk of the resistance term (Kouwen, 2000). Determining the drag coefficient of vegetation is, however, rather complex, as the frictional losses result from an interaction between plant biophysical properties and the flow. For example, at high flows the vegetation momentum absorbing area will reduce due to plant bending and flattening. Moreover, vegetation is highly spatially variable at scales typically smaller than the model grid, and correct treatment of features such as hedges will be important in assigning an effective roughness coefficient. To account for such effects, Kouwen and Li (1980) and Kouwen (1988) calculated the Darcy–Weisbach friction factor f for short

vegetation, such as floodplain grasses and crops, by treating such vegetation as flexible, and assuming that it may be submerged or nonsubmerged. f is dependent on water depth and velocity, vegetation height, and a product *MEI*, where M is the number of stems per unit area, E is the stem modulus of elasticity and I is the stem area's second moment of inertia. Whilst *MEI* often cannot be measured directly, it has been shown to correlate well with vegetation height (Temple, 1987).

Similar to topography, ground survey of grain size and vegetation parameters is extremely time consuming and, recently, research has begun to consider the use of remotely sensed techniques to determine certain of the above data. For example, photogrammetric techniques to extract grain size information from ground-based or airborne photography are currently under development (Butler *et al.*, 2001). Similarly, recent research developments allow extraction of specific plant biophysical parameters from LiDAR data. For vegetation >4 m in height, this latter technique uses the timing difference between the first and last points on the returned LiDAR waveform to determine the height of the canopy. For vegetation <4 m the method uses the local standard deviation of the last return heights (see Figure 14). Cobby *et al.* (2000, 2001) demonstrate that the height of short vegetation up to 1.4 m high can be estimated with such a technique to 0.14 m rmse. Taller vegetation (>10 m) is subject to greater height estimation error ($\sim 2-3$ m) as canopies are typically denser and it is less likely that the laser pulse will penetrate the full depth of the canopy, however, for the purpose of determining hydraulic resistance this is less of a problem. Given that other plant biophysical properties, for example, *MEI* correlate with plant height, Mason *et al.* (2003) have presented a methodology to calculate time and space distributed friction coefficients for flood inundation models directly from LiDAR data. Much further work is required in this area; however, such studies are beginning to provide methods to explicitly calculate important elements of frictional resistance for particular flow routing problems. This leads to the prospect of a reduced need for calibration of hydraulic models and therefore a reduction in predictive uncertainty (see Section "Uncertainties in flood-routing and inundation prediction"). Given the complexity of the flow being simulated, calibration of local effective friction values may still improve model results, but the methodology outlined above may be useful in constraining uncertainty in prior estimates of parameter values.

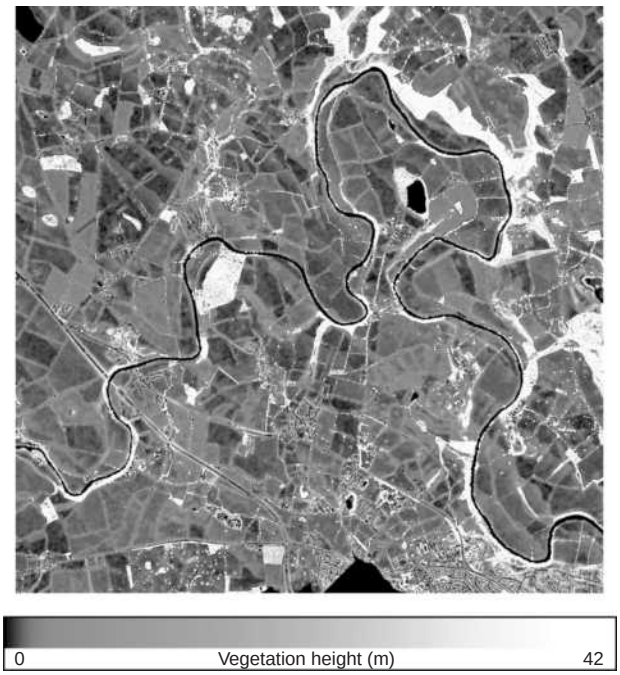

Figure 14 Vegetation height map at 10-m resolution derived from LiDAR data for a 6×6 km region of the River Severn floodplain in the United Kingdom using the processing algorithm of Cobby *et al.* (2003)

Model Validation Data

Traditionally, hydraulic models of reach scale flood inundation are validated using either water levels or discharge from maintained national gauging stations (Gee *et al.*, 1990; Bates *et al.*, 1992; Feldhaus *et al.*, 1992; Bates *et al.*, 1998). More rarely, individual flood levels are recorded during major events, although the reliability of such records can be questioned they have been relatively less used in the validation process. The spacing of national gauging stations is defined by their flood warning role and these are typically between 10 and 40 km apart. Such networks were never designed with hydraulic model validation in mind and the low density means that very few data points are available internal to a reach scale model domain. Whilst such data, particularly stage, are accurate, they are only 1D in time and 0D in space and do not directly test a model's ability to predict distributed hydraulics. Moreover, prior to the further development of the techniques for resistance parameter determination, calibration of hydraulic models by manipulating the friction coefficient will remain a necessity. Calibration and validation against bulk routing data can be simply achieved with spatially lumped friction parameters (Bates *et al.*, 1998) that represent the "average" frictional loss through the reach. In reality, friction parameters will vary in time and space, and many spatial patterns of frictional resistance will match the observed bulk flow data equally well yet give different distributed predictions. Such equifinality can only be reduced through the use of distributed validation data such as inundation extent, water depths, and flow velocities. This needs to cover a broad area with many points, and it again gives an advantage to remotely sensed data capture.

Inundation data provides a potential solution to the problem of hydraulic model validation as whilst these data

are 0D in time their 2D spatial format could provide "whole reach" data for both distributed calibration and validation of distributed predictions. Inundation extent can also be seen as a sensitive test of a hydraulic model, as small errors in predicted water-surface elevation would lead to large errors in shoreline position over flat floodplain topography. As well as data from post-flood ground surveys, such data can also be obtained using remote sensing. The sensors available for this task are reviewed by Bates *et al.* (1997), Pearson *et al.* (2001), and Bates *et al.* (2004) and are:

- Optical imagers on airborne and satellite platforms.
- SAR imagers on airborne and satellite platforms.
- Digital video cameras mounted on surveillance aircraft.

Processing such data, particularly SAR, to yield accurate shoreline information is not straightforward (see e.g. Horritt *et al.*, 2001 and Figure 15), and tends to be prone to misclassification. Yet, such data are at least wide area and distributed, and are therefore increasingly used in hydraulic model validation (see Horritt, 2000).

Despite the utility of inundation extent information, Mason *et al.* (2003) identify a situation where discrimination between competing models is impossible with satellite-derived SAR data but would be relatively easy given information on distributed velocities across the floodplain. Present methods of determining water velocities rely on making in-situ point measurements, which are necessarily limited in spatial extent, can be dangerous to undertake and difficult to interpret in terms of the time and space averaged velocities predicted by a given model. A resolution to this problem is potentially provided by Microwave Doppler radar. When the transmitted radar signal is scattered from a rough water surface, a Doppler frequency shift is produced by the centimeter-length surface waves that backscatter. The magnitude of the shift is a function of the stream current at the surface. The principle has been used to map surface velocities of coastal currents for a number of years (e.g. Hwang *et al.*, 2000), and has recently been applied to the measurement of the spatial distribution of river currents using a radar mounted on a van parked next to a river (Costa *et al.*, 2000). By aiming the radar across the river in two directions about 30 degrees apart, one looking upstream and the other downstream, Costa *et al.* found that the difference in the Doppler shifts of the two return signals gave the downstream surface velocity component. However, similar to velocity meter data, surface velocities must still be related to the time and space averaged velocity components predicted by a model.

Experiments are also now starting to be conducted on the use of along-track airborne radar interferometry for measuring water-surface velocities (Srokosz, 1997). These employ aircraft having microwave coherent real-aperture radar with two antennae aimed a few degrees apart in the along-track direction. If the two radars are arranged to look across- rather than along-track, it is possible to perform across-track interferometry instead, allowing a map of water-surface elevations to be constructed remotely. Such studies are still at the research stage and a useable technique is still some way off. Nevertheless, the model validation potential of such surface current measurements is considerable and deserving of further exploration.

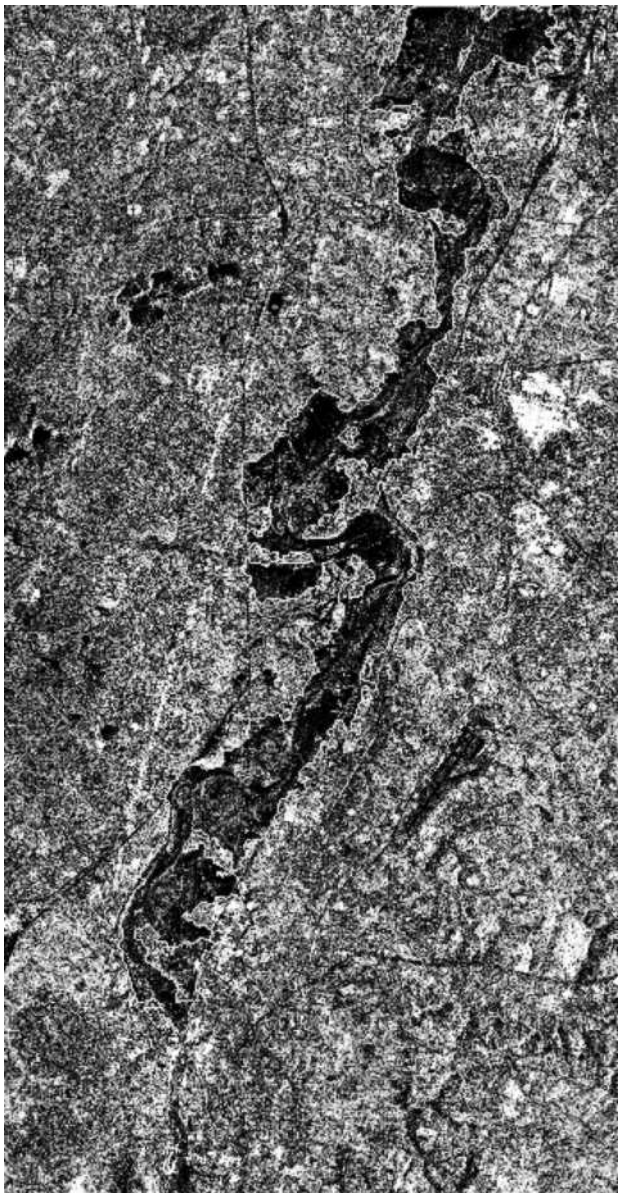

Figure 15 Satellite Synthetic Aperture Radar image of the January 1995 flooding on the River Meuse, The Netherlands. The image size is $\sim 70 \times 30$ km and the waterline extracted from the data using the statistical active contour processing algorithm of Horritt *et al.* (2001) is shown. The high speckle and low signal to noise ratio of this data leads to difficulties in accurate waterline determination

Model Data Assimilation

Increasing use of the above remote sensing techniques has caused a rapid shift in hydraulic modeling from a data-poor to a data-rich and spatially complex modeling environment with attendant possibilities for model testing and development. Despite an increase in computational power, the relative resolution of model and topography data has now reversed for most codes typically used to simulate flood inundation at the reach scale (see Bates and De Roo, 2000 for a review). A newly emergent research area is therefore how to integrate such massive data sets with lower resolution numerical inundation models, in an optimum manner that makes maximum use of the information content available. This is the direct opposite to the problem that most environmental modelers have traditionally faced (see Grayson and Blöschl, 2001 for a general discussion).

For example, Marks and Bates (2000) describe the integration of a LiDAR data set with a two-dimensional hydraulic model where the unstructured mesh discretization was derived independent of the topography. The topography was then assimilated into the model in an *a posteriori* step using weighted nearest neighbor interpolation to assign an elevation value to each computational node. This is typical of finite element mesh construction in many fields, but may not produce a mesh that captures those attributes of the original surface that are critical to the modeling problem in hand and may also lead to high data redundancy. To overcome these problems, Bates *et al.* (2003) describe a processing chain for high-resolution data assimilation into a lower resolution unstructured model grid. This consists of: (i) variogram analysis to determine significant topographic length scales in the data; (ii) identification of topographically significant points in this data set; (iii) incorporation of these points into an unstructured model grid that provides a quality solution for the relevant numerical solver; and (iv) uses the data left over from the mesh generation process to parameterize the Bates and Hervouet (1999) subgrid scale algorithm for dynamic wetting and drying. This method is demonstrated for the case of LiDAR topographic data but is general to any data type or model discretization. Cobby *et al.* (2003) take this process further and develop an automatic mesh generator that produces an unstructured grid, refined according to vegetation features (hedges, stands of trees etc.) on the floodplain (see Figure 16) identified automatically from LiDAR.

Similarly for friction parameters, Mason *et al.* (2003) use an area-weighing method to calculate area effective frictional resistance from the high-resolution height information contained in LiDAR data (see Figure 17). This method aims to yield model parameters that are appropriate to the particular discretization used, rather than being scale and discretization independent although this has yet to be fully tested.

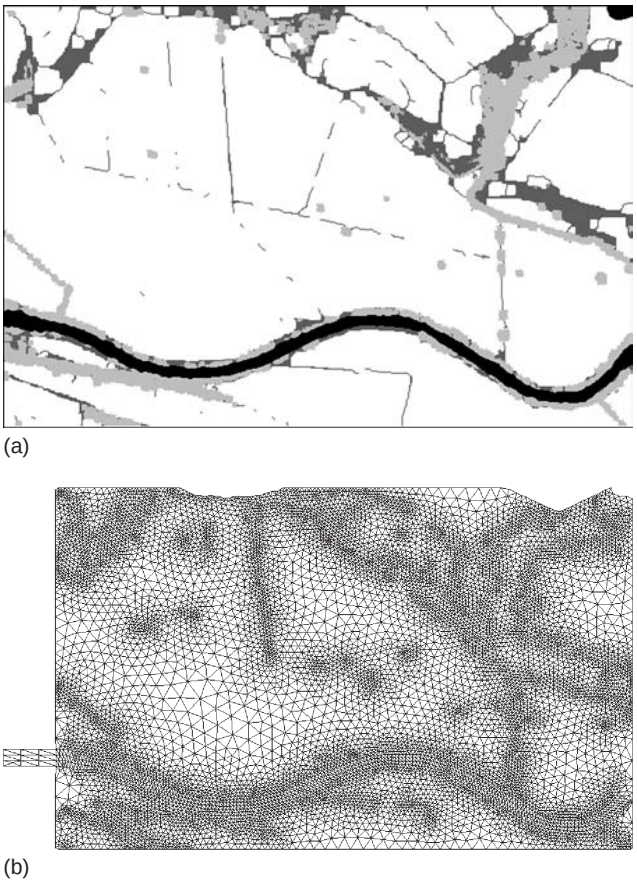

Figure 16 Results of the automatic unstructured two-dimensional mesh generator developed by Cobby *et al.* (2003). The software takes as input a LiDAR derived vegetation height map and produces an unstructured grid decomposed according to vegetation features (hedges, stands of trees, etc.) on the floodplain

UNCERTAINTIES IN FLOOD ROUTING AND INUNDATION PREDICTION

Flood inundation predictions used to aid design and planning decisions are typically derived from single realizations of numerical hydraulic models applied in a forward modeling framework (e.g. Anastasiadou-Partheniou and Samuels, 1998; Bates *et al.*, 1998). Rigorous calibration studies are undertaken to define a single parameter set that optimizes the model fit to some observed data. Typically, these data consist of flows or levels at a small set of discrete points, and only rarely are distributed flood extent data available that can be used to test the model over a wide area. If sufficient data (level or extent) are available, best practice is to undertake some form of split sample analysis, as advocated by Klemeš (1986) in the context of catchment hydrologic models, to test the validity of the optimized parameters for an independent set of observed data. The

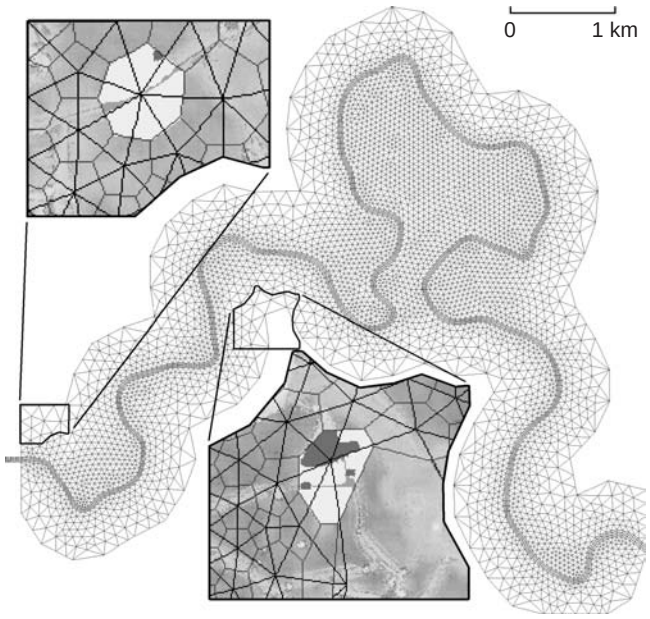

Figure 17 Assignment of an ''effective'' friction value for each element of a finite element mesh using the vegetation height data shown in Figure 14 and the friction mapping algorithm of Mason *et al.* (2003). For each mesh node, an instantaneous friction factor is calculated at each time step, given the frictional material in the neighborhood of the node and the current water depth and flow velocity there. A node's neighborhood is defined as a polygon whose vertices are the centroids of the elements surrounding the node. Subregions of connected regions in the vegetation height map are formed by intersecting the node polygon map with the vegetation height map. Each subregion in a polygon may contain either sediment or one of three vegetation height classes. If a subregion contains vegetation its region's average vegetation height is attributed to the subregion (after Mason *et al.*, 2003). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

success of this process requires that there is a single, well-defined optimum that can be identified by the calibration procedure and which is stationary between events. If this is not the case, a further period of calibration and testing is required, which at present is based on subjective intervention by a skilled operator (see the discussion in Werner, 2002). The identified single optimum is then used to predict flood extent and level for a design flood for which calibration and validation data are unlikely to be available. The result is a single deterministic prediction of flood extent for the design event, which is impossible to validate directly.

However, recent work using multiple simulations of different parameter sets (Romanowicz *et al.*, 1996; Romanowicz and Beven, 1998; Aronica *et al.*, 1998; Aronica *et al.*, 2002; and Romanowicz and Beven, 2003) has shown for a variety of flood prediction models that many combinations of model structure, input data, and parameters may fit sparse validation data equally well. This has been shown by modeling within a Monte Carlo framework, where an extensive sampling of the model parameter space reveals multiple acceptable (or "behavioral") solutions and even multiple discrete optima in different parts of the parameter space. By contrast, traditional calibration methodologies seek only a single optimum parameter set. Thus, when the parameter space is comprehensively searched, optima are unlikely to be well defined (e.g. Aronica *et al.*, 2002) and may occur at multiple points on the response surface (e.g. Horritt and Bates, 2001a).

Despite these difficulties, for any parameter identification problem, an optimum parameter set will exist. It may, however, be sensitive to errors in the input data and model definition and to the choice of performance measure used in the optimization. Monte Carlo simulation, whilst generally more computationally demanding, does allow the identification of multiple behavioral models with the advantage that using such multiple models in prediction allows a more meaningful estimation of the risk of flooding at any point on the floodplain during a future event. This is the basis for the Generalized Likelihood Uncertainty Estimation (GLUE) methodology originally developed by Beven and Binley (1992) and applied to the flood inundation problem by Romanowicz *et al.* (1996), Romanowicz and Beven (1998), Aronica *et al.* (2002), and Romanowicz and Beven (2003). In reality, the risk of flooding for a particular design event is better conceived as a "fuzzy" map in which there will be significant spatial structure. Hence, the uncertainty in flood risk at a given point on the floodplain can be thought of as the sum of input data uncertainty, model structural error, and parameterization uncertainty.

An example of this is provided by Aronica *et al.* (2002) who use the GLUE procedure to estimate the spatially distributed uncertainty in flood extent prediction, as a result of uncertainty over friction parameterization in the LISFLOOD-FP two-dimensional storage cell model. The binary pattern of wet/dry areas predicted for a 1 in 5-year flood event on a 3-km reach of the River Thames in the United Kingdom was compared to an observed inundation map obtained from a SAR image of the flood to yield a zero-dimensional global performance measure for each of 500 simulations in a Monte Carlo ensemble. To unearth the spatial uncertainty in model predictions for the particular flood being modeled, Aronica *et al.* (2002) took the flood state as predicted by the model for each pixel in each realization, and weighted it according to the measure of fit, $F^{\langle 2\rangle}$, between observed (A_{obs}) and modeled (A_{mod}) flooded areas:

$$F^{\langle 2\rangle} = \frac{A_{\text{obs}} \cap A_{\text{mod}}}{A_{\text{obs}} \cup A_{\text{mod}}} \tag{24}$$

for that simulation.

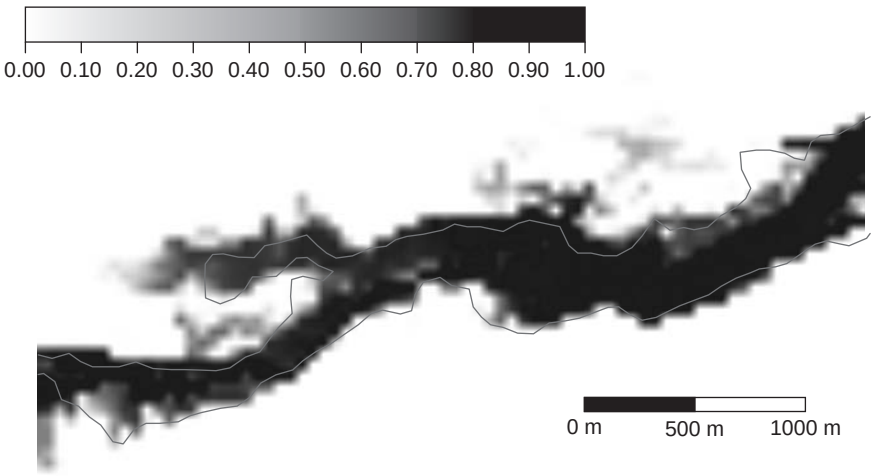

Figure 18 Probability map of predicted inundation P_i^{flood}, calculated using 500 realizations of the LISFLOOD-FP two-dimensional storage cell model for a 1 in 5-year recurrence interval event on a 3-km reach of the upper River Thames, UK. The observed shoreline derived from satellite SAR data is shown. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

This information could then be used to give a flood probability for each pixel i, P_i^{flood}.

$$P_i^{\text{flood}} = \frac{\sum_j f_{ij} F_j^{(2)}}{\sum_j F_j^{(2)}} \tag{25}$$

where f_{ij} takes a value of 1 for a flooded pixel and is zero otherwise and $F_j^{\langle 2\rangle}$ is the global performance measure for simulation j. P_i^{flood} will assume a value of 1 for pixels that are predicted as flooded in all simulations and 0 for pixels always predicted as dry. Model uncertainty (here defined by the interaction of the global performance measure and spatially distributed probabilities of the event being modeled) will manifest itself as a region of pixels with intermediate values, maximum uncertainty being indicated by pixels with $P_i^{\text{flood}} \approx 0.5$. The result is a distributed uncertainty measure P_i^{flood}, mapped over real space (see Figure 18). Such mapping can even be done in real time with updating of the probabilities using Bayes equation (Romanowicz and Beven, 1998). The advantage of the approach is that it both captures distributed uncertainty and contains information on global likelihood that can be used to condition predictions of further events for which observed data are not available. The method reveals the spatial structure in simulation uncertainty and simultaneously enables mapping of flood probability predicted by the model.

CONCLUSIONS

Standard methods of flood-routing and inundation extent modeling are currently undergoing critical re-evaluation and development as a result of the new opportunities afforded by remotely sensed data and the application of uncertainty analysis techniques in hydraulics. Future research in these areas is capable of yielding major improvements in our ability to parameterize and validate hydraulic models, and may lead to greater understanding of the dominant physical processes relevant to flood wave hydraulics at a variety of scales. However, uncertainty is unlikely to be eliminated and dealing with this challenge in a way that can be readily communicated to environmental managers and decision makers needs to be an integrated component of any hydraulic modeling study.

125: Rainfall-runoff Modeling for Flood Frequency Estimation

ROB LAMB

JBA Consulting – Engineers & Scientists, Skipton, North Yorkshire, UK

Rainfall-runoff models are amongst the most important tools for the practical solution of flood estimation problems, as well as for theoretical investigations of controls on the flood frequency curve or for analysis of catchment and climate change. This article aims to provide a discussion of the use of rainfall-runoff modeling for flood estimation, with an emphasis on overall methodology rather than on specific hydrological models. After a brief introduction to some basic concepts of flood analysis, the article describes the two main approaches for applying rainfall-runoff models in flood estimation, namely, event-based modeling and continuous simulation. The theoretical basis for each approach is described along with typical model structures. Topics covered include rainfall models, hydrological model calibration and the estimation of parameters for modeling at ungauged or data-poor sites. The article concentrates on the development of the continuous simulation method, and includes a number of illustrations of its application, both from research studies and applied hydrology.

INTRODUCTION

Rainfall-runoff models are used for flood frequency estimation to simulate storm events or continuous time series of runoff for which the probability of exceeding a given flow can be determined. Event-based procedures simulate flows for discrete "design" storms and are an established complement to statistical methods for flood frequency estimation. Continuous simulation has developed from process-based ideas about modeling, in which the runoff that produces flood flows is modeled, at least in principle, as part of a wider range of catchment responses. In this way, the approach may be distinguished from the statistical and design-event flood estimation methods where specific features of the catchment response (flood peaks and individual event hydrographs, respectively) are separated out as the objects to be modeled. Methods that seek to integrate rainfall-runoff modeling and statistical frequency analysis can also be referred to as "derived distribution" approaches.

This article considers flood estimation in non-urban settings, although many of the techniques reviewed have parallels in urban drainage modeling. It gives a brief overview of event-based hydrograph models, but does not seek to duplicate the many detailed descriptions available in standard textbooks and technical manuals (*see*, for example, Natural Environment Research Council, 1975; Institution of Engineers, 1987; Chow *et al.*, 1988; Beven, 2001). The article instead concentrates on the rapidly progressing continuous simulation approach. There are now a great number of (often very similar) hydrological models that could be described in this context. Rather than reproducing a long list of models, the aim here is to explore how rainfall-runoff modeling fits within a whole framework for flood estimation, which may also need to include rainfall and flow routing models. Before examining the development of rainfall-runoff models for flood estimation, it will be useful to survey very briefly some basic concepts and features of statistical methods used for flood frequency analysis.

CONCEPTS OF FLOOD FREQUENCY

Flood frequency estimation is concerned with the quantification of rarity. This can be expressed in terms of the probability of observing a flood of a given size at any given time. Consider a gauging site where there is a long, continuous record of flow data, Q. There will be some probability

$$p = \Pr(Q > Q') \tag{1}$$

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

of observing flows greater than a given value Q'. This "exceedance probability" is commonly expressed as a return period,

$$T = \frac{1}{p} \tag{2}$$

Generally the return period is the long-term average interval between flows greater than Q'. Often it is convenient to define the size of floods in terms of the largest flow recorded in any year, known as the *annual maximum or AMAX series*. In this case, the return period has the more specific interpretation of the long-term average interval between years containing a flood peak larger than Q' and p is the annual exceedance probability. An alternative is to define the series of flood peaks above a given threshold, where the threshold is set so as to include an average of, say, three peaks per year. This "Peaks-Over-Threshold" (POT) or "partial duration" series generally provides a larger sample size for a given record length.

The relationship between Q and T (or p) is referred to as the flood frequency curve. The current probability of exceeding a specified flow Q' could easily be determined with confidence if a river had been gauged over a very long period of stationary physical and climatic conditions, during which time the flow Q' had been observed many times. These conditions are not usually true in practice. For this reason, the exceedance probabilities associated with peak flows have to be estimated, especially for flows close to or greater than the maximum on record. All determinations of flood rarity are therefore estimates, and "flood frequency estimation" will be used here to refer both to estimates of the size of floods of a given rarity and to the estimation of rarity for specified flood flows.

STATISTICAL APPROACHES

Flood Frequency Distributions

River flows have long been measured and used by engineers in the design of hydraulic structures and for planning development in, or for management of, the floodplain. Flood frequency analysis has been the basis for engineering design and economic analysis, and methods have been developing since at least the early twentieth century (Benson, 1968). The usual approach has been to regard the size of floods in a catchment, when arranged as a series of independent peak flows, as a sample drawn from some underlying parent distribution. Many statistical distributions have been used at different times (see, for example, Bobée and Rasmussen, 1995, Clarke, 1994; Institute of Hydrology, 1999; Reimann, 1989).

In flood frequency analysis, measured peak flows can be used to estimate the form and parameters of the parent distribution. Once the parent distribution is established in this way, it can be used as a basis for extrapolation to estimate flood quantiles for very rare conditions, especially peak flows whose return period is much longer than the period of recorded flows. Typically, this is done under an assumption that the flood-producing regime of the catchment does not change greatly over time (the flood "regime" includes here both runoff production mechanisms and the driving climatic patterns). However, the stationarity condition can be relaxed. For example, Clarke (2003) has incorporated trend into estimates of the probability of future extreme events on both annual maximum and POT scales, while Cunderlik and Burn (2003) show that even weakly significant trends may "seriously bias" flood estimates. This could be a problem in practice even over a relatively short design life of 10 or 20 years. Whilst the statistical tools exist to fit probability distributions in the presence of trend, there has often been considerable uncertainty over the exact parameterization, future persistence and even the existence of such trends (whether they are associated with changes in climate or catchment land use). Useful surveys of the issues have been provided by Robson and Kundzewicz (2000) and Kundzewicz (2004, and papers cited therein).

Sophisticated methods are available for fitting the distribution for a flood series. The conventional methods are maximum likelihood and equating moments of the theoretical distribution with sample moments calculated from flow data. More recently, Probability Weighted Moments or PWMs (Davison and Smith, 1990; Wang, 1991) and robust linear combinations of PWMs called *L moments* (Hosking, 1990) have been widely used. The factors that limit the presumed accuracy of a flood estimate are fundamentally the quality and amount of measured data, the suitability of the chosen distribution and the degree to which the statistical assumptions are met, including the robustness of the distribution over different flow ranges and over time. The simplest case is where a "single-site" distribution is fitted to flow data from a gauged location. Consistent, high-quality flow series rarely span more than 50 years or so in most parts of the world. Typical flow records therefore do not provide large samples of peak data and the uncertainty in a single-site distribution can be large, particularly when the distribution is extrapolated to estimate floods typically adopted for "design", say, of $T \sim 100$ years.

One response to this problem of record length is to add information from other locations to increase the effective sample size. This technique relies on assuming that data from sites within a geographical region, or from catchments of similar physical and climatic characteristics, can be combined to fit a distribution curve typical of those catchments. It is usually necessary to separate the scale and the shape of the frequency curve, where the scale is based on a single-site estimate of

an index flood of short return period, say the mean or median annual maximum flow, whilst the shape of the frequency curve is based on a dimensionless regional growth curve. A T-year flood estimate is then obtained as the product of the local index flood and the regional growth curve.

Combining data within fixed geographical regions is referred to as "regionalization". In some cases, the regionalization has been based on convenient administrative units, such as the boundaries of hydrological authorities (Natural Environment Research Council, 1975). A more recent development is to move away from using fixed geographical regions and instead, for any subject site, to pool peak flow data from a group of catchments that are similar in terms of hydrologically significant characteristics rather than geographical proximity (Acreman and Wiltshire, 1989; Burn, 1990). As with the fixed regionalization approach, the "pooling group" must contain catchments in which the flood regime is homogeneous. Pooling has become the recommended technique for flood estimation in the United Kingdom (Institute of Hydrology, 1999). Heterogeneity caused by particular features (such as engineered storage or differences in seasonality, for example) would reduce confidence in the pooled flood analysis, but the catchments forming a pooling group can be scrutinized to exclude these effects.

Ungauged Sites

One of the most important and challenging problems in flood frequency analysis is estimation at ungauged sites, where there are no data available for fitting a local model directly. This statement applies equally to statistical and other flood estimation methods (and, indeed, to models used for other hydrological purposes, *see* **Chapter 133, Rainfall-runoff Modeling of Ungauged Catchments, Volume 3**). In statistical flood estimation, a regionalized or pooled growth curve can be applied for an ungauged or data-poor subject site in much the same way as for a gauged site, based on physical similarity. However, the index flood obviously cannot be determined from flow data at an ungauged site, and so has to be estimated in a different way. This may be done using a regression model that relates values of the index flood at gauged sites to catchment properties, or by a nearest-neighbor approach, in which the index flood is computed as a weighted average from gauged sites most similar to the subject site.

Statistical methods for flood frequency analysis are very powerful tools, and are widely used and accepted in practice. Advantages include the direct empirical support through the gauged data, the ability to incorporate data from many locations, the relative ease of calculation and the appealing theoretical basis for representing floods using extreme value distributions. There are some limitations, however. Uncertainty arising from limited sample size remains, albeit moderated by the use of regionalized or pooling methods. Perhaps more limiting is the treatment of "floods" as discrete, independent observations of a stochastic process. Although it is possible to relax these assumptions, for example, by building distributional models that include autocorrelation and trend, the result is more difficult to work with than the conventional statistical methods.

Despite their empirical basis, it would be far from true to assert that statistical methods take no account of hydrological realities. Many studies using flood frequency distributions have been informed by knowledge of the catchment situation; for example, the analysis of multicomponent distributions that reflect different types of flood (e.g. Connell and Pearson, 2001; Rossi *et al.*, 1984; Waylen and Woo, 1982). Indeed, at a practical level, when deriving a flood frequency curve, the experienced analyst will make a careful study of the quality of any available local data. Often, this will include scrutiny of rating curves, which may reflect hydraulic characteristics such as transitions between channel and floodplain flows that can, in turn, affect the shape of the flood frequency curve (Naden, 1992a). However, statistical approaches to flood estimation are not structured in a way that corresponds in any detail to hydrologists' understanding of the processes that generate flood flows.

Statistical approaches become more difficult to apply where flood generation includes storage or threshold effects, or where the concept of flood frequency is really being used as a way of determining the hydrological conditions associated with a specified level of risk that results from a combination of factors. In many practical situations, it is necessary to model the response of a complex system to the prescribed risk, for example, in designing flood management schemes or for the purposes of planning where there are pressures to build or otherwise use the floodplain for development. Often, the flood response will be influenced by natural or engineered storage, such as floodplain inundation, storage behind raised embankments or in artificial retention ponds. In these cases, the volume of water and its timing may be as important as the peak flow.

EVENT-BASED RAINFALL-RUNOFF METHODS

Unit Hydrograph

To provide flood estimates in cases where dynamic processes are important, a point estimate of peak flows is unlikely to provide a realistic basis for analysis and a hydrograph is needed. A typical approach to this problem has

been to simulate "design" flood events using a rainfall-runoff model. Event models have evolved from the unit hydrograph theory of Sherman, 1932 (*see* Dooge, 2003, for a detailed discussion). The unit hydrograph (UH) is an empirical model that specifies the delays and attenuation of runoff in response to a given rainfall input. The model is linear so that the response to a rainfall input of N units is held to be N times larger than the response to a single unit input. The form of the unit response is also generally assumed to remain fixed over time. Consequently, the responses to successive unit inputs can be added together to provide a total response.

It has not always been considered necessary to specify a "hydrograph-shaped" UH; standard engineering applications often make use of a triangular approximation to simplify the calculations (e.g. Institute of Hydrology, 1999). The three principles of linearity, time invariance and superposition are illustrated in Figure 1. The linearity assumption is known to be physically only an approximation, both for flow routing (where the flood wave velocity changes with discharge for several reasons, *see* **Chapter 124, Flood Routing and Inundation Prediction, Volume 3**) and, in particular, for runoff production, which will be discussed further below. However, it has proven to be a useful approximation, given other sources of error in estimating flood magnitudes, especially where calibrated, using data from reasonably large flood events (return periods of ∼10 years or more), on catchments large enough for some averaging of runoff responses to take place (typically ∼10 to ∼100 km^2) and not too large for the distribution of rainfall to be significant. The UH model has therefore been successful enough to continue in routine engineering use around the world up to the present day (*see also* the general discussion of transfer function modeling techniques in **Chapter 128, Rainfall-runoff modeling: Transfer Function Models, Volume 3**).

Calculating Losses in Event Models

The accumulated response of runoff to rainfall is highly nonlinear because of the influence of soil moisture storage (*see* **Chapter 66, Soil Water Flow at Different Spatial Scales, Volume 2**– **Chapter 79, Assessing Uncertainty Propagation Through Physically based Models of Soil Water Flow and Solute Transport, Volume 2**), which may cause a transient "loss" of rainfall within the event timescale, and losses to groundwater (*see* **Chapter 145, Groundwater as an Element in the Hydrological Cycle, Volume 4** and **Chapter 150, Unsaturated Zone Flow Processes, Volume 4**) and evaporation (*see* **Chapter 41, Evaporation Modeling: Potential, Volume 1** and **Chapter 42, Transpiration, Volume 1**). The input to the UH response function should not be the total rain falling on the catchment, but instead some effective

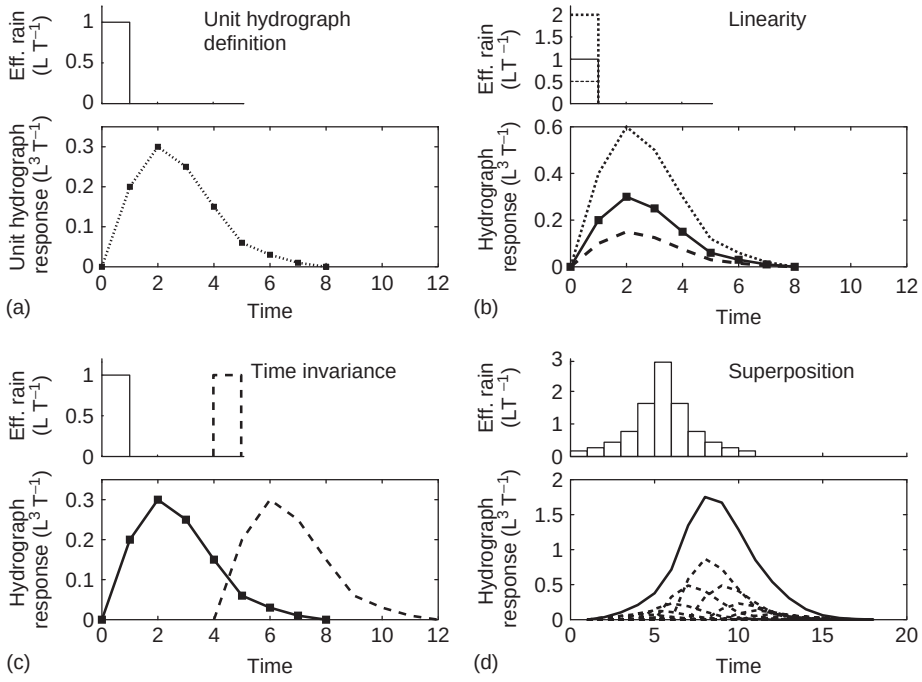

Figure 1 Principles of unit hydrograph theory: (a) definition of a triangular unit response as used in UK flood studies; (b) principle of linearity; (c) time invariance of the unit response; and (d) superposition, allowing the convolution of a storm rainfall profile with the unit hydrograph (Reproduced from Institute of Hydrology, 1999 by permission of Centre for Ecology and Hydrology (CEH))

rainfall that accounts for these losses. The UH is therefore generally coupled with a losses model to provide some variation in runoff rates as a function of an assumed antecedent catchment soil moisture status and of evaporation losses.

There are many possible forms for the losses model. Some seek to represent process understanding of the physics of interception, infiltration, and evaporation processes. Others are conceptual in nature, mixing parameters that have a physical basis (such as a hydraulic conductivity) with empirical ones (such as storage coefficients). Simple empirical methods are usually applied to represent losses in event-based models (which are anyway most often applied in situations where detailed physical modeling would be impractical because of lack of data). One such empirical method is the model of the USDA Soil Conservation Service (1985). This method calculates direct storm runoff

$$Q = \frac{(P - S_1)^2}{(P - S_1 + S_2)} \approx \frac{(P - 0.2S_2)^2}{(P + 0.8S_2)} \tag{3}$$

as a function of rainfall P, an initial rainfall loss S_1 occurring before the onset of runoff, and a maximum potential loss S_2. When the method was developed, losses were assessed by a graphical comparison of measured rainfall and runoff volumes, and interpreted as comprising interception, depression storage, an initial volume of infiltration and the volume of infiltration after runoff commenced. The great utility of the method is that S can be estimated from soil and land cover data, on the basis of relationships that were established from analysis of hydrographs for agricultural plots and small catchments in the Midwestern USA. The parameter S, originally defined in inches, is more commonly transformed into the curve number, $CN = 10\,000/(S + 10)$, to provide a more convenient scale. Whilst this general model derives from a consideration of basin water balance, it is entirely empirical in its application and not necessarily appropriate beyond the region in which it was calibrated.

In the United Kingdom, an alternative approach was developed as part of the Flood Studies Report (FSR, Natural Environment Research Council, 1975), again based on empirical analysis of recorded events. The FSR uses the concept of "percentage runoff" (*PR*) to represent losses as a combination of a standard percentage runoff parameter, *SPR* (which is treated as a fixed property of the catchment) and a "dynamic" modification to this that depends on an index of catchment wetness and on storm rainfall depth. In fact, the modification is only "dynamic" in the sense that it attempts to account for differences in *PR* between different storms; the *PR* is then applied as a constant proportional loss rate throughout the duration of the rainfall event.

The FSR percentage runoff model is

$$PR = SPR + DPR_{\mathrm{CWI}} + DPR_{\mathrm{RAIN}} \tag{4}$$

where DPR_{CWI} represents the contribution of antecedent catchment wetness, expressed as a catchment wetness index (CWI) and DPR_{RAIN} is a function of storm depth (and is zero for storms of less than a threshold depth). This approach was formulated with the explicit intention of providing a means of simulating individual runoff events, and DPR_{CWI} can be estimated from antecedent rainfall and soil moisture deficits. In the more common case where a hydrograph has to be produced for a statistically derived design rainfall, often at an ungauged location, then CWI and its associated *PR* contribution are estimated from an empirical function of long-term average rainfall. Like the curve number method, the parameters of the losses model are based on empirical relationships with catchment characteristics.

Design Inputs

Event-based procedures conform to the basic generic structure of any conceptual rainfall-runoff model, combining loss and attenuation modules. Typically, variables such as the shape and time-to-peak of the hydrograph and the runoff coefficient tend to be parameterized empirically (i.e. they are calibrated from analysis of gauged events). The event-based method makes good use of rainfall data, which itself brings potential advantages in regions where the rain gauge network is more extensive than the flow gauge network, or where longer records exist for precipitation.

For flood frequency estimation, a statistical rainfall model is used to estimate the storm that would cause a flood hydrograph of a given probability to occur. However, by making the flood-producing rainfall a probabilistic element, a link has to be made to the probability of the resulting flood. From a process point of view, this can become a complicated issue because the relationship between rainfall and flood probability must account for the dynamics of catchment storage (both within and between events). These are controlled by precipitation history, soils and topography, evaporation and other processes. Even in a relatively straightforward catchment not influenced by snowmelt, groundwater, or tidal boundary conditions, a complete event model would ideally account for the joint probability distributions of rainfall intensity, storm duration, storm profile, antecedent soil moisture conditions and evaporation losses (both being functions of past rainfall). Additionally, the model would have to represent the transformation of the joint inputs to produce a flood hydrograph, including rapid storm runoff and more slowly responding "baseflow" components.

The joint controls on the flood probability have generally been resolved by the specification of "design packages" of inputs that combine to generate flood events of specified probability, rather than attempting to resolve the joint probability issues explicitly. In the FSR, for example, a Monte Carlo analysis was undertaken to simulate the

outputs of many different combinations of design inputs to the UH model. The Monte Carlo simulation (MCS) allowed a link to be established between the probability of the rainfall event used as input to the UH model and the desired flood probability.

The four design variables that form the inputs to the FSR event model are rainfall duration, rainfall depth (or return period), design storm profile and antecedent CWI. MCS on 98 catchments demonstrated that the simple event model structure could reproduce the probability distributions derived from gauged annual maximum series. There followed a set of experiments in which three of the four input variables were fixed and the remaining variable optimized to agree with the flood magnitudes simulated by the Monte Carlo method. It was found that the flood magnitude was most sensitive to rainfall depth and antecedent wetness. For ungauged sites, the parameters that define the simplified triangular UH were related empirically to catchment characteristics and to the duration of the design rainstorm.

When antecedent wetness was also fixed, a relationship between the return periods of the storm depth and the resultant flood was established, and found to be "similar between catchments" (Natural Environment Research Council, 1975, p. 455). The relationship is shown in Figure 2. This analysis was a considerable achievement in that it provided users of the method with workable, scientifically based rules to apply the event rainfall-runoff model in practice. It is also, in effect, a form of calibration used to circumvent the joint probability issues in modeling. Because the method relies on this calibration, updating its component modules can affect its performance, as discussed by Ashfaq and Webster (2002). A more explicit solution of the joint probability issues has been demonstrated (Rahman *et al.*, 2002) for the Design Event Approach used in Australia (Institution of Engineers, 1987).

DERIVED DISTRIBUTIONS AS A GENERALIZATION OF RAINFALL-RUNOFF MODELING

Event-based methods provided a practical engineering solution for flood estimation based on statistical and theoretical approaches established, for the most part, in the early part of the twentieth century. Meanwhile, opportunities to advance the underlying theoretical approaches were also being investigated. In an important paper, Eagleson (1972) introduced the concept of derived flood distributions. The derived distribution approach was a step towards a flood frequency methodology that would combine a treatment of the dependence between causative factors with a conceptual model more closely linked to physical process. The three main steps in building a more "physically based" model of flood frequency were:

- a model of the rainfall process (or gauged rainfall data),
- a model for runoff production and routing,
- a method to combine the component models to derive the flood frequency distribution.

The basis of the methodology was to combine statistical distributions for effective rainfall with a kinematic wave model of runoff propagation. An important feature of the methodology was that it integrated analytically the probabilities governing rainfall with the runoff production functions in an attempt to derive a theory of flood frequency related to physical catchment parameters.

The intensity of rainfall excess after losses, i_e, and the duration of the rainfall excess, t_e, were assumed to be independent random variables described by the exponential joint probability density function

$$f(i_e, t_e) = \frac{b\lambda}{\kappa} e^{-(bi_e/\kappa + \lambda t_e)} \tag{5}$$

In developing equation (5), Eagleson made the simplifying assumption that storm rainfall is effective over a fixed proportion of the catchment area A_r that is assumed to generate direct runoff. The partial area A_r was assumed to be determined solely by physical characteristics of the catchment and the long-term climate (although, in reality, it would be expected to vary as a function of soil moisture changes between and during rainfall events). The treatment of rainfall excess also assumed a constant (in time) and uniform (in space) loss rate.

Both overland and channel flow were represented using the kinematic wave model on an idealized catchment consisting of two symmetrical overland flow planes draining into a linear stream channel. From a hydrological

and hydraulic point of view, the kinematic wave model is a highly simplified representation of the movement of water. However, it provides an acceptably accurate description over a range of typical physical conditions for overland and channel flow (Singh, 2002). The kinematic wave can be derived from the full 1-D Saint-Venant equations for open channel flow (*see* **Chapter 135, Open Channel Flow – Introduction, Volume 4**, **Chapter 136, Hydrodynamic Considerations, Volume 4**) and its parameters therefore have a physical interpretation.

If the discharge anywhere on a one-dimensional channel or overland flow "plane" of unit width is q and the depth of flow is y then the continuity equation can be written

$$\frac{\partial y}{\partial t} + \frac{\partial q}{\partial x} = i \tag{6}$$

where x is distance in the downslope or downstream direction, t is time and i is a rate of inflow. In the derived flood frequency analysis, the inflow for the overland flow (q_o) on each slope was rainfall excess i_e over duration t_e. For flow in the stream channel, the inflow was taken to be $2q_o$. Equation (6) can be rewritten as

$$\frac{\partial q}{\partial t} + c\frac{\partial q}{\partial x} = ic \tag{7}$$

where the wave celerity

$$c = \frac{\partial q}{\partial y} \tag{8}$$

is the speed with which a disturbance will propagate in the downslope or downstream direction. The total differential $\mathrm{d}x = c \cdot \mathrm{d}t$ describes the passage of a disturbance or wave at any location. Eagleson (1972) used the kinematic wave model formed by combining equation (7) with a flow law of the generic form

$$q = \alpha y^m \tag{9}$$

where the resistance parameter α can be related to the surface slope angle for overland flow or the channel slope for stream flow. For overland flow, the chosen parameterization was $m = 2$. For flow in the stream channel, $m = 3/2$ was chosen, which allows equation (9) to be interpreted as the Chezy equation for flow resistance. Equations (7) and (9) can be solved for constant and uniform inputs by integrating along the characteristic curves in the (x, t) plane defined by

$$\frac{\mathrm{d}y}{\mathrm{d}t} = i \tag{10}$$

for constant x and

$$\frac{\mathrm{d}x}{\mathrm{d}t} = c = m\alpha\ y^{m-1} \tag{11}$$

for characteristics of constant y. In carrying out the integration, three dominant event scenarios can be defined in terms of the duration of rainfall excess relative to the times of concentration of the catchment or hillslope, as follows:

- the duration of rainfall excess is greater than the catchment time of concentration,
- the duration of rainfall excess is less than the catchment time of concentration but greater than the time of concentration of overland flow, and
- the duration of rainfall excess is less than the time of concentration of overland flow.

Each of these scenarios leads to an expression for the maximum peak flow rate $Q_{\max}$ of the general form

$$Q_{\max} = g(i_e, t_e, \boldsymbol{\theta}) \tag{12}$$

where $Q_{\max}$ is a function of given values of the random variables for rainfall excess (intensity, i_e, and duration, t_e) and the set of fixed catchment parameters $\boldsymbol{\theta}$ (which includes the parameters for flow resistance and the proportion of the catchment assumed to generate direct storm runoff).

Equation (12) describes a curve on a graph of i_e against t_e beneath which the peak of a hydrograph will be less than the maximum possible value. The principle of the analytical derived distribution approach was then to integrate the joint probability distribution for the rainfall excess (equation (5)) over the region within which $Q < Q_{\max}$, that is, the region bounded above by the function g. This integration results in the derived flood frequency distribution

$$\begin{aligned} F'(Q_{\max}) &= \Pr(Q \le Q_{\max}) \\ &= \iint_{Q<Q_{\max}} f(i_e, t_e)\,\mathrm{d}i_e\,\mathrm{d}t_e \\ &= 1 - \Pr(Q > Q_{\max}) \end{aligned} \tag{13}$$

which may be compared with the general form in equation (1). Eagleson (1972) also added an annual average baseflow contribution (which does not alter the probability integration described above) to derive the flood frequency distribution in terms of total peak flows.

The derived distribution theory was shown to be reasonably successful in reproducing the frequency distributions of three river basins in Connecticut. The theory also attempted to relate flood frequency to the underlying mechanics of runoff production. However, the assumptions needed to derive the flood frequency distribution analytically may be considered to exclude some physical processes known to occur in reality. Two of the most conspicuous examples of this are the assumption of independence between the duration and mean intensity of rainfall excess and the fixed partial area for runoff production.

A number of authors have also developed derived flood frequency distributions using geomorphological unit hydrograph (GUH) theory (Rodriguez-Iturbe and Valdes, 1979; Rodriguez-Iturbe *et al.*, 1982; Rodriguez-Iturbe, 1993) as a flood routing mechanism with a link to physical basin parameters. Whilst the GUH is a concise way of building basin characteristics into a conceptual routing model, it also requires a method to estimate the actual depth or rates of runoff to be routed. Hebson and Wood (1982) applied the GUH with a fixed partial area mechanism for runoff production. Cordova and Rodriguez-Iturbe (1983) combined the GUH with a calculation of runoff production based on Soil Conservation Service Curve Numbers. Working with a triangular UH shape and initially assuming constant intensity of rainfall within a storm of duration t_r, Cordova and Rodriguez-Iturbe derived an expression for the peak of the response hydrograph Q' as

$$Q' = 2.42\frac{R_P A}{\pi}\left(1 - 0.218\frac{t_r}{\pi}\right) \qquad (14)$$

where A is the catchment area, R_p is the direct runoff depth generated by a rainfall depth P, as computed using the appropriate SCS curve for the catchment and π is a geomorphic parameter incorporating information derived from the geometry of catchment drainage network, but also dependent nonlinearly on R_p and t_r. Annual maximum rainfall depths were extracted from gauged records for a range of durations. By applying equation (14), a corresponding series of flood peaks were obtained for the different durations, and the largest value for each year was chosen as the annual maximum flood peak for that year. An extreme value distribution was then fitted to this synthetic series of annual maximum flood peaks. Wood and Hebson (1986) adopted similar methods, but specified the probability distribution for the rainfall excess used to generate runoff, rather than using gauged records.

The derived distribution theories cited above made an explicit link between flood frequency and physical basin parameters. This link was based not on empirical considerations, but on conceptual representations of the catchment processes. However, the representations had to be simple ones (at least compared to contemporary knowledge of physical processes) to allow exact solutions to be found for the derived flood frequency distributions. To obtain solutions in a convenient form necessarily places limits on the processes that can be represented within the model, in terms of both inputs and runoff production/routing. In particular, it is difficult to account analytically for different sequences of inputs occurring over different timescales. As noted by Beven (1986), the derived distribution models were, out of necessity, not "satisfactory descriptions of the runoff production process at the basin scale".

A solution to this problem would be to model the catchment inputs and outputs explicitly, requiring a stochastic approach to the modeling of precipitation (effectively generating a synthetic record of inputs) and a runoff model capable of transforming the input series into flood hydrographs. It would then be possible to generate relatively long sequences of inputs and use the catchment runoff model to keep track of the evolution of soil moisture, groundwater, or channel storage. Hence, the approach would be one of continuous simulation of streamflow responses.

CONTINUOUS SIMULATION METHODS

Although computer simulation models of catchment hydrology had been available since at least 1960, by the end of the 1970s, models of catchment runoff, along with processing and data storage capabilities, had advanced to the stage where it would become feasible to link them with stochastically generated input data. Free of the need to derive analytical solutions, the dynamics of catchment storage and threshold effects could be represented with greater flexibility, as could spatial variation in runoff responses. The three elements of the continuous simulation method are:

- a series of climatological inputs, derived either from observed data or using a stochastic or process model,
- a model of the catchment processes to be simulated,
- the extraction from the simulated data of important features of the flood response.

It will be seen that the three elements are similar to those of a "physically based" derived distribution approach to flood frequency. The main difference is that the elements need not be combined analytically to derive a flood frequency distribution. The end product is a time series of flow data, from which it is easy to extract different features of interest, including peak flows, volumes above a threshold and measures of flow duration. Potentially, any rainfall-runoff model could be used, ranging from a detailed, distributed physically based model to a black-box transfer function approach. At the center of most developments of continuous simulation are models of catchment hydrology that incorporate some structural knowledge or theory to describe the dynamics of runoff production, but that are simple enough to be computationally efficient.

One of the motivations for continuous simulation, as noted by Bras *et al.* (1985), is that rainfall data can often provide more information than streamflow data, at least in the sense that rain gauge networks may be denser, more extensive and longer established. Data are also required for the calculation of potential evaporation, and would obviously be needed to support snow accumulation and melt models in some regions. The cumulative effect of evaporative forcing may affect the flood regime in some catchments by controlling soil moisture deficits (and, in greater physical detail, aspects of vegetation cover and soil structure).

Evaporation must therefore be an important part of the continuous simulation approach, and compared to current process understanding, a simple uniform loss rate would seem to be too simple a model (*see* **Chapter 40, Evaporation Measurement, Volume 1**– **Chapter 45, Actual Evaporation, Volume 1**). However, it will generally be the case on an event-by-event basis that rainfall inputs dominate the hydrological response. Indeed, it has been found (Calder *et al.*, 1983; Fowler, 2002) that relatively simple representations of evaporation are often good enough for stream flow modeling.

Rainfall inputs are clearly of paramount importance. In some cases, there may be an interest in simulating flows directly from gauged rainfall records where there are limited flow records (but good rainfall data) to fit a frequency distribution; an early example using the Stanford Watershed Model (Crawford and Linsley, 1966) was reported by James (1965).

Often, however, rainfall records will be too short to drive the length of simulation that would be needed to sample floods of "design" magnitude. Whilst continuous simulation would still provide a means of estimating the whole flood hydrograph without needing to invoke baseflow separation or design package assumptions, there would be some justification for arguing that a better estimate of flood magnitudes could be obtained by making use of pooled statistical analysis. To overcome the limitations of gauged records, modeled rainfall can be used as the driving input for continuous simulation. In this way, a long artificial streamflow series can be generated, including floods of a magnitude that may not have been observed in the shorter, gauged record. As with event-based flood analysis, the use of a rainfall model (albeit of a different kind this time) provides a way of exploiting the information on extremes contained in the rainfall records.

RAINFALL MODELS FOR FLOOD FREQUENCY ESTIMATION BY CONTINUOUS SIMULATION

It is not the purpose of this article to offer an in-depth survey on rainfall modeling, but it is worth summarizing a few approaches that have been found suitable for use in continuous simulation for flood frequency. Cox and Isham (1994) identified three main approaches to rainfall modeling: purely empirical statistical models, dynamic meteorological models and intermediate stochastic models that have a structure based conceptually on physical phenomena. There is also a class of models based on fractal representations of rainfall (Lovejoy and Schertzer, 1985; Puente, 1996). The suitability of a model will depend on the space and timescales that are important for the particular application. For example, Acreman (1990) noted that Markov chain models that predict rainfall depths conditional on past rainfall can present a large number of parameters to be estimated when applied at relatively fine timescales (for instance, the hourly or subhourly scales often needed to resolve flood flows), where dependence can extend over many time steps. For catchments of area $\sim$10 to $\sim$1000 km^2, the chosen rainfall model may need to reproduce short bursts of high rainfall intensity embedded within medium-term and seasonal accumulations that set the antecedent conditions for runoff generation.

Point Rainfall Models

For a catchment that is small enough (relative to the dominant spatial structures in rainfall), rainfall can be considered as an areally averaged quantity. A one-dimensional, "point" model can then be used. Typically, such models simulate storms and dry periods separately to build up a continuous sequence of rainfall depths. In the simplest cases, storm intensities, durations, and interarrival times are simulated from prescribed distributions, and a typical profile is adopted for each storm event.

The approach requires suitable profiles to be generated for each storm, and also that storms can be generated that reflect the mixture of rainfall types encountered over a catchment. In this respect, it is useful to specify separate distributions for storms of "low" and "high" intensity, conceptually representing a distinction between steady, frontal rainfall, and intense convective storms (e.g. Cameron *et al.*, 2001). Further generalizations can be made, such as accounting for dependence between storm mean intensity and duration using a suite of duration classes, each with its own distributions of intensity. Seasonality can be incorporated by separate parameterization for different parts of the year, and different profile mechanisms can be used for storms of different intensity.

An alternative structure for stochastic rainfall models is based on simulation of pulses of rainfall. In this structure, rainstorm exteriors are modeled in terms of durations and arrival times, but each exterior contains individual rain cells, comprising pulses of individual intensity and duration. The total rainfall intensity at any time is the sum of the intensities of the active pulses. Two popular stochastic pulse mechanisms are the Neyman-Scott and Bartlett-Lewis models. These differ in the temporal pattern of rain cell arrival and survival, but in practice generate similar results.

The contrasting model types have been investigated by Cameron *et al.* (2000a) who compared a modified version of the exponential point model originally proposed by Eagleson (1972), a semiempirical profile-based model developed by Cameron *et al.* (1999) and the random-pulse Bartlett-Lewis gamma model of Onof and Wheater (1994). The three models were fitted to point data from three contrasting raingauge sites in the United Kingdom.

The exponential storm model was found to be too simple to represent features of the gauged records at a range of timescales. The model developed by Cameron *et al.*

(1999) performed well, benefiting from using empirical cumulative distributions for storm arrival times, durations, and intensities. Storm profiles were based on sampling a "library" of observed profiles. For data-rich situations, such as the test sites adopted, the empirical distributions would be expected to perform well, as was confirmed. A potential problem with all such empirical distribution models is extrapolation beyond data contained in the gauged record. This problem was addressed by Cameron *et al.* (1999) by use of a theoretical extension for the upper tails. However, the model was limited where storms were generated of durations or intensities for which there was only a limited sample of profile shapes available. Nonetheless, the rainfall model was thought to be suitable as an input for continuous runoff simulation.

The rectangular pulses Bartlett-Lewis model was found to work well, apart from its simulation of short-duration extreme rainfalls. Cameron *et al.* (2000a) attributed this to limitations of the gamma distribution, fitted on a seasonal or annual basis, to model pulse intensities. A suggested solution was to separate rain cells into "frontal" and "convective" intensity types. Hashemi *et al.* (2000) have demonstrated good performance for a Neyman-Scott pulse model structured in this way. In effect, the comparisons made in the United Kingdom, for rainfall stations featuring combinations of stratiform and convective rainfall, seem to indicate that either the storm-profile or rectangular-pulse algorithms may be suitable point models for generating continuous simulation inputs. Cowperthwaite *et al.* (1996) have reported a generalized parameterization of a point model, allowing regional application.

Spatial and Cluster Models

Structures in rainfall are also reflected in spatial patterns. In a recent review of progress in fluvial flood modeling, Wheater (2002) concluded that "the spatial and temporal variability of rainfall can be extremely important in influencing flood hydrograph shape and volume, but that the importance will vary greatly as a function of catchment and rainfall properties". As contrasting examples, this review cited Naden (1992b), who found that rainfall variability was smoothed out and had little influence on the flood responses in the largely permeable Thames catchment in southern England, whereas Michaud and Sorooshian (1994) had shown that a high spatial resolution (2 km) was needed to simulate flood peaks caused by convective rainfall in an arid environment in the southwest United States. Modeling studies, such as those of Ngirane-Katashaya and Wheater (1985) and Watts and Calver (1991) have shown the potential importance of storm velocities in determining flood magnitudes.

Wheater *et al.* (2000) have summarized key aspects of spatially structured stochastic rainfall models. One such model, by Cox and Isham (1988), features a hierarchical structure in which the highest-level objects are rainfall fields that are modeled as a temporal stochastic process, within which storms are modeled as a spatial process. The lowest level objects are rain cells, which are generated within each storm and may be clustered in space. Objects at all three levels may be assigned velocities. Clusters can be generated by creating cells as a temporal Poisson process from an origin, with the process ending after some time according to a prescribed distribution. Northrop (1997) has further generalized this approach to add more realistic spatial structure in which the origin of each storm cell has an additional spatial displacement.

Spatial-temporal models of this type are complex and require some ingenuity in order to fit the parameters. The ideal situation would be to make use of radar rainfall fields for model fitting; notwithstanding issues of radar calibration, such data offer a reasonable approximation to the continuous space-time fields that are represented in the model and thus allow derivation of the required statistical parameters. The data processing implications are substantial. If spatial-temporal rainfall models are to be applied successfully in driving rainfall-runoff models for flood simulation, there may be situations where rain gauge data have to be relied upon for parameterization. (Arguably, rain gauge data should in any case be incorporated in model fitting and testing, as these are a direct measurement of precipitation reaching the ground, unlike radar fields.)

A different approach designed to represent the movement of storm fronts over a catchment is the Modified Turning Band (MTB) method of Mellor (1996). This approach models the rainfall process with a layered structure. The first layer generates sets of intersecting parabolic prisms that move in the spatial plane and define a basic structure underlying a potential field for raincell generation. The second layer adds a modulating function that travels in the direction of the rainstorm and is used to represent the storm extent, as well as generating rainfall banding within the moving storm. Individual raincells are then generated as a Poisson process with occurrences according to the potential field derived from the larger scale layers. Mellor *et al.* (2000a) report that the method represents rainfall fields that display features observed in radar data, including raincells, cluster regions, and rain bands.

In an important application, Mellor *et al.* (2000b) have also shown how the MTB spatial rainfall model, calibrated on radar rainfall data, can be used to drive ensemble simulations of flood hydrographs. The authors made use of two rainfall-runoff models, the first being a detailed distributed process-based model (SHETRAN) and the second being the ARNO conceptual model, which handles runoff production in a way that is similar to the "semidistributed" approach taken in the Probability Distributed Model (PDM) (*see* the text below). The ARNO model was supplied with rainfall aggregated up to the catchment scale. It was concluded that

simulated floods were sensitive to the spatial distribution of rainfall, particularly after dry conditions. Whilst the Mellor *et al.* (2000b) study was set in the context of flood forecasting, rather than flood frequency, it would be a natural extension of the approach to simulate long rainfall sequences to provide design flood estimates. A significant finding was also that the simpler, semidistributed model of runoff production was adequate for flood generation.

RAINFALL – RUNOFF MODELS FOR CONTINUOUS SIMULATION

The choice of a continuous simulation rainfall-runoff model depends on the proposed application and available data. Models that have been most useful in continuous simulation studies tend to have been in the category of "semidistributed" conceptual models (*see* Beven (2001) and **Chapter 122, Rainfall-runoff Modeling: Introduction, Volume 3– Chapter 134, Downward Approach to Hydrological Model Development, Volume 3** for a taxonomy and further discussions of rainfall-runoff models). Such models have structures that are based on process knowledge, some facility to describe spatial and temporal variations in runoff production, and, perhaps above all, are designed to be parametrically efficient and hence capable of robust calibration. These models are also, of course, far from complete representations of catchment hydrology and their parameters are therefore not generally measurable directly in the field. Indeed, there have been a number of independent studies (Beven, 1993, 2002; Grayson *et al.*, 1992), arguing that even in explicitly physically structured models that build on the grid-based modeling "blueprint" of Freeze and Harlan (1969), physical parameters such as hydraulic conductivity and porosity become effective parameters.

The following models have been selected as representative of those applied to date to simulate flood frequency curves, although it should be understood that this is by no means a definitive selection. The models are notable for having been used for continuous simulation in different contexts, ranging from very detailed, catchment-specific engineering studies, through explorations of process controls to generalized, national applications. There are many other models, often based on similar concepts, that could also be described, but the chosen examples are typical. Boughton and Droop (2003) have recently reviewed various hydrological models applied in software systems used for continuous simulation in Australia, the United States, Europe, South Africa and elsewhere. The emphasis here is on the conceptual basis of the modeling approaches.

Distribution Function Models

TOPMODEL

As a compromise between a conceptual structure based on process knowledge and a parsimonious parameterization, the catchment model TOPMODEL (Beven, 2001; Beven and Kirkby, 1979; Beven *et al.*, 1995) is well suited to continuous simulation in environments where its assumptions are reasonable. The main assumptions are that the distribution of subsurface storage is driven by gravity drainage that follows topographic control, and that the transient dynamics of the saturated zone rapidly lead to a spatial equilibrium in which local storage has a unique relationship with the catchment average storage, and a few soils and topographic parameters. This concept works well in environments where runoff production mechanisms involve a shallow, near-surface water table that may intersect the surface at the base of slopes or in areas of flow convergence, causing saturated areas of rapid storm runoff as overland or shallow subsurface flow. The basic structure can be adapted to include other runoff production mechanisms, such as infiltration-excess overland flow, and also to relax some of the usual assumptions to cater for deep soils, spatially variable soil properties and other factors.

The distribution of storage in the simplest form of TOPMODEL is determined by topography via an index of upslope drained area, a, divided by slope, $\tan\beta$, which is used to approximate the hydraulic gradient of the saturated zone. This index can be calculated conveniently from a digital elevation model (DEM) using automated procedures. Figure 3 shows in schematic form how the area/slope index is defined and one, typical, arrangement of stores to account for subsurface moisture. Each "block" shown in cross section corresponds to a discrete class of values of the topographic index.

In most implementations of the TOPMODEL concepts, the local storage deficit due to gravity drainage (D) is expressed as a function of the form

$$D = \overline{D} + m\left[\gamma - \ln\left(\frac{a}{T_0 \tan\beta}\right)\right] \tag{15}$$

where $\bar{D}$ is the areal average storage deficit, γ is the areal average of the index $\ln(a/T_0\tan\beta)$ and T_0 is the lateral transmissivity of the soil profile when $D = 0$. The parameter m controls the rate of an assumed exponential decrease in transmissivity with depth, which corresponds to a local downslope saturated flow rate

$$q = (T_0 \tan\beta)e^{-D/m} \tag{16}$$

for a slope element of unit width. It is often assumed that the lateral transmissivity of the soil when just saturated has the same value throughout the catchment, although versions of TOPMODEL used to model flood frequency have instead allowed saturated transmissivity to be described by a statistical distribution. The saturated zone is often modeled as a lumped nonlinear store and the unsaturated zone can

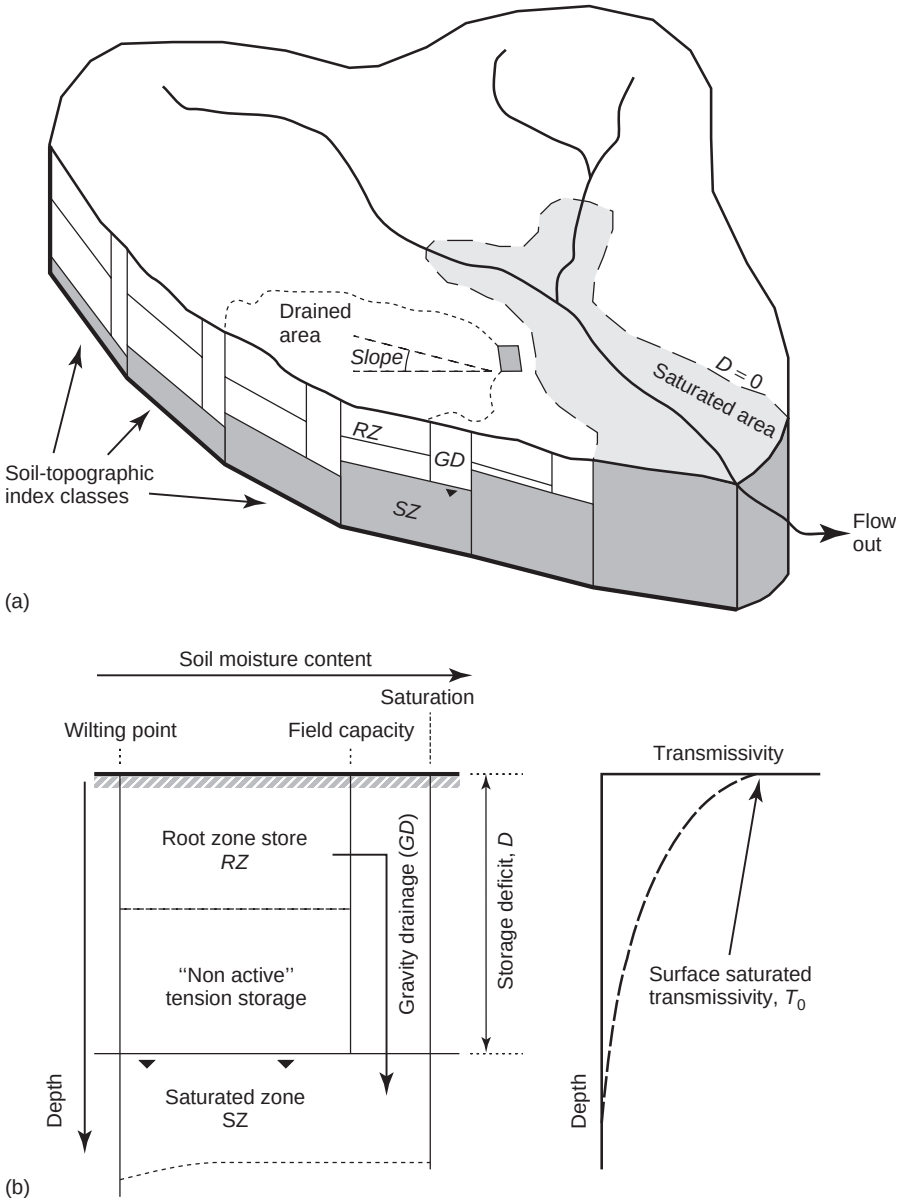

Figure 3 Schematic diagram of TOPMODEL

be represented in simple form by a root zone store, which has a uniform maximum depth. When filled by rainfall, any excess is routed to the saturated zone via a simple linear time delay. Evaporation is lost from the root zone as a function of the potential rate (supplied to the model as an input) and storage in the root zone.

The TOPMODEL concepts are simple representations of runoff production that can be applied with the estimation of as few as four parameters. Research applications for flood frequency estimation include those of Beven (1986, 1987), Blazkova and Beven (1995, 1997, 2002, 2004), Cameron *et al.* (1999, 2000b,c), Robinson and Sivapalan (1997) and Sivapalan *et al.* (1990). Most descriptions of TOPMODEL rely on the conceptualization of the catchment in terms of storage elements, although an alternative derivation (Kirkby, 1997) begins with the kinematic wave theory, with runoff being produced from linear strips on the hillslope draining into the stream network. The storage-based accounting generally used to compute rainfall losses, and the additional complexity of the spatial arrangement of the hillslope elements, preclude complete analytical solution of the theoretical model.

The PDM

The Probability Distributed Model (PDM) was developed by Moore and Clarke (1981). The distribution function

used to model runoff production in the PDM is based on statistical arguments. The PDM has been used in the development of a prototype national application of continuous simulation for flood frequency estimation in Britain (Calver *et al.*, 1999). The distinguishing feature of the model is that soil moisture storage is represented by a continuous distribution of storage capacity, c. This is shown schematically in Figure 4, where the stores are arranged on the left in rank order of capacity from zero to a maximum depth $c_{\max}$ and the probability distribution $f(c)$ for the storage capacity is shown to the right. The soil moisture store permits runoff to respond nonlinearly to rainfall inputs by varying the proportion of the catchment generating fast, "direct" runoff according to the amount of water stored in the soil. In the example shown in Figure 4, rainfall of depth P has fallen over an initially dry population of stores. The storage capacity will be filled for all parts of the catchment for which c is less than a critical value, c^* (which equals P for the dry initial condition). At subsequent times, c^* can be updated according to the time sequence of rainfall inputs and losses from the soil moisture store. The proportion of the catchment for which $c \leq c^*$ can be calculated from the cumulative distribution function

$$F(c) = \Pr(c \leq c^*) = \int_{\min(c)}^{c^*} f(c)\,\mathrm{d}c \tag{17}$$

This partial area is taken to be the area producing direct storm runoff, which is then routed, typically via one or more linear storage functions, before contributing as "quick flow" to the total catchment runoff. The remaining rainfall enters the soil moisture store, which is depleted by evaporation. Drainage from the soil moisture store (representing recharge) then takes place, typically via a nonlinear storage function, and generates baseflow after being routed by a further "slow flow" store.

The form of the storage functions used in the PDM can be varied as described by Institute of Hydrology (1996). A particular choice of functions may be best suited to any given catchment. The soil moisture storage capacity is often assumed to follow a Pareto distribution, for which the distribution function is

$$F(c) = 1 - \left(1 - \frac{c}{c_{\max}}\right)^b \tag{18}$$

where the parameter b controls the variability and the minimum value of storage capacity found in the catchment has been assumed to equal zero. Moore (1985) describes how the state of the soil moisture store is integrated over the distribution at each time step, as c^* varies, to calculate runoff and the volume of water retained in storage.

Rainfall inputs to the soil moisture store can be multiplied at every time step by a volume adjustment parameter. Although introduced notionally to compensate for errors arising in the estimation of spatially averaged rainfall from point gauge data, this parameter can also effectively compensate for components of the overall water balance not fully represented in the model, including losses to regional groundwater or gauge bypassing. Losses due to evaporation can be calculated as a function of potential evaporation and the status of the soil moisture store.

For the development of a generalized continuous simulation method, the choice of model may be determined by the need for a standardized formulation with a small number of parameters. The generic PDM structure has been

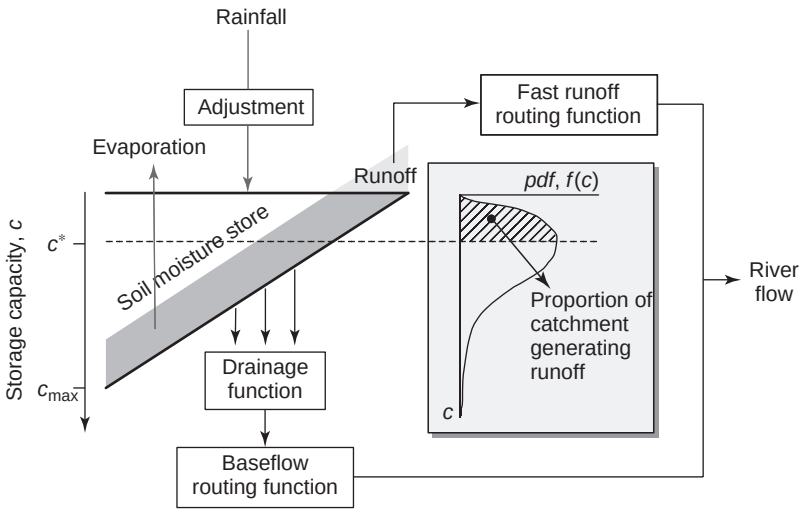

Figure 4 The Probability Distributed Model soil moisture storage concept of Moore and Clarke (1981)

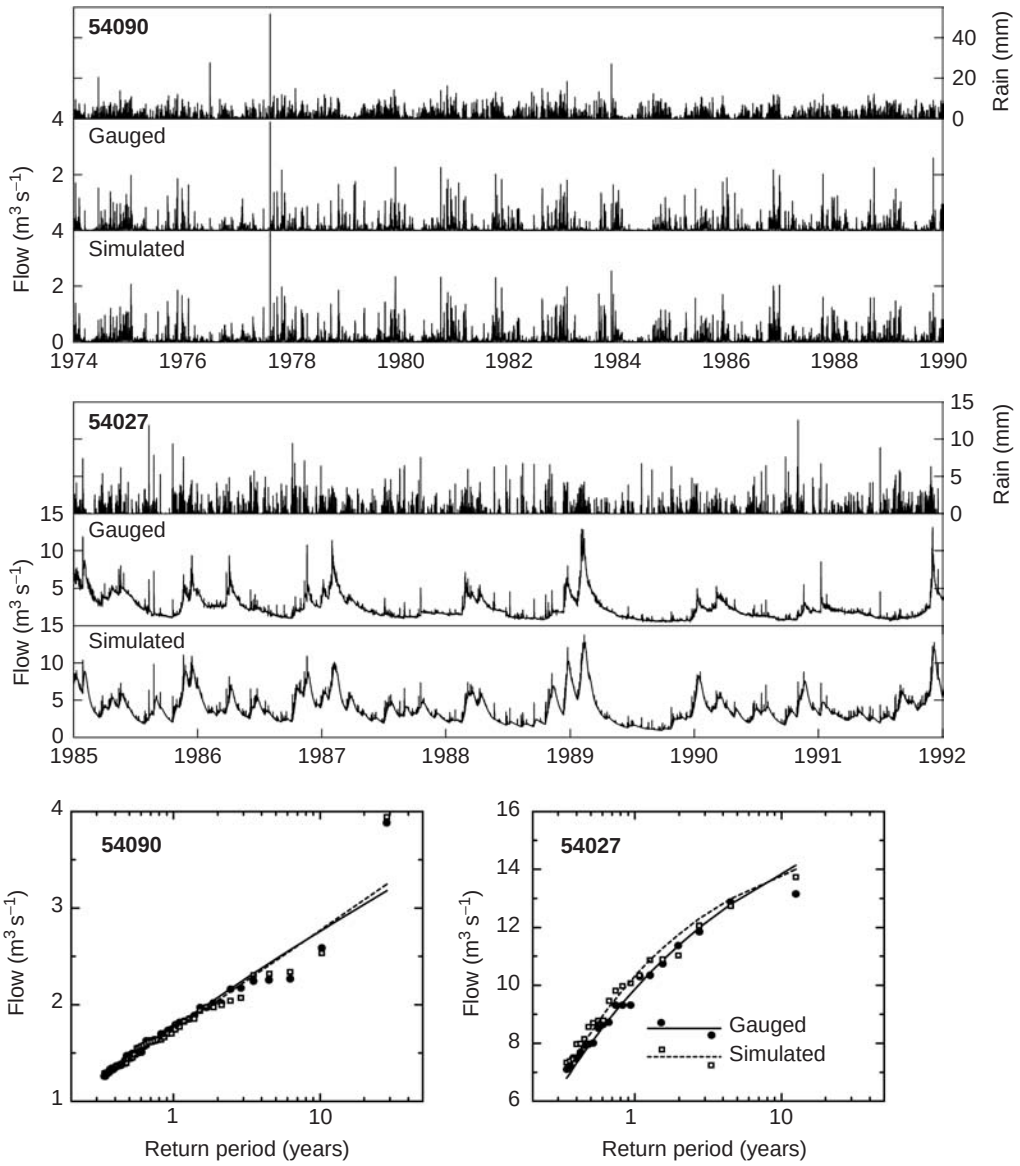

Figure 5 Long time series simulations and derived flood frequency distributions using the PDM rainfall-runoff model (Reproduced from Lamb, R & Calver, A 'Continuous simulation as a basis for national flood frequency estimation' in Continuous River Flow Simulation: Methods, Applications & Uncertainties edited by Littlewood, I. British Hydrological Society Occasional Paper 13 (2002) 67–75 by permission of British Hydrological Society)

found flexible enough to derive flood frequency distributions that agree well with distributions fitted to gauged flow records (up to the limit imposed by the record length) for a range of catchment types. Two contrasting examples are shown in Figure 5. The top panel shows rainfall, observed flows and flows simulated by the PDM after calibration for the Tanllwyth stream, a very small ($\sim$1 km^2) catchment with average annual rainfall of 2425 mm, shallow soils and a largely impermeable solid geology. The bottom panel shows calibrated model results for the River Frome, a 198 km^2 catchment with annual average rainfall of 827 mm and a highly permeable geology in its headwaters.

Although not strictly an application to flood estimation, the concept of the probability-distributed soil moisture store can also be used directly to derive expressions for the cumulative distribution of discharge (but not necessarily of peak flows). Hosking and Clarke (1990) derived such a result by assuming a Markov chain model for the occurrence of rainfall, probability distributions for rainfall and evaporation depths and a linear routing function for runoff to reach the catchment outfall. There are a number of other models in widespread use that apply distribution function concepts similar to those of the PDM, including the VIC (Variable Infiltration Capacity) model (Liang *et al.*,

1994), the Xinanjiang model (Zhao, 1992) and the ARNO model of Todini (1996).

The Time-Area Topographic Extension (TATE) Model

The "Time-Area Topographic Extension" (TATE) model is a parsimonious transfer function model developed by Calver (1993, 1996). It has been used alongside the PDM in the national continuous simulation pilot study of Calver *et al.* (1999). The principles of the TATE model can be traced back to the time-Area approach of Clark (1945). However the TATE model includes further recognition of hydrological processes by allowing runoff responses to vary over the catchment. The motivation for this was the observation that wetter conditions tend to prevail close to the channel leading to an increase in the wave speed of runoff responses, and a consequent reduction in response times. The reference to topography in the model's name follows from the use of the slope and stream channel configuration to define the relationship between drainage area and distance from the channel or catchment outlet, given a distribution of response velocities.

In principle, the relationships between distance from the channel/outlet, response velocity and drained area could be derived empirically from the analysis of topographic slopes and flow paths. However, Calver (1996) adopted a simple functional form in which the relationship between the response velocity, c (effectively a wave speed), and distance from the channel or outlet, s, was expressed as

$$c = k\left(1 - \frac{s}{s_{\max}}\right) = kx \tag{19}$$

where s was scaled by the maximum flow path or hillslope length $s_{\max}$ and $x = 1 - (s/s_{\max})$ is the dimensionless distance from the top of the hillslope. This relationship applies on a hypothetical flow plane or slope element. The relationship between a position on the slope and the corresponding cumulative fractional response area of the catchment, $A_s/A_{\max}$, was defined as

$$x = \left(1 - \frac{A_s}{A_{\max}}\right)^{1/\chi} \tag{20}$$

where χ is a parameter. Calver (1996) showed that Equation (20) with $\chi \approx 3$ would be a good approximation for a large number of catchments in Britain.

Equation (19) describes a physical response on a hillslope, or more generally along a flow pathway (which may include parts of the channel network), while equation (20) relates this response to the spatial layout of the catchment. Combining the two functions gives the expression

$$\frac{A_s}{A_{\max}} = 1 - e^{-\chi k\tau} \tag{21}$$

which defines the runoff response time, τ, of the partial catchment area $A_s/A_{\max}$. Equation (21) allows the catchment to be split into drainage area increments of equal response time, which can be convolved with a time series of rainfall excess to compute runoff from the catchment. In this respect, the TATE model is a form of UH, expressed as a linear transfer function. In its derivation, it shares some concepts with the GUH, which involves the idea of a distribution of time delays for runoff on hillslopes, but is also predicated more explicitly on the topology of the stream channel network.

The basic physical response described by equation (19) can also be related to the physical interpretation for runoff responses on a hillslope provided by the kinematic model discussed earlier. The wave speed is given by equation (11), which applies along characteristics of constant flow depth. The limiting characteristic defined by $y(x = 0, t = 0) = 0$ originates at the top of the slope at the start of rainfall excess and the plane reaches steady state when this characteristic reaches the base of the slope. After this time, $q = xi$ for constant and uniform rainfall excess. By substituting for q in the flow law specified by equation (9), the response velocity of a disturbance under conditions of unit rainfall excess can therefore be written

$$c = \alpha m\left[\frac{x}{\alpha}\right]^{(m-1/m)} \tag{22}$$

Equation (22) shows in general that the response velocity increases downslope, which is a premise of the TATE model. However, equation (19) specifies that the increase in response velocity should be a linear function of distance. The only flow law that can satisfy this assumption is a logarithmic form

$$q = \alpha e^{my} \tag{23}$$

in which case $c = mx = m(1 - s/s_{\max})$ for unit rainfall excess at steady state. This type of flow law (which is also assumed in TOPMODEL, *see* equation (16)) has been shown by Kirkby (1997) to be a suitable form for simplifying the dynamics of runoff responses as a succession of steady states because it tends to cause transients caused by changes in rainfall rate to disappear rapidly. In the TATE model, the simplified physical response is then used to define the form of a transfer function for the runoff response at the catchment scale.

The TATE model provides a compact and parsimonious structure that can be related to some aspects of catchment form, adding to its potential for generalization to ungauged sites. Its conceptual stores can be adapted as a basis for further functions, including calculation of groundwater recharge and levels (Calver, 1997), where the additional complexity is warranted.

Gridded Modeling

The three models described above have been presented as applied on a catchment basis. Adopting catchment units as the spatial basis for estimating flood frequency is convenient and consistent with existing approaches applied for event-based modeling. However, there are potential advantages in adopting a grid-based model that can be linked directly to raster data for land use, rainfall, and the river network topology. Indeed, gridded applications exist for the basic runoff production concepts used in the models already described. Another approach in rainfall-runoff modeling has been to develop models that attempt to solve the full equations for flow (or appropriate simplifications) in two or three dimensions. This "physics-based" approach to modeling is often traced back to the early work of Freeze and Harlan (1969) and is discussed in detail in **Chapter 122, Rainfall-runoff Modeling: Introduction, Volume 3** and **Chapter 127, Rainfall-runoff Modeling: Distributed Models, Volume 3**. Models of this type have not been as widely used as conceptual models for simulation of flood frequency (although a physically based model, not requiring calibration, could clearly be a very useful tool for flood estimation). One exception in flood frequency analysis has been applications of the SHETRAN model (Kilsby *et al.*, 1998).

Climate and Land Use Scenario Simulation in Catchments (CLASSIC)

A grid-based model that has been used for flood frequency estimation is called "CLASSIC" (Climate and Land use Scenario Simulation In Catchments), which was developed by Crooks *et al.* (1996). This model is mentioned here because it has been used in the United Kingdom for studies of climate change impacts (Reynard *et al.*, 2001) that have informed government planning policy guidance on flood risk (Office of The Deputy Prime Minister, 2001). Modeling the impacts of change often requires a continuous simulation approach to account for changes in hydrological response caused by the combination of changes in boundary conditions at different spatial and temporal scales (*see* **Chapter 132, Rainfall-runoff Modeling for Assessing Impacts of Climate and Land Use Change, Volume 3** and further discussion below).

CLASSIC works on grid cells of comparable scale to an elemental subcatchment unit; in the United Kingdom, a 40 km^2 grid cell size is a reasonable choice, and corresponds to the grid scale adopted for calculation of potential evaporation within the Met Office Rainfall and Evaporation Calculation System (MORECS). Other grid scales have also been used. The CLASSIC model accounts for losses using a simple, conceptual storage-based soil water balance module to calculate an effective rainfall sequence. Runoff production and attenuation is then computed using a linear transfer function model within each grid cell; the transfer function formulation employed is that of the "IHACRES" model (Jakeman *et al.*, 1990; Littlewood and Jakeman, 1994).

The conceptual soil moisture model has minimal parameters that have been related to broad land use categories within any grid square. A notable feature of the model is that the parameters of the runoff component, initially calibrated at 22 test catchments in the United Kingdom, have also been related to catchment properties, in this case to digital soils and land surface data, available for Britain on a 1×1 km grid. These relationships open the way for generalized applications to ungauged catchments.

The hydrological model performs soil moisture and runoff calculations separately within each component grid square. Runoff is then routed to the basin outlet using the network width function approach of Kirkby (1976). This approach makes use of the density of channels in the basin at each spatial step away from the outlet, which is convolved with a "standard" response function to produce a network response function (i.e. a form of UH). In CLASSIC, each grid square has its own network width function. The "standard" routing function, which applies over all grid cells, is based on a solution of the diffusion equation used by Naden (1992b) as a suitable routing model in moderately shallow sloping rivers. The result is that each grid square has its own UH for routing to the main basin outlet, with more distant grid squares naturally exhibiting greater attenuation and lag, as illustrated schematically in Figure 6.

CLASSIC has performed well in modeling daily streamflow and flood frequency (based on daily mean flows) within three contrasting basins of up to nearly 10 000 km^2, covering most of the main types of soils, geology, and land use in the British Isles. The grid-based structure makes this type of model particularly suitable for integration with GIS tools, and its direct link to soils data and simple representation of losses has been exploited to model effects of land use change. In general, calibration has been carried out for the main basin outlet and some key internal gauging stations. However, the model has been found to give good matches to gauged data at subcatchments where no calibration was carried out. Figure 7, for example, shows gauged and modeled daily flows for the Thames at Kingston (9948 km^2), a location that was used for calibration. Results are also shown for the Mole at Esher (470 km^2) and the Cherwell at Oxford (907 km^2) where the results depend on the parameterization derived from land use and soils data (after global calibration at Kingston); Figure 6 shows the locations cited.

INVESTIGATING CONTROLS ON THE FLOOD REGIME

As a research tool, early developments of continuous simulation stemmed from the potential to improve upon the

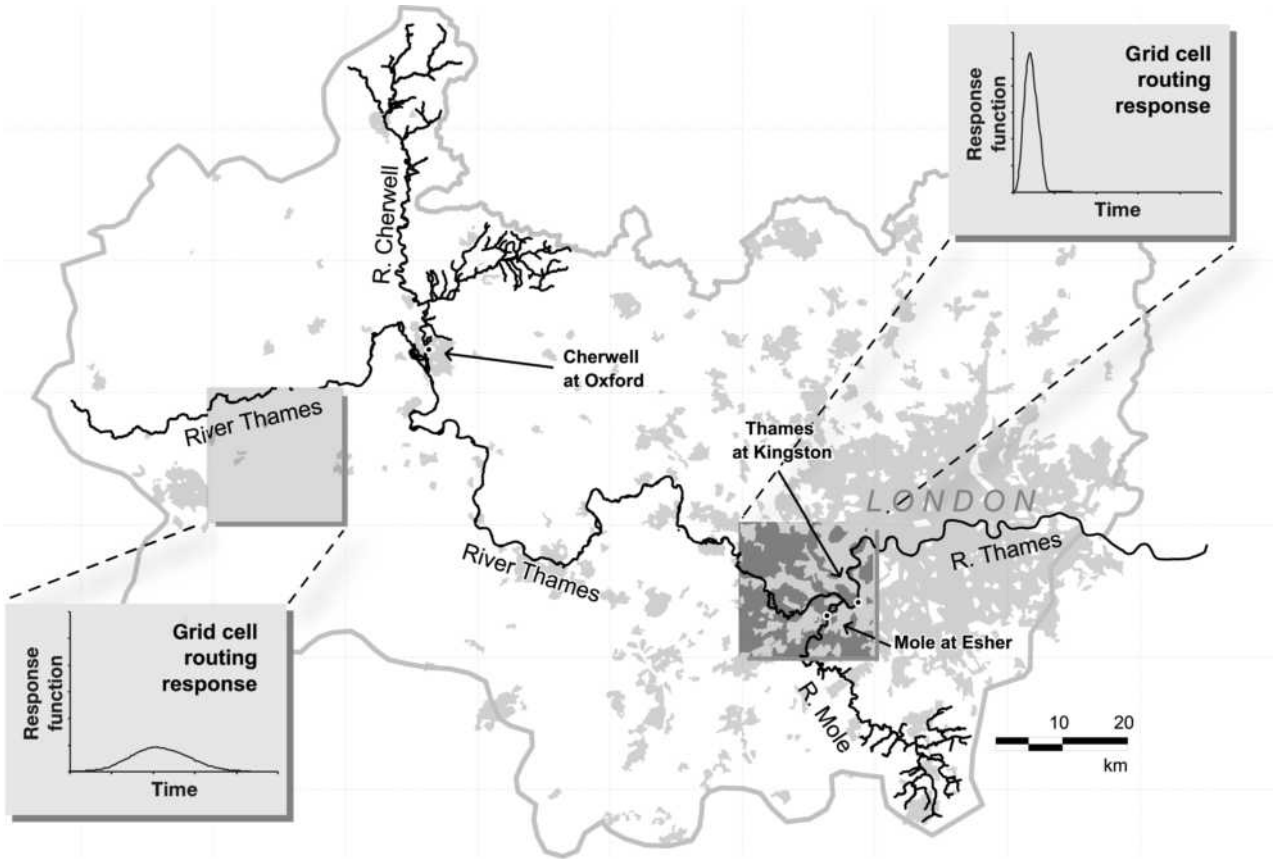

Figure 6 Application of the ''CLASSIC'' model of Crooks *et al.* (1996) to the Thames catchment, England. Triangle symbols show the locations of model simulations plotted in Figure 7. The expanded schematic plots show typical network response functions at a downstream point for two grid squares, with a more attenuated response being produced for runoff from distant parts of the catchment

catchment process representations in derived distribution models. If flood frequency can be modeled using physically based concepts, then there is the possibility of using such models to improve understanding of controls on flood regimes. This was the route explored by Beven (1986), who combined a stochastic rainfall model, based on the distributional assumptions used by Eagleson (1972), with the conceptual rainfall-runoff model TOPMODEL. In this study, the aim was to investigate the controls on catchment flood regime. The version of TOPMODEL applied in this case included both infiltration-excess and saturation-excess overland flow mechanisms. The study areas were three small ($\sim$1 to $\sim$10 km^2) catchments in United Kingdom in an area experiencing typically $\sim$1500 mm annual rainfall. Modeled runoff responses were dominated by saturation-excess flow, as would be expected from field knowledge for the catchments chosen in the study. Saturation excess produced rapid responses with high runoff coefficients. The dominant control on the flood frequency curve was, therefore, the shape of the rainfall growth curve, rather than catchment parameters.

A more complex response was noted by Sivapalan *et al.* (1990), again using TOPMODEL distribution function concepts. Experimentation with different modeled rainfall regimes suggested that the flood frequency curve was controlled at lower magnitudes by saturation-excess runoff production, which, having a "memory" of antecedent conditions, modified the rainfall growth curve. However, for larger, lower-probability, events, it appeared that an infiltration-excess mechanism would dominate runoff production, passing the slope of the rainfall growth curve more directly into the flood frequency curve.

Robinson and Sivapalan (1997) used an exponential stochastic rainfall model with a linear storage model of catchment runoff production to investigate effects of different temporal rainfall patterns and scaling. The study also examined scaling of catchment size (by an empirical scaling law for time of concentration). Catchments were categorized into distinct regimes based on the ratio of storm durations and inter-storm periods to catchment response time. The analysis showed that within-storm variation has greatest impact on flood frequency in fast-responding

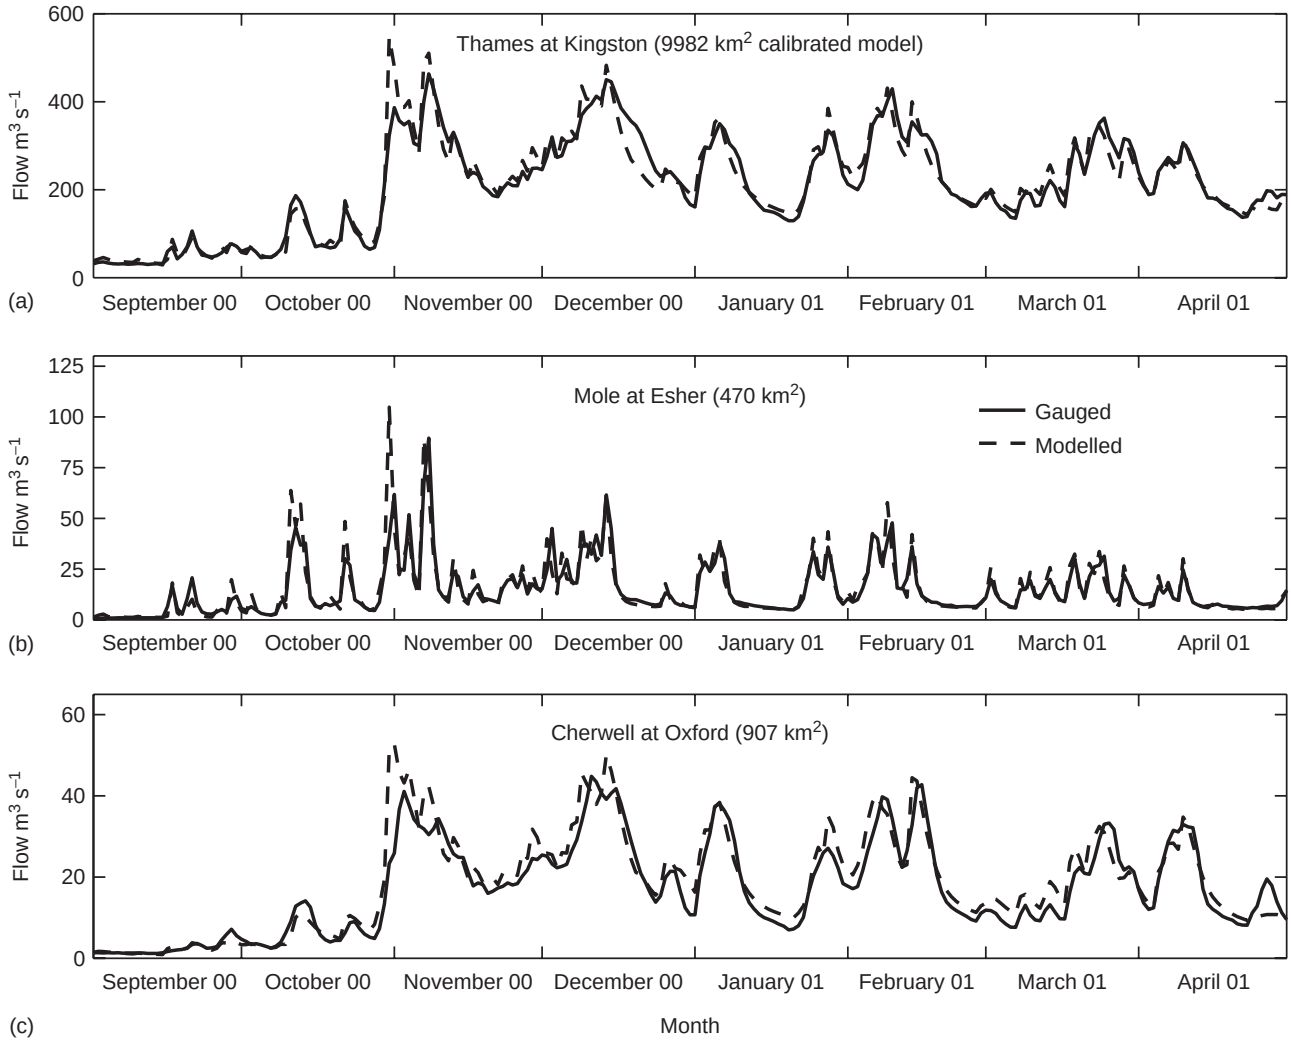

Figure 7 Daily mean flows simulated using CLASSIC

catchments, whereas multiple storms and seasonality have greater influence in slower catchments. The scaling of the mean and coefficient of variation of flood magnitude with area varied according to which "response time regime" a catchment occupied. In general, it would appear that nonlinearity in the runoff production and routing processes contributes to steeper flood growth curves (Bloeschl and Sivapalan, 1997). Such nonlinearity is likely to be associated with variable antecedent wetness, at least in temperate climatic zones.

The discussion here has centered on using modeling to investigate how the interaction of rainfall patterns and runoff production mechanisms controls the flood frequency curve. Continuous rainfall-runoff modeling is useful in this context because it is a technique that takes explicit account of patterns of precipitation and loss mechanisms in time (and, to some degree, in space). The effects of sequences of rainfall events or wet and dry periods can therefore be modeled, and associated with probabilities if the driving variables are modeled in a stochastic framework. The same features of continuous simulation can also be exploited for modeling the effects of climate or land use change on the flood regime. Rainfall-runoff modeling for assessing the impacts of climate and land use change is discussed in detail in **Chapter 132, Rainfall-runoff Modeling for Assessing Impacts of Climate and Land Use Change, Volume 3**.

CALIBRATION

The calibration of hydrological models has been a subject of extensive research (*see* **Chapter 131, Model Calibration and Uncertainty Estimation, Volume 3**). A few key points relevant to continuous simulation for flood frequency are noted here. Calibration strategies in the context of continuous simulation vary according to the type of model selected and the quality and quantity of rainfall and flow

data available at gauged sites. Parameter estimation for ungauged or data-poor sites is considered separately below.

An advantage of using models that have parameters based on some conceptual representation of catchment processes is that it is possible to consider the plausibility of the fitted parameter values. However, the parameters are in general not truly physical properties because of the scaling, averaging, and (often considerable) approximation of physical processes within hydrological models. Calibration is therefore required to seek model parameter values that maximize agreement between simulated and observed flows. The following calibration strategies are well known:

- visual assessment of fit;
- manual optimization of an objective function;
- automatic optimization of an objective function;
- use of a "split sample" to calibrate and test on separate periods of record;
- "multiobjective" methods in which a set of Pareto optimal solutions are identified;
- Bayesian approaches, which seek a posterior distribution for model parameters, conditioned on sample data.

The development of Bayesian and multiobjective approaches have been motivated by the observation that there is often not a single, global optimum solution (i.e. set of parameter values) when calibrating a hydrological model, but rather a set of possible solutions, leading to uncertainty about the model predictions. As discussed in **Chapter 131, Model Calibration and Uncertainty Estimation, Volume 3**, uncertainty in calibration can be reflected in the problems often encountered in trying to identify a single "best-fit" parameterization for a model. For instance, there might be long meteorological and flow records available for calibration at a gauged catchment, and hence no lack of data; however, even a conceptually well-founded catchment model is unlikely to be able to simulate every time step of the flow record successfully (especially at the short time steps often required for flood analysis) because of errors in measured data, errors in model specification and also errors arising from the differences in scales over which processes occur and are modeled.

Measures of fit based on the sums of squared errors at each time step have commonly been used to try to optimize rainfall-runoff models, or to report on the goodness of fit of simulations. Although this approach may work well for individual events or short records, errors about longer river flow time series tend to exhibit complicated structures including unstable variances and serial autocorrelation. These features reduce the efficiency of objective functions based on summing the squares of the residuals (for theoretical discussions of the reasons why, and possible alternatives, *see* Sorooshian and Dracup, 1980; Kuczera, 1983; Romanowicz *et al.*, 1994).

Working with the PDM rainfall-runoff model and time series of hourly data of up to 20 years, Lamb (1999) showed how attempting to optimize the well-known Nash and Sutcliffe (1970) efficiency measure was not very effective in calibrating for flood frequency estimation. A variety of alternative objective functions that give greater or exclusive weight to flood peaks were more useful, but nevertheless still gave rise to uncertainty reflected in a lack of any unique, global "optimum" parameter set. One partial solution to this problem was to consider a combination of objectives, such as fitting to the magnitudes of ranked flood peaks and flow duration curve quantiles, and even visual inspection of the plausibility of the overall hydrograph. There are still uncertainties associated with trade-off solutions in such multiobjective problems (*see* Gupta *et al.*, 2002; Vrugt *et al.*, 2003 and **Chapter 131, Model Calibration and Uncertainty Estimation, Volume 3**).

A different perspective on model calibration is to reject the idea that any single calibration solution exists. Instead, many different combinations of parameter values may be found that lead to equally or similarly plausible predictions. This "equifinality" concept suggests that model parameters can only be identified as distributions and that predictions should be expressed as intervals rather than a "best-fit" point or line. Applications of this approach to continuous simulation of flood frequency characteristics are provided by Cameron *et al.* (2000b,c) and Blazkova and Beven (2002, 2004).

In some cases, it may be possible to arrive at a satisfactory model calibration by a combination of tactics if a single solution is demanded for a particular application. However, with the possible exception of using continuous simulation to provide a more complete picture of flood volumes over the period of record at a gauged location, it is likely that real applications would require some extrapolation in time (using modeled rainfall), or in space (to ungauged locations). In both cases, the potential impacts of uncertainty in calibration are more serious.

GENERALIZED PARAMETERIZATION

A key requirement for a general method of flood estimation is to be able to carry out modeling across a range of catchments of different scale and type. As noted already, practical applications often include ungauged sites, where measurements of river flows are not available, and model calibration is therefore not possible. Overcoming this problem can be thought of as "spatial generalization". Some of the derived distribution studies attempted to do this by associating model parameters directly with physical properties. Generalization of rainfall-runoff models used for continuous simulation has recently been approached on

a more empirical basis, in common with the regionalization methods often used for statistical and event-based flood estimation.

Attempts have been made to generalize conceptual hydrological models in a number of studies, not necessarily motivated by flood estimation (e.g. Abdulla and Lettenmaier, 1997; Post *et al.*, 1998; Sefton and Howarth, 1998). Spatial generalization of model parameters remains a difficult problem for which there is no standard methodology. However, a typical approach is as follows:

- Select a set of gauged catchments covering a range of characteristics and with good quality rainfall and flow records.
- Calibrate hydrological model parameters at each gauged catchment.
- Fit predictive relationships between the calibrated parameters and physical catchment properties.
- Use the fitted relationships to estimate model parameters at ungauged locations.

Applying this approach in Britain, Calver *et al.* (1999) fitted univariate regression functions between calibrated "best" estimates of model parameters and catchment properties. This approach assumed that model parameters were independent, which is known to be an approximation. However, results at test catchments indicated for the first time that the continuous simulation approach could be developed successfully for flood frequency estimation on a national basis. Modeled peak flow series were generally consistent with statistical distributions of gauged flows and the results were considered promising for simulation of sites where calibration had not been carried out directly, and, by implication, for ungauged locations.

The same study also noted the difficulty of identifying unique, independent best parameter estimates for continuous simulation (even though the models applied, PDM and TATE, were only moderately complex). A response to this problem is to simplify the hydrological model structure with the hope of creating a more robust model, albeit at the expense of the description of catchment processes. Following their pilot study, Calver *et al.* (2001) therefore applied a simplified version of the TATE rainfall-runoff model, in which a number of the original parameters were fixed on the basis of average values (informed by earlier calibration) or as ratios, reducing the number of parameters for calibration from seven to three.

Table 1 shows the results obtained in terms of the unsigned differences between values on frequency curves fitted to gauged and modeled flood peaks, expressed as a proportion of the gauged value at specified return periods. The mean and standard deviation of the errors in Table 1 are aggregated over 40 test sites. The values shown are for return periods up to 20 years, which was chosen as a maximum value in view of the length of gauged records

Table 1 Summary statistics of generalized flood frequency estimation for Britain using the TATE rainfall-runoff model (Reproduced from Lamb, R & Calver, A 'Continuous simulation as a basis for national flood frequency estimation' in Continuous River Flow Simulation: Methods, Applications & Uncertainties edited by Littlewood, I. British Hydrological Society Occasional Paper 13 (2002) 67–75 by permission of British Hydrological Society)

Return period (years)		1	2	5	10	20
Full model[a]	Mean % error[b]	31	31	33	35	38
	sd % error	29	31	33	35	36
Simplified model	Mean % error	25	24	25	28	31
	sd % error	23	22	23	26	33

[a]Results after Calver *et al.* (1999).
[b]The quoted percentage errors are the difference between ordinates of distributions fitted to gauged and modeled flood peaks, expressed as a proportion of the gauged value. Quoted figures are mean and standard deviation (sd) over a sample of catchments, used both for calibration and subsequent testing of generalized model.

at the majority of test sites. It is clear that the simplified version of the TATE model gives better results than the full model when applied without site calibration (i.e. as if for an ungauged site). This is expressed both in terms of a reduced average percentage error at all of the return periods tested and in the somewhat reduced spread of errors over the group of test sites.

A second response to the problems posed by dependence between parameters in fitting a model for ungauged locations is to adopt a more explicitly multivariate approach. This can be done by concurrently seeking to fit model parameters at each site whilst relating the parameters to regional basin characteristics. Fernandez *et al.* (2000) attempted such an approach using 33 basins in the United States and found that it did not result in improvements in the ability to model streamflow at ungauged sites, although it did produce improved regional relationships for the model parameters.

An alternative approach to account for the interaction between parameters is a "sequential generalization" algorithm, in which model parameter predictor equations are derived one after another, with calibration of parameters later in the sequence made conditional on the generalized estimates for the earlier parameters. The approach is outlined in Figure 8 and described in more detail by Lamb *et al.* (2000). Clearly, the results depend on the order in which parameters are related to catchment properties. The sequence can be decided by visual inspection of profile plots showing the marginal distribution of goodness-of-fit functions against each model parameter, selecting the parameter that is most sensitive in terms of the goodness-of-fit function at each step.

Table 2 summarizes the trials of this method. Results are given first for the Calver *et al.* (1999) pilot study. The second set of results was obtained using the sequential method

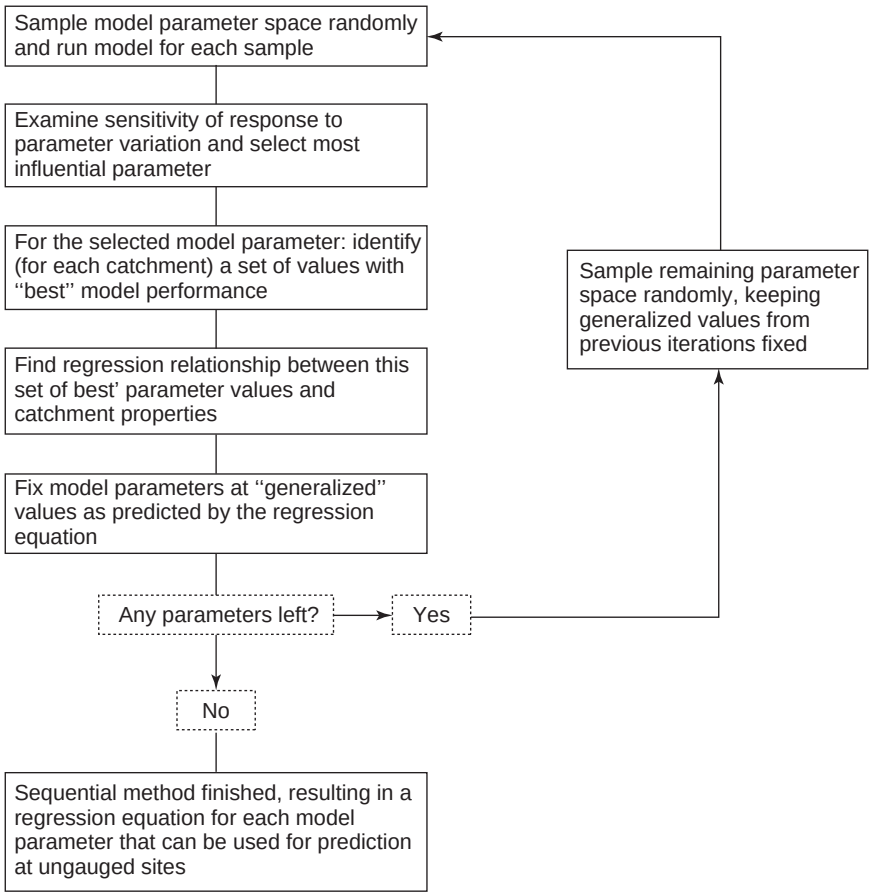

Figure 8 Outline flowchart for sequential calibration and generalization (Reproduced from Lamb, R & Calver, A 'Continuous simulation as a basis for national flood frequency estimation' in Continuous River Flow Simulation: Methods, Applications & Uncertainties edited by Littlewood, I. British Hydrological Society Occasional Paper 13 (2002) 67–75 by permission of British Hydrological Society)

outlined above. It can be seen that the revised generalization procedure, integrating "calibration" and "regionalization", has improved performance to a similar degree as the simplification of model structure discussed above. Figure 9 shows comparisons of flood frequency distributions fitted to gauged data and to flood peaks modeled using the generalized continuous simulation method (i.e. effectively treated as ungauged sites).

The overall conclusion from these experiments to explore the generalized application of continuous simulation has been summarized by Wheater (2002), who noted that the results provided "...the basis of a national methodology for continuous simulation modelling...". The same author commented that such modeling also provides the "...capability to analyse regional datasets and hence gain insight into the variability of hydrological response". In future, the link between model parameterization and process controls may be further tightened by regional analysis of the residuals in models to identify model deficiencies in a way that may not be apparent at an individual catchment.

Table 2 Summary statistics of generalized flood frequency estimation for Britain using the PDM rainfall-runoff model (Reproduced from Lamb, R & Calver, A 'Continuous simulation as a basis for national flood frequency estimation' in Continuous River Flow Simulation: Methods, Applications & Uncertainties edited by Littlewood, I. FLOOD ROUTING AND HYDRAULIC CALCULATIONS

Flood routing is discussed in detail in **Chapter 124, Flood Routing and Inundation Prediction, Volume 3**; a brief summary will be given here to relate routing approaches directly to rainfall-runoff modeling for flood frequency.

Routing will be required for larger catchments and as a means of linking distributed inputs from discrete subcatchments. The type of approach adopted depends on

the time and space resolution of available data, the types of predictions required, and the physical characteristics of the river basin. The derived distribution studies discussed above include simplified flow routing, both for overland flows and water in the channel, based on the kinematic approximation and the GUH theory. Channel routing may be needed where flood storage, diversion channels, extensive systems of embankments, or changes in channel conveyance are important features, and an event or continuous simulation model is needed to provide input hydrographs.

Flow Routing

Simple hydrological routing can be based on conceptual stores that act to lag and attenuate an input hydrograph. The UH, although often derived from transfer function principles, is also equivalent to a linear storage-based routing approach. In many continuous simulation rainfall-runoff models, combinations of stores are arranged in series or in parallel. The approach can be likened to level-pool routing in that the conceptual stores neglect hydraulic slope, friction, and momentum, instead relating the rate of flow uniquely to the depth of storage. The approach only modifies flows, rather than water levels, but can provide suitable hydrograph attenuation, especially when calibrated.

The kinematic wave is also essentially equivalent to storage-based routing in that the dynamic equation neglects local accelerations and is based only on a functional relationship between depth (or storage) and flow rate. The kinematic wave routes a flood without changing the peak discharge unless there are lateral inflows or changes in channel characteristics, and becomes a weaker approximation for small Froude numbers, shallow slopes, and high resistance (Daluz Viera, 1983), but does have the advantage of providing a direct parametric link to hydraulic theory. A more complete physical approximation is the diffusion wave, in which the energy gradient and channel slope can differ. To generate a catchment-wide network response, these simplified flow routing functions can be solved for an explicit network of channel segments, as would commonly be done in engineering river models, or used within the network width function approach, described above as part of the CLASSIC model.

Conversion of Flows to Water Levels

In engineering applications, it will often be necessary to calculate the stage or absolute water level within the channel for design or planning purposes. The simplified routing methods discussed above need to be combined with separate hydraulic calculations to do this, unless an empirical relationship between flow and stage (a rating curve) is available, which may be the case at a flow gauging station or other hydraulic control. Where no such relationship exists, an alternative is to use a hydraulic model to construct a rating curve, for which local information will be needed on channel cross sections and surface roughness coefficients. Where detailed local data are not available, it may be sufficient to rely on simplified calculations assuming steady, uniform flow and applying the Manning or Chezy flow law.

The most detailed approach for channel flows generally used in practice is numerical solution of the hydrodynamic Saint-Venant equations (*see* **Chapter 124, Flood Routing and Inundation Prediction, Volume 3**), which account for friction, local accelerations, and momentum. The hydrodynamic approach can be used to compute flows and water levels throughout a reach. It represents the varying relationship between depth and flow rate as a flood wave passes through the reach, which may be particularly important where there are relatively shallow bed slopes and high resistance, for example, when water flows out of bank onto a floodplain.

Raster Two-dimensional Routing

An alternative routing approach is to make use of digital elevation data that can be produced in grid form to a high spatial resolution and vertical accuracy using LIDAR remote sensing. In this raster approach, each grid cell can be treated as an individual water store, with the flows between cells being calculated using a suitable representation, such as Manning's equation. Inflows can be added to any cell, and flows are propagated between cells by explicit time-stepping to model the evolution of flood extents. This is primarily a floodplain modeling approach, and where the channel itself needs to be modeled in greater detail (e.g. where it contains hydraulically significant structures), a one-dimensional channel model can be combined with the raster floodplain method to good effect. A full discussion of this approach to flood modeling is given in **Chapter 124, Flood Routing and Inundation Prediction, Volume 3**. However, the technique is robust and capable of being applied over large areas, with boundary conditions being provided by a rainfall-runoff model.

CONFIDENCE AND UNCERTAINTIES

Uncertainty at Gauged Catchments

One of the main sources of uncertainty in statistical flood estimation is typically the limited sample size, especially for single-site analysis. The use of pooled data helps overcome this to bring greater confidence to flood estimates. For an ungauged site, however, there is a further issue related to the confidence with which the index flood can be estimated, as well as the uncertainty about the pooling group or regional growth curve. Analytical expressions are available to derive confidence intervals for many such models; for example,

the shape of the likelihood function in the vicinity of the maximum likelihood parameter estimate can be used for a fitted single-site distribution. For more involved models, such as pooled or multisegment growth curves, resampling methods may be needed to provide a general means of establishing confidence intervals (*see* Faulkner and Jones (1999) for an application to rainfall frequency analysis).

Where rainfall-runoff models are used for flood estimation, the situation becomes rather more complicated. One of the main sources of uncertainty in predictions is the lack of uniqueness in calibrated parameters discussed in the context of calibration. Rainfall-runoff models applied in continuous simulation tend to be highly nonlinear (including thresholds in their responses) and the probability distributions of their parameters can be complex. Conceptual models are also capable of simulating multiple output variables (e.g. flood peaks, low flows, soil moisture) against which observational data may be compared and different measures of performance evaluated.

As a consequence of these complications, measures of uncertainty have tended to be based on importance sampling using MCS methods, or concepts of Pareto optimality (Gupta *et al.*, 2002). For example, Cameron *et al.* (1999, 2000b) used the GLUE (Generalized Likelihood Uncertainty Estimation) method of Beven and Binley (1992), a Bayes Monte Carlo approach, to compute uncertainty bounds for flood frequency curves. A number of approaches were used to "measure" model error, including the likelihood function for statistical distributions fitted to observed and simulated flood peak data. The rainfall-runoff model used by Cameron was TOPMODEL. Even though it has few parameters, it was shown that there could still be interactions within the model parameter space leading to uncertainty in the modeled flood frequency curves.

Generalized Model Uncertainty

A further issue is the uncertainty associated with generalization of continuous simulation modeling. In a recent study, Lamb and Kay (2004) have used MCS to generate confidence intervals for flood frequency curves at ungauged catchments. The sequential procedure discussed earlier was used to develop regression relationships between hydrological model parameters and catchment properties. Random samples were then generated from the distribution of the residuals surrounding each regression equation and used to calculate confidence intervals at a set of test catchments.

The confidence intervals calculated for the generalized continuous simulation were compared with intervals derived for a statistical distribution fitted to gauged data. The degree of uncertainty in the spatially generalized continuous simulation varied between sites but was often no greater than for the site-specific frequency curve fitted directly to the gauged flows. This procedure only took account of calibration uncertainty at the gauged sites in that the "calibrated" parameter estimates were regarded as if they were samples, subject to random error. However, it has provided a first assessment of the confidence that could be expected in continuous simulation flood estimates at ungauged sites.

BROADSCALE MODELING

The Problem

Flood frequency analysis is routinely used for engineering studies carried out at a very local scale. Point estimates of flood flows can often be used in such circumstances. At the wider catchment scale, however, upstream and downstream flood processes and management measures interact to determine the flood risk at any given location. For example, economic development may affect the production of runoff whilst the effects of engineered or natural storage may be propagated some distance along the river network.

In many places, there are formalized policies for the sustainable management of whole river basins and the environmental implications of flood management at the catchment scale have to be considered within this context. Hence, there is a need to model the joint effects of runoff production, runoff routing, and interactions with engineered and natural environments on a "whole catchment" basis. Modeling of this type can rarely consider every location in as much detail as a local study would allow. Instead, the methods employed need to be sufficiently generalized to cope with both data-rich and data-poor situations, and can be defined as "broad-scale modeling" (although this general framework might include, for example, very detailed hydrodynamic modeling of specific river reaches within a broad conceptualization of catchment hydrological response).

Rainfall-runoff Modeling

Currently, typical engineering practice would be to use event-based rainfall-runoff models to represent runoff production within a broadscale model. Modeling event hydrographs in this way provides a suitable input to routing or full hydrodynamic river models. Event models offer the facility to investigate, albeit crudely, possible effects of land management scenarios by adjustment of parameters such as the runoff coefficients and time-to-peak of the UH.

The event-based approach also has drawbacks in this context. Simulation on a catchment scale may require inputs to a river model in many places. Runoff production can be modeled independently at each node for a specified local rainfall (and hence flow) exceedance probability. Parameters of the design input package (e.g. storm duration and antecedent soil conditions) can be calibrated to provide a worst-case total flow when combined at a downstream point. However, the link between a specified level of risk

and the design inputs needed to generate that risk becomes tenuous unless the joint probabilities of the inputs are modeled. This is a considerable challenge. The problem is essentially that the concept of a catchment-wide "T-year storm" is not always a realistic concept, but is difficult to avoid with event-based methods.

Continuous Simulation

The continuous simulation method appears an ideal approach for broadscale modeling to represent the generation and propagation of floods, including the broad spatial variation of runoff production. Each of the main elements of the modeling may be as simple or sophisticated as the situation demands (or as the data allow). One of the first practical applications of at least a quasi-continuous simulation approach was motivated by the need to model a complex catchment system, including the operation of engineered river management schemes, in what could be interpreted as a form of broadscale model. This study, reported by Bras *et al.* (1985), involved a 46 397 km^2 basin in Kentucky, which was divided into 17 subbasins. A stochastic rainfall model was developed in which storm exteriors were modeled using a choice of distributions (dependent upon season) and with spatial correlation structures represented within the subbasins. Storm interiors were generated conditionally on a subset of the exterior properties by a stochastic process that preserved the observed within-storm temporal autocorrelation. Rainstorms were generated in chronological order, but, to cut down on the amount of ineffective data, were screened using a very simple "surrogate" rainfall-runoff model to retain only the most hydrologically important.

Bras *et al.* simulated runoff responses using an empirical model to generate daily subbasin runoff in consecutive 6-h blocks. The runoff data were transformed by a UH procedure and then routed through a hydraulic model that included the operation of reservoirs and simulated conditions at specified damage locations. The approach allowed different operational scenarios to be compared to examine management of the reservoir system. Bras *et al.* noted that "the advantage of the methodology is that it permits otherwise impossible analysis. It not only exploits available rainfall records which are many times better than their streamflow counterparts, but it also allows study of the system under varying operational scenarios".

The same comments could be applied to a study in which a network of rainfall-runoff models were driven by long series of spatially structured rainfall data, and the resulting flows taken as a proxy record from which the system state under differing levels of risk could easily be computed. This complete broadscale modeling framework would bring together the following elements:

- generalized, spatially consistent rainfall models
- generalized, conceptually realistic runoff production models
- integrated data storage and analysis tools.

All three of the elements listed above have been developed at least to a proof-of-concept stage, and in some cases as prototype applications.

At a practical level, continuous simulation has already proven to be useful in circumstances where flood risk

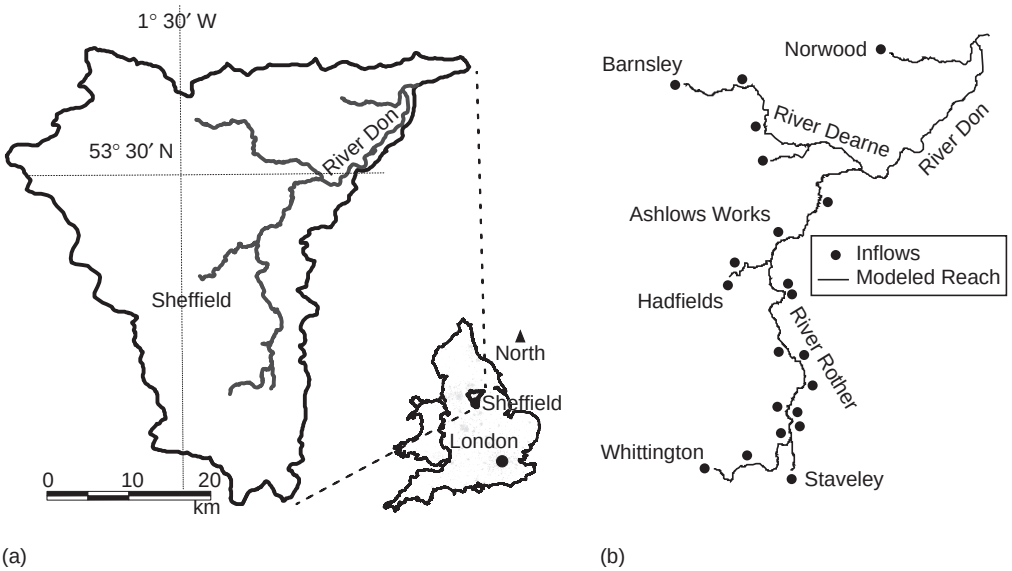

Figure 10 (a) Location of the River Don catchment. (b) Main river network and location of continuous simulation inputs to hydraulic model. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

within the catchment depends on the operation of engineered systems, where the flood risk at key locations is created by combinations of hydrological inputs, and where events can combine in different sequences. These issues alone may be sufficient to justify considering a continuous simulation approach for analysis of flood risk. If the flows at key locations within the catchment are sensitive to the combined inputs, and those locations are also physically sensitive to the flows (e.g. because defences could be overtopped), then continuous simulation is likely to be the best modeling approach. Modeling will be enhanced by any available gauged flow data that can be used for calibration, even relatively short records.

The following case study, reported in detail by Faulkner and Wass (2005), describes a situation where the above conditions all existed. The aim of the study was to generate maps indicating the extent of flooding at given probabilities for the catchment of the River Don, located in the central-eastern part of the United Kingdom (see Figure 10). This 1256 km^2 basin has various subcatchments of different elevation, slope, and hydrological response. It has a complex system of regulators and engineered storage (Figure 11), developed since 1958, which need to

(a)

(b)

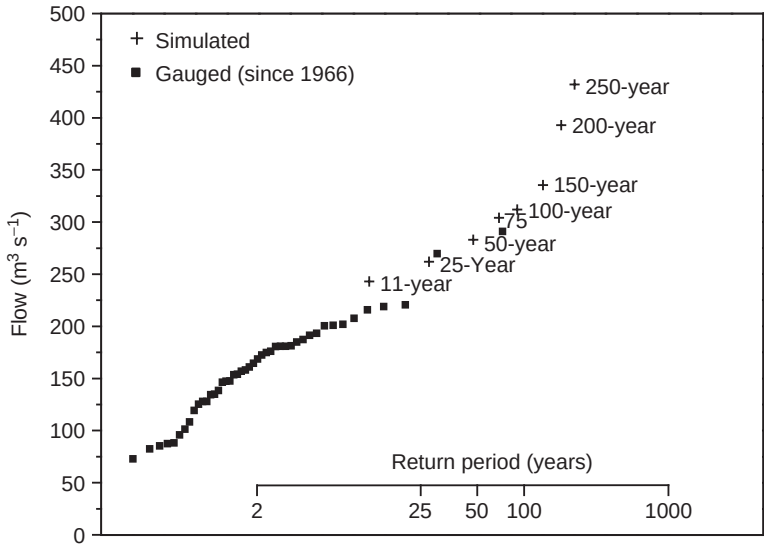

Figure 12 Gauged and simulated annual maximum (AMAX) flows as a function of return period using Gringorten plotting positions

be accounted for in any modeling, and they also make statistical frequency estimation difficult.

For the Don study, a point stochastic rainfall model was calibrated and applied to 20 subcatchment runoff models, with spatial variation in the rainfall to allow for differences in altitude. Each runoff model was a version of the PDM. Calibration was carried out at gauged subcatchments. For ungauged subcatchments, most parameters were transferred from calibrated catchments on the basis of catchment similarity. (The store parameters controlling the hydrological routing of storm hydrographs were estimated using empirical relationships derived with respect to existing UH models, for which general formulae are available.) A calibrated hydrodynamic model was used to connect the inputs in this study and to represent the operation of flood defences (although in other applications, simpler routing models could also be used for much of a catchment river network).

This catchment scale model was run for long (1000 year) sequences of synthetic rainfall data. The largest floods were extracted from the simulations and ranked to estimate the levels associated with specified return periods. Comparison of peak flows at the catchment outlet (Figure 12) with data gauged since 1966 (after the onset of regulation) would appear to support the results of the modeling.

What is significant about this study is the adoption of a complete continuous simulation approach, including rainfall, runoff, and river hydraulics, to solve a difficult catchment scale modeling problem. Whilst the initial outputs of the study were flood risk maps, it has been found that the large synthetic data set has other applications, such as the optimization of defences and the setting of flood warnings.

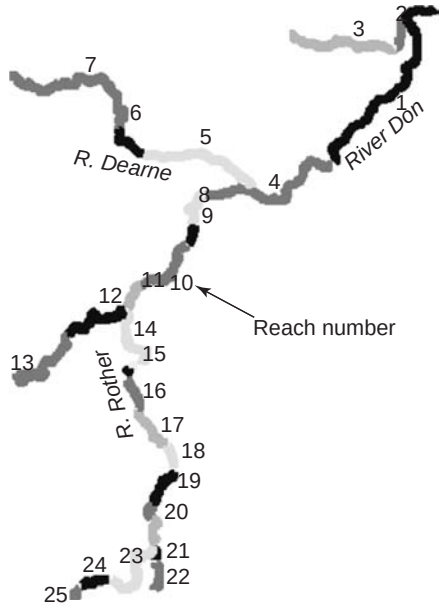

Figure 13 Don catchment main river network showing numbered reaches in which the 100-year flow arose from the same simulated event within each reach

The results illustrated the considerable spatial variation in the rank of the modeled event that constituted the local 100-year flood (Figure 13). There is clearly no assumption of a single, catchment-wide T-year event using this method, and the individual "events" making up the 100-year flood at each point vary in terms of antecedent conditions, hydrograph shape, volume, duration, and peak flow.

Concluding Remarks

Event-based rainfall-runoff models continue to be applied on a routine basis and are easily implemented in software packages. Despite some theoretical difficulties, the approach provides a practical solution for broadscale flood modeling when volumes and timing are important. Further development is likely to focus on resolving joint probabilities for design inputs and incorporating new data into event procedures to improve flood frequency estimates.

Continuous simulation models of runoff production are now becoming more widely used and understood, as are the techniques to apply them in combination with rainfall and river models. The most important challenge for continuous simulation is parameterization for ungauged catchments to provide generalized modeling of runoff production. Allied to this is the need for generalized rainfall models to allow flood estimation for long return periods. Continuous simulation is not yet widely accessible in "off-the-shelf" software form, but as the studies cited here indicate, the approach is now well established, both as a research method and in practice.

Acknowledgments

The author is grateful for help given by the following individuals and organizations during the writing of this review: Keith Beven (Lancaster University), Ann Calver, Sue Crooks, Alison Kay and Lisa Stewart (CEH Wallingford), Paul Wass and Duncan Faulkner (JBA Consulting – Engineers & Scientists). The two anonymous reviewers are thanked for their comments.

126: Modeling Recession Curves and Low Streamflows

CHARLES KROLL

Environmental Resources and Forest Engineering, SUNY College of Environmental Science and Forestry (ESF), Syracuse, NY, US

Low streamflow events are critical periods for water quantity and water quality management purposes. During most low streamflow events, the stream is comprised solely of groundwater sources. This section focuses on both theoretical and empirical methods for modeling groundwater discharge to a stream and the resulting streamflow recession. A review is provided of solutions to the Boussinesq equation for hillslope discharge, and methods for determining when specific solutions may be most appropriate. In addition, how to estimate baseflow recession constants that aid in the modeling of groundwater discharge to streams, has been discussed. This involves the presentation of numerous methods to parameterize baseflow recession characteristics, how best to represent error in these models, and experiments that have been performed to determine the most appropriate methodology.

INTRODUCTION

Importance of Low Streamflows

Understanding the frequency and duration of low streamflow events is critical to the efficient management of water resources throughout the world. This is especially important for water quality management, where low streamflows provide the necessary dilution of nonpoint source and point source pollution discharges, and water quantity management, where low streamflows greatly influence water use policy. Low streamflow predictions and forecasts are used to plan water supply, hydropower, and irrigation systems, design cooling-plant facilities, site treatment plants and sanitary landfills, determine waste-load allocations, and make decisions regarding interbasin transfers of water and allowable basin withdrawals. In addition, low streamflow events are often critical periods for aquatic habitats owing to potentially low dissolved oxygen concentrations and/or high concentration of pollutants. Low streamflows are also used in health risk assessments that quantify the long-term risk associated with exposure to carcinogenic substances in rivers.

Low streamflow and associated droughts can have a devastating impact on a society. Often a major impact of droughts is a reduction in agricultural production, which can cause large monetary impacts as well as widespread malnutrition, displacement of peoples, and loss of life. For some statistics regarding the worldwide impacts droughts (and other natural disasters), the reader is encouraged to access the Emergency Events Database (EM-DAT), which was developed by the World Health Organization (WHO) and the Belgium Government (EM-DAT, 2003). It is important to note that many drought "events" are not reported or quantified since they often occur over many years and the societal impacts are more difficult to assess than other natural disasters.

Difficulties with Lowflow Analyses

While flood frequency analyses have received considerable attention in the research literature, the estimation of low streamflow statistics has received relatively little. In some regions, there is evidence that droughts may be more influenced by climatic fluctuation and anthropogenic effects than floods. For instance, by examining historical records for the last 50 years, Douglas *et al.* (2000) found significant trends in lowflow series in some regions of the United States, while they found no such trends for flood flow series in any regions of the United States. Lowflow analyses are often complicated owing to precision problems regarding

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

recorded data. Analyses of historic streamflow records can involve the presence of intermittent streamflows, resulting in a truncation or censoring of the lower tail of the frequency distribution (which complicates many log-based analyses). Often low streamflow estimates are based on extrapolating rating curves (stage-discharge relationships), thus introducing additional error.

The physical processes responsible for lowflow events are also complex. Lowflows are primarily due to groundwater discharge to a stream. Despite advancements in measurement technology, "our knowledge of what goes on underground is still very limited" (Beven, 2001). The nonlinear partial differential equations describing these processes have only been solved analytically for idealized systems with specific boundary conditions. These solutions do not address the common heterogeneity of hydrogeologic properties observed within most watersheds, nor the complex physical structure of watersheds and aquifers. In addition, the spatial and temporal variability of infiltration and percolation processes complicates our understanding of groundwater recharge characteristics. Despite these complexities, we are often forced to model groundwater discharge processes to aid in the management of low streamflow events.

Rainfall-runoff Models: Baseflow Recession

There are many analyses related to lowflows and streamflow recessions (Smakhtin, 2001). Other sections of this encyclopedia cover many of these topics, such as frequency analyses and the estimation of low streamflow statistics at gauged and ungauged river sites. In this section, several topics related to understanding and parameterizing streamflow recession characteristics for rainfall-runoff analyses are discussed. There are a variety of ways to represent groundwater discharge, which is commonly referred to as baseflow, to streamflow. Baseflow can be defined in a number of ways, including just groundwater contributions, or more commonly groundwater and other delayed sources (Hall, 1968).

This section of is broken into two subsections: theoretical models of groundwater discharge, and parameterizing baseflow recession characteristics. The first subsection ("Theoretical Models of Groundwater Discharge") will discuss solutions to the Boussinesq equation, and variations of the Brutsaert and Nieber (1977) technique for analyzing the appropriateness of the Boussinesq solutions. This subsection presents theoretical relationships between groundwater discharge parameters and watershed characteristics, and ways in which the parameters of these models may be estimated and/or regionalized. The second subsection (Parameterizing Baseflow Recession Characteristics) will focus on estimating the parameters of some common groundwater discharge models employed in rainfall-runoff modeling. This will include discussions of the impact of error on recession constant estimators, as well as attempts to compare these estimators. Different rainfall-runoff models model baseflow in varying manners. A number of these techniques are discussed below. Tallaksen (1995) provides a review of additional baseflow recession analyses.

Some event-based rainfall-runoff models ignore baseflow contributions or consider them constant. In these models, it is the flood peak that is typically of interest (which can be orders of magnitude larger than the baseflow contributions), or stormflow contributions (e.g. to design detention ponds that delay and attenuate excess storm runoff). A common approach is to consider groundwater contributions to streamflow as a single linear reservoir, such as in HEC-1 (Feldman, 1995) (note that HEC-1 is now called HEC-HMS) and GWLF (Haith *et al.*, 1992). A linear reservoir means that groundwater discharge is modeled as a linear function of storage, resulting in an exponential decay of discharge with time. Another common technique is to assume two or more linear reservoirs to account for slower and quicker groundwater contributions. SAC-SMA (Burnash and Ferral, 2002), UBC (Quick, 1995), Tank (Sugawara, 1995), and HBV (Bergstrom, 1995) models employ this type of groundwater discharge model. Groundwater discharge in PRMS (Leavesley and Stannard, 1995) is modeled in a similar manner, but shallow subsurface flow is simulated as a 2nd order quadratic function.

Using the TOPMODEL assumptions that downslope transmissivity varies with depth of saturation as an exponential function of storage deficit, and that the water table remains parallel to the surface, a baseflow recession follows a first-order hyperbolic relationship (Beven *et al.*, 1995), though this was later generalized to other transmissivity profiles (Iorgulescu and Musy, 1997; Lamb *et al.*, 1997). In many spatially distributed models, groundwater is routed cell-by-cell and a distributed groundwater response is modeled. This distributed response can be based on Darcy's law and surface gradients, such as in DHVSM, (Wigmosta *et al.*, 1994); a nonlinear Boussinesq response, such as in SHE (Bathurst *et al.*, 1995); or approximated using a kinematic assumption, such as in THALES (Grayson *et al.*, 1995). Franchini and Pacciani (1991) and Singh (1995) review the components (including groundwater discharge) of numerous rainfall-runoff models.

THEORETICAL MODELS OF GROUNDWATER DISCHARGE

One approach to modeling groundwater discharge is by using a groundwater flow model. Distributed models, such as the finite difference model MODFLOW or the finite element model FEMWATER, are typically employed to examine small-scale groundwater transport problems. These

three-dimensional models require a large number of parameters and are usually not employed across an entire watershed, especially in the application of rainfall-runoff models. As mentioned previously, in most rainfall-runoff models groundwater discharge is modeled as a more simplified, lumped process. In this section, hillslope models based on the Boussinesq equation are discussed.

Solutions to the Boussinesq Equation

Partially saturated hillslope subsurface drainage can be described by the Richards equation (Brutsaert and El-Kadi, 1984). Since the resulting solutions from this method cannot easily be parameterized in practice, a hydraulic approach is typically taken (Brutsaert, 1994). In 1877 Boussinesq derived an expression for one-dimensional flow from an unconfined sloping aquifer (Childs, 1971):

$$q = -kh\left[\left(\frac{\partial h}{\mathrm{d}x}\right)\cos(\theta) + \sin(\theta)\right] \tag{1}$$

where q is the flow in the x-direction per unit width of aquifer, k is the hydraulic conductivity, and h is the thickness of the water layer perpendicular to the underlying impermeable layer with slope θ. This equation is based on the assumption that capillary effects and evapotranspiration are negligible. Combining this expression with the continuity equation, and neglecting any recharge from the unsaturated zone, one obtains:

$$\frac{\partial h}{\partial t} = \frac{k}{f}\left[\cos(\theta)\frac{\partial}{\partial x}\left(h\frac{\partial h}{\partial x}\right) + \sin(\theta)\frac{\partial h}{\partial x}\right] \tag{2}$$

where f is the drainable porosity. Equation (2) is usually referred to as the Boussinesq equation, and is based on assuming k, f, and θ are constant. This equation satisfies the Dupuit–Forchheimer conditions (horizontal flow lines and hydraulic gradient equal to the slope of the water table). Brutsaert (1994) used a linear approximation of equation (2) to derive an expression for drainage of a sloped, fully saturated aquifer. Brutsaert referred to this as the "unit response" (Green's function) of the aquifer.

Mizumura (2002) recently used the method of variations to approximate the solution of equation (2). Verhoest and Troch (2000) applied the approach of Brutsaert (1994) to time-varying recharge rates. This solution employs a quasi steady-state approach, where varying water table profiles between successive steady-state conditions can be computed. Troch *et al.* (2003) expanded the original Boussinesq equation (equation (2)) by reformulating the problem in terms of soil water storage as opposed to water table height. This leads to a new one-dimensional equation, the so-called hillslope-storage Boussinesq (hsB) equation, which accounts for the plan shape (convergent/divergent) and profile curvature (concave/convex) to describe groundwater flow and saturation in complex hillslopes. Paniconi *et al.* (2003) examined how solutions of the one-dimensional hsB equation compare with solutions to the three-dimensional Richard's equation. A more common solution is based on assuming the impermeable layer is horizontal ($\theta = 0$), resulting in:

$$\frac{\partial h}{\partial t} = \frac{k}{f}\left[\frac{\partial}{\partial x}\left(h\frac{\partial h}{\partial x}\right)\right] = \frac{k}{f}\left[h\frac{\partial^2 h}{\partial x^2} + \left(\frac{\partial h}{\partial x}\right)^2\right] \tag{3}$$

Solutions to this equation are based on the idealized aquifer presented in Figure 1, with a fully penetrating stream channel (stream channel bottom coincident with impermeable layer. There are three analytical solutions to this equation that have been applied (Brutsaert and Nieber, 1977). The first is based on the assumption that either the slope of the water table is nearly horizontal ($\partial \mathrm{h}/\partial \mathrm{x} = 0$) or that $\partial^2 \mathrm{h}/\partial \mathrm{x}^2 \gg (\partial \mathrm{h}/\partial \mathrm{x})^2$. Under this situation, equation (3) is linearized, and the resulting groundwater outflow from an initially saturated aquifer per unit length of channel can be written:

$$q = \frac{2kpD(D - D_c)}{B}\sum_{n=1,3,\ldots}^{\infty}\exp\left(-\frac{n^2\pi^2 kpDt}{4fB^2}\right) \tag{4}$$

where D is the depth of the aquifer, pD is the mean depth of the water table, D_c is the depth in the stream, and B is the aquifer breadth. After a long time this equation reduces to

$$q = \frac{2kpD(D - D_c)}{B}\exp\left(\frac{\pi^2 kpDt}{4fB^2}\right) \tag{5}$$

Equation (5) is often referred to as the linear solution of Boussinesq, who solved this equation in 1903 (Brutsaert and Nieber, 1977). Boussinesq also obtained an exact solution to equation (3) by assuming the water level in the channel was zero ($D_c = 0$), and the water table is initially described by an inverse incomplete beta function. The resulting groundwater discharge per unit length of channel

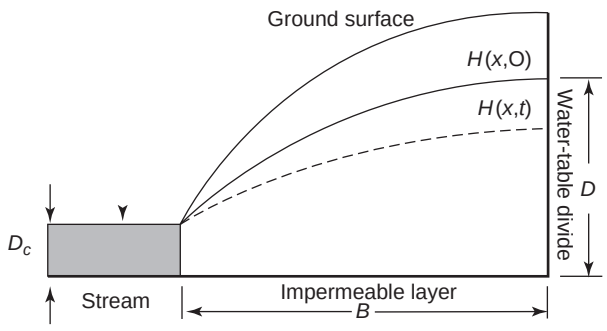

Figure 1 Idealized physical model of a hillslope

for this case is:

$$q = \frac{0.862kD^2}{B\left(1 + \frac{1.115kDt}{fB^2}\right)^2} \quad (6)$$

Equation (6) is not applicable when the aquifer is fully saturated, and thus is only applicable after a long time t. If one assumes the aquifer is infinitely wide ($B = \infty$) and again $D_c = 0$, then a solution for a small t can be found as:

$$q = \frac{1}{2}D_o t^{-1/2} = \frac{0.3321(kf)^{1/2}D^{3/2}}{t^{1/2}} \quad (7)$$

where D_o is the desorptivity (Brutsaert and Nieber, 1977):

$$D_o = 0.6642(kf)^{1/2}D^{3/2} \quad (8)$$

There are therefore three commonly cited solutions to the Boussinesq equation: a linear solution, and two nonlinear solutions (one for long t and one for small t). Of interest is which of these solutions is most appropriate for a given watershed or region of watersheds.

Hogarth *et al.* (1999) developed a new approximate solution to the one-dimensional Boussinesq equation for a semi-infinite aquifer with a time-varying hydraulic head as a boundary condition. A further approximation to the Boussinesq equation arises if it is assumed that the downslope hydraulic gradient stays constant at the slope angle. This then gives rise to a kinematic wave equation, which was used by Beven (1982) to model subsurface stormflow analytically for simple initial conditions and rainstorms and different conductivity profiles.

Power Relationship and the Boussinesq Solutions

Brutsaert and Nieber (1977) suggested a power equation relating outflow from the basin, Q, to the volume of water stored in the aquifer, S:

$$Q = mS^n \quad (9)$$

where m and n are constants. If $n = 1$ in equation (9), then the discharge-storage relationship is linear; such a system is described as a "linear reservoir". Combining this equation with a lumped continuity equation one obtains

$$Q = Q_0 K_b^t \quad (10)$$

for the case when $n = 1$. Q_0 is the outflow at time $t = 0$, and K_b is a constant, commonly referred to as the baseflow recession constant. This solution is consistent with the linearized solution to the Boussinesq equation, where

$$K_b = \exp\left(\frac{-\pi^2 kpD}{4fB^2}\right) \quad (11)$$

Thus the linear solution to the Boussinesq equation is consistent with the modeling baseflow as a linear reservoir, as is done in many circumstances. For the nonlinear solutions ($n \neq 1$), a general solution is:

$$Q = Q_0(1 + ct)^{n/(1-n)} \quad (12)$$

where c is a constant. With $n = 2$, this equation is consistent with equation (6), the nonlinear solution to the Boussinesq equation for a long time t. Wittenberg and Sivapalan (1999) used (12) to identify and quantify the main components of the groundwater balance using observed time series.

To eliminate the time frame (and thus avoid the estimation of Q_0), Brutsaert and Nieber (1977) suggested not examining the hydrograph itself, but instead its slope, $\mathrm{d}Q/\mathrm{d}t$, using a power function relating slope to discharge:

$$\frac{\mathrm{d}Q}{\mathrm{d}t} = -aQ^b \quad (13)$$

where a and b are constants. These constants are related to equation (12) by:

$$b = \frac{2n-1}{n} \quad (14)$$

and

$$a = \frac{n}{n-1}cQ_0^{(1-n)/n} \quad (15)$$

By assuming some geometric similarity of the catchment drainage patterns, such that the groundwater outflow per unit length of channel is

$$q = \frac{Q}{2L} \quad (16)$$

where L is the total stream length in the catchment, and the aquifer breadth is

$$\mathrm{B} = \frac{\alpha \mathrm{A}}{2L} \quad (17)$$

where α is the fraction of catchment underlain by aquifers and A is the drainage area, the three solutions to the Boussinesq equation can be put in the form of equation (13) (Brutsaert and Nieber, 1977). For the linear solution (equation (5)),

$$b = 1 \quad \text{and} \quad a = \frac{\pi^2 kpDL^2}{f(\alpha A)^2} \quad (18)$$

In this situation, the aquifer is being modeled as a single linear reservoir, and the parameter $a = \ln(K_b)$, where K_b is the baseflow recession constant. For the nonlinear solution for a long period (equation (6)), one obtains

$$b = \frac{3}{2} \quad \text{and} \quad a = \frac{4.804k^{1/2}L}{f(\alpha A)^{3/2}} \quad (19)$$

while for the nonlinear solution for a short time period (equation (7)), one obtains

$$b = 3 \quad \text{and} \quad a = \frac{1.133}{kfD^3L^2} \tag{20}$$

Brutsaert and Lopez (1998) noted α equals 1 in most watersheds, and thus usually can be removed from these expressions. Szilagyi and Parlange (1998) developed a method of baseflow separation using the two nonlinear solutions to the Boussinesq equation.

By examining b, the slope of a log–log plot of $\mathrm{d}Q/\mathrm{d}t$ versus Q, one can potentially assess the appropriateness of various solutions of the Boussinesq equation to describing groundwater discharge to a stream. This approach is sometimes referred to as the Brutsaert–Nieber procedure (Tallaksen, 1995), and is presented in the next section. In addition, the y-intercept, a, is a function of watershed characteristics, thus potentially allowing the parameters of a groundwater discharge model to be regionalized or estimated from watershed characteristics. In addition, the converse may be true, where watershed characteristics (such as regional hydrogeologic properties) may be estimated from the parameters of calibrated groundwater discharge models.

Appropriateness of Boussinesq Solutions

There are a number of difficulties associated with examining the appropriateness of solutions to the Boussinesq equation. One problem is determining when streamflow sources other than baseflow cease and when recharge from the unsaturated zone becomes negligible (i.e. when the streamflow is entirely baseflow and may be described by a Boussinesq solution). Another problem is determining how to fit a line to a log–log plot of $\mathrm{d}Q/\mathrm{d}t$ versus Q to obtain an estimate of the slope, b. This issue is further complicated by the precision with which the streamflow data are recorded. A few of the studies addressing this problem are discussed below.

Brutsaert and Nieber (1977) examined six catchments in the Finger Lakes region of New York. They considered only streamflow data 5 days after rainfall as baseflow, and fit only the "lower envelope" of data in a $\mathrm{d}Q/\mathrm{d}t$ versus Q plot (i.e. the lowest $|\mathrm{d}Q/\mathrm{d}t|$ at a given Q). The rationale for fitting the lower envelope is to remove data points that might be influenced by sources other than groundwater. A value of $b = 3/2$ appeared to have a good "visual" fit at these sites. Using these fits, a value of a in equation (13) was estimated at each site. These six values were regressed then against $\mathrm{LA}^{-3/2}$ to obtain a regional estimate of the quantity $k^{1/2}/(f\alpha^{3/2})$ using equation (18). Brutsaert and Nieber note that one would expect k, f and α to vary from site to site, yet felt a satisfactory relationship existed between a and $\mathrm{LA}^{-3/2}$ for 5 of the 6 sites. One obvious shortcoming of this study was the limited number of sites employed.

Troch *et al.* (1993) applied the Brutsaert and Nieber technique to 10 years of streamflow data at a single, well studied catchment in Belgium. Recessions began two days after the cessation of rainfall, which was approximately 2 times larger than the estimated time of concentration for the watershed. They examined fitting an ordinary least squares (OLS) regression line to all recession points, finding it to correspond well to $b = 3/2$. They also fit the lower envelope of the data with lines of $b = 3/2$ and $b = 3$, and performed a sensitivity analysis of the lower envelop fit by examining solutions excluding 5% and 10% of the data. Troch *et al.* noted that where the lines of $b = 3/2$ and $b = 3$ cross represents an estimator of the discharge threshold under which the long time solution to the Boussinesq equation is appropriate. Assuming a range of values for drainable porosity, they developed a catchment-scale estimator of effective depth to the water table (representing the initial storage in the aquifer) and hydraulic conductivity.

Brutsaert and Lopez (1998) examined recessions at 22 USDA subbasins in Oklahoma. They proposed fitting the lower envelop with a line they referred to as the line of organic correlation. Others have called this line the unique solution and the reduced major axis (Hirsch, 1982). Brutsaert and Lopez proposed this fitting technique owing to the error in both the independent and dependent variables in the regression. They used streamflows 2 days after the cessation of rainfall. In contrast to the other two studies mentioned above, they found in this region the long time response (corresponding to the smallest values of Q), was described by the linear Boussinesq equation ($b = 1$), while for shorter time periods (larger values of Q) $b = 3$. They thus had 2 estimates of a for each catchment (from the two lines of fit). Using these equations Brutsaert and Lopez obtained effective basin-scale estimators of various groundwater parameters, which allowed estimation of watershed hydraulic conductivity and drainable porosity. A watershed-scale parameter represents the integration of groundwater processes across the entire watershed, characterizing an equivalent homogeneous response. Eng and Brutsaert (1999) found similar results at 11 catchments in Kansas that were part of the same geomorphic region as the sites used by Brutsaert and Lopez; this result indicates the potential for regionalizing groundwater discharge characteristics.

One interesting observation in Eng and Brutsaert was a "stair-step" pattern in a log–log plot of $\mathrm{d}Q/\mathrm{d}t$ versus Q, which was also apparent in the studies by Vogel and Kroll (1992) and Kroll (1989). Below certain values of Q, there was a threshold below which no values of $\mathrm{d}Q/\mathrm{d}t$ occurred. This was because of the precision with which the US Geological Survey data employed is reported. For instance,

discharge values between 10 and 10 000 cfs are reported as integers, while values between 1 and 10 cfs are reported with 1 decimal. Thus it was impossible to have values of dQ/dt calculated from the data less than 1 if the discharges were greater than 10 cfs, but it is possible to obtain such a value at lower discharges. This phenomenon creates data voids in the dQ/dt versus Q plots, further complicating the analyses. There is also potential for uncertainty and nonstationarity in the rating curve at a gauging station at low flows. One should be keenly aware of the precision of the reported data when performing such an analysis.

Vogel and Kroll (1992) performed a similar analysis at 23 catchments in Massachusetts. They did not examine rainfall data to determine baseflow recessions, but instead examined removing a certain percentage of the recession to remove impacts of direct runoff. Vogel and Kroll found that when 30% of the hydrograph was removed, a log–log plot of dQ/dt versus Q produced a slope of $b = 1$ across the region. Vogel and Kroll fit all of the data and not just the lower envelope, since fitting only the lower envelope of the data neglects the presence of measurement error in the data. They developed a catchment lowflow response using the linear solution to the Boussinesq equation, and showed the parameters of such an equation are significant in a regional regression model for low streamflow statistics.

One common theme across these studies was the goal of developing relationships between the parameters of theoretical groundwater discharge equations and watershed characteristics. Unfortunately, these studies represent the beginning of such efforts. Assumptions regarding the homogeneity of hydrogeologic characteristics (such as the assumption of a watershed hydraulic conductivity required by the Boussinesq solutions) and the simplified physical structure of an aquifer used in these derivations are known to be incorrect in most watersheds. Also, these investigations have been performed in only a few regions, typically with only a small number of watersheds. It is difficult to obtain far-reaching conclusions based on these limited studies, but they do provide a framework by which one may continue further investigations of regional and at-site groundwater discharge response.

PARAMETERIZING BASEFLOW RECESSION CHARACTERISTICS

Lowflows in Model Calibration

One concern is how to estimate the baseflow recession parameters of rainfall-runoff models. A potential way to address this is to estimate these parameters when calibrating the model. Often estimating these baseflow parameters is not a priority, even for continuous simulation models. Most loss functions that are minimized in the calibration of rainfall-runoff models (such as minimizing bias or root mean square error of streamflow estimators) are developed to favor flood events, which are often of primary concern. In these situations, the model improves the fit of larger streamflow events at the expense of fitting small flows poorly. In addition, measured low streamflows, which are considered as "truth" in the loss function, often have large amounts of error (as do large streamflow events). To improve the fit of low streamflow events, one can employ either a log-spaced or relative loss function (such as relative bias, which is a percent); in these situations, though, the model fit to larger streamflow events is typically reduced. One should always consider the goals of the model when developing a calibration methodology.

Linear Reservoir Models

Model Form and Error Terms

Another common procedure is to estimate the baseflow recession parameters using available streamflow data. Barnes (1939) assumed that hydrograph recessions follow the basic relations

$$B_t = K_b B_{t-1} \tag{21}$$

$$O_t = K_o O_{t-1} \tag{22}$$

where B_t and O_t are the baseflow and other component of streamflow, and K_b and K_o are the baseflow and other component recession constants, respectively. Thus the streamflow during these recession periods is a combination of these two components

$$Q_t = B_t + O_t \tag{23}$$

Equation (21) corresponds to the linear solution to the Boussinesq Equation presented in equation (5), and is the "linear reservoir" (exponential decay) model employed in many rainfall-runoff models. Barnes (1939) was interested in hydrograph separation procedures, and estimated the recession constants graphically, though his methods contained many subjective judgments (Kulandaiswamy and Seetharaman, 1969; Anderson and Burt, 1980). Hall (1968) provides a review of many early recession analyses that were based on improved graphical procedures. Tallaksen (1995) presents many alternative forms of equation (21).

Recession constants can be estimated from an individual hydrograph or ensembles of hydrographs. Interpreting individual streamflow hydrographs is difficult owing to the poor quality of the data, the small number of data points, and the high variability in recession behavior both within and between catchments (Hall, 1968). This may lead one to favor ensembles of streamflow recessions. Perzyna (1990, as cited in Tallaksen, 1995) suggested a minimum of 10 years of streamflow data was necessary to provide reliable estimates of recession parameters. Regardless, one

should consider these estimates as random variables, and thus attempt to address their statistical properties (Vogel and Kroll, 1996).

If one was to wait a sufficiently long period of time, then the streamflow contribution of other sources, O_t, will approach zero in equation (23). Thus streamflow is comprised of only baseflow and might then be modeled as a single reservoir, the drainage of which might be described by a simple parametric function. In addition, the assumptions made regarding the form of the error in equations (21) and (22) impact the derived estimators. Some methods to estimate recession constants for single or double linear reservoir models are discussed below.

Consider equation (23) as a single linear model ($O_t = 0$) with an additive error term:

$$Q_t = K_b B_{t-1} + \varepsilon_t = K_b Q_{t-1} + \varepsilon_t \tag{24}$$

where ε_t are assumed independent error terms with mean zero and constant variance, and represent both time sampling and model errors. Equation (24) describes a first-order autoregressive process (AR(1)) (Box and Jenkins, 1976), where K_b is the autoregressive parameter. James and Thompson (1970) employed this model. If instead one assumes an additive error in log-space, equation (23) becomes:

$$Q_t = K_b B_{t-1} \exp(\varepsilon_t) = K_b Q_{t-1} \exp(\varepsilon_t) \tag{25}$$

Taking the logarithms of both sides of equation (25) results in an integrated moving average model (ARIMA(0,1,0)) with a constant drift parameter of $\ln(K_b)$ (Box and Jenkins, 1976).

Now consider streamflow recession to comprise both baseflow and other components (as in equation (23)), with an additive error term in real-space:

$$Q_t = K_b B_{t-1} + K_o O_{t-1} + \varepsilon_t \tag{26}$$

Vogel and Kroll (1996) show how this model can be rewritten as an AR(2) process (Box and Jenkins, 1976):

$$Q_t = \phi_1 Q_{t-1} + \phi_2 Q_{t-2} + \varepsilon_t \tag{27}$$

where:

$$K_b = \frac{1}{2}\left[\phi_1 + (\phi_1^2 + 4\phi_2)^{1/2}\right] \tag{28}$$

$$K_o = \frac{1}{2}\left[\phi_1 - (\phi_1^2 + 4\phi_2)^{1/2}\right] \tag{29}$$

Vogel and Kroll discuss the parameter conditions that must be satisfied for this process to be stationary. Spolia and Chander (1974, 1979) showed that if a watershed is represented as a cascade of n equal or unequal linear reservoirs, the streamflow process is equivalent to an ARMA(n, $n-2$) model; here $n = 2$. Another potential AR(2) model is to assume an additive error in log-space:

$$Q_t = (\phi_1 Q_{t-1} + \phi_2 Q_{t-2}) \exp(\varepsilon_t) \tag{30}$$

James and Thompson (1970) modeled recessions as an ARMA(1,1) and ARMA(2,2) process, with the autoregressive and moving average parameters equal; these models both contain parameter redundancy and the derived process reduces to white noise, that is, an uncorrelated random process with zero mean and finite variance (Box and Jenkins, 1976).

Least Squares Estimators

One possible estimator of the recession constants is to obtain an estimate for each individual recession, and then take the average (or a weighted average) of the ensemble to obtain a single estimator for the site. Vogel and Kroll (1996) note how the time series estimators of the parameters are downwardly biased when sample size is small, as is the case for an individual recession. They suggested instead an ensemble of data from all recessions be employed to obtain a single estimator for a site using least squares regression procedures, as was employed by James and Thompson (1970). For the AR(1) model of equation (24), the least squares estimator of K_b is:

$$K_b = \frac{\sum_{t=1}^{n} Q_t Q_{t-1}}{\sum_{t=1}^{n} Q_t^2} \tag{31}$$

where n is the number of pairs of consecutive streamflow recessions. For the ARIMA(0,1,0) model, the least squares estimator of K_b is:

$$K_b = \exp\left[\frac{1}{n}\sum_{t=1}^{n}(\ln(Q_t) - \ln(Q_{t-1}))\right] \tag{32}$$

For the AR(2) model with an additive error in, one could estimate ϕ_1 and ϕ_2 as ordinary least squares (OLS) estimators. Vogel and Kroll (1996) found the error terms to be heteroscedastic (nonconstant variance), and thus the OLS estimators would not be the best linear unbiased estimators (BLUEs). By transforming the model to:

$$\frac{Q_t}{Q_{t-1}} = \phi_1 + \phi_2 \frac{Q_{t-2}}{Q_{t-1}} + \eta_t \tag{33}$$

where the transformed error terms η_t are approximately homoscedastic. ϕ_1 and ϕ_2 can now be estimated from a simple linear regression model, and K_b and K_o then

estimated by equations (28) and (29), respectively. For the AR(2) model with additive error terms in log-space, any standard two-dimensional search algorithm may be employed to estimate the parameters. Kroll (1989) used an iterative least squares approach to estimate this model's parameters.

Recall that then when $b = 1$ in equation (13), the parameter $a = \ln(K_b)$. Using this relationship with an error term additive in log-space Vogel and Kroll (1996) derived another least squares estimator of K_b:

$$K_b = \exp\left\{-\exp\left[\frac{1}{n}\sum_{t=1}^{n}\left\{\ln(Q_{t-1} - Q_t) - \ln\left(\frac{1}{2}(Q_{t-1} + Q_t)\right)\right\}\right]\right\} \quad (34)$$

which they referred to as the linear reservoir estimator.

Comparison of Least Squares Estimators

It is often difficult to determine conclusively the best estimator of a statistic among several competing estimators. One method to do this is a Monte Carlo simulation, which requires definition of an underlying model. Since groundwater processes are complex, such a model is difficult to construct, and most models would resemble one of the models presented above, thus most likely favoring that estimator. The many studies that have investigated baseflow recession modeling (see examples in Tallaksen, 1995), have typically examined only a limited numbers of recessions and/or sites, and thus have been unable to develop conclusive recommendations for baseflow recession estimation methodology.

Vogel and Kroll (1996) attempted to assess a baseflow recession constant estimator's performance based on its ability to describe low streamflow statistics in regional regression models. The watershed model employed was developed by Vogel and Kroll (1992) based on a linear solution to the Boussinesq equation. In this model, lowflow statistics are related to three watershed characteristics: drainage area, basin slope, and the baseflow recession constant. One would expect a better baseflow recession constant estimator to produce a better low streamflow regional regression model.

Vogel and Kroll (1996) performed this experiment with 23 watershed from Massachusetts for the 7-day, 10-year ($Q_{7,10}$) and 7-day, 2-year ($Q_{7,2}$) low streamflows. All five of the baseflow recession constant estimators proposed in the section "Least Squares Estimators" above were analyzed as well as a sixth estimator, which was the summation of baseflow recession constants estimated from individual recessions with an additive error term in log-space. One major conclusion from this analysis was that for the baseflow recession constant estimators based on the AR(1) and AR(2) models with error terms additive in real-space, model performance was worse than using the other four estimators, all of which assumed additive error terms in log-space. The AR(1) model was shown to have heteroscedastic error terms, a violation of the model assumptions. While the performance of the four log-space error term estimators was difficult to distinguish, based on the standard error of estimators across both models, the estimator from an AR(2) with an additive error in log-space (equation (30)) was best. The linear reservoir model estimator (equation (34)) was second best, and slightly worse than the AR(2) model with log-space error. The estimator based on average estimates from individual recessions performed nearly as well, and had the benefit of allowing one to easily assess the variance of the estimator. The AR(2) model is more complicated to implement in practice, and produced only slight parameter improvement; in practice using one of the other three log-space error term estimators is recommended, with the linear reservoir model (equation (34)) preferred. Recently Kroll *et al.* (2004) examined the use of baseflow recession constants based on equation (34) for estimating low streamflow statistics across the United States. They found that by using 3-day moving averages instead of daily averages in this model, lowflow regional regression models were improved in all regions. The use of 3-day moving averages reduces some of the precision problems of recorded low streamflows discussed previously, thus producing a better baseflow recession constant estimator.

Alternative Models and Indices

The linear reservoir models presented in section "Linear Reservoir Models" are not applicable in all circumstances. Often, as has been mentioned previously, the groundwater discharge from a watershed does not exhibit tendencies consistent with the linear solution to the Boussinesq equation. A number of alternative theoretically motivated models of groundwater discharge exist. In addition, researchers have suggested a variety of empirical relationships to model groundwater discharge. A number of these models are discussed below.

Based on the storage-discharge relationship given in equation (9), if the $n \neq 1$ then the general baseflow discharge equation given in equation (12) is:

$$Q = Q_0(1 + ct)^{n/(1-n)} \quad (35)$$

Brutsaert and Nieber (1977) note that Maillet first employed this equation to model low flows on the Vanne River in 1905. Wittenberg and Sivapalan (1999) used an iterative least squares procedure to determine c and n from observed recession data. Hornberger *et al.* (1970) used this

equation with $n = 2$ to model outflow from an unconfined aquifer. A value of $n = 2$ is consistent with the nonlinear solution to the Boussinesq equation for a long time t.

Beven *et al.* (1995) noted that if a linear relationship between storage deficit and depth to the water table holds with a nonlinear (exponential) relationship between transmissivity and storage deficit, as is assumed using TOPMODEL concepts, then groundwater discharge has a first-order hyperbolic relationship to time:

$$\frac{1}{Q_t} = \frac{1}{Q_o} + \frac{t}{m} \tag{36}$$

Using a plot of $1/Q_t$ against time, a linear relationship should exist. The estimated slope of a simple linear fit would be an estimator of 1/m (Beven *et al.*, 1995). Similar results for other transmissivity functions are given by Iorgulescu and Musy (1997) and Duan and Miller (1997).

Werner and Sundquist (1951) modeled the outflow from a confined aquifer as:

$$Q_t = Q_o \sum_{i=1}^{n} b_i \exp(-a_i t) \tag{37}$$

where a_i and b_i are constants. They suggested only the first term was needed, resulting in the linear reservoir model discussed previously. A model similar to equation (37) was employed by Nutbrown (1975), who applied a normal-mode analysis to groundwater discharge to a partially penetrating stream. Barnes (1939) suggested modeling the entire streamflow recession with $n = 3$.

There have also been a number of empirical relationships proposed to model groundwater discharge. Tallaksen (1995) provides a review of many of these models. Tallaksen notes that one-parameter models are preferable when comparing catchments and their responses; as more parameters are added, the fit to observed data improves, but the uncertainty of predictions from the model may increase and parameter sets may not be unique (Beven, 1989). One common empirical model is:

$$Q_t = (Q_o - b) \exp\left(\frac{-t}{C}\right) + b \tag{38}$$

where b and C are constants. With this model, Q_t asymptotically approaches b for large t. Toebes and Strang (1964) suggested this model for areas with snow and ice present. Otnes (1978, as cited in Tallaksen, 1995), found that Norwegian catchments, which have a high lake percentage, are modeled well by the empirical expressions

$$Q_t = at^{-r} \tag{39}$$

or

$$Q_t = at^{-r} + b \tag{40}$$

where a, b and r are constants.

It is also possible to develop an empirical nonparametric recession curve relationship with relative storage under the assumption that recharge from the unsaturated zone is negligible and that only baseflow contributes to the stream discharges. Traditionally, multiple recession curves for a catchment were overlain manually. A set of computer routines for this purpose was reported by Lamb and Beven (1997).

The baseflow recession constant, K_b, is often thought of as a hydrogeologic index, since it attempts to represent concisely the complex hydrogeologic processes in a catchment. In the linear reservoir model with a daily time step and no groundwater recharge, K_b represents the fraction of yesterday's baseflow, that is expected today. Another common hydrogeologic index is the baseflow index, which is an estimate of the fraction of annual streamflow that is comprised of baseflow (Institute of Hydrology, 1980). To estimate the baseflow index, streamflow is divided into 5 day blocks, and the minimum discharge of each of these blocks is flagged. The flagged discharges are put in a time series, and grouped in overlapping groups of three. If 0.9 times the central value of the group is less than both of the outer values, then the central value is identified as a turning point. By connecting all the turning points with straight lines, and estimating the area under the lines, an estimate of baseflow discharge, V_B, is obtained. After calculating the total volume of streamflow discharge using the original daily streamflows, V_A, the baseflow index can be estimated as:

$$\text{BFI} = \frac{V_B}{V_A} \tag{41}$$

The annual values of BFI have been found to be relatively stable, with a typical standard deviation of 0.04 (Institute of Hydrology, 1980).

Estimating Hydrogeologic Indices from Watershed Characteristics

Of great interest is how to estimate hydrogeologic indices, such as K_b and BFI, from available watershed information. This would allow parameterization of these indices at ungauged river sites. Various researchers have attempted to examine the geologic controls on groundwater storage and baseflow discharge. These studies have met with very limited success, and have often been qualitative in nature (see Tallaksen, 1995, for a list of citations). Some of these studies are discussed below.

Baseflow is a function of many factors, including topography, geology, soils, vegetation, and climate (Lacey and Grayson, 1998). These factors vary both spatially and/or

temporally in most watersheds, thus making it difficult to estimate an integrated watershed baseflow response from these factors. Zecharias and Brutsaert (1988) examined geomorphic impacts on groundwater discharge in 19 Appalachian watersheds. They found a function of baseflow recession, which they called the reaction factor, to be significantly correlated with basin ground surface slope. Aquifer breadth and the effect of a soil parameter, hydraulic conductivity divided by drainable porosity, were not significant at a 5% level.

Nathan *et al.* (1996, as cited in Lacey and Grayson, 1998) performed a regression analysis of baseflow index (BFI) versus watershed characteristics at 164 catchments in Victoria, Australia. They found drainage area, stream length, and elevation of the catchment centroid to be significant variables. Lacey and Grayson (1998) attempted to examine likely physical controls on baseflow response. They related BFI to a number of dimensionless topographic and climatic parameters, and a classification scheme representing geology, vegetation, and soils. Unfortunately, they found no trends in plots of BFI versus any of their explanatory variables.

While our instincts tell us that hydrogeologic indices should be a function of watershed characteristics, our ability to develop such relationships using actual data has been difficult. This may be due to a number of reasons, including difficulties in measuring watershed properties (such as hydrogeology), the lack of homogeneity and complex physical structure of most watersheds, and uncertainty in the derived hydrogeologic indices. In spite of this, this topic is ripe for further research activity, and will aid in our understanding and ability to predict hydrologic response at ungauged watersheds.

PAOLO REGGIANI[1] AND JAAP SCHELLEKENS[1,2]

[1] *Inland Water Systems, Foundation Delft Hydraulics, Delft, The Netherlands*
[2] *Earth and Life Sciences, Vrije Universiteit Amsterdam, Amsterdam, The Netherlands*

The present article presents a discussion of distributed modeling used in watershed hydrology from a modern perspective. The need for distributed modeling is explained on the basis of situations encountered in hydrological practice. The basic equations governing water and energy transfer in hydrology are introduced at the point- or microscale. It is explained how these equations are used in the different approaches through change in spatial scale from the microscale to an intermediate scale, the macroscale, or the megascale, which corresponds to the spatial dimension of some smaller or larger parts of the catchments. The strengths and limitations that have been recognized for the various approaches will be pointed out. As a possible alternative a flux-based approach, formulated entirely at the megascale, is highlighted. Its potential scope for practical applications will be discussed in the context of the closure problem for mass momentum and energy fluxes in hydrology.

INTRODUCTION

The demands by policymakers, implementers, and stakeholders with respect to the prognostic capabilities of hydrological models become increasingly sophisticated. Experts are asked to predict hydrological variables, such as water table depth, y, soil saturation, s, saturated catchment surface fraction ω, pore pressure p, flow velocity $\vec{v}$, and hydrological fluxes like surface runoff R, infiltration I, bare soil evaporation E_s, plant transpiration E_v, rainfall interception E_i, recharge of the water table, and capillary rise, q, in a spatially distributed fashion and at a level of accuracy not demanded previously. These demands are primarily driven by two reasons:

Firstly, it is widely recognized that decisions on land-use practices, deployment of infrastructure, exploitation of natural resources, or change of climate can irreversibly perturb the local and the large-scale equilibrium of a hydrological system and, subsequently, alter runoff behavior, yield and water quality, with potentially adverse socioeconomic implications for stakeholders, economic actors, and current, as well as future generations living within or downstream of the watershed boundaries.

Secondly, there is a common belief, which is, however, not shared by several experts (see e.g. the essay by Grayson *et al.*, 1992 or the debate between Beven, 1996a, b; Refsgaard and Storm, 1996), that the recently experienced leap in availability and affordability of radar-, space-, and airborne high-resolution datasets will lead to significant progress in the representation of hydrological systems through digital simulation models, thus bringing a "sufficiently accurate" description within reach.

By the same token, the prognosis of the spatially distributed hydrological variables y, s, ω, p, and $\vec{v}$ cannot be achieved at all using *lumped models*, or at least not at the level of spatial resolution required by the end-user. Among those models, we list the pioneering Stanford Watershed model by Crawford and Linsley (1966), and its spin-off, the Sacramento model, the largely operationally used HBV model described by Bergström (1995), the LASCAM model by Viney and Sivapalan (1999, 2001) or the Xinanjiang model by Zhao (1977) and Zhao and Liu (1995). This argument also applies to their possible grid-based, rasterized applications.

The zero-dimensional structure of lumped models is based on the conservation of mass and represents entire portions of the landscape as interconnected reservoirs, for

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

which the mass fluxes exchanged between entities are parameterized in terms of power-law-type relationships. Conservation of momentum or energy is not considered explicitly, nor is the effect of topography and its relation with gravity. Nevertheless, the role of such models as robust forecasting tools for operational watershed management is invaluable if merely discharges or water quality at a catchment outlet need to be predicted over a restricted period into the future. For those periods, changes within the system remain negligible and the statically calibrated lumped model structure continues to give acceptable simulations.

The listed hydrological variables, together with the hydrodynamic properties of the shallow subsurface, may control the hydrological fluxes R, I, E_s, E_v, E_i, and q. These act as source or sink terms for moisture and energy stored in the subsurface, the canopy, and the planetary boundary layer. Therefore, they have a direct impact on the mass and energy budget of the soil-vegetation-atmosphere continuum, and consequently on weather formation and its long-term pattern, the climate.

In this context, it is important to note that predicting the behavior of the hydrological variables or the fluxes can be required in response to forcing by individual events ("forcing" can be either wetting during storms or drying during inter-storm periods). A typical example of this kind of application is the use of a hydrological model for flood or drought forecasting purposes.

Alternatively, the long-term behavior of the variables and fluxes may need to be studied. In this case, the modeler is not interested in their fluctuations induced by single events, but in their mean behavior over a critical period, typically a year or longer. The aim of such an analysis is to understand catchment-average response to particular forcing patterns classified collectively as "climate", which is expressed in terms of time-averaged fluxes and long-term water yield. Such an analysis, based on particular restrictive hypotheses, has been carried out by Eagleson (1978a, b, 1982) and Eagleson and Tellers (1982). Salvucci and Entekhabi (1995) extended the theory of Eagleson to an entire hillslope in the presence of a shallow water table. They carried out case studies for a variety of different hillslope shapes, soil parameters, and climatic forcing. By applying restrictive hypotheses yielding mathematically tractable expressions for the various time-averaged fluxes, it is deduced that the climate, together with local factors such as the geology and topography, exerts control on the hydrological fluxes and ultimately on the yield, expressed in terms of a single hydrological state variable, namely, the space and time average saturation of the soil column.

At a practical level, such hydrological equilibrium theories and underlying hypotheses would require verification via distributed modeling tools that are able to explicitly account for spatial variability of land use, geology, and topography. Their actual implementation, however, will be hampered by the difficulty of determining the necessary parameterizations for the fluxes (see e.g. Beven, 1989, and also Grayson *et al.*, 1992 and Beven, 1993, 2001).

As well as circulating water and energy, the hydrological cycle is also the vehicle for other substances, such as nutrients, pesticides, and agricultural fertilizers that influence water quality in rivers, lakes, coastal zones, and the shallow subsurface. The impact of policies on fertilizer and pesticide application at a national or international level (e.g. the EU Water Framework Directive) is strongly linked to the hydrological cycle. The effect of agricultural management practices on water quality can be studied efficiently only with hydrological modeling tools permitting the prognosis of y, s, p, ω, and $\vec{v}$, and of the resulting fluxes R, I, E_s, E_v, E_i, q at a sufficiently high spatial resolution, such as, for example, the characteristic size of land-use patterns of forested and cultivated areas.

Similar arguments can be put forward for the study of other problems related to the hydrological cycle. Amongst those we list the quantification of the impacts of agricultural practices on soil erosion in the tropics, shown by Bruijnzeel (1990, 2004), or the problem of dryland salinity in Australia, studied by Peck and Hurle (1973).

Finally, the continuous development of global circulation models (GCM) used to forecast future climate scenarios (for relevant references see e.g. the IPCC, 2001 report), requires an increasingly detailed description of the soil-vegetation-atmosphere feedback for an accurate representation of the mass, momentum, and energy fluxes exchanged with the atmospheric boundary layer (ABL). These constitute the lower boundary conditions for the equations governing atmospheric mass, momentum, and energy circulation. This should be achieved by representing the hydrological fluxes in a spatially distributed manner by taking the shape of drainage basins and the landscape explicitly into account (see e.g. Koster *et al.*, 2000), rather than through a lumped representation of landscape entities as conceptual buckets matching the GCM grid cell size.

The issues addressed here are complicated further because the phenomena evolve over vastly different spatial scales that can range from a few centimeters for a wetting front infiltrating into the unsaturated zone, up to spatial scales of several kilometers for mass, momentum, and energy fluxes for land–atmosphere interaction processes. Similar arguments apply to temporal scales that can extend from a few seconds, typical for eddy fluctuation of an air current flowing over a forest canopy, to the several years or decades that it can take a pesticide to reach the water table through filtration across the unsaturated zone.

The present article looks at commonly used distributed modeling approaches, suited for the prediction of a subset of y, s, p, ω, and $\vec{v}$, whereby an attempt is made to explain the approaches starting from first principles: the balance laws for a continuum formulated at the *microscale*. By averaging

the equations, these are mapped to a particular, usually larger, scale of interest. From this perspective, it will be shown how various authors of distributed hydrological models have cast the balance laws into a form, which would suit the description of a hydrological system in mathematical and physical terms. They did so with the aid of a series of hypotheses, and by choosing the spatial domain through a sensible partitioning of the landscape into averaging regions and domains of integration.

BALANCE LAWS

Distributed hydrological models are commonly based on the conservation equations for mass, momentum, and energy, whereby the mass balance is employed in virtually all model formulations. The momentum equation is difficult to apply to hydrological systems because it is vectorial and it is generally seen as difficult to close the various force terms via suitable parameterizations. The most common use of the momentum balance in hydrology is made through Darcy's law, a parameterization of the up-scaled conservation of momentum for water contained within the voids of a porous medium at the scale of a conceptual *Representative Elementary Volume* (REV; Bear, 1979; Hassanizadeh and Gray, 1980).

People describing the hydrodynamics of open water systems such as lakes, rivers, and estuaries feel more comfortable with the momentum equation, especially as they have the clear advantage of working with one and the same medium. In addition, observation permits a far better knowledge of the boundary conditions and geometry in terms of, for example, the bathymetry and wind shear on the open water surface, than for hydrologists, who often do not know where the water is (for more discussion see e.g. Beven, 2001).

The energy equation, especially the conservation of thermal energy, is necessary for describing land–atmosphere interaction across the soil-vegetation-atmosphere continuum. This is particularly relevant in view of the fact that in dry areas of the world up to 95% of the mean annual precipitation leaves the system through evapo-transpiration and not via surface runoff. In this superficial part of the system, which is exposed to the incoming radiation energy, it is essential to capture the terrestrial energy balance, as it greatly influences the bare soil evaporation E_s, rainfall interception E_i, and plant transpiration E_v. The thermal energy balance is rarely explicitly included in hydrological model formulations, mainly because it plays no significant role when merely runoff processes are investigated.

Balance laws formulated at the microscale describe the conservation of a physical property at a point in a phase, where with "*phase*" we understand water, air, or the porous medium soil matrix. The mass, momentum, and energy conservation laws are written as follows:

Balance of mass:

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \vec{v}) = R \tag{1}$$

where ρ is the mass density for the phase and $\vec{v}$ is the phase velocity, a vector.

Balance of momentum:

$$\frac{\partial (\rho \vec{v})}{\partial t} + \nabla \cdot (\rho \vec{v}\vec{v} - \vec{T}) - \rho \vec{g} = 0 \tag{2}$$

where $\vec{T}$ is the stress tensor for the phase and $\vec{g}$ is the gravity vector.

Balance of total energy:

$$\rho \frac{\partial}{\partial t} \left(E + \frac{1}{2} v^2 \right) + \nabla \cdot (\vec{q} - \vec{T} \cdot \vec{v}) + h - \rho \vec{g} \cdot \vec{v} = 0 \tag{3a}$$

where E is the internal energy, $\vec{q}$ is the heat-flux vector, and h is the external energy supply (e.g. radiation). Scalar multiplication of equation (2) with $\vec{v}$ and subtraction from (3a) yields the thermal energy equation:

Balance of thermal energy:

$$\rho \frac{\partial}{\partial t} E + \nabla \cdot \vec{q} + h = 0 \tag{3b}$$

For the water in overland or channel flow, only a single phase is present. In the subsurface, different phases coexist and the balance laws hold at every point in each phase. The laws form the theoretical basis for a quantitative description of a physical system.

CHANGING SPATIAL SCALE

In the representation of environmental systems and their subset, hydrological systems, we commonly map the balance laws from a representation at the *microscale* to larger scales of interest, referred to as the *macroscale* and the *megascale* by Gray *et al.* (1993). The *macroscale* D is defined as an intermediate scale of interest that is larger than the *microscale* l, but smaller than the size of the entire modeling domain, denoted as the *megascale,* L. It is not uniquely defined, but its choice depends on the particular needs of the modeler. In the context of the present article, with *megascale,* we understand the spatial scale corresponding to a small part of a catchment. However, in the context of a channel or overland flow sheet, for example, the dimension of the cross section or the depth of the flow sheet is also considered *megascopic* because it represents one or two dimension(s) of the domain.

The mutual relationship between *micro, macro*, and *megascale* obeys to the relation:

$$l < D < L \tag{4}$$

While in a *macroscale* representation of a system, internal variations of properties in space are considered, at the *megascale* spatial variations are ignored and properties are expressed as their averages over the domain.

These concepts can be explained by looking at a few approaches used typically in the description of environmental systems. For example, the integration of the microscale balance equations (1), (2), and (3) over different phases, such as water, solid, and air contained within a spherical REV, yields a macroscale representation of multiphase flow (Bear, 1979; Hassanizadeh and Gray, 1979a, b). The upscaled equations represent the conservation laws at a new *macroscale* point with a diameter equal to that of the REV. The REV is larger than the *microscale* but smaller than the size of the domain. Application of commonly accepted hypotheses for porous media flow yields a generalized form of Darcy's law for multiphase flow.

The microscopic balance equations can be scaled to the macroscale over two dimensions out of three, and to the *megascale* over the third dimension. For example, integration over an upright cylindrical REV across a confined aquifer leads to horizontal flow equations that are *macroscopic* along the two horizontal directions (*macroscopic* dimension D) and *megascopic* over the vertical dimension of the aquifer (*megascopic* dimension L).

Alternatively, we can map conservation equations directly from the *microscale* to the *macroscale* in two dimensions, while preserving a *microscale* representation along the third dimension. For example, if (1) and (2) are integrated over a slab of infinitesimal thickness representing the cross section of a river channel, we obtain a description of the system that is *megascopic* over the cross section and *microscopic* along the channel axis. Application of the classic hypotheses assumed for open channel flow reduces the scaled balance laws to the Barré de Saint-Venant (1871) equations used to model one-dimensional flow in a channel.

This perspective allows mapping physical conservation laws consistently between scales of representation without requiring *a-priori* assumptions. Such assumptions may lead to the neglect of important terms early in the scaling process, thereby restricting the application to the particular situations for which the hypotheses hold.

This framework also casts a particular view on model formulations underlying the Freeze and Harlan (1969) blueprint and model (Freeze 1971, 1972a, b), SHE Abbott *et al.* (1986a, b), InHM (VanderKwaak and Loague, 2001), TOPOG (O'Loughlin, 1986), Vertessy *et al.* (1993), TOPMODEL (Beven and Kirkby, 1979), and other distributed modeling tools. A formulation developed entirely at the *megascale* and proposed as the *Representative Elementary Watershed* (REW) approach by Reggiani *et al.* (1998, 1999, 2000) is based on up-scaling the balance equations from the micro to the megascale and given here as a possible alternative distributed model concept.

TRADITIONAL DISTRIBUTED FORMULATIONS

In the following subsections on "The Freeze–Harlan (FH) blueprint and derived models" and "Other distributed models", we introduce the most commonly used distributed modeling tools that are based on the solution of the upscaled balance equations by means of partial differential equations (PDE) (e.g. SHE; InHM) or via analytical expressions (e.g. TOPMODEL or the TOPKAPI model of Liu and Todini, 2002). Using PDE's in hydrology is commonly seen as a significant effort, mainly because of the difficulty associated with determining the necessary *effective* parameter values in a spatially distributed fashion for a heterogeneous domain like a watershed. Also, the simultaneous solution of coupled PDEs is numerically and computationally demanding. The hydrological variables are calculated at the nodal points of a model mesh, at a spatial resolution that is not required for most practical applications. The full validation of the results is data-intensive, as pointed out by Refsgaard (2000) or Beven (2002a, b), and is rarely performed for many distributed model applications. Thus, many distributed models remain insufficiently validated. Limited verifications are presented only in terms of outflow hydrograph comparisons instead of a satisfactory prediction of spatially distributed variables, such as, for example, piezometric heads, soil moisture, or the spatial pattern of overland flow generation. Such a validation is also often precluded by the lack of sufficient high-quality spatial data.

Another difficulty in applying the equations lies in the representation of processes occurring at scales smaller than the scale of the discretization grid (e.g. Finite Element Method (FEM) or Finite Difference Method (FDM) mesh size) or other spatial model entities (e.g. flow tubes, TOPOG elements, or the pixel size). Hydrologists refer to these processes collectively as *subgrid* variability. Subscale processes are usually less relevant for simulating a lumped variable such as the outflow hydrograph. It becomes relevant for the representation of other spatially distributed hydrological processes such as runoff generation due to seepage or infiltration excess or localized groundwater recharge and the formation of perched systems, to mention just a few. These subscale processes can hardly be represented in terms of the independent variables calculated at the model grid nodes. The main reason is that the high heterogeneity of the soils and subsurface pathways is difficult to capture via parameters such as the saturated hydraulic conductivity, lumped at the scale of a *REV* or model mesh

size, despite the fact that the assumption of the REV forms the basic hypothesis for the description of porous media flow and is generally accepted for the description of a variety of hydrological processes. A common example for the just mentioned difficulties is the procedure of expressing a water retention curve at the scale of a model mesh element in terms of soil structural and textural parameters identified at the laboratory scale and inserting the resulting expression into a Richard's equation solver, which is implemented at the grid size of a kilometer.

It is, however, understandably argued by Refsgaard and Storm (1996) that to date these tools constitute the *best there is* and that improvement of future air or space-borne measurement techniques will help to bring data resolution and scale of process representation closer together. The following paragraphs will briefly review the most commonly used distributed modeling approaches.

The Freeze–Harlan (FH) Blueprint and Derived Models

The first and most radical attempt to propose a complete distributed modeling framework is known as *Freeze–Harlan Blueprint* (1969) (see also Freeze, 1978). The authors of the blueprint proposed using the conservation equations (1) and (2) to describe flow within a watershed. Most of these equations originated from various disciplines that are linked for historical reasons to engineering problems. It is only later that the fields of their original application have been extended to more general hydrological systems. Typically, the Saint-Venant equations (Barré de Saint-Venant, 1871) come from the domain of river engineering and Richards' equation from soil physics (Richards, 1931) as an extension of the empirical Darcy's Law for saturated flow through a porous medium (Darcy, 1856). Lighthill and Whitham (1955) were the first to show through a mathematical analysis that the kinematic wave equation could be applied to predict flow in rivers under circumstances for which the spatial derivatives of stage and velocity could be considered negligible (in contrast to dynamic waves for which this is not the case). Henderson and Wooding (1964) extended the use of the kinematic wave to predict flow on hillslopes and subsurface flow.

Freeze and Harlan aggregated these equations into a modeling framework, which would cover most flow types observed in a watershed through an appropriate continuum description in terms of PDE and suitable parameterizations of the fluxes. The equations constitute up-scaled versions of equations (1) and (2), averaged to the macroscale over appropriate REVs (Darcy's law for saturated or unsaturated porous media flow) or integrated to the *megascale* over one or two spatial dimensions (to represent averaged variables over the flow depth or flow cross section respectively). In those days, putting the approach into practice seemed to be limited solely by computer power and insufficient availability of spatial data.

Different interpretations and numerical implementations of the Freeze–Harlan approach led to various catchment models based on the outlined blueprint. The most widely known is the *Système Hydrologique Europeén* (SHE) model developed by different European laboratories. The SHE model has been described first by Abbott *et al.* (1986a, b) and is currently distributed by the Danish Hydraulic Institute under the name of MIKE-SHE (*see* e.g. Refsgaard and Storm, 1995) and by Newcastle University under the name SHETRAN (e.g. Birkinshaw and Ewen, 2000; Bathurst *et al.*, 2004). In SHE, the governing PDE equations are solved through finite difference schemes. Through recent work by Christiansen *et al.* (2004), the model has been adapted in order to be able to take macropore flow into account.

The *Institute of Hydrology Distributed Model* (IHDM), described in the report by Beven *et al.* (1987) and summarized by Calver and Wood (1995), is based on similar design principles as SHE, but relies on the FEM in variable-width hillslope elements for the solution of PDEs.

Similar models are still being proposed and implemented. Among the most recent contributions, we list the *Quasi-physically Based Rainfall-runoff Model* (QPBRRM) based on simplified governing equations and applied by Loague and Kyriakidis (1997) to reproduce the response of the 0.1 km^2 R5 Washita River Experimental Watershed catchment, Oklahoma. The even more numerically sophisticated 3-D PDE-based *Integrated Hydrology Model* (InHM) (**`http://inhm.org`**) accounts for variably saturated flow and transport in macropores and 2-D flow and transport over the land surface and in open channels. First-order coupling effects can be accounted for explicitly. The tool has been used for research work (VanderKwaak and Loague, 2001; Loague and VanderKwaak, 2002) on the R5 experimental watershed and is currently being applied also to large-scale applications including solute transport (Loague and VanderKwaak, 2004). Figure 1 shows a typical example of a 3-D model element mesh, in this particular case, the *InHM* finite element grid, used to model the R5 catchment, and Figure 2 shows some results on flow velocities and water depth computed for the overland flow, given a particular precipitation event.

Similarly, the SHE model has been employed on the Rimbaud catchment in France by Parkin *et al.* (1996) or on the 440 km^2 Karup catchment in Denmark (Refsgaard, 1997). Paniconi and Wood (1993) proposed another 3-D unsaturated–saturated simulation code, for which an application in combination with data assimilation techniques (Newtonian nudging) for distributed physically based hydrological modeling is shown in Paniconi *et al.* (2003).

All these tools have in common that they solve essentially coupled PDE-based governing equations through

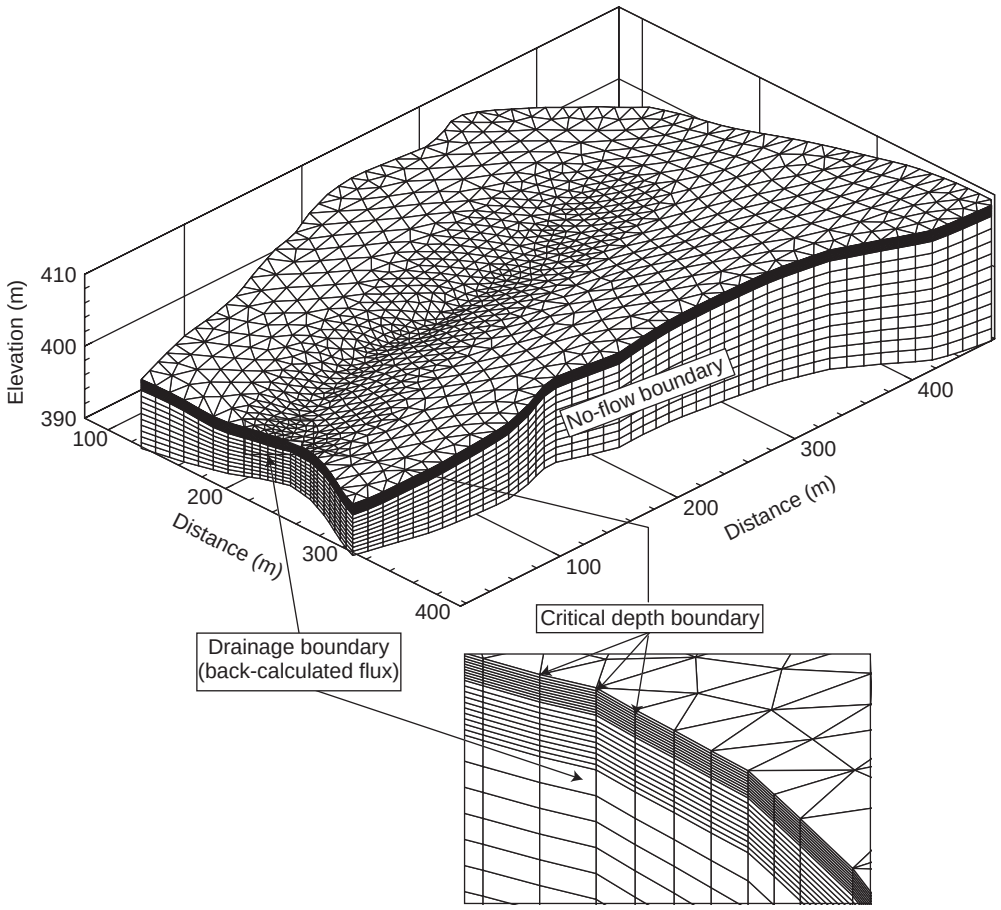

Figure 1 The Integrated Hydrology Model (InHM) Finite Element Mesh used to model the R5 Watershed (JE VanderKwaak and K Loague, Hydrologic-response simulations for the R-5 catchment with a comprehensive physics-based model, Water Resources Research, **37**(4), pp. 999–1013 (2001) American Geophysical Union. Reproduced by permission of American Geophysical Union)

finite element or finite difference schemes and focus on describing flow processes at the *macroscale* or various combinations of *micro* and *macroscale.*

It is interesting to observe that the choice of titles for the series of publications by Loague and coworkers (e.g. Loague and Freeze 1985; Loague and Kyriakidis 1997 or Loague *et al.*, 2000) and others (Beven, 1989, 1993, 2001; Woolhiser, 1996) is very much an indication for the challenges faced in reproducing hydrologic behavior even for a small basin like the R5 at Chickasha, Oklahoma, for which data are available in quantities and at a spatial resolution that are limited to only a few exceptionally monitored experimental watersheds.

However, the principal criticisms expressed with respect to physically based distributed modeling approaches focus on the Freeze–Harlan (1969) blueprint itself, rather than on any particular derived model. Several concerns have been raised during the last two decades by Beven (1989, 1993, 1996a, b), or Grayson *et al.* (1992). A flux-based approach with a representation at the *megascale (see* Section "The REW approach"), along the lines of the REW concept, is envisaged as a possible alternative to the Freeze–Harlan (FH) blueprint.

TOPMODEL

TOPMODEL (Beven and Kirkby, 1979) is a distributed simulation tool, which calculates runoff production because of saturation excess along 1-D flow tubes representing the catchment hillslopes. The concept of flow tubes was later replaced by a terrain analysis based on raster grid data, for which a topographic index is calculated on a per-pixel-basis using the digital terrain analysis program DTM Analysis (see `http://www.es.lancs.ac.uk/hfdg/topmodel.html`). In TOPMODEL, the transmissivity, or vertically integrated saturated hydraulic conductivity at a particular location, is estimated by assuming an exponential decline of the conductivity over depth and by vertically integrating the resulting mathematical expression over the depth of the saturated soil layer. The authors also assume that the shallow subsurface flow is driven by a hydraulic gradient equal

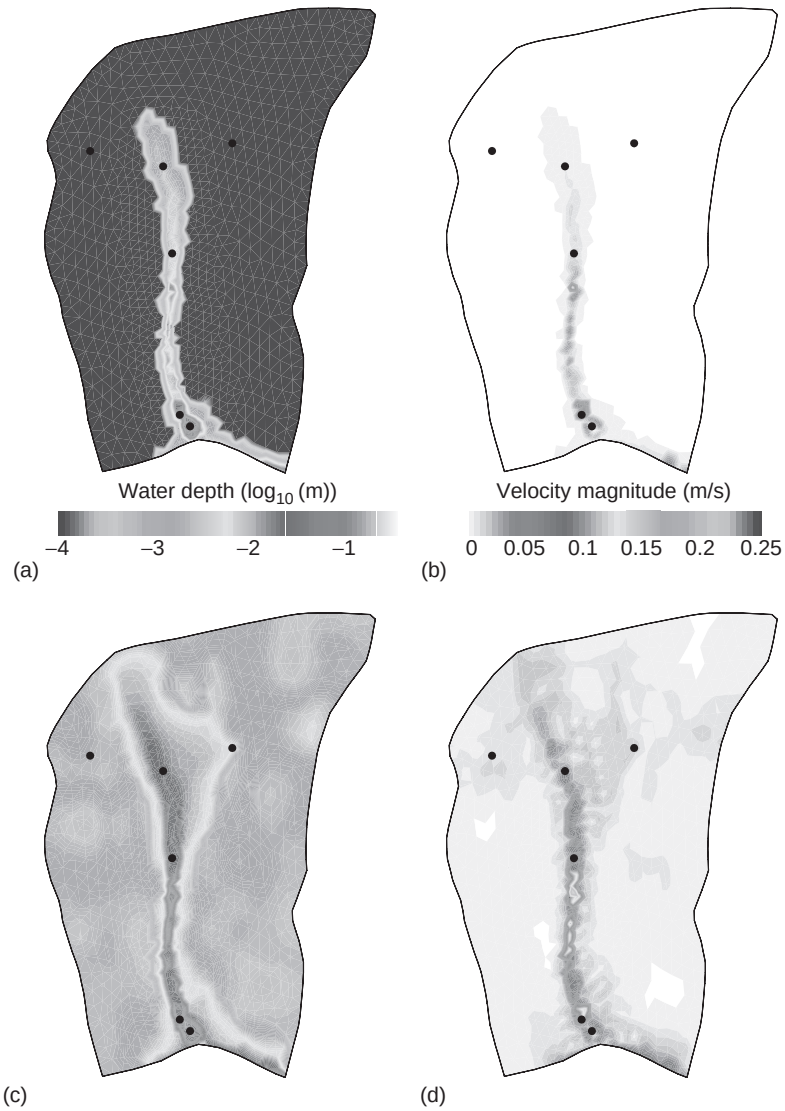

Figure 2 Plan view plots across the R-5 catchment of the I*n*HM-simulated surface water depths. (a) and (c) and velocities (b) and (d) for a particular precipitation event; (a) and (b) are the initial conditions, (c) and (d) are at the time of peak stream flow (JE VanderKwaak and K Loague, Hydrologic-response simulations for the R-5 catchment with a comprehensive physics-based model, Water Resources Research, **37**(4), pp 999–1013 (2001) American Geophysical Union Reproduced by permission of American Geophysical Union). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

to the local topographical slope. Thanks to the exponential form of the conductivity, an analytical expression for the transmissivity is found. This expression is subsequently used to define a water table shape for a given catchment storage as if local discharge was equal to a constant recharge to the water table integrated over the catchment area accumulated uphill of a particular contour segment.

The authors manipulate this equality, recasting it in terms of (i) a topographic index, (ii) an average water table depth over the catchment, and (iii) the local moisture deficit (or water table depth) at the particular point. They establish a criterion that allows regions that are unable to discharge the subsurface runoff from uphill to be identified, because either the local water table is too high or the local hydraulic gradient is too small. The excess flow leads to local saturation of the subsurface and is evacuated as surface runoff. From a deterministic perspective, the authors utilize a *macroscopic*, vertically averaged momentum balance equation in steady state to estimate local subsurface runoff, while the average water table is controlled by a *megascopic* (catchment-scale) water balance equation for the entire catchment. The surface excess water budget and the channel routing component are also controlled by respective mass balance equations at the *megascale*.

This fundamental concept has served as platform for many other spin-off projects. Just to cite a few, an extension to include a dimensionless version (Sivapalan *et al.*, 1987), to handle spatially variable soil depths (e.g. Saulnier *et al.*, 1998), water quality issues (e.g. Robson *et al.*, 1992; Hornberger *et al.*, 1994), or the study of particular features such as spatial variability of subsurface runoff (e.g. Woods *et al.*, 1997). A further important application is the use of the TOPMODEL concept for representation of lower boundary conditions in GCMs by Koster *et al.* (2000).

TOPOG and THALES

TOPOG is founded on a contour-based terrain analysis method pioneered by O'Loughlin (1986) and Moore *et al.* (1988) at CSIRO. The approach was initially developed for the study of Australian catchments. The concept underlying the original idea of TOPOG is quite similar to the one of TOPMODEL and based on the local transmissivity to identify areas of the catchment that are subject to saturation and give raise to saturation excess runoff. The main difference between the initial concept of TOPOG and TOPMODEL is the way in which the landscape is dissected. While TOPMODEL is based on geometrical elements in the form of flow tubes and, more recently, pixels for the evaluation of the saturated areas, in TOPOG irregular elements are identified by breaking flow tubes in smaller interconnected and irregularly shaped elements by intersecting the lines of steepest descent with the contour lines. Figure 3 shows a typical example of the TOPOG model mesh. The elements are shadowed based on spatially distributed soil properties and surface slope classes. These terrain analysis algorithms are distributed through the stand-alone software package TAPES-C. The original TOPOG design has undergone substantial changes and expansion since its initial conception. The most recent versions distributed by CSIRO Land and Water have, with exception of the terrain analysis component, little in common with the original concepts. For example, a finite element-based groundwater module has been added next to a Richard's equation solver to study moisture dynamics in the unsaturated zone, yielding an entirely

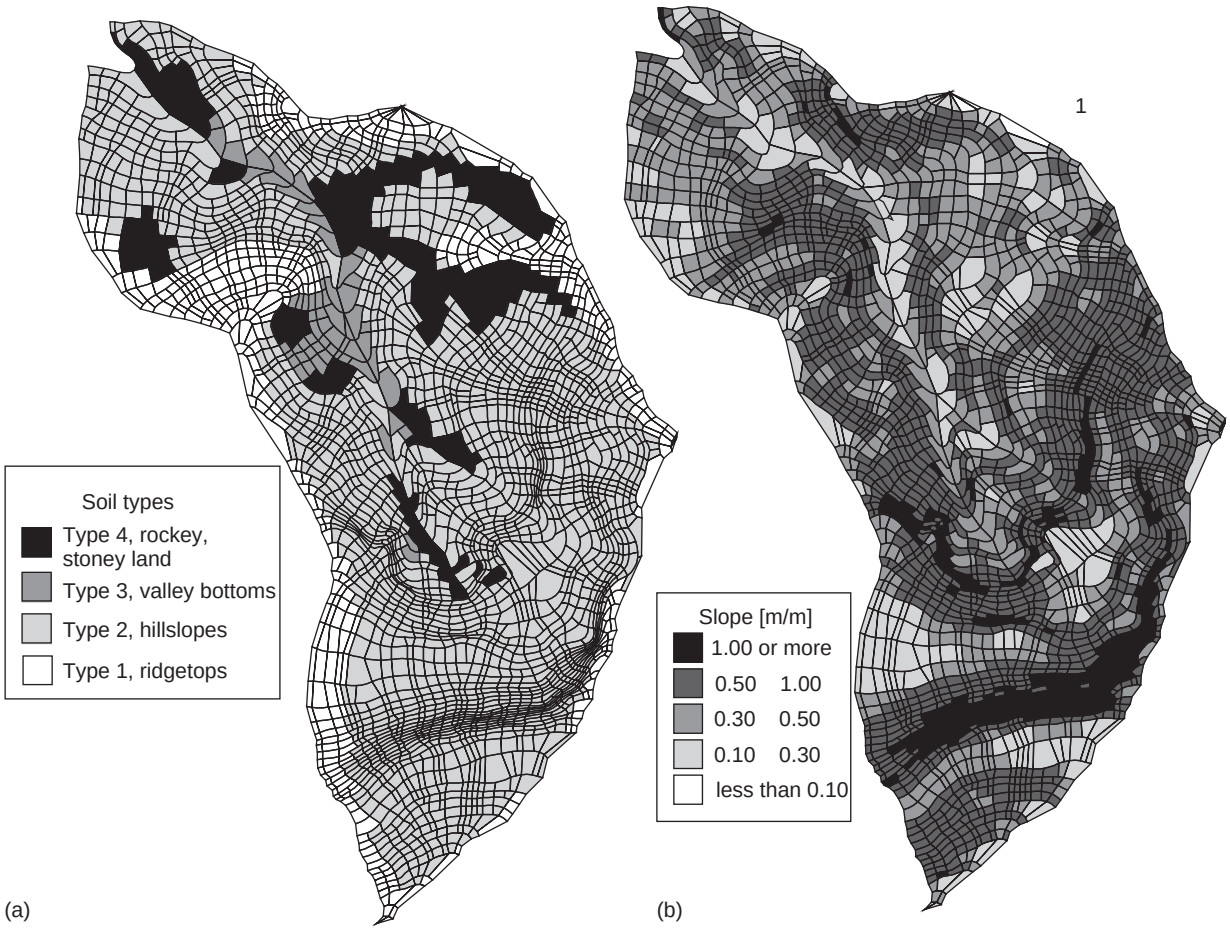

Figure 3 View of the irregularly shaped mesh of the TOPOG model obtained by dissecting the landscape on the basis of contour and flow lines. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

micro- or *macroscale*-based physical description. Explicit representation of transpiration for various plant species, including the carbon and the nutrient cycle (see e.g. Vertessy *et al.*, 1993) is also incorporated.

TOPOG has now been applied to many catchments outside of Australia, including a small Amazonian catchment (Vertessy and Elsenbeer, 1999) and, in an adapted version, to a small semiarid watershed in China by Zhu *et al.* (1999). Schellekens and Bruijnzeel (2004) used TOPOG in a small six-ha catchment in Puerto Rico to model runoff response in combination with extensive hydrometric and tracer validation of the runoff sources in the catchment (see also Schellekens *et al.*, 2004).

The TAPES-C routine is also used in another Australian-distributed modeling tool akin to TOPOG, called *THALES*. The developers of THALES use predominantly analytical steady-state solutions for the balance laws at the *micro* or the *macroscale* for estimation of infiltration, saturation excess, and subsurface runoff within model elements. References on THALES can be found in Grayson *et al.* (1995).

Other Distributed Models

Beyond the instruments mentioned here, other distributed modeling tools such as the TOPKAPI model (Liu and Todini, 2002) can be found in the literature. TOPKAPI integrates the point-scale conservation equations for mass and momentum over individual pixels of digital elevation maps (DEM). Restrictive assumptions reduce the governing equations to kinematic waves for subsurface, overland, and channel flow, for which analytical solutions are proposed.

Giving more detailed descriptions or listing even more models would go beyond the scope of this contribution. The reader is referred further to the books by Singh (1995) and the more recent publications by Singh and Frevert (2002a, b) for a more complete overview. Finally, it is relevant to observe that recent (Palacios-Vélez, 1998) and ongoing (Vivoni *et al.*, 2004) research is focussing on the use of triangular irregular networks (TIN) for discretizing a landscape into smaller hydrologic units. The discretization method is based on Delaunay triangulation and was proposed first in a hydrologic context by Palacios-Vélez and Cuevas-Renaud (1986). The TIN-based distributed modeling tool TRIBS currently developed at MIT seems to be promising in terms of the efficiency attributable to the method of spatial subdivision of the landscape. However, the relevant research is still at an early stage in order to allow drawing further conclusions.

THE REW APPROACH

As an alternative to the distributed approaches listed above, Reggiani *et al.* (1998, 1999, 2000) have introduced recently a distributed hydrological modeling concept formulated directly at the megascale. The motivation to undertake this research was the lack of a consistent formulation at a spatial scale larger than the macroscale, which would differ from the Freeze–Harlan (1969) blueprint by not requiring the solution of aggregated sets of PDE equations.

The authors of the REW approach went back to the conservation equations for mass (1), momentum (2), and energy (3) at the *microscale* and mapped them to the *megascale* by integration over appropriately chosen averaging regions, called *REWs*. It is important to note that in doing so, one of the main objectives of the REW approach is to provide a general framework, which would also be able to accommodate the wide range of temporal scales encountered in hydrological systems. In this way, the approach becomes suitable for studying instantaneous hydrological problems as well as long-term average behavior and yield (see Section "Introduction"), for which fluctuations at smaller timescales are less relevant. Consequently, the equations have also been averaged in time over a characteristic interval that is problem-specific and dictated by the particular application. A year could be such a typical averaging period.

The averaging regions or REWs are defined in such a way as to allow the definition to be generally applicable and scale-independent. Three-dimensional spatial regions were chosen that are determined by subcatchments of a particular size and that are delimited laterally by a prismatic mantle surface. They can be seen as extracted with a cookie cutter from the landscape.

A concrete example of a REW is depicted in Figure 4. In practice, a REW can be extracted from a digital terrain map with the threshold area method (Band, 1986) or by means of similar criteria (Tarboton, 1997) by imposing the first or higher Horton–Strahlerstream order as threshold for identifying a given number of subcatchments.

A REW communicates with neighboring REWs across the prismatic mantle surface via lateral exchange of groundwater. On the surface, the REWs are interconnected through the stream network that drains surface water towards a common catchment outlet. This mutual interconnection of REWs for a generic watershed structure is visualized in Figure 5. The definition of the REW allows a scale-independent subdivision of a watershed into irregular modeling elements, which are not tied to a square grid, but allow the natural footprint of the landscape to be preserved in the discretization.

The REW could be seen as a kind of Hydrologic Response Unit (HRU), used frequently as a concept in the discretization of hydrological systems. HRUs are based on superimposition of particular characteristics in the landscape such as topography, aspect, soil properties, or land

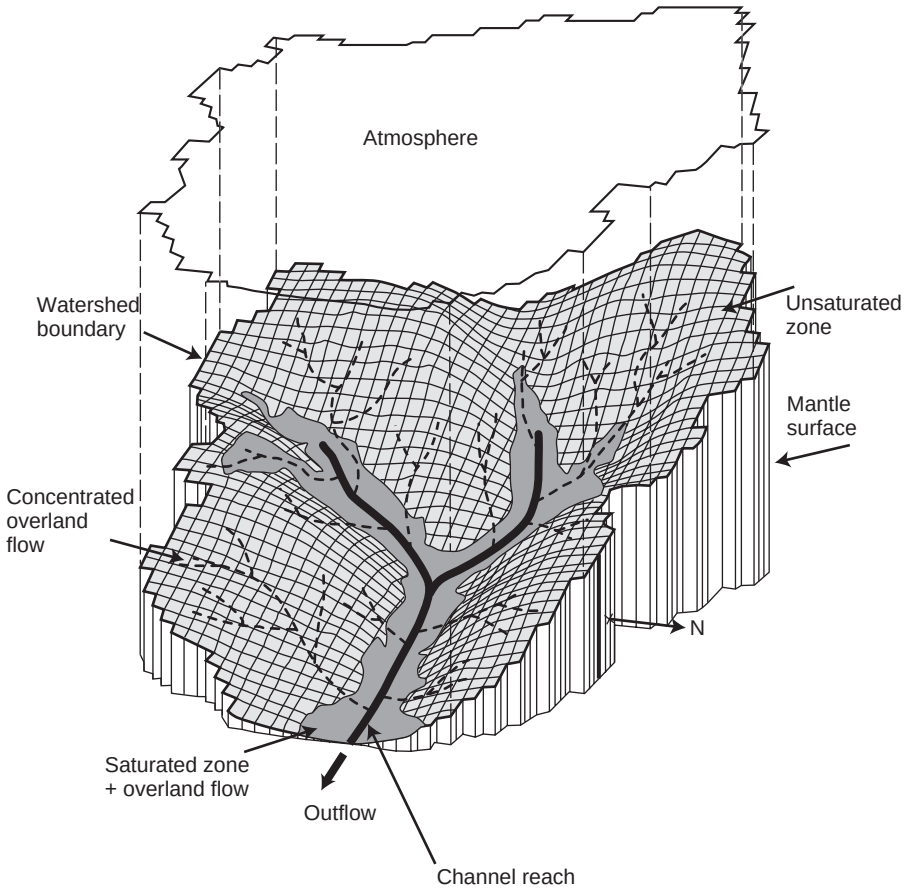

Figure 4 View of a Representative Elementary Watershed (REW) as a 3-D spatial entity

use with the aim of identifying spatial regions that can be considered compact hydrological entities for which the mass balance can be applied. The definition of REW is based on scalable spatial entities, whose reoccurring structure can be recognized at scales that range form a watershed of a few hectares to much larger entities, which may measure several tens of square kilometers. These entities represent hydrologically meaningful volumes over which the conservation equations for mass, momentum, and energy are integrated. Given a chosen spatial scale, suitable closure expressions for the respective REW-scale fluxes need to be parameterized. The parameterized expressions depend on the size of the entity and the degree of heterogeneity of the hydrological entity to be modeled.

The point-scale equations (1), (2), and (3) are integrated over particular zones of the REW that are identified on the basis of their hydrological role (i.e. porous medium or just water) and their hydrodynamic behavior (i.e. unsaturated porous media flow, channel flow). In the case of the saturated zone, the entire saturated soil within a REW is considered as integration volume; in the same way as the unsaturated zone, the overland flow volume or the channel volume constitutes separate integration volumes.

The resulting *megascale* governing equations are obtained without making any *a-priori* assumptions and represent scale-independent ordinary differential equations (ODEs), which conserve physical properties for a REW in terms of spatially and temporally averaged variables.

Equations (1), (2), and (3) can be restated more generically in terms of a variable ψ, a non-convective interaction $\vec{i}$, and a rate of external supply for ψ, f, which are placeholders for the properties summarized in Table 1. Integration of the microscopic conservation equations over a phase volume V and a characteristic time interval $(t - \Delta t, t + \Delta t)$ yields the following generic *megascale* (or REW-scale) conservation law, from which specific conservation equations for mass, momentum, and energy can be deduced:

$$\frac{\mathrm{d}}{\mathrm{d}t}\int_{t-\Delta t}^{t+\Delta t}\int_{V}(\rho\psi)\,\mathrm{d}V\,\mathrm{d}\tau + \sum_{j}\int_{t-\Delta t}^{t+\Delta t}\int_{A_j} [\rho\psi(\vec{v}-\vec{w}) - \vec{i}]\cdot\vec{n}\,\mathrm{d}A\,\mathrm{d}\tau - \int_{t-\Delta t}^{t+\Delta t}\int_{V}\rho f\,\mathrm{d}V\,\mathrm{d}\tau = 0 \tag{5}$$

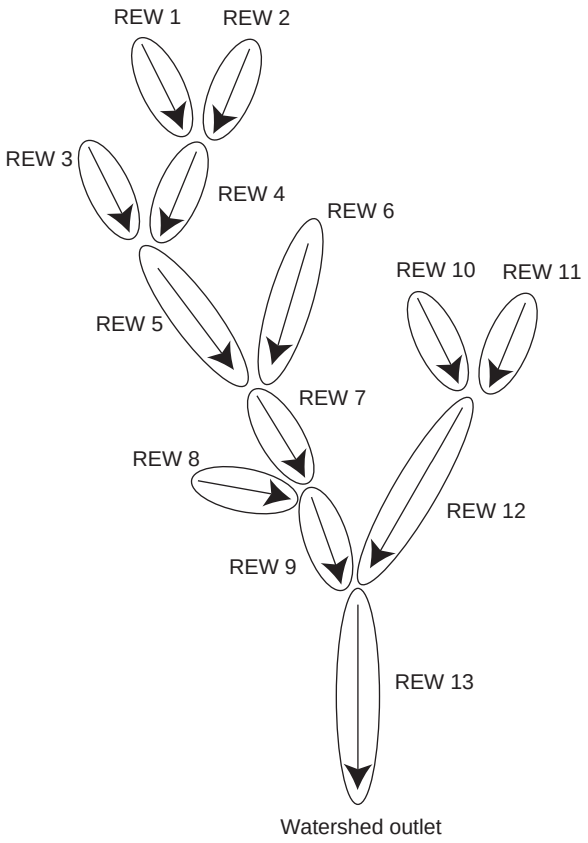

Figure 5 Aggregation of 13 REWs into a binary tree structure for representation of a catchment

Table 1 Microscopic properties in balance laws

	ψ	$\vec{i}$	f
Mass	*1*	*0*	*0*
Momentum	$\vec{v}$	$\vec{T}$	$\vec{g}$
Energy	$E + v^2/2$	$\vec{q}$	h

In (5), $\sum_j A_j$ is the sum of boundary surface segments delimiting the volume V and $\vec{w}$ the surface velocity. The second integral on the left-hand side represents the sum of fluxes of the various properties across the boundary surface segments delimiting the control volume. These flux terms constitute unknown exchange terms for mass, force or energy between phases and system compartments that result from the integration procedure. Such terms are frequently encountered in the mathematical description of environmental systems. Their expressions can be evaluated in closed form only in rare cases, for which the geometry and the velocity of the fluid and the interfaces are uniform and known. The field of fluid mechanics is well acquainted with handling such unknown flux terms (e.g. see Stull, 1988 for applications in ABL meteorology).

THE CLOSURE PROBLEM AND HYDROLOGY

The parameterization of unknown flux terms in space and time is challenging in practice. This is a well recognized problem in fluid mechanics, where perturbation and subsequent averaging in time of the governing equations, under the assumption of statistically stationary and homogeneous turbulence, gives rise to correlations of small-scale fluctuations of the independent variables known as *eddy correlations*. These terms are responsible for transfer of significant quantities of mass, momentum, and energy within the system and are measurable with relative ease at a point (e.g. eddy fluctuation sampling from a measurement tower for ABL experiments).

For representation in a numerical model, the correlation terms, which constitute excess unknowns with respect to the available number of prognostic equations, need to be expressed via constitutive relationships as functions of the independent variables. The independent variables are usually the (computation cell) mean velocity, the temperature or saturation, calculated from the solution of the prognostic equations at the nodal points of the model grid. The constitutive relationships are collectively referred to as *closure* schemes. A typical example for such a closure is the $K - \varepsilon$ scheme (for reference, see e.g. Stull, 1988), relating the eddy momentum diffusivity to the turbulent kinetic energy, for which there is a prognostic equation.

Hydrologists encounter similar problems, but do not approach them in the same systematic fashion as people in fluid mechanics, the reason being that hydrologists are confronted with a much higher degree of heterogeneity in their systems and with processes characterized by a wide range of temporal scales. *Closure* in hydrology means mainly parameterization of mass and energy fluxes exchanged between different system compartments and between land surface and canopy and the ABL. The closure is not achieved systematically, through closure schemes, but rather heuristically via *ad hoc* parameterizations, for which suitable parameter values are tuned by calibration. A rare example, where closure of mass fluxes between the saturated and the unsaturated store in a hillslope is exposed as a problem *per se* and approached directly, can be found in an article by Duffy (1996). The infinite choice of possible parameter sets in reproducing the response of a hydrological system (and thus its internal mass fluxes) for a given model architecture opens a window on the difficulties and arbitrariness hydrologists are facing already when attempting to close just the mass balance (e.g. Beven and Binley, 1992; Beven, 2002a).

In fluid or continuum dynamics, the geometry, the fluxes or stresses, and the material properties are generally well known, or can be estimated with sufficient accuracy thanks to a reasonable level of homogeneity in the system. This

is rarely the case in hydrology where the flow processes occurring in highly heterogeneous soils are difficult to predict and generally do not allow to translate parameter values, measured and validated at the laboratory scale or *in situ* to larger spatial scales used in the models.

Flux profiling for the determination of eddy diffusivity coefficients in a well-mixed or uniformly stratified water body or a homogeneous clay layer, for which a Brooks–Corey water retention curve can be fitted, are examples of privileged situations, for which analogues are rarely encountered in a hydrological context. Hydraulic conductivity values measured through an infiltration experiment in the field or in the laboratory cannot be extrapolated simply to larger spatial scales, as the processes at those scales have good chances not to obey to the laws governing their behavior at smaller scales (see e.g. Beven, 1993). This uncertainty on process representation underlying hydrological models is amply discussed throughout works by Beven (e.g. 1993, 2002a, 2002b) and needs to be born in mind when pursuing distributed hydrological modeling, whatever the approach.

Finally, it needs to be emphasized that the closure of fluxes in a hydrological context precludes, due to the inherent heterogeneity of the landscape and soils, the arbitrary scaling of parameterized closure expressions form a measurement point to the model grid scale, as it is common practice in fluid mechanics. These need to be adapted to unique hydrologic situations and to the chosen spatial discretization. The sensitivity of model behavior with respect to given parameterizations will remain the principal criterion for accepting or rejecting a model based on a specific set of flux parameterizations and a topic for further research.

DISCUSSION

What can be thus said about traditional distributed hydrological models based on the FH69 blueprint *vis à vis* a megascopic flux-based formulation such as the REW approach? In general, both formulations, one based on a mix of micro, macro, and megascale representation and the other one exclusively on megascale physics, are consistent with established physical principles in the form of stated assumptions and balance laws (Beven, 2002a). However, to be truly physically based, a model based on either theory needs to satisfy the additional condition of consistency with available hydrological observation at the spatial scale at which the governing equations are formulated. It has been shown exhaustively during the last 30 years in various simulation experiments for data-rich experimental watersheds (e.g. the R5 watershed amongst others, Woolhiser, 1996) that this is not the case for FH69-based models.

It has become clear that, notwithstanding high-quality data from dense logging networks (including information on soil texture and structure, piezometer levels, weirs, surface runoff rates, infiltration rates, and precipitation), achieving improvements of the results beyond a certain point is incommensurate with the efforts to be invested. In other words, it is like trying to squeeze a couple of horse powers more out of an engine that is already operating at its design limits. Achieving added model skill is an expectedly asymptotic effort in terms of the increased spatial resolution of input data and the computational resources required for a successively improved model run, with the hypothetical end-of-the-line being the solution of the full microscale Navier–Stokes equations. This fact could eventually lead to the FH69 blueprint being abandoned like the search of the Spanish conquistadores for "El Dorado" (Woolhiser, 1996) under pressure of having to go back to the drawing board.

In contrast, the *megascale* REW or other control volume–based approaches (Duffy, 1996) are based on a formulation, where a change in spatial scale from the *micro*- to the *megascale* transforms the gradients in the PDE equations into fluxes across the boundary of the control volumes (second left-hand side terms in equation (5)). A successful application lies in representing these fluxes and the hysteretic behavior of the control volume in response to changes in boundary fluxes in the best way possible, whereby the already emphasized difficulties in the necessary parameterizations remain to be addressed. But at least it may point into a viable direction for a way-out from the modeling dilemma experienced in the context of FH69.

The hypothetical measurement at the REW-scale and the correct parameterization of mass or energy fluxes across large surfaces identified between zones in a REW, such as the water table and the land surface or the REW mantle segments, pose the principal challenges in applying this approach and giving it a status of a blueprint for a physically based solution at the *megascale* in its own right (see Beven, 2002a for a discussion of the issues in formulating an alternative blueprint).

However, the flux-based philosophy of the formulation rests on scale-independent and generally valid conservation equations and should draw the attention of the hydrologist towards improving constitutive relationships for fluxes, as currently done in other disciplines, rather than towards reducing mesh sizes, improving numerical algorithms, or attempting to employ data at denser spatial resolution in line with the FH69 philosophy. It needs to be said, however, that improving the megascale representation of hydrological fluxes will remain a significant scientific challenge that needs to be tackled systematically from both the theoretical and the practical side. Some fluxes, such as evaporation, may eventually become measurable thanks to improved technology. Other fluxes, particularly in the subsurface, perhaps never will become measurable, and, thus, need to be estimated indirectly via inverse techniques based on known megascale fluxes or internal state variables. Finally,

it is important to note that the uncertainty intrinsic to the estimation of these quantities will need to be taken into account and dealt with systematically.

GIS, DATABASES, AND DEM DATA IN DISTRIBUTED MODELING

A discussion on distributed hydrological modeling must be accompanied by a note on Geographical Information Systems (GIS) and Databases (DB), tools that play an increasingly important role in the implementation and operation of distributed models. All distributed models require input data of different kind that extend from DEM to soil properties, digital land-use charts, infrastructure typology maps, and a variety of hydraulic properties. In addition, models need to be initialized by assigning initial conditions, need to be driven by spatially distributed environmental forcing, and require the imposition and update of spatially distributed boundary conditions. During run-time, data assimilation procedures can be applied (see e.g. Paniconi *et al.*, 2003). After termination of the model runs, large amounts of data distributed in space and time need to be processed. The handling of this substantial amount of information is facilitated through GIS that allow storing, converting and analyzing spatial data sets arranged in vector or raster formats.

At the moment, world-wide coverage of hydrologically sound digital terrain data is available at a 1×1 km resolution (the HYDRO1k Elevation Derivative Database is accessible at **`http://edcdaac.usgs.gov/gtopo30/hydro/`**). At the same time, more detailed data is freely available at 30×30 m resolution from the ASTER sensor on board of the EO-1 satellite. To date, nobody has compiled a hydrologically sound world-wide coverage from this data source, which remains, however, a significant undertaking. In addition, the IFSAR programme will use the Shuttle Radar Topography Mission (SRTM) data to construct a 30×30 m resolution DEM of high quality (accessible at: **`http://www.fas.org/irp/program/collect/ifsar.htm`**). It is foreseen that this data set will be the primary focus for building DEM data for hydrological modeling in the coming years. This fact will stimulate modelers to reduce the resolution of distributed models and to drive them with an increasingly large amount of information. In this context, GIS are becoming progressively an essential component of hydrological models.

Similar arguments are valid for DB tools. The access and storage of long time-series of historical or simulated discharge, temperature, water level or water quality data are facilitated significantly with the use of third-hand party information tools that are optimized in the handling of large data sets (at the date of publication in the order of Gigabytes). For this reason, distributed hydrological models are required to interface routinely with such instruments.

Alternatively, entire distributed models can be run from a GIS environment, whereby the GIS is not just used as a simple user interface. This is the case for programmable GIS, in which "traditional" programming statements can be applied to entire maps (a drainage networks). One such system is PCraster (Van Deursen, 1995) that has been used to build a variety of hydrological models for large catchments, such as RHINEFLOW (Van Deursen and Kwadijk, 1993) and LISFLOOD (De Roo *et al.*, 2000). Although running a distributed hydrological model through a GIS can have important advantages such as easy programming, and raster data integration from various sources, it remains essentially based on conventional process formulations and respective parameterization. It provides, however, a user-friendly platform for building, running, and presenting a variety of models relatively quickly.

Finally, it must be said that the rapid growth in quantity and the reduction in cost of data and relevant information will not provide an answer to the basic scientific questions underlying the use of data in a hydrological context discussed above. Data are recorded by sensors, which capture electromagnetic signals and convert them into digital ones. To digital signals, numerical values are assigned. These signals can be distorted at the source through a series of factors that decrease the quality of a scan. A good example is the presence of snow or topography interfering with an active radar signal for precipitation-intensity measurements or distortion induced by the atmosphere for altitude measurements of a topographic relief.

Measured quantities employed in hydrological models, such as soil moisture content, water levels, or rainfall intensity, are attributed to the recorded digital signal with the aid of *interpretative* models. This procedure leaves a large space for erroneous interpretation. Once more, the use of radars to predict the intensity of precipitation fields is a typical example for a situation, where significant effort over the last decades has still not led to a robust and reliable calibration procedure. The same can be said for remote sensing of land use and airborne soil moisture measurements, although considerable progress has been made in recent years in the quantitative use of passive microwave in space-borne soil moisture determination (see e.g. Owe *et al.*, 2001; De Jeu and Owe, 2003). However, it is to be expected that these measurements will only deliver surface soil moisture affected by uncertainty that provides limited information on change of moisture storage over the soil depth profile at the model grid scale.

In the near future, the availability of remotely sensed data from which hydrologically relevant information (e.g. soil moisture, land-cover features, leaf-area index) can be derived via interpretation models is bound to grow. The risk that the information will be misused for modeling purposes due to too large a trust in what is promised by suppliers and too much emphasis on the aspects related to

data processing will grow proportionally. As a general rule, common sense and a critical attitude from the side of the hydrologist will never go astray, however sophisticated the data logging instruments and however affordable the data might become.

CONCLUSIONS

In the late 1960s and during the 1970s, the rapid development of computer power led hydrologists and environmental modelers to believe that it was only a matter of time, until a complete distributed catchment model, based on the solution of PDEs, would become available. It was envisaged that, in line with growing CPU speed, improved numerical algorithms, falling hardware prices, and more sophisticated measurement techniques, these models would improve and allow detailed simulations of hydrological systems. This belief was justified at the time, in particular in view of the rapid progress made in other areas, such as in the fluid mechanics of oceanography and meteorology, and in continuum mechanics, where these developments have, in fact, led to impressive predictive skills of the models.

In hydrology, however, more than a quarter of a century later, this initial optimism has been visibly dampened. Repeated applications on heavily monitored catchments at higher spatial resolution and with ever more powerful computers than the one available earlier, have shown that, despite being able to solve the coupled equations numerically, other problems started to appear. Hydrologists using models based on the Freeze–Harlan blueprint could not share the enthusiasm of their colleagues in the fields of fluid dynamics or continuum mechanics.

The reasons are manifold. The processes represented at the micro or macroscale require parameterization of subgrid variability (the variability of the system at scales smaller than the scale of the numerical discretization grid), an extremely challenging if not impossible task for highly heterogeneous systems such as natural soils or a vegetated land surface. Lumping of highly nonlinear processes into parameter representations at larger scales is conceivable in theory in analogy to more homogeneous systems, but has turned out to be unsatisfactory for applications in hydrological practice.

The difficulty underlying the parameterization, in addition to the rather large number of individual processes to be represented, result in a problem of *equifinality* of models and parameter sets that are consistent with the observed data available (e.g. Beven, 1993, 2005; Beven and Freer, 2001). Equifinality leads to various sets of parameter values, which might give a good calibration result, but are often far apart from the values that are observed in the field, raising the question about how *physical* the description actually is. This fact will continue to characterize distributed hydrological modeling and will be exacerbated even further by increasing the spatial resolution of the models.

The *REW* approach offers an alternative by proposing a flux-based method that makes use of appropriately chosen control volumes. The *megascopic* nature of the approach is oriented towards specifying the fluxes across the volume boundaries, rather than towards trying to increase the detail of the process description within the system. In addition, fluxes, such as evaporation, might also have a greater chance of being measurable over large areas, thus aiding the closure procedure. A higher level of detail in the REW approach can be potentially obtained through a breakdown of the areas, for which the fluxes are estimated. In the interest of handling model uncertainty systematically in hydrological modeling *sensu* Beven (2002a), the REW approach could, through an appropriate choice of alternative closure schemes and respective parameterizations, serve as platform for the construction of a multidimensional model and parameters space for the simulation of hydrological systems. However, the aspect of the uncertainty inherent to any attempt of physical description will persist and remain a fact to be catered for systematically in hydrological studies based on megascopic modeling concepts.

128: Rainfall-runoff modeling: Transfer Function Models

PETER C YOUNG

Centre for Research on Environmental Systems & Statistics (CRES), Lancaster University, Lancaster, UK (Also, Centre for Resource & Environmental Studies, Institute of Advanced Studies, Australian National University, Canberra ACT 2020, Australia)

This article discusses continuous and discrete-time transfer function (TF) models within the context of the Data-Based Mechanistic (DBM) modeling of hydrological systems. Although, at a superficial level, TF models simply provide a convenient and concise way of presenting differential or difference equations in an input-output form, they are much more than this. In particular, they allow for the consideration of linear dynamic systems in simple algebraic terms and for their analysis within a dynamic systems and control context. This is useful in various ways, particularly where a higher order TF model is identified and estimated directly from hydrological data. Often, this data-based model can then be decomposed into serial, parallel, and feedback connections of first-order systems that can be interpreted in hydrologically meaningful terms, thereby facilitating the model's use in hydrological systems analysis. The article also shows that TF models can be considered in time-variable and state-dependent parameter (SDP) form, so allowing for them to describe nonstationary and nonlinear systems. And, since it is straightforward to consider all TF models in stochastic terms, they provide a powerful vehicle for uncertainty, forecasting, and risk analysis. The practical utility and power of DBM TF models is illustrated by two real hydrological examples.

INTRODUCTION

From a conceptual standpoint, most mathematical models of hydrological systems are formulated on the basis of natural laws, such as dynamic conservation equations, often expressed in terms of continuous-time (CT) linear or nonlinear differential equations. The objective of *Data-Based Mechanistic* (DBM) modeling (e.g. Young and Lees, 1993; Young, 1998 and the prior references therein) is to infer the nature and structure of such models directly from hydrological data, using powerful methods of statistical identification and estimation, and to then interpret the model equations in physically meaningful terms. One important generic model class that facilitates such DBM modeling studies is the Transfer Function (TF) family of models, which is the subject of this article. The article starts by reviewing briefly some of the background to the use of TF models in hydrology, concentrating on prior publications concerned with the modeling of rainfall-flow (RF) processes. This is followed by a tutorial section that discusses the formulation of linear, constant parameter TF models in the derivative operator $s = \mathrm{d}/\mathrm{d}t$, which are simply the CT, TF form of ordinary differential equations. It then proceeds to develop and discuss the discrete-time (DT) equivalents of these CT models, namely, TFs in the backward shift operator z^{-1} (see later text), before outlining methods for the statistical identification and estimation of both CT and DT models from noisy time series data. In this manner, the models take on a natural stochastic form that is appropriate to their use in applications such as hydrological forecasting, uncertainty, and risk analysis. Two practical examples help demonstrate the practical utility of the TF approach in hydrology, one concerned with RF modeling and the other with the dynamics of solute transport and dispersion in rivers. Finally, the article also shows that TF models can be extended to incorporate time-variable and "state-dependent" parameters, so allowing them to describe nonstationary and nonlinear stochastic systems.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

TF MODELS IN HYDROLOGY

The most common application of TF models in hydrology is connected with the modeling of RF processes, where the objective is to characterize the dynamic relationship between rainfall and *total* measured flow in the river. Note that the term "rainfall-flow" is used here, with an emphasis on the total flow in the river rather than the ubiquitous term Rainfall-Runoff (RR). As we shall see later, this is because the most recent work on the application of data-based TF models in this context has shown how they are able to quantify other components of the flow; most importantly, those arising from groundwater processes that dominate the base flow in the river.

The characterization of the nonlinear dynamic relationship between rainfall and river flow is one of the most interesting and challenging modeling problems in hydrology. It has received considerable attention over the past 40 years, with mathematical and computer-based models ranging from simple black-box representations to complex, physically based catchment models. Other articles in this Encyclopedia will deal more comprehensively with this topic and there are many books that consider it, either in whole, or in part: for example, Anderson and Burt (1985: see particularly, the chapter by Wood and O'Connell); Shaw (1994), Singh (1995) and Beven (2001). But, in attempting to consider the historical context of this topic, we should recall Beven's comments in the latter book:

> "It is now virtually impossible for any one person to be aware of all the models that are reported in the literature, let alone know something of the historical framework of the different initiatives."

On this basis, it is clear that any treatment of such extensive and quite often controversial literature will tend to be somewhat subjective.

Wheater *et al.* (1993) have categorized RF models into four, broad types: conceptual models, physics-based models, metric models and Hybrid Metric-Conceptual (HMC) models. Conceptual and physics-based models tend to be driven by deterministic, reductionist thinking. As a result, they are often very large and suffer from problems of overparameterization that make rigorous statistical identification and estimation from the available data difficult or even impossible. At the other extreme, metric models, such as the neural network (e.g. Hsu *et al.*, 1993) and *neuro-fuzzy* types (e.g. Jang *et al.*, 1997), are the epitome of "black-box" modeling, revealing very little of their internal structure that has any physical meaning.

The HMC models are an attempt to combine the ability of metric models to efficiently characterize the observational data in statistical terms (the "principle of parsimony" (Box and Jenkins, 1970); or the "Occam's Razor" of antiquity), with the advantages of *simple* conceptual models that have a prescribed physical interpretation within the current scientific paradigm. Transfer functions have become a very useful tool in HCM modeling because their outward "black-box" nature obscures an underlying ability to explain the more physically meaningful mechanisms that underlie this input-output description; mechanisms that can be revealed using the "system theoretic" procedures of TF decomposition. In one important sense, TF models provide a rather natural model form for hydrologists because the impulse response of a continuous-time TF is equivalent to the Instantaneous Unit Hydrograph (IUH); while the pulse response of the discrete-time TF is equivalent to the discrete-time Unit Hydrograph (UH) (or TUH): see later Section "The unit hydrograph and finite impulse response TF models".

System theoretic modeling ideas have had quite a strong influence in hydrology over many years: to name but a few contributions, for example, see Amorocho and Hart (1964); Salas *et al.* (1980); Wood (1980); O'Connell and Clarke (1981); Sorooshian (1983); Gupta (1984); Bras and Rodriguez-Iturbe (1985) and Singh (1988). However, such models do not often attempt to represent the nonlinear dynamics inherent in the transformation of rainfall to runoff and, therefore, may not always perform well over long periods of time when the catchment storage and soil wetness is changing over a wide range. Sometimes, piecewise linearity has been assumed to handle some aspects of the nonlinear behavior (e.g. Natale and Todini, 1976a,b); while, in other cases, the model parameters have been allowed to vary with time (Young, 1974; Whitehead and Young, 1975; Whitehead *et al.*, 1976; Young and Wallis, 1985; Young, 1986).

The latter Time-variable Parameter (TVP) approaches to TF estimation have led on to a more overt treatment of nonlinearity, sometimes by the use of nonlinear black-box models (e.g. the early example of Hsu *et al.*, 1993), and sometimes by the extension of TF models to allow for nonlinearity, as considered in this article. As we shall see, this latter approach has the advantage of allowing for the easier inclusion of conceptual ideas and the retention of physical meaning within the estimated model structure. This desire to associate a physical meaning with TF models has a rather natural appeal to hydrologists and was probably first adumbrated by Young (1974) and Whitehead and Young (1975). The idea of a Physically Realizable Transfer Function (PRTF: see Han, 1991) tackled this problem by ensuring that the estimated TF model maintained mass conservation and did not have any nonphysical, oscillatory modes of dynamic behavior. It was also the basis for the work of Jakeman *et al.* (1990) and provided the philosophical and methodological underpinning of the DBM approach to modeling RF processes (Young, 1993; Young and Beven, 1994) that is discussed further in the following sections of this article.

Finally, it must be emphasized that TF models are not restricted to RF processes: since they provide a generic tool for modeling linear and nonlinear, stochastic dynamic

systems, they can be applied to data-based modeling problems in many areas of science, engineering, and the social sciences (see the wide variety of examples in Young, 1998). In the hydrological context, they have already been used for flow routing down rivers (see Section "Continuous-time TF models") so that, together with the rainfall-flow TF models, they allow for characterization of a whole river catchment. As we shall see in a later example, TF models are also fundamental to the Aggregated Dead Zone (ADZ) modeling of pollution transport and dispersion in rivers and soils. Given this flexibility, it seems likely that they will be used even more widely in the future as a basic tool for modeling in hydrological and environmental sciences.

CONTINUOUS-TIME TF MODELS

In order to introduce TF models, let us consider first a conceptual catchment storage equation in the form of a continuous-time, linear storage (tank or reservoir) model: see, for example, the review papers by O'Donnell, Dooge and Young in Kraijenhoff and Moll (1986); or more comprehensive treatments, such as the recent books by Beven (2001) and Dooge and O'Kane (2003). Here, the rate of change of storage in the channel is defined in terms of water volume entering the linear storage element (e.g. river reach) in unit time, minus the volume leaving in the same time interval, namely,

$$\frac{\mathrm{d}S(t)}{\mathrm{d}t} = GQ_i(t-\tau) - Q_o(t) \tag{1}$$

where $Q_i(t-\tau)$ represents the input flow rate delayed by a pure time or "transport" delay of τ time units to allow for pure advection; and G is a gain parameter inserted to represent gain (or loss) in the system. Making the reasonable and fairly common assumption that the outflow is proportional to the storage at any time, that is,

$$Q_o(t) = TS(t)$$

and substituting into (1), we obtain,

$$T\frac{\mathrm{d}Q_o(t)}{\mathrm{d}t} = GQ_i(t-\tau) - Q_o(t) \tag{2}$$

This equation is a first-order, linear differential equation model whose response, from an initial steady flow condition, to a unit impulsive change Q_i^{imp} of the input flow at time $t = t_0$, is given by

$$Q_o(t) = Q_e + Q_i^{\mathrm{imp}}\mathrm{e}^{-(t-t_0)/T}$$

where Q_e is the initial steady flow level. This has a typical hydrograph recession shape, with a decay *Time Constant*, T, that defines the *Residence Time* of the model. As we shall see later, combinations of two or more such first-order models exhibit a typical UH form (e.g. Dooge, 1959; Beven, 2001).

By introducing the derivative operator s, that is, $s = \mathrm{d}/\mathrm{d}t$, and collecting like-terms together, it is easy to see that equation (2) can be written as,

$$(1+Ts)Q_o(t) = GQ_i(t-\tau)$$

so that, dividing throughout by $1+Ts$, we obtain the following continuous-time TF form of equation (2),

$$Q_o(t) = \frac{G}{1+Ts}Q_i(t-\tau) \tag{3}$$

where,

$$H(s) = \frac{G}{1+Ts}$$

represents the TF in terms of the derivative operator s. Note that the same letter s (or sometimes p) is used to represent the related Laplace transform operator. Considered in these Laplace transform terms, it is possible to utilize Laplace transform methods to handle initial conditions on the variables in the model and analytically compute its response (here $Q_o(t)$) to variations in input variable (here $Q_i(t)$). However, this is not essential in the present context, although the interested reader should find the article a good primer for the study of Laplace transform methods (e.g. Schwarzenbach and Gill, 1979).

Physically Interpretable Parameters

The TF model 3 is characterized by three parameters: G, T, and τ. However, there are five, physically interpretable model parameters associated with the model that are worth discussing. The Steady State Gain (SSG), denoted by G, is obtained by setting the s operator in the TF to zero (i.e. $\mathrm{d}/\mathrm{d}t = 0$ in a steady state). It shows the relationship between the equilibrium output and input values when a steady input is applied. For this reason, *if the input and output have similar units*, G is ideal for indicating the physical losses or gains occurring in the system. In the case of a flow-routing model, for example, it indicates whether water has been added ($G > 1$) or lost ($G < 1$) between the upstream and downstream boundaries; and the percentage of water lost or gained can be defined by *Loss Efficiency* $LE = 100(1-G)$, which will be negative if $G > 1.0$. As pointed out above, the *Residence Time* or *Time Constant* T is the time required for the storage element output to decay to e^{-1} or 0.3679 of its maximum value in response to an impulsive input. Finally, the pure *Advective Time Delay* τ indicates the time it takes for a flow increase upstream to be first detected downstream: and $T_t = T + \tau$ defines the *Travel Time* of the system. These five parameters typify the

equilibrium and dynamic characteristics of the TF model and provide a physical interpretation of the TF model in terms of its mass transfer and dispersive characteristics.

TF Manipulation and Block Diagrams

The first-order TF model (3) is often written in the form,

$$Q_o(t) = \frac{g_0}{s + f_1} Q_i(t - \tau) \quad i.e. \quad H(s) = \frac{g_0}{s + f_1} \qquad (4)$$

where,

$$g_0 = \frac{G}{T}; \qquad f_1 = \frac{1}{T}$$

because this is the form in which the model is normally estimated (see later). Typically, a Channel or Flow-routing model for a river catchment will contain a number of elemental models, such as 3 or 4, connected in a manner that relates to the structure of the catchment. For instance, a serial connection of n such elements constitutes the lag-and-route model of a single river channel (Meijer, 1941; Dooge, 1986) and, with $\tau = 0$ and all elements identical, it becomes the well known "Nash Cascade" model (Nash, 1959). More complex river systems can be represented by a main channel of this type, with tributaries modeled in a similar manner. Also, a typical TF model between effective rainfall and flow often contains a parallel connection of two or more such storage elements (see Young, 1992; 2001b,c, 2002a, 2003). Related serial and parallel arrangements characterize the mass conservation equation of the ADZ model for the transport and dispersion of a solute in a river channel (e.g. Wallis *et al.*, 1989 and the prior references therein). And ADZ-type models can lead to more complex interactive water quality models, including chemical and biological interaction, such as dissolved oxygen-biological oxygen demand (DO-BOD) models (e.g. Beck and Young, 1975; Whitehead and Young, 1975; Young, 1999b). Practical examples of both RF and ADZ modeling are described later in Section "STATISTICAL IDENTIFICATION AND ESTIMATION OF TF MODELS".

The TF formulation allows for the visual representation of a total system model in the form of a *Systems Block Diagram*. Figure 1 is a typical example of such diagram that represents a catchment model consisting of a effective RF submodel involving two *different* first-order TFs of the form (3) with $\tau = 0$,

$$H_1(s) = \frac{G_1}{1 + T_1 s}; \quad H_2(s) = \frac{G_2}{1 + T_2 s}$$

that are connected in parallel. The flow output of this submodel forms the input to a flow-routing submodel composed of two *identical*, first order TFs,

$$H_3(s) = \frac{G_3}{1 + T_3 s}$$

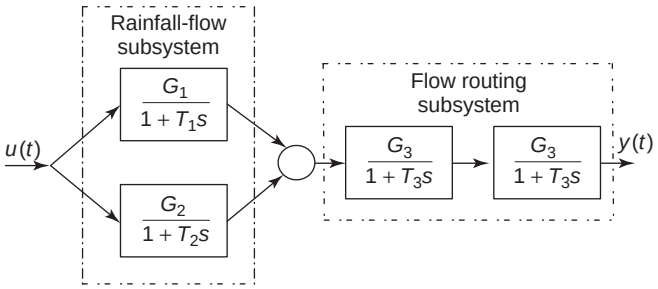

Figure 1 Block diagram of a hypothetical catchment model consisting of a parallel pathway, rainfall-flow subsystem in series with a two reach, flow-routing subsystem

again of the form (3) with $\tau = 0$, but this time connected in series as a "Nash Cascade". The upstream input to this complete system is an effective rainfall measure, represented by $u(t)$, that is generated from the gauged rainfall $r(t)$ (not shown) by a nonlinear relationship $N(s)$ involving a measure of the catchment wetness (see later example). The downstream output of the complete system is denoted by $y(t)$.

One advantage of the TF formulation of the model shown in Figure 1 is that it allows for the computation, using *Block Diagram Algebra*, of a single, multiorder TF that represents the total system. Here, TFs connected in parallel are additive; while those connected in series are multiplicative. Consequently, in this case, the two submodels can be represented by the following composite TFs:

$$H_{rf}(s) = H_1(s) + H_2(s); \quad H_{ff}(s) = H_3(s).H_3(s)$$

So that, with the above definitions of $H_1(s)$, $H_2(s)$ and $H_3(s)$,

$$H_{rf}(s) = \frac{G_1}{1 + T_1 s} + \frac{G_2}{1 + T_2 s} = \frac{(G_1 + G_2) + (G_1 T_2 + G_2 T_1)s}{(1 + T_1 s)(1 + T_2 s)}$$

and

$$H_{ff}(s) = \frac{(G_3)^2}{(1 + T_3 s)(1 + T_3 s)}$$

Now, since $H_{rf}(s)$ and $H_{ff}(s)$ are connected in series, the TF of the total system $H(s)$ is obtained as the multiplication of these two composite TFs: that is,

$$H(s) = H_{rf}(s).H_{ff}(s) = \frac{(G_1 + G_2) + (G_1 T_2 + G_2 T_1)s}{(1 + T_1 s)(1 + T_2 s)} \times \frac{(G_3)^2}{(1 + T_3 s)(1 + T_3 s)}$$

Multiplying out these expressions, we see that the complete $H(s)$ is a 4th order TF that can be manipulated to the form:

$$H(s) = \frac{g_0 + g_1 s}{s^4 + f_1 s^3 + f_2 s^2 + f_3 s + f_4} \tag{5}$$

where we will leave the definition of the parameters $f_i, i = 1, 2, \ldots, 4$ and $g_j, j = 0, 1$ in 5, as an exercise for the reader (*hint*: carry the above analysis with the TF representation 4 rather than 3: then it will be clear why the former representation is better for analysis, although it lacks the direct physical interpretation of the latter, which provides a better form for the block diagram representation).

The General, Multi-Order TF Model

It is clear from the above example that, in general, serial, parallel (or even feedback) connections of elemental first order TF models, such as 3 or 4, lead to a multi-order TF model. The block diagram algebra for a feedback connection is a little more complicated but, since it is not particularly relevant in the current context, the interested reader should consult a standard text on the subject (e.g. Schwarzenbach and Gill, 1979) to find the details. In the present context, the general multi-order TF form is as follows:

$$x(t) = \frac{G(s)}{F(s)} u(t - \tau) \quad y(t) = x(t) + \xi(t) \tag{6}$$

where $F(s)$ and $G(s)$ are polynomials in s of the following form:

$$F(s) = s^p + f_1 s^{p-1} + f_2 s^{p-2} + \cdots + f_p$$
$$G(s) = g_0 s^q + g_1 s^{q-1} + g_2 s^{q-2} + \cdots + g_q$$

in which p and q can take on any positive integer values. Here $u(t)$ and $x(t)$ denote the deterministic input and output signals of the system at its upstream and downstream boundaries, respectively; τ is a pure advective time (transport) delay affecting the input signal $u(t)$; and $y(t)$ is the observed output, which is assumed to be contaminated by a noise or stochastic disturbance signal $\xi(t)$. This noise is assumed to be independent of the input signal and it represents the aggregate effect, at the downstream boundary, of all the stochastic inputs to the system, including distributed unmeasured inputs, measurement errors, and modeling error. Multiplying throughout equation (6) by $F(s)$ and converting the resultant equation to alternative ordinary differential equation form, we obtain:

$$\frac{d^p y(t)}{dt^p} + f_1 \frac{d^{p-1} y(t)}{dt^{p-1}} + \cdots + f_p y(t) = g_0 \frac{d^q u(t - \tau)}{dt^q} + \cdots + g_q u(t - \tau) + \eta(t) \tag{7}$$

where $\eta(t) = F(s)\xi(t)$ is a modified noise signal generated by the manipulation of the equation. The structure of this model, in either form (6) or (7), is defined by the triad $[p\ q\ \tau]$.

If the noise $\xi(t)$ can be assumed to have specific statistical characteristics, then this can help in obtaining low or minimum variance estimates of the TF model parameters. But, as we see later when discussing the identification and estimation of TF models, such assumptions are not an essential requirement of statistical estimation and good, low variance parameter estimates can be obtained without invoking them. Also, depending on the objectives of the modeling study, it may be necessary, in a complete system consisting of many sub-elements such as (3) or (4), to consider noise inputs *within* the system, associated with collections of subelements that have distinct physical meaning: for example, stochastic lateral inflows.

Discrete-time, Sampled Data TF Models

To date, the most popular form of TF modeling has been carried using the DT equivalents of the models (4) and (6). In the case of equation (4), this discrete-time TF model takes the form:

$$Q_{o,k} = \frac{b_0}{1 + a_1 z^{-1}} Q_{i,k-\delta} \tag{8}$$

Here, $Q_{o,k}$ is the downstream flow measured at the kth sampling instant, that is at time $k\Delta t$, where Δt is the sampling interval in time units. $Q_{i,k-\delta}$ is the input flow at time $(k - \delta)\Delta t$ time units previously, where δ is the advective time delay, normally defined as the nearest integer value of $\tau/\Delta t$ (thus incurring a possible approximation error); and z^{-1} is the backward shift operator, that is, $z^{-r} Q_{o,k} = Q_{o,k-r}$. Of course, this model can be written in its "difference equation" form, namely:

$$Q_{o,k} = -a_1 Q_{o,k-1} + b_0 Q_{i,k-\delta} \tag{9}$$

which is obtained by simple cross multiplication and application of the z^{-1} operator. This reveals that the flow $Q_{o,k}$ at the kth sampling instant is a proportion $-a_1$ (note that, in the present context, a_1 will be a negative number less than unity, so that this is a positive proportion) of its value $Q_{o,k-1}$ at the previous $(k-1)^{th}$ sampling instant, plus a proportion b_0 of the delayed upstream flow input $Q_{i,k-\delta}$ measured δ sampling instants previously.

The values of the parameters a_1 and b_0 in equations (8) and (9) can be related to the parameters of the model (4) in various ways depending upon how the input flow $Q_i(t)$ is assumed to change over the sampling interval between the measurement of $Q_{i,k-1}$ and $Q_{i,k}$ (since it is not measured over this interval). The simplest and most common assumption is that it remains constant over this

interval (the so-called zero-order hold, ZOH, assumption), in which case the relationships are as follows:

$$a_1 = -\exp(-f_1 \Delta t) \quad b_1 = \frac{g_0}{f_1}\{1 - \exp(-f_1 \Delta t)\} \quad (10)$$

Note that, because these relationships are functions of the sampling interval Δt, for every unique CT model such as (4), there are infinitely many DT equivalents (8), depending on the choice of Δt, all with different parameter values defined in equation (10). Following from the definition of this first-order DT model at the chosen Δt, the general multiorder equivalent of the general CT model (6) is defined as follows:

$$x_k = \frac{B(z^{-1})}{A(z^{-1})} u_{k-\delta} \quad y_k = x_k + \xi_k \quad (11)$$

where,

$$A(z^{-1}) = 1 + a_1 z^{-1} + a_2 z^{-2} + \cdots + a_n z^{-n}$$
$$B(z^{-1}) = b_0 + b_1 z^{-1} + b_2 z^{-2} + \cdots + b_m z^{-m}$$

Normally $n = p$ but m may be equal or greater than q. The structure of this DT model is defined by the triad $[n\ m\ \delta]$. Note finally that the TFs in both (11) and (3) are composed of ratios of polynomials (in z^{-1} and s respectively), so they are sometimes referred to as *Rational Transfer Functions*.

The Unit Hydrograph and Finite Impulse Response TF Models

The reader can verify that the division of the numerator polynomial $B(z^{-1})$ by the denominator polynomial $A(z^{-1})$ in the TF model (2) normally results in a infinite dimensional polynomial $G(z^{-1}) = g_0 + g_1 z^{-1} + g_2 z^{-2} + \cdots + g_\infty z^{-\infty}$, so that the equation can also be written in the alternative form:

$$y_k = \sum_{i=\delta}^{\infty} g_i u_{k-i} + \xi_k; \quad g_j,\ j = 0, 1, \ldots, \delta - 1 = 0 \quad (12)$$

This will be recognized as the discrete-time form of the convolution integral equation associated with the solution of differential equations (here with a pure time delay of δ sampling intervals or $\delta \Delta t$ time units) and, once again, we see that the TF model is simply a discrete-time equivalent of a continuous-time differential equation model.

Equation (12) has important connotations in hydrology because, if the noise $\xi_k = 0$ for all k, then its unit impulse response (that is the response of the equation to a unit impulse input: $u_k = 1.0$ for $k = 1; u_k = 0$ for all $k > 0$), is equivalent to the hydrological UH. Sometimes, indeed, the equation (12) is referred to as a TF model, although its infinite dimensional nature is an obvious restriction. Despite this disadvantage, some hydrologists have used the equation directly in RF modeling by considering it in a Finite Impulse Response (FIR) form, in which the upper limit of the summation is set to some value $r < \infty$ where it is considered that the ordinates of the impulse response have become small enough to be ignored.

Unfortunately, it can be shown that the number of FIR model parameters (or "weights"), $g_i, i = 1, 2, \ldots, r$, is nearly always much larger than the number of parameters in the rational TF form (11). As a result, the statistical estimates of these parameters will normally have unacceptably high variance and have to be constrained in some manner. For instance, Natale and Todini (1976) use quadratic programming to compute the constrained least squares estimates of the FIR parameters in order to ensure that they are all positive and, if necessary for conservation purposes, they all sum to unity (i.e. the model has unity steady state gain). Even with this approach, however, it is difficult to recommend the FIR model because the rational TF model (11), normally with far fewer parameters, is not only entirely equivalent to the infinite dimensional IR model, without any approximation, it is also easier to estimate from RF data using the methodology discussed in the next Section "STATISTICAL IDENTIFICATION AND ESTIMATION OF TF MODELS".

STATISTICAL IDENTIFICATION AND ESTIMATION OF TF MODELS

In statistical terms, the modeling of a system using a TF model is a problem of time-series analysis (e.g. Box and Jenkins, 1970; Young, 1984) that involves identification and estimation of the model from time-series data. Here, Identification means the definition of the most appropriate model structure: in particular, the values of the elements in the triads $[p\ q\ \tau]$ and $[n\ m\ \delta]$. *Estimation* is then the estimation of the parameters that characterize this structure ($f_i, i = 1, 2, \ldots, p$; $g_j, j = 0, 1, \ldots, q$; and τ in the CT case; $a_i, i = 1, 2, \ldots, n$; $b_j, j = 0, 1, \ldots, m$; and δ in the DT case). Much has been written about the identification and estimation of the DT model (11) but much less on the CT model 6. This is almost certainly for two reasons: first, it is easier to analyze the DT model in statistical terms; second, in these days of digital instrumentation and computers, the DT model provides a more convenient model form. For these reasons, attention will be concentrated initially on the DT model (11) and we will return to the more physically transparent CT modeling later.

Discrete-time TF Model Identification and Estimation

Much has been written on the identification and estimation of discrete-time TF models and the reader is advised to

consult one or more of the many texts on the subject (e.g. Ljung and Söderstrom, 1983; Young, 1984; Norton, 1986). Here, we will not attempt to review this literature but simply refer briefly to a number of topics that are particularly pertinent to the use of TF models in hydrology.

The Box–Jenkins Model

The best known work on the identification and estimation of the DT model (11) is by Box and Jenkins (1970: see Chapter 10), to which the reader is directed for a comprehensive description of how the model can be estimated using the Maximum Likelihood (ML) approach, under the assumption that the noise ξ_k has rational spectral density. This assumption leads to the formulation of the following *Box–Jenkins* model:

$$y_k = \frac{B(z^{-1})}{A(z^{-1})}u_{k-\delta} + \xi_k \quad \xi_k = \frac{D(z^{-1})}{C(z^{-1})}e_k \quad e_k = N(0, \sigma^2)$$

or,

$$y_k = \frac{B(z^{-1})}{A(z^{-1})}u_{k-\delta} + \frac{D(z^{-1})}{C(z^{-1})}e_k \quad e_k = N(0, \sigma^2) \qquad (13)$$

where,

$$C(z^{-1}) = 1 + c_1 z^{-1} + c_2 z^{-2} + \cdots + c_s z^{-s}$$
$$D(z^{-1}) = 1 + d_1 z^{-1} + d_2 z^{-2} + \cdots + d_r z^{-r}$$

and e_k is defined as normally distributed "white noise", defined in statistical terms as $N(0, \sigma^2)$: that is a zero mean, serially uncorrelated sequence of normally distributed random variables with variance (an additional unknown parameter) σ^2. We see, therefore, that the "colored" noise ξ_k is assumed to be generated from the white noise e_k by passing it through a "filter" that has a similar TF form to the system model, but with both polynomials in z^{-1} having leading unity elements (monic polynomials). This particular type of filter is called a AutoRegressive Moving Average (ARMA) model (see Box and Jenkins, 1970). With the noise process defined in this manner, it is clearly necessary to identify the order of the noise model polynomials $C(z^{-1})$ and $D(z^{-1})$ and estimate the associated parameters $c_i, i = 1, 2, \ldots, s$ and $d_i, i = 1, 2, \ldots, r$ and σ^2.

The ARMAX Model

In the systems and control literature, the most widely used approach to DT model estimation is probably the Prediction Error Minimization (PEM) method (e.g. Ljung and Söderstrom, 1983), which is the preferred method in the Matlab™ Identification Toolbox. PEM estimation is most often applied to the alternative AutoRegressive Moving Average eXogenous (ARMAX) TF model form: that is,

$$A(z^{-1})y_k = B(z^{-1})u_{k-\delta} + C(z^{-1})e_k; \quad e_k = N(0, \sigma^2) \qquad (14)$$

Despite the popularity of this ARMAX model in the systems literature, there are good theoretical and practical reasons for preferring the model (13), as discussed below.

Refined Instrumental Variable (RIV) Estimation

One approach to TF model estimation that is simpler and more robust, because it does not rely on the assumption that the noise has rational spectral density, is the Refined Instrumental Variable (RIV) method, which has proven particularly useful and robust in hydrological applications. The RIV approach (see Young and Jakeman, 1979; Young, 1984) is based on the TF models (11) and (13) and was initially developed with environmental applications in mind, where robustness to the kinds on nonstandard conditions met in the environment, including hydrology, is very important. The RIV method has three primary advantages that are pertinent to the discussion here.

1. In the case of the full Box–Jenkins model (13) and following from an important theorem by Pierce (1972), the estimates of the "system" parameters in $A(z^{-1})$ and $B(z^{-1})$ are asymptotically independent of those for the "noise" parameters in $C(z^{-1})$ and $D(z^{-1})$. This has important consequences on parameter estimation (Jakeman and Young, 1981, 1983) that justify the RIV estimation of the TF model (13) rather than the ARMAX model (14). They also expose deficiencies in the ARMAX model estimates if the data are generated by the model (13).
2. Like all instrumental variable methods (see e.g. Young, 1984), the RIV approach does not necessarily require the concurrent estimation of a noise model and, indeed, remains statistically efficient (i.e. the parameter estimates are optimal in the sense that amongst all estimates, they have the minimum variance) if the noise ξ_k is itself white (i.e. $C(z^{-1}) = D(z^{-1}) = 1.0$). Used in this manner, the RIV algorithm is, for obvious reasons, called the Simplified RIV (SRIV) algorithm (Young, 1985).
3. As pointed out by Wellstead (1978) and considered further by the present author and his colleagues (Young *et al.*, 1980; Young, 1989), model structure identification (definition of the triad $[n\ m\ \delta]$) is greatly facilitated by the special properties of the Instrumental Product Matrix (IPM) that is a fundamental component of IV estimation and has optimal statistical properties in the case of RIV/SRIV estimation. This has been exploited in the development of the Young Information Criterion (YIC) order identification criterion mentioned later.
4. The RIV/SRIV algorithms for DT models utilize a special form of adaptive prefiltering. This is further exploited in the RIV method for continuous-time systems (the RIVC algorithm: Young and Jakeman, 1980; Young, 2002b) to bypass the need for direct

differentiation of the input and output signals. This algorithm is discussed further in the following section.

Continuous-time TF Model Identification and Estimation

Following on the point 4. in the previous subsection, the statistical estimation of the CT model (6) is straightforward if completely continuous-time data are available. However, the hydrologist is normally confronted by discrete-time, sampled data and the problem of modeling continuous-time models such as this, based on discrete-time, sampled data at sampling interval Δt, is not so obvious. This problem can be approached in two main ways.

- *The Indirect Approach:* Here, the identification and estimation steps are first applied to the DT model (11) or (13). This estimated model is then converted to the CT model (6), again using some assumption about the nature of the input signal $u(t)$ over the sampling interval Δt. In the first-order, ZOH case, this conversion is given by the relationships in equation (10) but, in more general terms, the multiorder conversion must be carried out in a computer, using a conversion routine such as the *d2cm* algorithm in the Matlab Control Toolbox.

- *The Direct Approach:* Here, the RIVC algorithm, together with an appropriate order identification criterion (see the following text), is used to identify the most appropriate, identifiable CT model structure defined by the triad $[p \;\; q \;\; \tau]$; and then estimate the TF parameters $f_i, i = 1, 2, \ldots n$, $g_j, j = 0, 1, \ldots m$ and τ that characterize this structure. Of course, some approximation will be incurred in this estimation procedure because the inter-sample behavior of input signal $u(t)$ is not known and it must be interpolated over this interval in some manner (see the preceding text).

Model Structure Identification

Finally, as mentioned previously, an important aspect of TF modeling, in both continuous and discrete-time, is *Model Structure Identification* (the definition of the model structure triads). This can be approached in various ways. For example, Box and Jenkins (1970) discuss the topic at length and Akaike (1974) suggested an alternative approach that has since spawned several other, related methods. Within the context of the instrumental variable methods discussed previously, however, model structure identification is based conveniently on two statistical criteria. First, the *Coefficient of Determination*, R_T^2, a normalized measure based on the variance of the error between the sampled output data y_k and the simulated (CT or DT) model output at the same sampling instants (this is normally equivalent to the well known *Nash-Sutcliffe Efficiency* measure (Nash and Sutcliffe, 1970); and $100 \times R_T^2$ is the percentage of the variance of the output data explained by the model). Note that R_T^2 should not be confused with its well known relative R^2, as used in classical regression and time-series analysis, which is defined in terms of the one-step-ahead prediction errors. In general, R_T^2 is a more discerning measure of model adequacy in a dynamic systems context than R^2 since it quantifies the ability of the model to explain the whole of the output data from the input data, without any reference to the output data. In contrast, R^2 only measures the ability of the model to predict one-step-ahead on the basis of the latest input and output data. The second statistic is the YIC, which is a heuristic measure of model identifiability and is based on the properties of the IPM matrix (see the previous discussion). These statistics are discussed in more detail in Young (1989) and Appendix 3 of Young (2001b).

TWO PRACTICAL EXAMPLES

TF models can be applied in many areas of hydrology and provide a good basis for DBM modeling. Two typical examples are outlined in this section. The first is a TF model of the relationship between effective rainfall and flow in an Australian river catchment. This DBM model could provide a direct basis for flow forecasting at the flow measurement station or it could be extended to incorporate flow-routing TF elements down the river in order to allow for forecasting over the whole catchment area (that may involve other RF modules). The second example is an ADZ model for the transport of a conservative dye tracer in a Florida wetland area. This DBM model describes the physical aspects of solute advection and dispersion in the wetland and so could provide the physical basis for more complex, nonconservative water quality modeling involving biological and chemical mechanisms.

Rainfall-flow Modeling

Figure 2 shows a portion of effective rainfall $u(t)$ and flow $y(t)$ data from the River Canning, an ephemeral River in Western Australia. A longer set of these data has been analyzed comprehensively in Young *et al.* (1997), using DT modeling. The effective rainfall series plotted in part (b) of Figure 2 is generated from the effective rainfall nonlinearity identified in this earlier study, with the effective rainfall generated by the equation

$$u(t) = r(t)y(t)^{\gamma} \tag{15}$$

where $r(t)$ is the measured rainfall and γ is a power law parameter. Here, the flow $y(t)$ is acting as a surrogate measure of the catchment storage, rather than attempting to model this storage separately in some conceptual manner (see e.g. Jakeman *et al.*, 1990; Wheater *et al.*, 1993; Young 2001b, 2003). In the following, we obtain direct and indirectly estimated, linear CT models between the effective

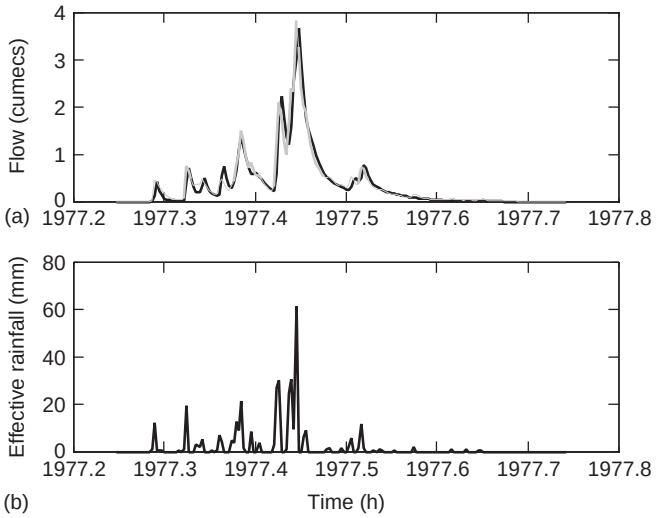

Figure 2 Daily effective rainfall (b) and flow (a) data for the River Canning in Western Australia. The dotted line appears to me to have come out as a grey line (a) is the simulated output of the DBM model (see text)

rainfall $u(t)$, as defined in the above manner, and the flow $y(t)$. Of course, the DT model is useful in its own right and provides an excellent basis for applications such as flow forecasting (see e.g. Lees *et al.*, 1994; Lees, 2000a,b; Young, 2001c, 2002a). However, the transparency of the CT model in revealing, more obviously, the physical interpretation of the model makes it more useful as a vehicle in DBM modeling and the use of the model in wider catchment studies.

Direct CT Identification and Estimation

Let us consider first identification and estimation based on the measured daily data shown in Figure 2. The RIVC algorithm, in combination with the R_T^2 and YIC statistics, identifies a [2 3 0], second order model with the parameter estimates:

$$\begin{array}{ll} \hat{f}_1 = 0.457 \ (0.032) & \hat{f}_2 = 0.0248 \ (0.0045) \\ \hat{g}_0 = 0.0138 \ (0.001) & \hat{g}_1 = 0.0505 \ (0.002) \\ \hat{g}_2 = 0.0046 \ (0.0008) & \end{array}$$

where, here and elsewhere in the paper, the figures in parentheses are the estimated standard errors obtained from the RIVC algorithm. This model output (shown as the dotted line in (a) of Figure 2) explains the data very well with $R_T^2 = 0.980$ (98% of the output flow variance explained by the simulated CT model output) and a residual variance of 0.00723 (standard deviation 0.085 cumecs, where the maximum flow is 3.86 cumecs). The model can also be decomposed by standard TF decomposition (see earlier text) into a parallel pathway form. The three pathways are: (i) an instantaneous effect, accounting for 7.4% of the flow, which is a measure of rapid flow that occurs in the very short term (within one sampling interval; here one day); (ii) a quick pathway, accounting for 54.1% of the flow, that represents a linear store with a residence time of about 2.53 days, probably the result of surface and shallow, subsurface processes in the catchment; and (iii) a slow or base-flow pathway, accounting for 38.5% of the flow, that passes through a much longer 15.9 day residence time, linear store, probably representing the effects of deeper groundwater processes and the displacement of old water.

Indirect CT Identification and Estimation

The first step of indirect CT modeling involves DT identification using the RIV algorithm (see earlier). This identifies a similar [2 3 0] structure TF with the following parameter estimates:

$$\begin{array}{ll} \hat{a}_1 = -1.6034 \ (0.008) & \hat{a}_2 = 0.6244 \ (0.007) \\ \hat{b}_0 = 0.0140 \ (0.001) & \hat{b}_1 = 0.0151 \ (0.002) \\ \hat{b}_2 = 0.0252 \ (0.0013) & \end{array}$$

However, since this is a discrete-time model, it has to be converted to continuous-time form. The *d2cm* algorithm in Matlab (see Section "CONTINUOUS-TIME TF MODELS".) accomplishes this conversion, using a ZOH approximation (i.e. the input effective rainfall is assumed to be constant over the sampling interval). The resulting CT model parameter estimates are:

$$\begin{array}{lll} \hat{f}_1 = 0.4711 & \hat{f}_2 = 0.0264 & \\ \hat{g}_0 = 0.0140 & \hat{g}_1 = 0.0514 & \hat{g}_2 = 0.0049 \end{array}$$

In this case, the model is quite similar to the directly estimated CT model in the previous subsection (i). But note that there are no standard errors quoted here: this is because these are not available after the conversion and must be computed separately in some manner, usually by the less convenient and lengthy Monte Carlo simulation analysis.

This lack of directly available estimation statistics is not the only disadvantage of the indirect approach. Unlike the CT model parameters, which are independent of the sampling interval Δt, the estimated DT model parameters are a function of Δt, so that different numerical estimates of the parameters are obtained for different values of Δt. Moreover, the *quality* of these estimates is also a function of Δt: in particular, if the sampling interval is too small, then the estimates are poorly defined statistically; the resulting CT model parameter estimates will be impaired; and the whole estimation process is less robust (see Young, 2004a, for discussion on the reasons for this). Conveniently, it is under these same, rapid sampling (small Δt) conditions that the direct CT approach works best. So, in practical terms, indirect CT model estimation works very well when the data are not sampled too rapidly but direct CT estimation is preferable at rapid sampling intervals.

Aggregated Dead Zone (ADZ) Modeling of Tracer Data

Tracer experiments can provide important information on how solutes are transported and dispersed in hydrological systems. This example is concerned with TF modeling of the input-output data shown in Figure 3 (TF modeling is also applied to a different set of tracer data in the article **Chapter 134, Downward Approach to Hydrological Model Development, Volume 3**). These tracer data were obtained from a bromide tracer experiment carried out in a Florida wetland area receiving treated domestic wastewater for further nutrient removal. The experiment was part of a study carried out by Chris Martinez and Dr. William R. Wise of the Environmental Engineering Sciences Department, University of Florida for the City of Orlando. The bromide tracer was injected 765 meters upstream of a weir, at which samples were taken with a sampling interval Δt of 2 h. As we shall see, TF models are not only able to explain these tracer data well, but following the requirements of DBM modeling, they can also be interpreted in ADZ model terms that have physical meaning (see Wallis *et al.*, 1989). Here, we will consider the discrete-time TF model and utilize the SRIV algorithm (see earlier text) to identify the model order and estimate the parameters. However, continuous-time TF estimation using the continuous-time SRIV algorithm yields similar (albeit not identical) results and the discrete-time analysis is used here simply for illustration.

Although the impulsive ("gulp") input does not perturb the system continually (in the systems literature, it is said to be "not persistently exciting"), the SRIV algorithm has no difficulty identifying and estimating a low order model. The best identified TF, based on the R_T^2 and YIC criteria, is either 3rd or 4th order, but subsequent analysis, described later, suggests that the latter is superior from a physical standpoint. The estimated [4 2 22] (4th order denominator, 2nd order numerator and a 22 sampling interval pure time delay) takes the form:

$$y_k = \frac{\hat{B}(z^{-1})}{\hat{A}(z^{-1})} u_{k-22} + \xi_k \tag{16}$$

where,

$$\hat{A}(z^{-1}) = 1 - 3.67z^{-1} + 5.06z^{-2} - 3.11z^{-3} + 0.72z^{-4}$$
$$\hat{B}(z^{-1}) = 0.00103 - 0.00101z^{-1}$$

Here the "hat" denotes the estimated value; y_k is the observed tracer concentration at the weir and u_k is the impulsive input of tracer (186.33 mg l^{-1}), both measured at the kth sampling instant. Note that, although the standard errors on the parameters are available they are not cited specifically. However, the uncertainties on the physically meaningful, derived ADZ model parameters are discussed later. Note also that the large advective time delay of 22 sampling intervals (44 h) is the time taken for the solute to first reach the weir. The noise ξ_k is small and so the model explains the data very well with $R_T^2 = 0.997$ (i.e. 99.7% of the output variance is explained by the model).

Unfortunately, despite its ability to describe the data very well, the model (16) is not immediately acceptable from a DBM standpoint, primarily because the eigenvalues are $\{0.988, 0.964, 0.860 \pm 0.132j\}$, where $j = \sqrt{(-1)}$ is the complex number. Here, the pair of complex roots are associated with oscillatory response and this is difficult to justify in ADZ modeling terms. In particular, the elemental, single reach ADZ model is a first-order differential equation based on mass conservation (Wallis *et al.*, 1989) and so, other than in exceptional circumstances, multiple reach ADZ models must be characterized by real eigenvalues when considered in TF terms.

In the present circumstances, the most obvious approach is to re-estimate the model in a form where the eigenvalues are constrained to be real. This was carried out by means of constrained, nonlinear least squares optimization using the *leastsq* optimization procedure in Matlab. To ensure that the most parametrically efficient model was obtained, both [3 2 22] and [4 2 22] models were considered in this analysis but the latter yielded much the best constrained model, which has the following form:

$$y_k = \frac{\hat{B}(z^{-1})}{\hat{A}(z^{-1})} u_{k-22} + \xi_k \tag{17}$$

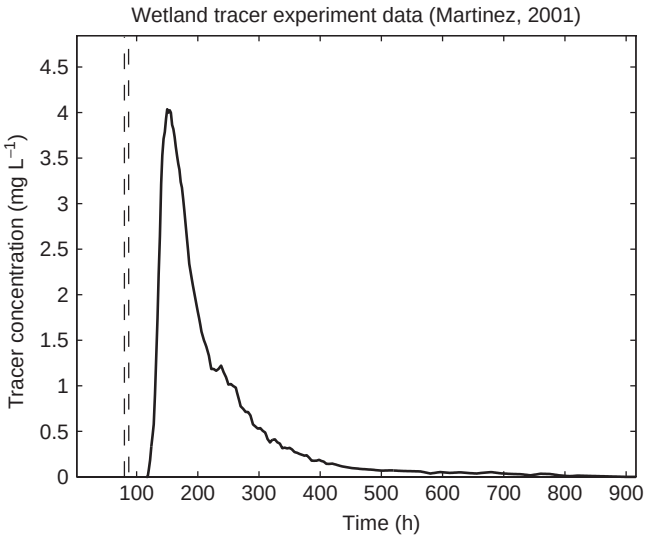

Figure 3 Wetland tracer experiment data: the input u_k is an impulsive or "gulp" application of bromide tracer (dashed line) and the output y_k is the concentration of bromide measured every 2 h at a downstream weir (full line)

where,

$$\hat{A}(z^{-1}) = (1 - 0.980z^{-1})(1 - 0.855z^{-1})^3$$
$$\hat{B}(z^{-1}) = 0.00127 - 0.00121z^{-1}$$

This model is well defined statistically and it explains 99.7% of the experimental data ($R_T^2 = 0.997$), the same as the unconstrained model (1). Figure 4 compares the model output (full line) with the measured output y_k (circular points).

Unlike the TF model (16), the model (17) not only has four real eigenvalues, as required, but three of these are repeated, so defining three identical ADZ reaches. These eigenvalues define ADZ residence times (time constants) of 99 h and 12.8 h (×3), giving a total estimated residence time for the wetland cell of 137.4 h ($99 + 3 \times 12.8$). One particular, physically meaningful, decomposition and interpretation of the model defined in this manner is again obtained by partial fraction expansion of the TF in equation (17). This decomposition is shown in the block diagram of Figure 5 which, it will be noted, has exactly the same form as Figure 1, except for the addition of the pure advective time delay, τ, demonstrating the widely applicable, generic nature of TF models such as these.

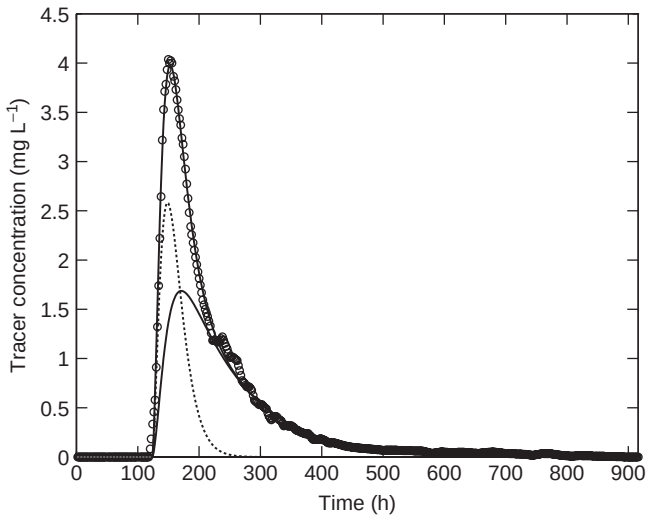

Figure 4 Comparison of the DBM model output (full line) and tracer experiment data (circular points). Also shown are the inferred slow-flow component (dashed line) and quick-flow component (dotted line)

The block diagram in Figure 5 shows that the solute is partitioned initially into a parallel pathway form with a "quick-flow" pathway, consisting of a single ADZ reach with a residence time of 12.8 h, and a "slow-flow" pathway with a much longer residence time of 99 h. The two pathways then add together and the solute passes further downstream, through two more ADZ reaches, each with a residence time of 12.8 h. The total *travel time* for this complete system is 181.5 h (the sum of the 44 h advective time delay and the cumulative overall time constant of 137.4 h). This means that the *dispersive fraction* (see Wallis *et al.*, 1989; Young and Wallis, 1994; Young, 1999a) is 0.76 (i.e. 137.4 ÷ 181.5): in other words, 76% of the water appears to be effective in dispersing the solute. This is a very high proportion, reflecting the nature of the system in this case, with a much higher potential for dispersion of tracer than in normal, faster moving streams, where the dispersive fraction is normally in the range 0.3 to 0.4. The inferred responses of the two pathways are plotted in Figure 4: the dotted line shows the estimated concentration changes in the quick-flow pathway (effectively three 12.8 h residence time ADZs in series), which accounts mainly for the initial response measured at the weir; while the dashed line shows the estimated changes in the slow-flow pathway (effectively a 99 h residence time ADZ in series with two 12.8 h ADZs), and these are mainly responsible for the raised tail of the measured response.

It is possible to compute estimates of other physical attributes associated with the model. First, the steady state gains associated with the two parallel pathways define the partitioning of the flow, with 33% of flow associated with the quick pathway and 67% with the slow pathway. And since the flow rate is known in this example, the Active Mixing Volumes (AMVs: Young and Lees, 1993), based on the estimated partitioned flow, are 361 m^3 in the quick

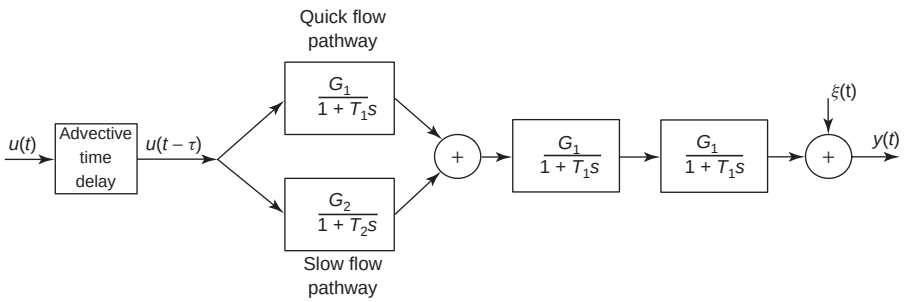

Figure 5 Block diagram of a transfer function decomposition for the ADZ model that can be interpreted in physical terms as a parallel-serial decomposition of ADZ reaches. $T_1 = 12.8$ h; $T_2 = 99$ h; $\tau = 22$ h

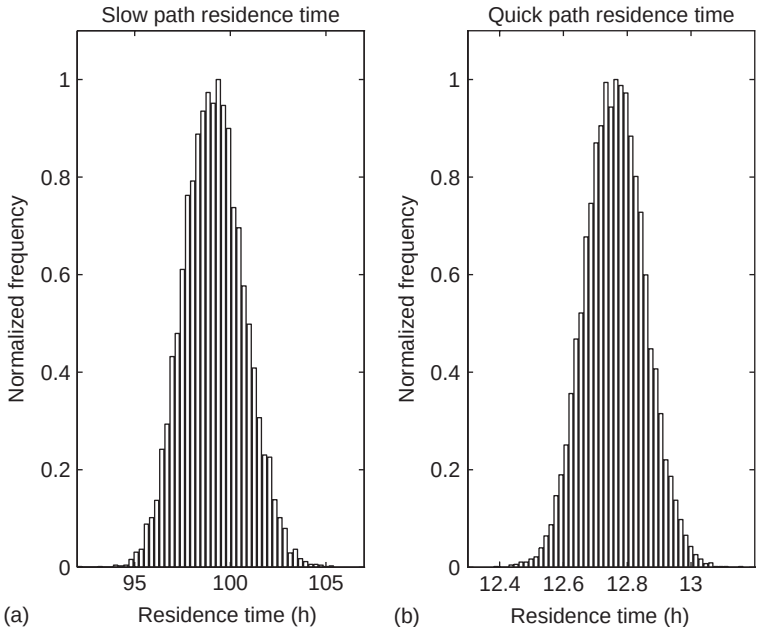

Figure 6 MCS analysis results: normalized histograms of the slow-flow (a) and quick-flow (b) pathway residence times

pathway and $5656\,m^3$ in the slow pathway. As a result, the total estimated AMV is $5656 + 3 \times 361 = 6739\,m^3$, which seems reasonable when compared with the $9749\,m^3$ for the total volume of the wetland, estimated by physical measurement. This suggests that about 70% of the wetland is important in dispersing the tracer (and, therefore, the waste water) and compares reasonably with the dispersive fraction derived percentage of 76%.

Of course, all of the results above are statistical estimates and so they are inherently uncertain. The advantage of the DBM/TF approach is that we can quantify and consider the consequences of this uncertainty (see Young, 1999a). For instance, based on the covariance matrix of the parameters produced by the SRIV estimation analysis, empirical probability distributions, in the form of histograms, can be computed for the "derived" physical parameters, such as the residence times, partition percentages, AMVs, total AMV, and steady state gain, using Monte Carlo Simulation (MCS) analysis. Figure 6 is a typical example of such analysis: it shows the normalized empirical distributions for the two residence times obtained by MCS using 10 000 random realizations (the procedure used here is discussed in Young, 1999a).

Of course, it should be noted that the parallel decomposition of the estimated TF used here is not unique: there are other decompositions that are just as valid and give precisely the same input–output response. For example, two other examples are: (i) a serial connection of the three ADZs with residence times of 12.8 h, in parallel with another serial connection, this time of an ADZ with residence time of 99 h in series with two 12.8 h residence time ADZs the same as those in the first parallel pathway; (ii) various decompositions including feedback processes. However, the latter seem less supportable in physical terms and are rejected according to the DBM ethos.

Finally, how can decompositions of ADZ reaches, such as those shown in Figure 5 be interpreted in terms of the wetland system? The most plausible mechanism is that the pure time delay allows for the flow-induced pure advection of the solute (chemical engineers would call this "plug-flow"). The quick-flow parallel pathway then represents the "main stream-flow" that is relatively unhindered by the vegetation; while the slow-flow pathway represents the solute that is captured by the heavy vegetation and so dispersed more widely and slowly before rejoining the main flow and eventually reaching the weir. It is this latter pathway, which we have shown above accounts for some 67% of the flow, together with the large associated dispersive fraction of 76%, that is most useful in terms of nutrient removal, since it allows more time for the biological activity to take place.

NONSTATIONARY AND NONLINEAR TF MODELS

Although the RF model discussed in Section "DISCRETE-TIME TF MODEL IDENTIFICATION AND ESTIMATION" is characterized by an input nonlinearity, the example has emphasized the constant parameter, linear TF part of the model (which defines the shape of the catchment UH). However, the nonlinearity is very important because

it defines the way in which the model responds under different catchment wetness conditions. So, in general, it is necessary to consider extensions to the constant parameter, linear TF model that allow for the consideration of more complex hydrological processes such as this. Fortunately, it is possible to extend TF models to handle "nonstationary" situations described by TVP models or "nonlinear" situations characterized by State-Dependent Parameter (SDP) models. The latter model class encompasses a wide variety of nonlinear, stochastic, dynamic phenomena, including chaotic systems.

Although such TVP and SDP models are beyond the scope of this article, they are introduced briefly in the following subsections. Both types of models can be considered in either continuous or discrete-time. However, since statistical estimation is more straightforward in the DT case, it often provides the more practical approach. Consequently, the brief descriptions that follow are limited to this DT situation.

Nonstationary Time-Variable Parameter (TVP) Models

In the DT case, the TVP form of the TF model (11) can be written as follows:

$$x_k = \frac{B(k, z^{-1})}{A(k, z^{-1})} u_{k-\delta} \quad y_k = x_k + \xi_k \tag{18}$$

where,

$$A(k, z^{-1}) = 1 + a_{1,k} z^{-1} + a_{2,k} z^{-2} + \cdots + a_{n,k} z^{-n}$$
$$B(k, z^{-1}) = b_{0,k} + b_{1,k} z^{-1} + b_{2,k} z^{-2} + \cdots + b_{m,k} z^{-m}$$

Here, all the parameters are assumed to be functions of the time index k, that is it is assumed that they may vary over time in an unknown manner that needs to be estimated from the data.

Some of the latest research on TVP estimation is reported in Young (1999b, 2000, 2004b) where the reader will find a complete description of the recursive estimation algorithms that allow for the estimation of the time-variable parameters. A simple example would be a model such as (8) in which the "gain" parameter $b_0 = b_{0,k}$ is assumed to vary over time in order to reflect any changes in the dynamic behavior of the channel that may occur over a wide range of flow conditions. An approach similar to this is suggested by Cluckie (1993), who refers to the gain as a "model scaling factor" and points out that it is analogous to the "variable proportional loss method" of defining effective rainfall. An example of adaptive gain adjustment that has been implemented in practice is the adaptive flood warning system for the River Nith at Dumfries, in south west Scotland (Lees *et al.*, 1993, 1994). Here, a recursive estimation algorithm has been used for over a decade to continually update a gain parameter, based on telemetered data from the catchment, in order to provide an adaptive capability. In this case, however, the adaptive gain parameter is only required to "fine-tune" an *already computed* effective rainfall input generated from the measured rainfall by a "state-dependent parameter" nonlinearity, as discussed in the next section.

Nonlinear State-Dependent Parameter (SDP) Models

Again, in the discrete-time case, the SDP form of the TF model (11) can be written as follows:

$$x_k = \frac{B(\mathbf{w}_k, z^{-1})}{A(\mathbf{v}_k, z^{-1})} u_{k-\delta} \quad y_k = x_k + \xi_k \tag{19}$$

where,

$$A(\mathbf{v}_k, z^{-1}) = 1 + a_1(v_{1,k}) z^{-1} + a_2(v_{2,k}) z^{-2} + \cdots + a_n(v_{n,k}) z^{-n}$$
$$B(\mathbf{w}_k, z^{-1}) = b_0(w_{0,k}) + b_1(w_{1,k}) z^{-1} + b_2(w_{2,k}) z^{-2} + \cdots + b_m(w_{m,k}) z^{-m}$$

Here, the possibility that the parameters may be functions of other "state" variables is investigated. In other words, it is assumed that any parameter in the model may vary over time as a function of one or more other variables (e.g. the input u_k or output y_k and their past values), so introducing nonlinear behavior into the model. In the SDP model (19), these variables are denoted by $v_{i,k}, i = 1, 2, \ldots, n$ and $w_{j,k}, j = 0, 1, \ldots, m$ and they are, respectively, the elements of the vectors $\mathbf{v}_k$ and $\mathbf{w}_k$.

The first applications of SDP estimation in hydrology are described in Young (1993); Lees *et al.* (1993, 1994) and Young and Beven (1994); while the latest research on this topic is reported in Young (2000, 2001a) and Young (2002). A simple example of SDP estimation is provided by the estimation of the effective rainfall nonlinearity (15) of the RF model discussed in Section "DISCRETE-TIME TF MODEL IDENTIFICATION AND ESTIMATION". Here, SDP estimation identifies that, in order to explain the RF data well, the numerator parameters b_0, b_1 and b_2 in a *linear* TF model of the RF data need to vary significantly as functions of the flow: that is, they are identified as SDPs $b_0(y_k)$, $b_1(y_k)$ and $b_2(y_k)$. However, the inclusion of a power law nonlinearity such as equation (15), operating on the input rainfall, removes the need for these variations, leaving the model as a serial connection of the nonlinearity (15) and the linear, constant parameter TF, as described in Section "Discrete-time TF model identification and estimation". Other related examples have been discussed recently in Young (2001b,c, 2002a, 2003).

CONCLUSIONS

At one level, TF models are simply elegant and convenient representations of continuous-time, stochastic differential equation models, or their discrete-time equivalents. This article demonstrates, however, that they are much more than this: they also provide a powerful, generic method of modeling hydrological systems. This method provides a useful block diagram interpretation of the input–output dynamics of the system under study that can be decomposed straightforwardly into physically meaningful sub-systems that are in an ideal form for DBM modeling studies. The utility of the method is further enhanced by the powerful methods of statistical identification and parameter estimation that have been developed for such TF models over many years. These are not only robust in practical application, but they also provide valuable information about the stochastic nature of the system and allow for the quantification of the uncertainty associated with the model parameter estimates and its output predictions. Moreover, these estimation methods are normally available in a recursive form that allows for their use in on-line, real-time applications, where they provide a natural basis for adaptive modeling and data assimilation. Recent developments in recursive time-variable and state-dependent parameter estimation have enhanced the utility of TF models still further, so that they are now able to characterize both nonstationary and nonlinear stochastic systems.

Finally, it should be emphasized that DBM models, in general, and data-based TF models, in particular, naturally require real time-series data for their identification and estimation. Also, their primary use is for improving our understanding of the system dynamics and/or for implementing model-based prediction, as in flood warning and forecasting applications, where the main changes that are likely to occur in future relate to the input variables (measured rainfall and upstream flows). They are not particularly appropriate, at least in their basic form, for assessing the impacts of changes to the nature of the system ("what-if" studies) unless the derived, physically meaningful parameters associated with the DBM model (as, for example, in the case of the Florida wetland example) can be associated with physical environmental characteristics, such as the topography or other physical features of a catchment ("regionalization studies": see e.g. Kokkonen *et al.*, 2003 and the **Chapter 134, Downward Approach to Hydrological Model Development, Volume 3** in this Encyclopedia). In this regard, it is likely that the derived parameters will be "bulk" parameters that relate to the behavior of the system at the catchment scale, rather than the kind of "process" parameters used in hydrological simulation models.

It is clear, however, that when suitable, measured time-series data are available, DBM/TF models should always be used as an adjunct to simulation model synthesis because they define well the "dominant mode" behavior of the system that is identifiable from the historical data (*see* **Chapter 134, Downward Approach to Hydrological Model Development, Volume 3** in this Encyclopedia). In this way, they can alert the model builder to those aspects of the simulation model that are not well defined in relation to the available data and so are of a more speculative nature.

Acknowledgments

The author is grateful to Professor Tony Jakeman of the Centre for Resource and Environmental Studies, Australian National University for providing the Canning River data; and to Chris Martinez and Dr. William R. Wise of the Environmental Engineering Sciences Department, University of Florida, for providing the tracer experiment data.

129: Rainfall-runoff Modeling for Integrated Basin Management

GEORGE LEAVESLEY

United States Geological Survey, Denver, CO, US

Integrated basin management is concerned with the interactions of physical, ecological, economic, and social systems as they affect the operation, planning, and policy making processes inherent in the management of land and water resources. Systems of integrated hydrological, chemical, biological, ecological, and socioeconomic models are typically used to assess the effects of proposed management alternatives on basin resources, or to manage basin resources in real time. Water is a common thread linking many of the components among these models. The ability to adequately simulate rainfall-runoff processes and their interactions with processes related to other system components significantly affects the integrated system results. Model complexity and compatibility, data availability, and a number of error sources that include data, model parameters, and model structure, are major concerns in the use of integrated modeling systems. The effects of these error sources on the uncertainty in simulation results become even more complex in integrated system application in which output from one model is typically used as input to other models. The number and complexity of available integrated modeling systems represent a wide variety of approaches with different models, operational features, user interfaces, data formats, and analytical tools. For this review, integrated modeling systems have been characterized as using either a (i) dedicated-system approach with a predefined set of models or (ii) modeling-framework approach that typically enables the application of a user-selected set of models. A number of available integrated systems within these two classifications are described and an example of application of a modular-framework approach is presented.

Integrated basin management can be described as a coordinated form of management that considers the interactions of physical, ecological, economic, and social systems as they affect the operation, planning, and policy making processes inherent in the management of land and water resources (*see* **Chapter 185, Integrated Land and Water Resources Management, Volume 5**). Integrated basin management issues are the concern of local, national, and international organizations. In the United States, integrated basin management has been advanced in something termed the *watershed approach* to environmental management by the federal government's Environmental Protection Agency (EPA, 2005). In Europe, the European Union's Water Framework Directive directs member states to begin implementing the principles of sustained development and integrated river basin management (European Commission, 2004). Comparable efforts have been, or are being initiated in a large number of river basins around the world.

Water is a common thread linking many of the issues in integrated basin management. The ability to predict the results of existing or proposed actions on all components of a basin system is dependent to a large degree on the ability to adequately simulate rainfall-runoff processes and their interactions with processes related to other system components. This entails linking hydrological models with a variety of chemical (*see* **Chapter 100, Water Quality Modeling, Volume 3**), biological, ecological (*see* **Chapter 103, Terrestrial Ecosystems, Volume 3**; **Chapter 107, Natural and Constructed Wetlands, Volume 3**; **Chapter 108, Lake Ecosystems (Stratification and Seasonal Mixing Processes, Pelagic and Benthic Coupling), Volume 3**), and socioeconomic models. The development and application of these types of models for integrated basin

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

management has been the topic of a number of conferences and symposia (e.g. Simonovic *et al.*, 1995; Schumann *et al.*, 2001; Hays and McKee, 2001; Marino and Simonovic, 2001).

Systems of integrated models are generally used to address "what if" questions, such as the effects of proposed management alternatives on basin resources, or to manage basin resources in real time. Most integrated system applications to date have been for the assessment of resource-management alternatives or the potential effects of natural disasters such as fire, floods, or droughts. However, where real-time meteorological, streamflow, and other natural resource data are available, integrated systems can be applied for both management-alternative assessment and real-time resource management. Real-time applications have the advantage of continuous measures of model performance. However, this also necessitates identifying the sources of simulation errors and making the appropriate corrections or adjustments to the input data or/and model state variables to keep the model results consistent with observations.

Error sources include data, model parameters, and model structure. Integrated modeling applications are often on large basins where many types of data may have limited availability. Such data limitations can constrain or adversely affect the ability to adequately calibrate parameters for some models (*see* **Chapter 131, Model Calibration and Uncertainty Estimation, Volume 3**; **Chapter 122, Rainfall-runoff Modeling: Introduction, Volume 3**). In some basins, an absence of data for some processes may prevent calibration and limit parameter determination to estimation from related physical measures or expert opinion (*see* **Chapter 133, Rainfall-runoff Modeling of Ungauged Catchments, Volume 3**). The effects of these error sources on the uncertainty in simulation results are always a concern in the application of individual models to the decision making process (*see* **Chapter 131, Model Calibration and Uncertainty Estimation, Volume 3**). The issue of uncertainty becomes even more complex, however, in the integrated system application where output from one model is typically used as input to other models. The development of methods and tools to provide measures of the uncertainty resulting from the cascade of errors through multiple models is an area of current research.

The linking of models and/or model processes can be accomplished using either a loosely or tightly coupled approach. Loosely coupled models provide for information flow in only one direction. Models are run sequentially with the output of one model providing the input to the next model. Loosely coupled models are most appropriate for applications where there is no need to consider feedback among the models and processes being coupled. Tightly coupled models provide for information flow in two directions and support the simulation of feedback between or among processes. The number and complexity of coupled processes range among models, but can include the integration of surface water, groundwater, sediment, nutrient, pesticide, and biological processes.

The coupling of models to build an integrated modeling system is not a trivial task. Many individual models have been developed for problem specific and/or site-specific applications. They have been constructed using a wide variety of operational features, user interfaces, data formats, analytical tools, and documentation standards. To overcome some of these complexities of integrating such a diverse set of models and tools, a variety of modular strategies have been developed. These modular approaches support the linking of loosely and tightly coupled models and model processes into integrated modeling systems for basin management applications. Most integrated modeling systems can be characterized as using either a (i) dedicated-system approach with a predefined set of models or (ii) modeling-framework approach that typically enables the application of a user-selected set of models.

DEDICATED SYSTEMS

Dedicated systems typically have monolithic-type architecture where process algorithms, individual models, data management components, and analytical tools are hard-wired together into a comprehensive modeling system. These systems are usually developed for specific types of application and are limited in scope to the process models and tools included in the system.

Stand-alone watershed models that couple rainfall-runoff processes with chemical and ecological processes represent the most basic form of the dedicated systems. Some of the more comprehensive models include the Hydrologic Simulation Program – Fortran (HSPF) (Bicknell *et al.*, 1997), the Soil and Water Assessment Tool (SWAT) (Arnold *et al.*, 1998), the Soil and Water Integrated Model (SWIM) (Krysanova *et al.*, 1998), and the Integrated Catchments (INCA) model (Whitehead *et al.*, 1998). All are river basin scale models whose major components include hydrology, weather, sedimentation, nutrients, and agricultural management. HSPF and SWAT also include a pesticide component.

Differences among stand-alone models are primarily a function of the number and degree of complexity of process conceptualizations included in the model. The more complex models are typically those with fully coupled surface/subsurface modeling capabilities. SHETRAN (Parkin *et al.*, 2000) for example, is a 3D, coupled surface/subsurface, physically based, spatially distributed,

finite-difference model for coupled water flow, multifraction sediment transport and multiple, reactive solute transport in river basins.

The functionality and complexity of the existing models can be increased by adding or replacing selected components. MODFLOW (McDonald and Harbaugh, 1988; Harbaugh and McDonald, 1996) has been used to replace simpler groundwater components in SWAT (Sophocleous and Perkins, 2000) and in the Precipitation–Runoff Modeling System (PRMS) (Markstrom *et al.*, 2002) to provide a more physically based, fully distributed, groundwater component in each of these models.

Some dedicated modeling systems allow the user to select the degree of complexity by selecting process conceptualizations from a module library to construct a model of appropriate complexity. Selection is limited, however, to the modules provided. The MIKE SHE modeling system (Danish Hydraulics Institute, 2005) offers the choice of several different approaches ranging from simple, lumped, and conceptual to distributed and physically based. In its most complex configuration, it provides a coupled surface/groundwater system using a 2D or 3D finite-difference groundwater model that is similar to MODFLOW. In a future release, it will include MODFLOW as an option.

In contrast to the single model approach, some dedicated systems use a multiple, stand-alone model approach. These systems provide a common graphical user interface, database structure, and a set of analysis tools in support of a set of selected models. Links between or among models are accomplished using the common database and models may be loosely coupled in most systems. The US Environmental Protection Agency's (EPA's) Better Assessment Science Integrating Point and Nonpoint Sources (BASINS) (U.S. Environmental Protection Agency, 2001a) software system integrates a GIS package, meteorological and digital data coverages of the United States, and the models HSPF, SWAT, QUAL2E (Barnwell and Brown, 1987; U.S. Environmental Protection Agency, 1995) and PLOAD (U.S. Environmental Protection Agency, 2001b) into a single package. BASINS was developed to support the assessment of total maximum daily loads (TMDLs), a required analysis for all river systems in the US. The Watershed Modeling System (WMS) (Environmental Modeling Systems, 2005) is a dedicated modeling environment that provides tools to support HEC-1 (U.S. Army, 1998), HEC-HMS (U.S. Army, 2001), TR-20 (U.S. Natural Resource Conservation Service, 1992), TR-55 (U.S. Natural Resource Conservation Service, 1986), and HSPF.

FRAMEWORK MODELING SYSTEMS

The second approach to integrated modeling system development is the modeling framework. The framework provides a flexible platform in which to integrate a variety of models and tools of the user's choice. A library of modules, models, and data management and analytical tools is normally provided. When selected library components are not available, options are typically provided for adding new components to the framework library. In theory, the applicability of the modeling-framework approach is limited only by the models and process modules that can be incorporated into the framework library.

In some frameworks, existing models are considered to be individual modules and are incorporated into the framework with little or no modification. In other frameworks, existing models are disaggregated into their process components, which then become process modules in the system library. Considerations in the selection and linking of process modules to build a model include problem objectives, types of data available, and spatial and temporal scales of application. These issues must also be considered in the selection of individual models to be coupled or linked within the framework.

Another consideration in module and model selection is the level of complexity in process simulation needed to address the desired management objectives. For example, the simulation of runoff volume and timing may be accomplished using a relatively simple modeling approach. However, if the simulation of water-quality constituents in the runoff is also an issue, a more process-based watershed model may be needed. This might be a model that considers flow paths, residence times, and biogeochemical processes, in order to provide the level of detail in process simulation and output needed by other models selected within the framework.

One of the earlier modular frameworks was the U.S. Geological Survey (USGS) Modular Modeling System (MMS) (Leavesley *et al.*, 1996a). MMS supports the development of models using modules from a system library and the coupling of multiple models for application to complex, multidisciplinary problems. A major limitation of MMS is that, given its age, it is object-based and not fully object oriented. To address this limitation, the concepts of MMS have been used to create the Object Modeling System (OMS) (U.S. Department of Agriculture, 2003) which is a fully object-oriented framework. OMS is a Java-based system that uses the NetBeans IDE as its framework platform. A Java wrapper is used to integrate model and module code in other programming languages.

Other framework development efforts in the United States include the Framework for Risk Analysis in Multimedia Environmental Systems (FRAMES) (Whelan *et al.*, 1997) and the Dynamic Information Architecture System (DIAS) (Sydelko *et al.*, 2001). FRAMES supports the linking of a variety of existing models for use in assessing the impacts of hazardous and radioactive releases on the environment. DIAS is an object-oriented, Java-based framework

that supports the coupling of complete models and/or process modules to build integrated models for a wide range of environmental management problems. DIAS also uses a Java-wrapper approach to integrate models and modules in other programming languages.

Comparable framework developments are also being conducted in Australia. The Interactive Component Modeling System (ICMS) is an object-oriented framework that supports model integration and the development of custom interfaces for each application (Reed *et al.*, 1999). Tarsier (Watson *et al.*, 2001) is an object-oriented framework that supports a broader range of models and data handling and analysis tools than ICMS but is limited in that it only supports model code developed in C++. A collaborative effort is being conducted to integrate ICMS and Tarsier to build a more comprehensive framework called the *Catchment Modeling Toolkit* (Argent and Vertessy, 2002).

In Europe, the Generic Framework (GF) (Blind *et al.*, 2001) is an open framework for linking models, which is being developed by a large consortium of groups in the Netherlands. The basic design principles of the GF focus on a modular approach to separate model, tool, and data components. The Open Modeling System (**`http://www.dutch-oms.org/intro.html`**) is another framework being developed in the Netherlands to support 2D and 3D simulation of flow and transport processes. The Open Modeling System architecture is designed to support data exchange and synchronization between legacy codes. Current development is focused on the integration of the Delft3D system (Delft Hydraulics, 2003) and the SIMONA system (National Institute for Coastal and Marine Management, 2000).

With the proliferation of modeling frameworks, some of the original difficulties in the linking of individual models, as noted above, have also been recognized in attempts to share modules, tools, and other resources among frameworks. In an attempt to resolve these problems, coordinated efforts by collaborative groups of research and operational agencies have been initiated to develop more generic frameworks and standards. In the United States, a Memorandum of Understanding (MOU) has been signed by 10 federal agencies to establish a framework for facilitating cooperation and coordination in research and development of multimedia environmental models and related tools and databases, and to facilitate their application to human and environmental health risk assessment (**`http://www.iscmem.org`**).

In Europe, support of the integrated basin management requirements of the EU Water Framework Directive has spawned a number of group efforts. The HarmonIT project is a collaborative effort among 14 government, university, and private organizations to develop and implement a European Open Modeling Interface and Environment (OpenMI), which will simplify the linking of models and their application to integrated basin management (Gijsbers *et al.*, 2002). As part of this effort, a state-of-the-art review was conducted to evaluate existing capabilities in linking models and resolving issues within the project (Hutchings, 2002). In a related effort, the Benchmark Models for the Water Framework Directive project is by a group of eight organizations that are developing a scheme for selecting and benchmarking existing model systems for integrated basin management applications (Finnish Environmental Administration, 2002).

APPLICATIONS

Integrated systems are applied at basin scales ranging from a few tens of square kilometers to several thousands of square kilometers. One can enter the name of almost any major river basin in the world into a web search tool, along with key words such as "integrated basin modeling", and find that one or several local, national, and/or international organizations are supporting the development and application of some type of integrated modeling and decision support system. The small number of these that are currently operational, as compared with the total number of systems being developed, indicates the number of challenges and limitations in the development and application of such systems. These include limited data, process knowledge, financial resources, consensus on approach, and social and political agreement on resource allocation. However, the large number of systems in development also indicates the recognition of the need for objective tools to address water and environmental resource allocation problems and a willingness to use integrated basin management systems to address these problems.

A sample application of an integrated modeling system that is operational is the Watershed and River System Management Program (WARSMP) (Leavesley *et al.*, 1996b, **`http://wwwbrr.cr.usgs.gov/warsmp`**; **`http://www.usbr.gov/pmts/rivers/warsmp`**). The WARSMP is a cooperative effort between the USGS and the Bureau of Reclamation (BOR) to develop an operational, database-centered, decision support system for application to complex water and environmental resource-management issues. The USGS MMS has been coupled with the BOR RiverWare software (Zagona *et al.*, 2001; **`http://cadswes.colorado.edu/riverware`**) using a shared relational database. RiverWare is an object-oriented reservoir and river-systems modeling framework developed to provide tools for evaluating and applying optimal water allocation and management strategies.

The WARSMP is operational on the Gunnison River Basin in Colorado, where MMS provides forecasts of daily inflows from 15 headwater basins to a series of three reservoirs (Leavesley *et al.*, 2002). RiverWare uses these inflow

forecasts to manage the reservoirs for power generation, flood control, irrigation, fisheries, and recreation. Streamflow forecasts are made using the Ensemble Streamflow Prediction methodology (ESP) (Day, 1985). Snowmelt is the dominant source of streamflow in the Gunnison Basin and so decisions on reservoir storage levels and releases rely on the forecasts of the volume and timing of snow accumulation and melt. Optimal operation of the Gunnison Basin maximizes power generation, irrigation water volume, and environmental water uses, while minimizing flooding below the reservoirs. Use of the WARSMP decision support tools, as compared with the historic management approach, was evaluated by Ryan (1996). His evaluation demonstrated an increase in power generation revenues and decrease in flooding as a result of the use of these tools.

The WARSMP tools are also being applied to the Yakima River Basin in Washington (Maston and Vaccaro, 2002; U.S. Geological Survey, 1998; **http://wa.water.usgs.gov/projects/yakimawarsmp**); the Rio Grande Basin in Colorado and New Mexico; and the Truckee River Basin in California and Nevada. Integrated water-management issues in these basins include efficiency of water-resources management, environmental concerns such as meeting flow needs for endangered species, groundwater/surfacewater interactions, water-quality issues related to irrigated agriculture, and optimizing operations within the constraints of multiple objectives such as power generation, irrigation, and water conservation.

130: Fuzzy Sets in Rainfall/Runoff Modeling

ANDRÁS BÁRDOSSY

Universität Stuttgart, Institut für Wasserbau, Stuttgart (Vaihingen), Germany

Fuzzy sets offer an alternative to statistical methods to quantify uncertainties in modeling natural systems. Three types of applications for hydrological modelling can be considered:

- *the quantification of the uncertainties related to inexact knowledge of the model parameters that describe the underlying hydrological processes using fuzzy numbers and the extension principle*
- *alternative description of individual hydrological processes using fuzzy rules*
- *introduction of model performance measures which reflect soft information coded with fuzzy membership functions.*

One of the major problems in the application of fuzzy sets is the assessment of the membership functions. Model parameters and performance measures are usually estimated subjectively. Fuzzy rules can be assessed using automated learning algorithms. Examples show that fuzzy sets, if they are applied in the combination with hydrological expertise, can be well used for rainfall runoff modelling.

INTRODUCTION

The rainfall runoff process is a complicated nonlinear process. Even though one is dealing with a physical system, its modeling contains considerable uncertainties. Uncertainty is usually treated with the help of statistical methods. In the last few years, the theory and application of fuzzy sets has advanced considerably. Fuzzy sets offer an alternative approach to the treatment of uncertainties that is often complementary to statistical methods.

The application of fuzzy sets is not widely spread in hydrology. Besides "hard" hydrological data, such as rainfall or discharge measurements, "soft" information such as expert knowledge on soils and/or governing processes is useful for modeling. Very often only the hard information is considered – leading to an unrealistic approach. The coding of expert knowledge in the form of fuzzy sets offers an interesting alternative. On the other hand, fuzzy sets should not be misused to introduce arbitrariness into hydrological models.

In this article, the application of fuzzy methods for three types of uncertainties in hydrological modeling will be discussed.

1. A part of these uncertainties is related to an inexact knowledge of the model parameters that describe the underlying physical process. Soil hydraulic properties, for example, are highly variable in space (and to some extent even variable in time). Measurements and laboratory experiments are carried out on small scales, while the processes they are part of take place on large scales. This leads to difficulties in the estimation of model parameters. This uncertainty can be considered as partly due to spatial variability. However, often a small amount of direct measurement can be combined with "soft" information, such as soil type, in an informative way. In this case, expert knowledge can be transferred to model parameters. One possible method that can be applied in this context is the idea of fuzzy sets.
2. Besides the inherent uncertainty in the model parameters, there is a considerable uncertainty in the mathematical process description of hydrological models. The physically based concepts are usually not applicable on larger scales. Expert knowledge is here again an important source for enriching the modeling process.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

It can be used not only in finding appropriate parameters or forms of equations, but also in the form of case-dependent rules. Fuzzy rules provide appropriate tools to code expert knowledge and thus are also well applicable for rainfall/runoff modeling.

3. Rainfall/runoff models are (as are most environmental models) simplified descriptions of complicated natural processes. Therefore, they cannot perfectly describe all aspects of the processes. One has thus to select appropriate measures to identify model parameters (calibration) and to judge the performance of models (validation). Model performance measures are usually based on statistical principles. One of the most frequent measures applied is the Nash–Sutcliffe efficiency – which is a purely statistical measure based on a least squares principle. In the case of model calibration and validation, expert knowledge might also play a very important role. Qualitative measures of model performance exploiting this expert knowledge can be introduced in the form of fuzzy measures.

The purpose of this contribution is to provide examples and guidelines for the application of fuzzy sets for the above mentioned three types of problems. The article is divided into six parts. After the introduction of fuzzy sets, fuzzy arithmetic and fuzzy rules are presented. In Section "Fuzzy Hydrological Data and Model Parameters", problems of applying fuzzy parameters in rainfall/runoff models are discussed. Section "Fuzzy Rules for Hydrological Modeling", presents the application of fuzzy rules for rainfall/runoff related processes. In Section "Fuzzy Calibration Measures", qualitative and quantitative performance measures are discussed in a fuzzy context. Finally, in Section "Conclusions", further research needs are discussed.

FUZZY SETS, FUZZY NUMBERS, AND FUZZY RULES

Fuzzy sets were first introduced by Zadeh (1965). The impact of this paper was enormous. Among others, environmental scientists found the idea very appealing and tried to apply it to different problems. A short introduction to the basic principles is given in the next sections.

Membership Functions

A fuzzy set is a set of objects without clear boundaries or without perfectly (precisely) defined characteristics. In contrast with ordinary sets, where for each object it can be decided whether it belongs to the set or not, a partial membership in a fuzzy set is possible. An example of a fuzzy set could be "the set of days with heavy rain". There are days with rainfall amounts that clearly belong to the above set, and others (for example, dry days) that clearly cannot be considered as days with heavy rain. But, if the concept of heavy rain is not exactly defined (for example, daily total >30 mm), then there is a certain "gray" zone where the judgment outcome is not obvious. An exact definition of heavy rain is possible but does not necessarily conform with the human way of thinking. Why should a day with 30.1 mm rain be a day with heavy rain and another with 29.9 mm not be? The normal human observer cannot perceive the difference – only precise measurements could decide on the membership and then a nearby gauge would read differently anyway. However, in real life one can use the concept even without taking any measurements. Weather forecasts use the expression *heavy rain* without quantitative definition.

Formally, a fuzzy set (or often called a fuzzy subset) is defined as follows:

Definition: Let X be a set (universe). A is called a fuzzy subset of X if A is a set of ordered pairs:

$$A = \{(x, \mu_A(x)); x \in X, \mu_A(x) \in [0, 1]\}$$

where $0 \leq \mu_A(x) \leq 1$ is the grade of membership of x in A. The function $\mu_A(x)$ is called the membership function of A.

The closer $\mu_A(x)$ is to 1 the more x is considered to belong to A – the closer it is to 0 the less it is taken as belonging to A. If [0,1] is replaced by the two-element set $\{0, 1\}$, then A can be regarded as an ordinary subset of X because then x is definitely either in A or not in A.

Fuzzy Numbers

Special cases of fuzzy sets are fuzzy numbers, which are generalizations of our usual concept of numbers. While Boolean operations such as union, intersection, or complement can be performed on general fuzzy sets, arithmetic operations such as addition or multiplication can only be performed on fuzzy sets defined on the set of real numbers. The simplest generalizations of real numbers are fuzzy numbers:

Definition: A fuzzy subset A of the set of real numbers is called a fuzzy number if there is at least one z such that $\mu_A(z) = 1$ (normality assumption) and for every real number a, b, c with $a < c < b$

$$\mu_A(c) \geq \min(\mu_A(a), \mu_A(b)) \tag{1}$$

Any real number can be regarded as a fuzzy number with a single point support, and is called a *'crisp number'* in fuzzy mathematics. The simplest fuzzy numbers are

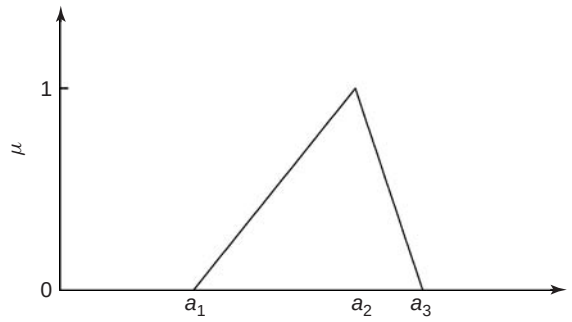

Figure 1 Membership function of the triangular fuzzy number $A = (a_1, a_2, a_3)_T$

those known as *triangular fuzzy numbers*. The membership function of the triangular fuzzy number consists of an increasing and a decreasing linear function – forming a triangle. The formal definition is:

Definition: The fuzzy number $A = (a_1, a_2, a_3)_T$ with $a_1 \leq a_2 \leq a_3$ is a triangular fuzzy number if its membership function can be written in the form:

$$\mu_A(x) = \begin{cases} 0 & \text{if } x \leq a_1 \\ \dfrac{x - a_1}{a_2 - a_1} & \text{if } a_1 < x \leq a_2 \\ \dfrac{a_3 - x}{a_3 - a_2} & \text{if } a_2 < x \leq a_3 \\ 0 & \text{if } a_3 < x \end{cases}$$

Figure 1 shows the membership function of a triangular fuzzy number.

The *extension principle* (Zadeh, 1965) is a method of extending point to point operations to fuzzy sets. It is the basic tool for the development of fuzzy calculations and fuzzy arithmetic.

Definition:

If X and Y are two sets, and f is a point to point mapping from X to Y

$$f: X \longrightarrow Y \quad \text{for every} \quad x \in X \quad f(x) = y \in Y$$

then f can be extended to operate on fuzzy subsets of X in the following way:

Let A be a fuzzy subset of X with membership function μ_A, then the image of A in Y is the fuzzy subset B with the membership function

$$\mu_B(y) = \begin{cases} \sup\{\mu_A(x); y = f(x), x \in X\} \\ 0 \quad \text{if there is no } x \in X \quad \text{such that } f(x) = y \end{cases} \tag{2}$$

Figure 2 illustrates the extension principle. The highest membership of the three elements x_1, x_2 and x_3 all with $f(x_i) = y$ is assigned as membership to y.

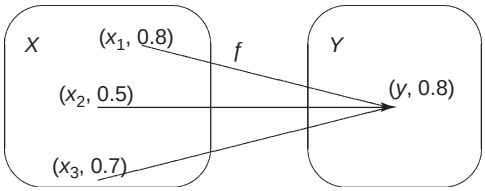

Figure 2 The extension principle

Using the extension principle for the bivariate functions

$$f_a(x_1, x_2) = x_1 + x_2$$
$$f_m(x_1, x_2) = x_1 \cdot x_2$$
$$f_d(x_1, x_2) = \frac{x_1}{x_2}$$

one can derive the rules of fuzzy arithmetic (Kaufmann and Gupta, 1985). For example, for fuzzy addition one can derive from the extension principle that:

$$(a_1, a_2, a_3)_T + (b_1, b_2, b_3)_T = (a_1 + b_1, a_2 + b_2, a_3 + b_3)_T \tag{3}$$

h-level sets of fuzzy sets are useful when one applies the extension principle:

Definition: The h-level set of a fuzzy set A is

$$A(h) = \{x; \mu_A(x) \geq h\}$$

The h level sets are defined for $0 < h \leq 1$.

One can prove that the extension principle leads to the equation:

$$f(A(h)) = B(h) \tag{4}$$

This means that the h level set of the image of a set can be calculated directly from the h level set of the original set. This fact makes the application of the extension principle in general much simpler.

The extension principle is a kind of *pessimistic* way of treating uncertainties. In modeling contexts, it can be regarded as a systematic sensitivity analysis.

The extension principle can be applied to complicated functions either directly or in a step-by-step manner. Consider for example, the case of $g(x) = f_1(x) + f_2(x)$. There are two possible ways of calculating the membership function of $g(A)$ for a given fuzzy number A:

1. The first one calculates the fuzzy sets $B_1 = f_1(A)$ and $B_2 = f_2(A)$ using the extension principle. Then the extension principle is applied to the bivariate function $y = x_1 + x_2$ with the fuzzy arguments B_1 and B_2 to obtain the fuzzy set $g(A) = B$.

2. The extension principle is directly applied to the univariate function g.

The first approach is computationally much simpler, but leads to an increased uncertainty due to the fact that a univariate function is treated as a bivariate one when the two fuzzy numbers B_1 and B_2 are added. This example shows the problem of applying fuzzy arithmetic mainly based on bivariate operations – without considering whether some of the arguments are related (or even identical) or not. The application of fuzzy arithmetic in hydrological modeling is therefore not recommended because in most of the models the same parameters are used for different time steps. Fuzzy arithmetic would lead to a very fast growth in uncertainty as demonstrated in Dou *et al.* (1995), leading to useless results after a few time steps.

Fuzzy Rules and their Assessment

In contrast with, or in complement to, a probabilistic approach, we may consider the treatment of imprecision (or vagueness) in hydrology, corresponding, for example, to the statements: "runoff increases with higher antecedent moisture".

The most popular fuzzy direct reasoning technique is Mamdani's method (Mamdani, 1974). It is composed of direct IF-THEN statements with fuzzy premises and fuzzy conclusions. It is widely applied in fuzzy control (Sugeno and Yasukawa, 1993), however, its use in fuzzy modeling is still restricted to a few specific case studies (Bardossy and Disse, 1993). Mamdani's method is very well suited to describe the complicated, case-dependent nature of hydrological/environmental systems.

A Mamdani type fuzzy rule consists of a set of arguments $A_{i,k}$ in the form of fuzzy sets with membership functions $\mu_{A_{i,k}}$ and a consequence B_i also in the form of a fuzzy set.

$$\text{If } a_1 \text{ is } A_{i,1} \odot a_2 \text{ is } A_{i,2} \odot \ldots \odot a_K \text{ is } A_{i,K} \text{ then } B_i \tag{5}$$

Note that in general, the order in which a statement is evaluated plays a central role. The operator $\odot$ stands for a logical combination of the arguments such as AND or OR or XOR. The statement "a_k is $A_{i,k}$ " is, for simplicity, replaced by $A_{i,k}$ in the following text. The rule (equation 5) will thus be written as

$$\text{If } A_{i,1} \odot A_{i,2} \odot \ldots \odot A_{i,K} \text{ then } B_i \tag{6}$$

The truth value corresponding to the fulfillment of the conditions of a rule for given premises $(a_1, \ldots, a_K)$ is called the *degree of fulfillment* (DOF) of that rule.

Since the DOF depends on the premise vector $(a_1, \ldots, a_K)$ the DOF of rule i is denoted $D_i(a_1, \ldots, a_K)$.

Knowledge of the DOFs does not provide the information about the results – it only indicates what kind of responses could occur. In order to obtain a "unique" result the fuzzy responses have to be combined, and, for the sake of a single response, defuzzified.

Verbal rules are often translated into fuzzy rules using linguistic variables.

It has been shown by Wang and Mendel (1992) that all continuous real functions can be approximated by fuzzy rules. This means that in theory each hydrological model can be well approximated by fuzzy rules.

Another class of fuzzy rules are the Takagi–Sugeno rule systems. In this case, the response of a fuzzy rule is not a fuzzy set but a function. This means that the rule has the form:

$$\text{If } a_1 \text{ is } A_{i,1} \odot a_2 \text{ is } A_{i,2} \odot \ldots \odot a_k \text{ is } A_{i,K} \text{ then } f_i(a_1, \ldots, a_K) \tag{7}$$

This type of formulation is advantageous as it allows a partly functional relationship between input and output variables. Further, the use of more than one rule means that the functional relationships are not necessarily universal, their validity is limited to the cases where the rule is applicable.

Fuzzy rules can be assessed directly from expert knowledge or by derivation from observed data. A combination with artificial neural nets in some cases enables an automatic derivation of fuzzy rules.

Fuzzy rule-based modeling shows much potential in cases when: a causal relationship is well established, but difficult to calculate under real-life conditions; data are scarce and imprecise; and/or when a given input vector may have several contradictory responses, which may be true to varying degrees. These features are often present in hydrology and water resources problems.

FUZZY HYDROLOGICAL DATA AND MODEL PARAMETERS

The uncertainty of a hydrological model parameter or an input variable can be described using fuzzy numbers. For example, if there are no measurements of soil hydraulic conductivity available at a given site, one can use a soil map. The knowledge of the soil type does not provide an exact value of the hydraulic conductivity. Instead, we can have a "best" estimate, and we can also provide a range in between which the soil hydraulic conductivity might be. This information can be translated to a triangular fuzzy number by assigning a membership value of one to the most likely value, zero to the lowest and the highest possible values, and assuming a linear membership function between these values as in Figure 1. One could also assign a fuzzy

number to the rainfall amounts. In this case, the systematic undercatch of the rain gauges would lead to a nonsymmetric triangular fuzzy number.

The uncertainty of the fuzzy soil hydraulic conductivity and the fuzzy rainfall amounts however have a different character. One can assume that the soil hydraulic properties do not change appreciably in time (at least below the surface and during one precipitation event). Therefore, even though their value is uncertain, we can assume that it remains much the same for all-time steps. In contrast, the rainfall uncertainty is time dependent. The systematic errors corresponding to different time steps might be very different, and should be treated accordingly. This leads to a different way of treating these uncertainties in models. If this is not correctly taken into account in modeling, then the uncertainty grows rapidly in time as presented by Dou *et al.* (1995) and Kunstmann and Kinzelbach (1997).

The difference between the application of fuzzy arithmetic (Kaufmann and Gupta, 1985) and the extension principle of Zadeh (1965) is demonstrated in the simple example presented in the next section.

Example – The Fuzzy Unit Hydrograph

We assume that the unit hydrograph is not known exactly, instead only imprecisely. In the case when one applies statistical methods, the statistics of the deviations are usually used to characterize the inprecision. In the fuzzy case, an *envelope* type approach is selected. One would like to obtain a set of functions that approximate the hydrograph both from below and above. For each time t, $u(t)$ is assumed to be a fuzzy number. This means that in the discrete form (2) the fuzzy discharge is calculated as:

$$\hat{Q}_u(t_n) = \sum_{i=0}^{n} p(t_i) \cdot \hat{u}(t_n - t_i) \tag{8}$$

$\hat{u}(t)$ being a fuzzy number, and $p(t_i)$ is the sequence of (crisp) depths of effective rainfall. The fuzzy direct discharge $\hat{Q}_u(t_n)$ can be calculated using two different methods:

1. Using fuzzy arithmetic (Kaufmann and Gupta, 1985) or
2. Using the extension principle (Zadeh, 1965).

The two methods are illustrated with the following example:

Assume that $u(t_0) = (1, 2, 3)_T$ and $u(t_1) = (0, 1, 2)_T$ and that there are effective rainfalls of $p(t_0) = 1$ and $p(t_1) = 2$

Then by the application of fuzzy arithmetic we obtain:

$$\begin{aligned} Q(t_0) &= 1 \cdot (1, 2, 3)_T = (1, 2, 3)_T \text{ m}^3\,\text{s}^{-1} \\ Q(t_1) &= 2 \cdot (1, 2, 3)_T + 1 \cdot (0, 1, 2)_T \\ &= (2, 4, 6)_T + (0, 1, 2)_T = (2, 5, 8)_T \\ Q(t_2) &= 2 \cdot (0, 1, 2)_T = (0, 2, 4)_T \end{aligned}$$

The highest possible discharge is $8\,\text{m}^3\text{s}^{-1}$ at time t_1. However, if we investigate this discharge we can see that it is the result of taking $u(t_0) = 3$ and $u(t_1) = 2$. This choice, however, would violate the mass conservation constraint being

$$p(t_0) + p(t_1) = u(t_0) + u(t_1) = 3.$$

Consequently, the range of the calculated discharge increases leading to a false estimation of uncertainty.

This problem can be avoided if one considers the extension principle. In this case, a membership value is assigned to each fuzzy number $u(t)$ under the constraint that the mass conservation is not violated. This leads to the membership function of the discharge at time t:

$$\mu_{Q_u(t)}(Q) = \max \left\{ \begin{array}{l} \min(\mu(u(t_0))..., \mu(u(t_n)) \\ \text{such that } \; Q = \sum p(t_i) u(t - t_i) \\ \text{and} \sum_{i=0}^{n} u(t_i) \; = \gamma A_E \end{array} \right\}$$

As one can see, the difference between the use of fuzzy arithmetic and the extension principle lies in the additional constraint on the integral of the unit hydrograph. This means that by introducing $u(t_0) = x$, mass conservation leads to $u(t_1) = 3 - x$

$$Q(t_1) = x \cdot 2 + (3 - x) \cdot 1 = x + 3$$

if $1 < x \leq 2$ then for this x we have $\mu_{u_1}(x) = x - 1$ and $1 \leq 3 - x < 2$ leading to $\mu_{u_2}(3 - x) = 2 - (3 - x) = x - 1$ if $2 < x < 3$ then $\mu_{u_1}(x) = 3 - x$ and $0 < 3 - x < 1$ $\mu_{u_2}(3 - x) = 3 - x\; x + 3$ has the membership value (in the result) of $x - 1$ if $1 < x < 2\; x + 3$ membership of $3 - x$ if $2 < x < 3$ leading to the result:

$$Q(t_1) = (4, 5, 6)_T$$

This result is much crisper than the previous one $(2, 5, 8)_T$ and reflects the physical constraint of mass conservation. The application of fuzzy arithmetic in models generally leads to an unrealistic increase of uncertainty. Therefore, it is suggested that the extension principle should be used in all fuzzy calculations.

The application of the extension principle requires additional effort. The calculations can to some extent be simplified if one uses h-level sets.

Assessment of the Fuzzy Model Parameters

The fuzzification of hydrological models using fuzzy parameters is in most cases not a very complicated exercise. The identification of the parameters from observations is in this case a much more complicated task.

Rainfall/runoff models cannot perfectly reproduce measured discharges. The deviations have different causes, for example, the simplification of the process descriptions, the uncertainties associated with the assessment of the model parameters (for example, spatial variability or temporal variations of parameters assumed to be time independent).

The fuzzification of the parameters means that a part of the uncertainty should be treated as fuzzy, another part as probabilistic. Ozelkan and Duckstein (2001) presented different fuzzy conceptual rainfall/runoff models. They suggested the use of a fuzzy linear regression type approach (Tanaka *et al.*, 1982; Bardossy *et al.*, 1990) for the estimation of the model parameters. Using the fuzzy parameters for each time step, a fuzzy discharge is calculated. The observed discharge should have a reasonably high membership level in the calculated fuzzy discharge value set. This condition could be fulfilled by infinitely many parameter sets – one tries to find the crispest among them. For this purpose, an acceptable level and a measure of crispness have to be defined. Ozelkan and Duckstein (2001) suggest a multiobjective methodology. The parameter estimation procedure in this context, as in the statistical type of approach, leads to an optimization problem. Owing to the fact that the uncertainty is in this case explicitly considered in the fuzzy parameters, the number of unknowns to be identified increases. For example, instead of a simple linear reservoir storage parameter K, in this case a triangular fuzzy number $(K_1, K_2, K_3)_T$ would have to be identified.

A combination of statistical and fuzzy uncertainty for the identification of the parameters offers an interesting possibility. Some of these aspects are discussed in the next section.

Fuzzy Versus Stochastic Uncertainty

As stated in the introduction of this section, different types of uncertainties should be treated differently. Unknown systematic errors and natural variability have a very different influence on modeling results. The major difference between the two approaches lies in the treatment of the interdependence between variables. While if considered as fuzzy the dependence of the variables is considered in a pessimistic way leading to large uncertainties, the probabilistic approach allows a whole range of different dependence structures.

For example, for a given time interval, the precipitation amount can be treated both as a random variable or as a fuzzy quantity. The systematic undercatch of the raingauges can be well modeled as a fuzzy number. On the other hand, the uncertainty due to spatial and/or temporal variability of can be better described using random variables. In many cases, a combination of fuzzy and stochastic methods could yield an interesting quantification of uncertainties. For example, spatial variability of soil parameters can be well described using geostatistical methods. The expert knowledge in the form of fuzzy parameters can be combined using fuzzy Kriging (Piotrowski *et al.*, 1995) or fuzzy conditional geostatistical simulation. A fuzzy number can be used to describe the unknown mean of a field while stochastic methods are used for the spatial variability. A joint treatment of the methods requires the combination of Monte Carlo methods with the appropriate application of the extension principle. This effort is however rewarded by the insight gained though the separation of the different kinds of uncertainty in the model results. Expected values, exceedence probabilities, or other statistical quantities become fuzzy numbers, their memberships depending on the fuzzy uncertainty, while the memberships of certain physical properties (for example, travel times, peak values, etc.) are characterized using their probabilistic type distribution. The author of this article does not know any application of the above sketched methodology in hydrology. It is subject of future research to explore the capacity of these approaches.

FUZZY RULES FOR HYDROLOGICAL MODELING

Fuzzy rules can describe relationships between variables in a linguistic form. Owing to their case-specific validity, rules can be usefully employed to describe complicated nonlinear relationships. Thus, they have a good potential in rainfall/runoff modeling. As rules are universal approximators (Wang and Mendel, 1992), all hydrological models could be formulated in terms of fuzzy rules. Hundecha *et al.* (2001) used this principle and developed a fuzzy rule-based version of the HBV model (Bergstrom and Forsman, 1973). The fuzzification of existing rainfall/runoff models is an interesting intellectual exercise, but does not necessarily advance hydrological modeling. The replacement of complicated models by fuzzy rules might however be advantageous for processes, where the traditional formulation of the model requires extensive calculations.

For example, the modeling of water dynamics in the unsaturated zone, a common approach is to solve the Richards equations using suitable algorithms. The main idea of using fuzzy rules is that the water movement at a certain time and at a selected point depends to a very high degree only on the conditions (moisture content) in the immediate neighborhood of the point. The fuzzy rules to describe the vertical water movement can be formulated with the help of relative soil moisture contents. The parameter set can be reduced by extracting two *linear coefficients*, the saturated hydraulic conductivity K_s and the moisture content θ_i, with the idea of including all the nonlinearities into the rule system. A rule be formulated verbally as:

If the relative soil moisture in element i is $A_{1,i}$ and the relative moisture content of the adjacent element below is $A_{2,i}$ then the normalized flux between the elements is B_i.

Normalized flux means in this case that a specific value K_s is selected for which the rules are specified. As the flux is proportional to the K_s value, a simple multiplication makes the rule applicable to the case of a value of K_s different from the selected reference value. In Bardossy and Disse (1993), the above unsaturated flow model is described in detail. Schulz and Huwe (1999) presented a fuzzy model for the transport in the unsaturated zone.

The application of fuzzy rules in hydrological modeling requires an assessment of the rules. The rules can be assessed from experiments or even from numerical models. The first approach would fully disregard the physical knowledge. Furthermore, measurement errors and inaccuracies would influence the rule system. Using numerical models has the advantage, that rules for arbitrary conditions can be assessed. A combination of experimental and model results is also possible.

As the processes are complicated and depend on a large number of parameters the derivation of rules from datasets is not a trivial task. The membership functions of the arguments can be defined as triangular or trapezoidal fuzzy numbers over the range of the possible parameter values. For each parameter, a certain number of membership functions should be allowed. If one considers all possible combinations of the parameter membership functions, this might lead to an explosion of the rule system. The available information might not be enough for a reasonable assessment of the rules; in the case of rule systems one should try to be parsimonious. In hydrology the number of influencing variables is usually high, but the dominant processes depend on only a few of them. If rule systems are built by considering only the important variables for modeling, the number of rules might be reduced to a maximum of 10 to 40. Bardossy *et al.* (2003), presented an automated methodology for the assessment of a small number of rules based on simulated annealing. Neuro-fuzzy approaches offer another possibility for the automatic assessment of fuzzy rules and the corresponding membership functions. An application of this methodology for flood forecasting is presented by Stuber and Gemmar (1997).

Fuzzy rules can also be used to combine the results of different models. Each hydrological model has its own strengths and weaknesses. If one can recognize *a priori* whether in a given situation, the model can be trusted or not, then a case-dependent combination of the model results can lead to substantial improvements. Xiong *et al.* (2001) developed a Takagi-Sugeno rule system to combine the results of flood forecasting models. Their results showed that the combination lead to substantial improvements. The nonlinearity of the combination played a central role in their approach.

FUZZY CALIBRATION MEASURES

Expert knowledge can be very valuable for the identification of hydrological model parameters and for the judgement as to what extent a model can be regarded as a reasonable representation of the natural system under study.

Hydrological models calculate the different components of the water cycle in a spatial resolution, which is usually finer than the resolution of the observations. Further, there are often processes that are only modeled and not quantitatively measured. Despite there being no hard data available, these variables might be used for model calibration. Expert knowledge can give plausible ranges for these variables and maximum and minimum possible values for individual states or for time integrals. These expert opinions can be described with the help of fuzzy sets, for example, as trapezoidal fuzzy numbers. For each calibration variable, a soft measure in the form of a fuzzy set A_k with the membership function $\mu_{A_k}(S_k)$ is defined. The membership value is defined on the state variable S_k. The value of S_k depends on the parameter vector $\mathbf{p}$ of the hydrological model. The calibration procedure can now be transformed to an optimization problem with constraints or to a bivariate optimization problem. The first is:

$$\mu_{A_k}(S_k(\mathbf{p})) \geq h_0 \quad k = 1, \ldots, K$$
$$O(\mathbf{p}) \rightarrow \max \tag{9}$$

where $O(\mathbf{p})$ represents the "crisp" performance measure of the hydrological model. Alternatively, a bivariate optimization problem can be formulated:

$$\min(\mu_{A_k}(S_k(\mathbf{p}))\ ;\ k = 1, \ldots, K) \rightarrow \max$$
$$O(\mathbf{p}) \rightarrow \max \tag{10}$$

Fuzzy sets are used for multiobjective calibration as a kind of value function. The performance measures are transformed to the unit interval and are interpreted as fuzzy membership values. This approach was used by Cheng *et al.* (2002) for the calibration of the Xinanjiang model. Yu and Yang (2000) presented a multiobjective fuzzy methodology for model calibration. Fuzzy sets are not essential for such purposes, but they provide a kind of unified framework for treating the different measures of model performance in a reasonable balance.

Samanta and Scott Mackay (2003) present an interesting methodology for the calibration of hydrological models, which considers the set of acceptable model parameters as a fuzzy set.

CONCLUSIONS

Fuzzy sets provide a methodology to handle uncertainty in mathematical models describing natural systems. Until now, their application in hydrology has been limited to a relatively small number of cases. The possibility of including information and knowledge into the model-building and calibration procedure, which due to its uncertainty was not used before, offers a great potential for hydrological modeling and makes fuzzy sets attractive. The correct and appropriate use of the methods requires further research. The author believes that the number of successful applications of fuzzy sets in hydrology will increase substantially in the future.

All rainfall-runoff models are, by definition, simplifications of the real-world system under investigation. The model components are aggregated descriptions of real-world hydrologic processes. One consequence of this is that the model parameters often do not represent directly measurable entities, but must be estimated using measurements of the system response through a process known as model calibration. The objective of this calibration process is to obtain a model with the following characteristics: (i) the input-state-output behavior of the model is consistent with the measurements of catchment behavior, (ii) the model predictions are accurate (i.e. they have negligible bias) and precise (i.e. the prediction uncertainty is relatively small), and (iii) the model structure and behavior are consistent with current hydrologic understanding of reality. This article describes the historic development leading to current views on model calibration, and the algorithms and techniques that have been developed for estimating parameters, thereby enabling the model to mimic the behavior of the hydrologic system. Manual techniques as well as automatic algorithms are addressed. The automatic approaches range from purely random techniques, to local and global search algorithms. An overview of multiobjective and recursive algorithms is also presented. Although it would be desirable to reduce the total output prediction error to zero (i.e. the difference between observed and simulated system behavior) this is generally impossible owing to the unavoidable uncertainties inherent in any rainfall-runoff modeling procedure. These uncertainties stem mainly from the inability of calibration procedures to uniquely identify a single optimal parameter set, from measurement errors associated with the system input and output, and from model structural errors arising from the aggregation of real-world processes into a mathematical model. Some commonly used approaches to estimate these uncertainties and their impacts on the model predictions are discussed. The article ends with a brief discussion about the current status of calibration and how well we are able to represent the effects of uncertainty in the modeling process, and some potential directions.

THE NATURE OF RAINFALL-RUNOFF MODELS

The hydrology of any catchment involves complex interactions driven by a number of spatially distributed and highly interrelated water, energy, and vegetation processes. Any computer-based model intended to represent the behavior of a catchment must, therefore, conceptualize this reality using relatively simple mathematical equations that involve parameters to be specified for any particular application. Two characteristics of the modeling process are relevant to our discussion. First, all rainfall-runoff (RR) models, regardless of how spatially explicit, are to some degree lumped, so that their equations and parameters describe the processes as aggregated in space and time. As a consequence, the model parameters are typically not directly measurable, and have to be specified through an indirect process of parameter estimation. This process of parameter estimation is often called model *calibration* if values of parameters are adjusted to fit some observations made

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

on the system of interest. Rainfall-runoff models usually contain several such "conceptual" parameters. While many of these parameters cannot be assumed to have direct physical (measurable) interpretations, they are often assumed to have physical relevance, insofar as they are related to inherent and invariant properties of the hydrologic system. Second, the structure of the RR model is generally specified prior to any attempt to model the catchment being undertaken (Wheater *et al.*, 1993). While this specification is usually based on observed characteristics of the catchment, other factors that play a major role include the availability of data, modeling goal, and a variety of subjective considerations including personal preference and experience. This article will not address the issue of model structure specification, but will focus on the difficulties of model calibration, assuming that a suitably representative and acceptably accurate model structure has already been selected. The article reviews the historical development leading to current views of model calibration, and discusses the estimation and propagation of uncertainties in RR modeling.

MODEL CALIBRATION

Calibration is a process in which parameter adjustments are made so as to match (as closely as possible) the dynamic behavior of the RR model to the observed behavior of the catchment (Figure 1). The process therefore requires measurements of catchment behavior, usually in terms of the inputs (rainfall) and the outputs (e.g. streamflow at the catchment outlet). Because, the outputs of RR models are usually related to the parameters in a nonlinear way, explicit linear-regression-type solutions are generally not possible, and some degree of directed iterative guesswork is required to arrive at a suitable solution (estimates for the parameters). Necessary conditions for an RR model to be "well-calibrated" are that it has (at least) the following three characteristics: (i) the input-state-output behavior of the model is consistent with the measurements of catchment behavior, (ii) the model predictions are accurate (i.e. they have negligible bias) and precise (i.e. the prediction uncertainty is relatively small), and (iii) the model structure and behavior are consistent with a current hydrologic understanding of reality. Note that, for the second requirement to be met, some method for estimating and reporting model prediction uncertainty must be included (Figure 2). Further, the third requirement is critical if the model is to be used to estimate the effects of perturbations to the structure of the real system (e.g. land-use changes).

It is important to stress that the process of model identification should not be understood as that of simply finding a model structure and parameter set that "fits the model to the data". It is actually a process of progressive model identification in which the initial (large) uncertainty in our knowledge of what constitutes a good model structure and good parameter estimates is sequentially reduced while constraining the model to be structurally and functionally (behaviorally) consistent with the available qualitative (descriptive) and quantitative (numerical) information about the catchment. Because, as mentioned before, any selected model will be (at best) a structural and functional approximation of the true (unknown) watershed structure and function, the calibrated estimates of the parameters and the resulting predictions will always contain some remaining uncertainty. These and other uncertainties will also lead to the result that our model will generally not be able to fit the data perfectly, that is, we will not be able to perfectly track the observed system behavior with our model.

Early methods for the calibration of RR models were based on manual, so-called "trial-and-error" procedures. The manual calibration process can be considered to have three levels (Boyle *et al.*, 2000). In Level Zero, the initial uncertainty of the estimates is defined by selecting feasible

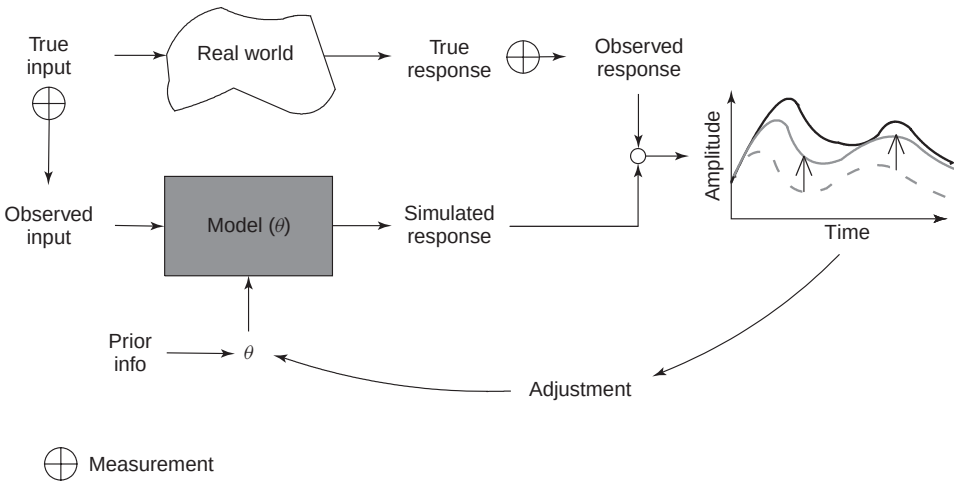

Figure 1 Strategy for model calibration. The model parameter set is represented by θ

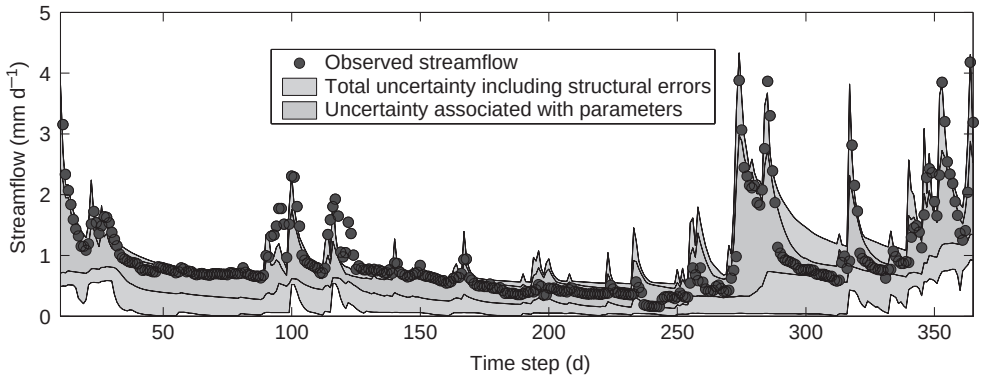

Figure 2 Probabilistic streamflow prediction. Flow is shown in transformed space. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

ranges for each parameter, using estimates from similar catchments, look-up tables, maps, and databases. In Level One, the hydrologist attempts to reduce the size of the parameter uncertainty by adjusting one parameter at a time to try and match the particular segments of the catchment input-output (IO) response to which those parameters are most sensitive. Parameter interaction is usually ignored at this stage. Finally, in Level Two, the behavior of the entire hydrograph is examined, and the parameters further adjusted to allow for parameter interactions, while further reducing the distance between simulated response and the observed catchment behavior. This last stage is the most difficult, owing to the complex nature of the parameter interactions and the nonlinear nature of the model. A systematic approach to Level Two parameter estimation requires (i) a strategy to define (measure) the closeness between the observations and the model response, and (ii) a strategy to reduce the size of the feasible parameter space.

While the manual approach to model calibration (as described above) is based on subjective judgment and expertise, a trained and experienced hydrologist can often obtain excellent results, so that the model response generates a realistic simulation of the response of the catchment. However, the process can be very time consuming, and because it involves subjective decisions by the modeler, requires considerable training and practice. Further, the knowledge and skills so obtained are not easily transferred from one person to another. These limitations have led to interest in methods for model calibration that can be carried out automatically using the speed and power of a digital computer.

The goal of the automatic calibration approach is to use a computer to perform the difficult Level Two stage of the three-level strategy outlined above. Level Zero is still performed manually to provide a crude description of the feasible parameter space, and the Level One stage is generally ignored (see Wagener *et al.*, 2003a, for a discussion of this problem). The potential advantages of a computer-based approach are not difficult to enumerate – properly designed computer algorithms can be fast and objective, while handling more complex problems (e.g. stronger nonlinearities and larger numbers of parameters). The closeness between the simulated and observed responses is typically measured by one (sometimes two or more) mathematical measures (called *objective functions*; OFs) and the parameters are adjusted by an iterative search procedure (called an *optimization algorithm*) towards the optimal value(s) of the OF(s).

An objective function (OF) is a numerical summary of the magnitude of the residuals, that is, the difference between the observed (measured) and the simulated system response (typically the streamflow hydrograph). The goal of calibration is usually to minimize (or maximize depending on definition) the value of this OF. The residuals are calculated as follows,

$$e(\theta) = y_t{}^{\text{obs}} - y_t(\theta) \tag{1}$$

where $y_t{}^{\text{obs}}$ is the observed response at time t, $y_t(\theta)$ is the simulated response, and θ is a vector of parameter values. The residuals are usually aggregated using a prespecified function,

$$F(\theta) = F\{e_t(\theta), \quad t = 1, 2, \ldots, n\} \tag{2}$$

The most commonly applied OFs are of the Weighted Least Squares (WLS) type (e.g. Sorooshian and Gupta, 1995), derived from regression theory,

$$F(\theta) = \sum_{t=1}^{n} w_t \cdot [y_t{}^{\text{obs}} - y_t(\theta)]^2 \tag{3}$$

where w_t is the weight at time t, and n is the number of data points analyzed. In absence of additional information, the weights are commonly set to the value 1.0 for all-time steps. This leads to the Simple Least Squares (SLS)

OF that yields unbiased parameter estimates when the following assumptions regarding the residual distribution are valid: (i) the residuals are independent and identically distributed (i.i.d.), (ii) the distribution shows a homogeneous variance, and (iii)] the residual distribution follows a normal distribution with zero mean (e.g. Gershenfeld, 1999). Because these assumptions are often violated in RR modeling, several researchers have tested the use of alternative error models, and therefore alternative OFs (e.g. Sorooshian and Dracup, 1980; Sorooshian *et al.*, 1983; Kavetski *et al.*, 2003). Examples include the Heteroscedastic Maximum Likelihood Estimator (HMLE, Sorooshian and Dracup, 1980; Sorooshian *et al.*, 1983), which considers a heteroscedastic variance in the system response measurements, and the Bayesian Total Error Analysis (BATEA, Kavetski *et al.*, 2003), which also considers errors in the input data. A more general form of OF, which can be adjusted to be consistent with different error models, was introduced to hydrologic modeling by Thiemann *et al.* (2001), and is based on an exponential power density (Box and Tiao, 1973).

Research into automatic methods (by the hydrologic community) began in the 1960s and 1970s. At that time, it was assumed that the problem of model calibration is similar to that of estimating the parameters in a nonlinear statistical regression. As mentioned above, the OF was typically selected to be some kind of l-norm, such as the weighted sum of squared errors ($l = 2$) shown in equation (3). The minimization of the OF was typically carried out using a "Local Search" algorithm, beginning with an initial parameter guess and employing a preprogrammed iterative strategy to move the parameter search in a direction of local improvement.

In general, Local Search strategies belong to one of two classes – derivative-free (direct) methods and derivative-based (gradient) methods. Examples of popular direct methods include the Downhill Simplex (Nelder and Mead, 1965), the Pattern Search (Hooke and Jeeves, 1961), and the Rotating Directions (Rosenbrock, 1960) algorithms. Gradient methods are potentially more powerful than direct methods, because they use additional information – estimates of the local downhill direction based on the first and/or second derivative of the response surface with respect to the model parameters (Bard, 1974). Although Gupta and Sorooshian (1985) and Hendrickson *et al.* (1988) showed that analytical or numerical derivatives could be computed, even for complex conceptual RR models, Hendrickson *et al.* (1988) found that, in practice, gradient methods do not perform better than direct methods. The use of local search algorithms for model calibration has been tested extensively (Ibbitt, 1970; Johnston and Pilgrim, 1976; Pickup, 1977; among many others), with the general conclusion that such methods are unable to provide a reliable estimate of the globally optimal solution to the RR model minimization problem. Instead, the solution to a Local Search is typically strongly dependent on the accuracy of the initial guess.

Initial responses, during the 1980s, to the failure of automatic calibration methods based on Local Search, were to try and put the optimization problem onto a more rigorous statistical footing. Two (related) directions can be found in the literature, one based on the use of maximum likelihood theory (e.g. Sorooshian and Dracup, 1980) and the other based on the use of Bayesian theory (e.g. Kuczera, 1983a,b). However, neither of these directly addressed the causes of the inability to find the optimum for a selected OF.

Towards the end of the 1980s, with the advent of easier access to powerful digital computers, attention shifted to the testing of "Global Search" algorithms (e.g. Brazil and Krajewski, 1987). A characteristic of many Global Search algorithms is to begin with a number of initial guesses distributed throughout the feasible parameter space, and to evolve this population of guesses iteratively towards promising regions of the OF response surface. Global search algorithms that have been tested include Adaptive Random Sampling (Masri *et al.*, 1980; Brazil, 1988), Simulated Annealing (Kirkpatrick *et al.*, 1983; Thyer *et al.*, 1999), Controlled Random Search (Price, 1987; Klepper *et al.*, 1991) and the Genetic Algorithm (Holland, 1975; Goldberg, 1989; Wang, 1991). Duan *et al.* (1992) conducted a detailed analysis of the properties of the OF response surface associated with a typical RR model and found that:

- It contains more than one main region of attraction.
- It has many local optima within each region of attraction (Figure 3).
- It is rough with discontinuous derivatives.
- It is flat near the optimum with significantly different parameter sensitivities.
- Its shape includes long and curved ridges.

These insights were incorporated into the design of a novel Global Search procedure called the *Shuffled Complex Evolution* (SCE-UA) algorithm, which combines elements of a number of different strategies, including the Downhill Simplex, Controlled Random Search, and Competitive evolution with the newly proposed idea of "Complex Shuffling" (Duan *et al.*, 1992, 1993, 1994; Sorooshian *et al.*, 1993). Extensive testing of the SCE-UA method by numerous researchers has proven its effectiveness, ability to consistently find the global optimum), and efficiency (low probability of failure of any trial) in reliably finding the global solution, when a unique solution exists.

However, these studies have also demonstrated that numerous parameter sets usually exist, widely distributed throughout the feasible parameter space, which have very similar values for the selected OF. This poses difficulties for local or global optimization methods, referred

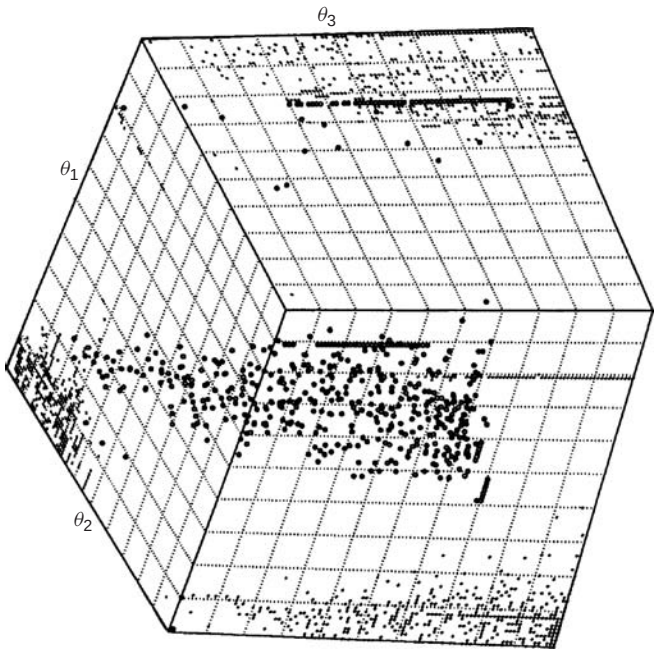

Figure 3 Three-parameter (θ_i) subspace of a simple conceptual catchment model (SIXPAR, Duan *et al.*, 1992), showing locations of multiple local optima

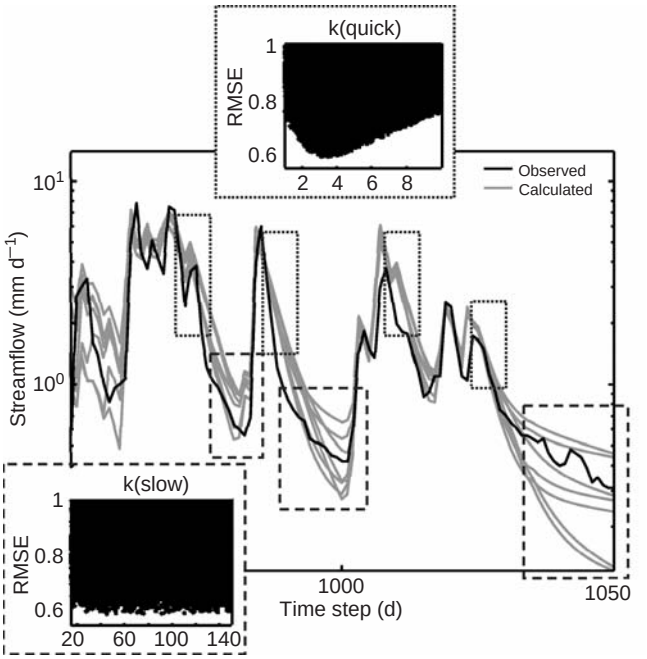

Figure 4 Hundred days extract of six years of daily streamflow data. Observed flow in black, seven different model realizations in grey. Inlets show dotty plots for the linear reservoir residence times k(quick) and k(slow) versus their corresponding Root Mean Squared Error (RMSE) values. The model structure used consists of a Penman soil moisture accounting and a parallel routing component of linear reservoirs with fixed flow distribution

to in the optimization literature as problems of non-uniqueness, indeterminacy, or nonidentifiability. In reviewing this problem, Beven (1993) applied the term "equifinality" to describe the generic nature of finding multiple feasible models that make predictions consistent with any observations available for model calibration in any reasonably complex modeling problem.

The consequences of this progression of events have been some shifts in the underlying philosophy and perceived objectives of model calibration. Model calibration procedures were traditionally based on an attempt to find a "best" (most likely) estimate of the parameter values conditioned on the data, and a subsequent best (most likely) estimate/prediction of the catchment response. Efforts were concentrated on finding the most efficient techniques for doing so with a view to saving computer time in model calibration. The findings reported above have helped to make it clear that the inherent uncertainty (indeterminacy) in the estimated parameter values must be explicitly considered during both calibration and prediction. Approaches to do so are discussed in the section "Considering parameter uncertainty".

Another response has been to look for causes of the parameter indeterminacy and to design ways to address them. In particular, the traditional way to pose the model calibration problem relies on the specification of a single OF, which provides an aggregate measure of the mean distance between observed and calibrated hydrograph over the whole length of the data time-series, as the measure of performance. This action is now understood to result in considerable loss of important information that can be used to distinguish between competing parameter sets. For example, Figure 4 shows a number of model-simulated hydrographs (from different parameter sets) that produce identical OF values, but are clearly visually and behaviorally different (Wagener *et al.*, 2003c). Based on this, Gupta *et al.* (1998) suggest that a calibration approach with higher discriminative power is required and proposed use of a multiobjective methodology. This approach is described further in the section "Considering structural uncertainty".

A special case of parameter estimation arises in predicting the response of ungauged catchments. These are catchments for which observed records of the variable of interest, usually streamflow, are either too short or nonexistent. The main approaches to estimate the parameters of lumped rainfall-runoff models for ungauged catchments are through *physical reasoning* (e.g. Koren *et al.*, 2003), *statistical analysis* (e.g. Jakeman *et al.*, 1992; Wagener *et al.*, 2003b), or a mixture of both. Physical reasoning in this context means that parameters are derived from catchment properties, either directly or through empirical equations. Koren *et al.* (2003) suggest that reasonable initial estimates

for the parameters of the Sacramento soil moisture accounting (SAC-SMA) model can be derived from data such as average field capacity or wilting point of the soil in a catchment. The main approach to ungauged modeling however is the derivation of statistical relationships between model parameters and catchment characteristics for a large number of gauged catchments. Typically, a single model structure is selected that is assumed suitable to represent all the available catchments. The parameters of this structure are derived through a calibration process for all the gauged catchments, and an attempt is then made to develop regression relationships between model parameters and catchment characteristics. It is hoped that these statistical relationships can then be used to predict the parameters in ungauged catchments. See Wagener *et al.* (2003b) and **Chapter 133, Rainfall-runoff Modeling of Ungauged Catchments, Volume 3** for a discussion on this type of approach.

It should be noted that, regardless of the chosen approach, it will generally be impossible to reduce the total output prediction error, that is, the difference between observed and simulated system behavior to zero. Even if we could be sure that we had the correct model equations, errors in the input data and observations used in calibration will result in a residual prediction error. Indeed, experience suggests that reducing the error during one system response mode, often leads to an increase in the error during another mode (Gupta *et al.* 1998). In the following sections we will discuss the components and characteristics of the error.

It should also be noted that streamflow is not the only catchment response that can be used in model calibration. There is a wide range of studies where alternative hydrological variables are used for this purpose. Examples are Lamb *et al.* (1998) and Blazkova *et al.* (2002b) using distributed groundwater levels; Kuczera and Mroczkowski (1998) using groundwater level observations and stream salinity data; Franks *et al.* (1998) and Blazkova *et al.* (2002a) using information on saturated areas; and Seibert and McDonnell (2003) using "soft" data on the nature of catchment responses.

ON THE SOURCES AND THE NATURE OF THE TOTAL ERROR IN RAINFALL-RUNOFF MODELING

There is a problem, in any modeling application, of trying to understand the origins of the error between model predictions of a variable and any observational data of the same variable. The difficulty arises because there are a variety of sources for the error but (at any given time) only one measure of the deviation or residual between prediction and observation (i.e. the "total error"). Thus, disaggregation of the error into its source components is difficult, particularly in cases common to hydrology where the model is nonlinear and different sources of error may interact to produce the measured deviation.

Obvious sources of error in the modeling process include the errors associated with the model inputs and boundary conditions, the errors associated with the model approximation of the real processes, and the errors associated with the observed (measured) variables. A less obvious source of error is when the variable predicted by a model is not the same quantity as that measured (even though they might be referred to by the same name) because of scale effects, nonlinearities or measurement technique problems. A soil moisture variable, for example, might be predicted as an average over a model grid element several 100 m in spatial extent and over a certain time step; the same variable might be measured at a point in space and time by a small gravimetric sample, or by time domain reflectrometry integrating over a few tens of cm, or by a cross-borehole radar or resistivity technique, integrating over several tens or hundreds of meters. Only the latter might be considered to approach the same variable as described by the model (but will also be associated with its own interpretation errors of the geophysical signal in obtaining a soil water estimate). Fortunately, in rainfall-runoff modeling, the predictions are most usually compared with the measured discharges at the outlet from a catchment area. The measured discharges may be considered to be essentially the same variable as that predicted by the model, although subject to measurement errors.

In general, no satisfactory approach to separate the sources of error that contribute to the total error has yet been proposed. In line with traditional statistical estimation theory, the total error is often treated as a single lumped additive variable of the form:

$$Q(t) = M(\Theta, t) + \varepsilon(t) \tag{4}$$

where $Q(t)$ is a measured variable, such as discharge, at time t; $M(\Theta,t)$ is the model prediction of that variable using parameter set Θ; and $\varepsilon(t)$ is the total remaining error. Note that a multiplicative error form could also be used if appropriate by taking logs of the observation and the predicted variables. The additive form allows application of the full range of statistical estimation techniques to model calibration and uncertainty analysis, subject to the limitations of dealing with the nonlinearity of the model.

Implicit in this approach, however, is the assumption that the model structure is at least adequate, if not correct. In catchment RR modeling we cannot generally be sure of this. Further, it is generally necessary to make assumptions about the structure of the total errors $\varepsilon(t)$ – typical assumptions include normality of the underlying error distribution, constancy of variance and simplicity of the correlation structure. While such assumptions are convenient to the application of statistical theory, they have usually not been supported by the actual series of model residuals, which

may show variations in bias (nonstationarity), variance (heteroscedasticity), and correlation structures under different hydrologic conditions.

In the following sections we analyze the main contributors to model error and to the uncertainty in predictions of our current models in general. Approaches to deal with these are outlined and open research questions are discussed.

CONSIDERING PARAMETER UNCERTAINTY

It was mentioned above that a large number of widely different parameter sets could, in many cases, yield practically identical results with respect to a particular OF. Three main responses to this problem of perceived equifinality can be found in the literature.

First, the finding of parameter indeterminacy can be interpreted as an indication that the chosen model structure is overly complex given the information about hydrologic behavior actually observable in the data. Following this interpretation, various researchers have tested and successfully applied simpler model structures such that the number of associated model parameters is only so large as to allow confidence in the results of the calibration (Wheater *et al.*, 1993; Jakeman and Hornberger, 1993; Young *et al.*, 1996; Young, 2001; Wagener *et al.*, 2002, 2003c).

Second, the finding can be interpreted as supporting the need for set theoretic approaches, which assume that all plausible models should be retained unless and until evidence to the contrary becomes apparent. Many of these set theoretic approaches are related to the Regional Sensitivity Analysis (RSA; also sometimes called the *Hornberger-Spear-Young approach*) concept advanced by Spear and Hornberger (1980) that evaluates the sensitivity of the model output to changes in parameters without referring to a specific point in the parameter space (such as a most likely value for a parameter). These techniques commonly apply random sampling procedures to explore the feasible parameter space in search for plausible (behavioral) models. Examples of the set theoretic approach applied to RR modeling include the Generalized Likelihood Uncertainty Estimation (GLUE) technique of Beven and Binley (1992), the Dynamic Identifiability Analysis (DYNIA) approach of Wagener *et al.* (2003a), the PIMLI approach of Vrugt *et al.* (2002), the Monte Carlo set membership (MCSM) approach of van Straten and Keesman (1991), the explicit Bayesian approach of Kuczera and Mroczkowski (1998), the Bayesian Recursive Estimation (BARE) technique of Thiemann *et al.* (2001), and the Shuffled Complex Evolution Metropolis (SCEM-UA) algorithm of Vrugt *et al.* (2003b).

Third, the finding can be attributed to a failure to properly specify the (automatic) calibration problem in such a way as to properly exploit the information contained in the data. There are two (related) responses to this. On the one hand, a multicriteria approach can result in better exploitation of the information in the data, while the resulting optimal population solution (optimal in a multicriteria sense) defines a kind of parameter uncertainty attributable to model structural errors. This is discussed further in the section "Considering structural uncertainty". In addition to the improved use of information, recursive processing of the data can provide better extraction of the information in the data, because the temporal aggregation associated with batch processing of data is reduced. Examples of recursive algorithms that can be applied to RR models for the estimation of parameter uncertainty include the Kalman Filter and its extensions (e.g. Kitanidis and Bras, 1980a,b; Beck, 1987), the PIMLI approach (Vrugt *et al.*, 2002), the DYNIA approach (Wagener *et al.*, 2003a), the BaRE approach (Thiemann *et al.*, 2001) and the application of Transfer Functions (TF) with time-varying parameters identified using Instrumental Variable techniques (Young, 2001). The GLUE methodology can also be applied recursively with appropriate choice of the Likelihood criterion. Recursive approaches can also provide a method for checking violations of the underlying assumption that the parameters are constant – for example, both Wagener *et al.* (2003a) and Misirli (2003, BaRE2) reported that certain parameters of the models they tested displayed significant temporal variations, and suggested that this may be an indication of model structural error.

We now take a closer look at four approaches representative of the second and third responses to dealing with parameter uncertainty, that is, the use of set theoretic methods, GLUE and SCEM-UA, and the application of recursive approaches, DYNIA and BaRE. Common to these approaches is the selection or identification of a *set* (population) of models (different combinations of model structures and parameter values), and assignment of some relative degree of believability to each member of the set. That degree of believability is translated into interval estimates of the uncertainty (confidence) in model simulations/predictions. The approaches differ in the suite of assumptions underlying each technique, based on which the methods used to compute the relative degree of believability are derived. The idea is that, in principle, the sensitivity of the predictions and associated uncertainty to the underlying assumptions of the methods are testable and can be evaluated.

The GLUE methodology evolved out of early Monte Carlo studies of different realizations of parameter sets in rainfall-runoff modeling as a way of estimating the sensitivity of model predictions to different parameter values (see, e.g., Hornberger and Spear, 1981). The Hornberger-Spear-Young approach to sensitivity analysis involves the classification of many different parameter sets into those that are behavioral and those that are nonbehavioral in some predefined way. The parameter distributions for each

of these sets are then examined to check for significant differences between them.

The additional step in the GLUE methodology of Beven and Binley (1992) is to associate each of the behavioral simulations with a likelihood measure (as a way of quantifying model believability), to estimate the uncertainty associated with the model predictions as conditioned on some calibration data used in the likelihood value calculation. Models that perform well in the calibration period will be associated with a high likelihood weight in prediction, those that perform less well will carry a low likelihood weight. Those that are considered nonbehavioral will not be used in prediction. Such an approach allows for the equifinality of different parameter sets in fitting the available calibration data, it allows that different types of likelihood measure might be used in model evaluation, and it allows for the likelihood weights to be updated as new calibration data become available (see the review of applications by Beven and Freer, 2001). The steps in the GLUE methodology are as follows:

- Decide on a model structure or structures to be used.
- Sample multiple sets of values from prior ranges or distributions of the unknown parameters by Monte Carlo sampling, ensuring independence of each sample in the model space.
- Evaluate each model run by comparing observed and predicted variables.
- Calculate a likelihood measure or measures for those models considered behavioral.
- Rescale the cumulative likelihood weights over all behavioral models to unity.
- Use all the behavioral models in prediction, with the output variables being weighted by the associated rescaled likelihood weight to form a cumulative distribution of predictions, from which any desired prediction quantiles can be extracted.

The methodology depends on obtaining an adequate sample of behavioral models. In some model applications this may require from many thousands to even billions of simulations to adequately define the behavioral regions in the multidimensional model space (Iorgulescu *et al.*, 2005). In most problems it remains quite difficult to define prior distributions for effective values of the different parameters, even in terms of simple means and covariances. Thus, most applications of GLUE define only a range for each parameter and sample uniformly within that range. For cases where the region of behavioral models is relatively small this will result in inefficient sampling and alternatively sampling strategies may be required. However, in many applications it has been found that behavioral models are scattered widely in the model space so that efficiency in sampling behavioral models is difficult to achieve. It is, of course, possible that no behavioral models will be found, particularly where models must satisfy multiple criteria to remain behavioral (see for example Freer *et al.*, 2003) giving a good indication that there are problems either with the data set or with the model structure. A statistical estimation strategy might still find an optimal model in such a case, but would generally assign the deficiencies to a large "total error" component (unless other statistical inadequacy components had been added, as for example in Kennedy and O'Hagan, 2001).

In fact, the GLUE methodology is general, in that statistical error assumptions and likelihood functions can be used where the assumptions are satisfied, but a much wider range of likelihood measures including fuzzy measures can also be used. The only requirements are that the relative likelihood value should increase monotonically with improving model performance and that nonbehavioral models should be given a likelihood of zero. These are much less stringent requirements than those of statistical theory and the GLUE approach does avoid the assumption that the model is correct (implicit where a statistical error model with zero bias is assumed in model calibration). As a result, unlike a statistical approach, GLUE does not attempt to estimate the probability of predicting an observation given the (optimal) model. Instead, it predicts the probability of a model prediction, conditioned on the ranges of model structures and parameter values considered, the period of calibration (or evaluation) data used and the likelihood measures used in model evaluation. The method therefore assumes that the error structures associated with a particular behavioral model parameter set will remain "similar" during any prediction period, so that the likelihood weights determined in calibration can be used to weight the predictions of any variable of interest. In this way, distributional assumptions are avoided, and nonlinear changes in predicted distributions of variables are allowed (as demonstrated in Freer *et al.*, 1996, where such changes between high and low discharges are shown to be consistent with expectations of system response). The emphasis is on the parameter set in obtaining a behavioral model, rather than on individual parameters and their covariation. The approach can be extended to including multiple model structures, provided that different models can be evaluated with respect to the same likelihood measures. Different applications of the GLUE methodology are described in Beven *et al.* (2000), Beven and Freer (2001), and Beven (2001).

Vrugt *et al.* (2003b) extended the SCE-UA algorithm (described above) to allow for both the estimation of the most likely parameter set, and also for its underlying posterior distribution. The authors replaced the Downhill Simplex method used for population evolution by Duan *et al.* (1992) with the Metropolis Hastings (MH) algorithm. By merging the strengths of the MH algorithm, controlled random search, competitive evolution, and complex shuffling, the SCEM-UA is designed to evolve to a stationary

posterior target distribution of the parameters. The stochastic nature of the MH annealing scheme avoids the tendency of the SCE-UA algorithm to collapse into a single region of attraction (i.e. the global minimum), while the information exchange (shuffling) between parallel sequences allows the search to be biased in favor of better regions of the solution space. Examination of the posterior parameter distribution allows the user to detect whether multiple and/or large regions of the parameter space continue to remain consistent with the current data, and this parameter uncertainty can be projected into the output space as uncertainties on the model predictions (in a manner similar to both BaRE and GLUE). A detailed description of this algorithm appears in the article by Vrugt and Dane (**Chapter 77, Inverse Modeling of Soil Hydraulic Properties, Volume 2**).

The dynamic identifiability analysis (DYNIA) approach developed by Wagener *et al.* (2003a) is a recursive parameter identification approach, based on elements of the GLUE methodology, the popular Regional Sensitivity Analysis (RSA; Spear and Hornberger, 1980), aspects of wavelet analysis (e.g. Gershenfeld, 1999), and the use of Kalman filtering for hypothesis testing as applied by Beck (1987). Monte Carlo sampling based on a uniform prior distribution is used to examine the feasible parameter space. In contrast to the GLUE procedure, DYNIA uses only a window period rather than the full data period to calculate a measure of performance. This window is moved through the available time-series in a step-wise fashion, that is, at time step t one considers the residuals between $t - n$ and $t + n$. The size of n is selected depending on the length of time over which the parameter is influential, and on the quality of the data. The performance measure is then used to condition the marginal parameter distribution at that particular time step. A threshold is applied to consider only the best performing parameter sets (e.g. best 10%), which represent the peak of the parameter distributions. The shape of the resulting distribution is projected into the time-parameter space and variation of its shape in time can be visualized. This methodology can be applied to track the variation of parameter optima in time, to separate periods of information and noise, or to test whether model components (and therefore parameter values) represent those processes they are intended to represent (Wagener, 2003).

The Bayesian Recursive Estimation (BaRE) algorithm, developed by Thiemann *et al.* (2001) based on assumptions similar to those used in the SCEM-UA batch calibration algorithm, employs a recursive scheme for tracking the conditional probabilities associated with several competing parameter sets (models) in an on-line mode instead of searching for a single best solution in an off-line mode. The parameter probabilities are used to compute probabilistic predictions of the desired output variables (Figure 2). Probability updating, via Bayes theorem, facilitates the assimilation of new data as they become available. The BaRE algorithm belongs to a broad class of ensemble methods, which include the Ensemble Kalman Filter (EnKF, see e.g. Evensen, 1994; Madsen and Canizares, 1999; Reichle *et al.*, 2002) and which use multiple possible model realizations (possibly involving multiple parameter sets, model structures, error sequences, etc.). The main difference is that BaRE employs a full nonlinear updating procedure, while the EnKF uses a linear correlation updating rule. The initial BaRE algorithm suffered from several shortcomings (Beven and Young, 2003; Gupta *et al.*, 2003; Misirli, 2003), the most important being that the parameter distribution collapsed onto a single point owing to an insufficient sampling density. Misirli (2003) addressed this and other problems by developing BaRE2, an improved version of the original BaRE algorithm, introducing (among other things) a resampling procedure to ensure an appropriate sampling density in the high probability region. The development of BaRE has helped to stimulate some discussion about appropriate methods for handling various sources of uncertainty, including model structural uncertainty. Please see the comment and reply on this topic published recently in Water Resources Research (Beven and Young, 2003; Gupta *et al.*, 2003).

An alternative to Monte Carlo based approaches to the estimation and propagation of uncertainty are the "point" methods based on first-order analysis. Such techniques can be used to calculate the mean and variance of the predicted variable based on the mean and variance of uncertain inputs and parameters only. They do not require computer intensive Monte Carlo schemes to estimate the shape of the response surface that is then mapped into the output space. These techniques are thus particularly attractive for practical applications. An overview of such methods can be found in Melching (1995). They commonly apply a Taylor series expansion of the OF or the model output around a specific point in the parameter space, usually truncated after the first-order term, hence the term first-order analysis. In the Mean-value First-Order Second-Moment (MFOSM) method, the selected point is the mean value. Numerical and sometimes even analytical derivatives can be used (Melching, 1995) to calculate the expected value and the variance of the predicted variable (e.g. streamflow). An advantage of this approach is its relative simplicity and computational efficiency. The main weakness is *the* assumption that *a single linearization of the system performance function at the central values of the basic variables is representative of the statistical properties of system performance over the complete range of basic variables* (Melching, 1995). This is a difficult assumption to make in RR modeling where the system under investigation usually exhibits a strongly nonlinear behavior. The Advanced First-Order Second-Moment (AFOSM) improves on the MFOSM approach by using a "likely" point in the

parameter space, instead of the mean. Rosenblueth's point-estimation method (Rosenblueth, 1981) uses the mean and the covariance of the variables in a Taylor series expansion and does not require the calculation of derivatives, as do MFOSM and AFOSM. For applications of Rosenblueth's approach to hydrological models, see, for example, Rogers *et al.* (1985), Binley *et al.* (1991), Melching (1992), or McIntyre *et al.* (2002). Harr's point-estimation method (Harr, 1989) reduces the number of simulations required for Rosenblueth's method from 2^p to 2p, where p is the number of model parameters. See McIntyre *et al.* (2002) for details on this method and for an application in hydrology.

All of the point-estimation methods described above, are, however, limited by some assumptions made during their application, most importantly approximate linearity of the model. The first two moments of the predicted variable can sometimes be calculated accurately using these approaches if the nonlinearity of the model (and model structural error) and the uncertainty in the model parameters is not too large (Garen and Burges, 1981; Kuczera, 1988; Høybye, 1998).

CONSIDERING STRUCTURAL UNCERTAINTY

RR models are, by definition, simplifications of reality that aggregate catchment processes into simpler representations. The process of defining a perceptual model of the catchment and translating this model into mathematical code depends on the imagination and hydrologic understanding of the modeler. To corroborate or reject a model as suitable for the anticipated purpose, a procedure of model testing and evaluation must be applied. The imperfect model representation arising from the aggregation process introduces a degree of uncertainty into the model predictions, which is difficult to quantify. However, some of the consequences of this uncertainty can be detected and even used for improvements in the model structure.

A major consequence of model structural imperfection is that the model is incapable of reproducing all aspects and portions of the hydrograph equally well with a single parameter set. Because the classical manual modeling/calibration approach seeks a single "best" parameter set, the hydrologist is forced to select a trade-off between the errors in fit to different parts of the hydrograph, thereby arriving at some suitable compromise parameter set that meets the needs and objectives of the modeling exercise. The manual approach typically depends on visual examination of the "local" fit between various segments of the simulated and observed hydrographs, while also checking to see that some selected "global" OFs take on values that are within acceptable distance of their "optimal" values. The goal is to find a parameter set that produces a realistic hydrograph shape while giving an acceptable level of overall (statistical) performance. The classical single OF automatic calibration approaches result, in essence, in an implicit (difficult to specify or control) aggregate weighting of different aspects of hydrograph fit, which, in practice, tends to produce simulations that are biased towards specific aspects of the observed hydrograph (e.g. high or low flows). To date, it has not become clear if the complex thought processes that lead to successful manual calibration could be encapsulated into a single OF. This has fueled the recent research on multicriteria approaches.

Gupta *et al.* (1998) argued that the calibration of RR models is inherently a multiobjective problem. Their multiobjective approach offers a way forward by emulating the ability of Manual-Expert calibration to employ a number of complementary ways of evaluating model performance, thereby compensating for various kinds of model and data errors, and extracting greater amounts of information from the data. The outcome is a set of models that are constrained (by the data) to be structurally and functionally consistent with available qualitative and quantitative information and which simulate, in an uncertain way, the observed behavior of the watershed. By maintaining the independence of the various performance criteria, and by performing a full multicriteria optimization, the entire set of Pareto optimal solutions is identified. Chankong and Haimes (1993) define the concept of a Pareto optimum as follows: "A solution is said to be Pareto optimal (also synonymously known in the literature as efficient, noninferior, and nondominated) if the value of any OF cannot be improved without degrading at least one of the other Ofs." In simple language, it is possible to divide the parameter space into 'good' and 'bad' solutions, but one cannot objectively favor one of the good solutions, since there is always another one that is better in a certain aspect, that is, with respect to another OF.

Yapo *et al.* (1998), and later Vrugt *et al.* (2003a), presented algorithms capable of solving, in a single optimization run, the multiobjective problem posed by this approach. Yapo *et al.* (1998) developed the multiobjective complex evolution (MOCOM-UA) algorithm that uses a population evolution strategy (similar to the one employed by the SCE-UA algorithm) to converge to the Pareto set. In brief, the MOCOM-UA method involves the initial selection of a "population" of p points distributed randomly throughout the n-dimensional feasible parameter space Θ. In the absence of prior information about the location of the Pareto optimum, a uniform sampling distribution is used. For each point, the multiobjective vector $E(\theta)$ is computed, and the population is ranked and sorted using a Pareto-ranking procedure suggested by Goldberg (1989). Simplexes of $n + 1$ points are then selected from the population according to a robust rank-based selection method. The MOSIM procedure, a multiobjective extension of the Downhill Simplex method (Nelder and Mead, 1965), is used to evolve each simplex in a multiobjective improvement direction. Iterative application of the ranking and evolution procedures causes the entire population to converge towards the Pareto

optimum. The procedure terminates automatically when all points in the population become nondominated.

Vrugt *et al.* (2003a) replaced the Downhill Simplex approach in the MOCOM-UA algorithm with an efficient Markov Chain Monte Carlo sampler (similar to the one employed in the SCEM-UA algorithm), which additionally allows for the estimation of the underlying probability distributions with respect to the different objective functions. They also improved on some of the weaknesses of the original approach such as the tendency of the MOCOM-UA algorithm to cluster the Pareto solutions in the most compromise region among the objectives, and premature convergence of the algorithm for cases involving a multitude of parameters and highly correlated performance measures. The multiobjective implementation of the SCEM-UA algorithm is termed *MultiObjective SCEM-UA* (MOSCEM-UA).

Several researchers used the fact that different parameter sets are required to represent different response modes of the hydrologic system in a more structured manner (e.g. Beck, 1985; Young, 2001; Wagener *et al.*, 2003a). Beck (1987) applied the extended Kalman filter (EKF) to recursively estimate optimum parameter values, and used the variation of these optima in time to detect structural inadequacies. He reported that the EKF was inadequate for this purpose owing to a lack of robustness and owing to restrictions imposed by the filter assumptions. Wagener *et al.* (2003a) used the DYNIA methodology described earlier for the same purpose and showed structural problems in a RR model having typical structural elements by tracking parameter variations in time.

Kennedy and O'Hagan (2001) on the other hand, focused on deriving a more complex error model. They include a model inadequacy function in their Bayesian calibration framework. The goal, similar to the approach by Sorooshian and Dracup (1980; see next section), is to produce an error series having the desirable properties of constant variance and independence in time and space, so that unbiased estimates of the various parameters and correction terms can be more easily estimated. If the model structure is at least approximately correct, the statistical approaches lead to a concentration on finding a probabilistic description for the optimal values of the model and error parameters. Where there are model structural errors on the other hand, the statistical error model will, to some extent, be required to compensate for those errors. It is therefore important to carry out postcalibration diagnostic tests to ensure that the model and error assumptions are sound.

Another approach, arising from the equifinality concept (where more than one model or model structure appear to provide acceptable representations of the available observations; Beven, 1993), suggests that complications arising owing to the presence of nonlinear model structural error make it difficult to properly apply a rigorous statistical estimation procedure. This approach rejects the idea that an "optimal" model exists and concentrates instead on the task of finding a *set* of models that are *behavioral* in the sense of being acceptably consistent with the observations (however acceptable might be defined), or, more importantly, rejecting all those models that can be shown to be nonbehavioral. As discussed earlier, this is the basis for the Generalized Likelihood Uncertainty Estimation methodology and other set theoretic approaches to model calibration, which are easily extended to consider multiple objectives and multiple model structures, at the expense of significant additional computer run time. Within this framework, as noted earlier, it is possible that all the models tried will be rejected where such consistency with the observations cannot be demonstrated (Freer *et al.*, 2003; Beven, 2005), leading to the serious reconsideration of model structure, input data, or calibration data that would be justified in such a case.

Other researchers have also explored the same premise, that is, the need to consider multiple model structures. Neuman (2002), for example, suggests that not allowing for different system conceptualizations can lead to statistical bias and an underestimation of uncertainty. He introduces an approach based on Bayesian model averaging (Hoeting *et al.*, 1999) to account for this problem, where each model is treated as if it were the correct structure in trying to maximize its contribution to the averaging process.

CONSIDERING DATA UNCERTAINTY

Data used for RR modeling are measurements of the input and output fluxes of the hydrologic system, and sometimes of its states. The input is precipitation, usually as rainfall or snow, while output data are streamflow and potential evapotranspiration. The latter is sometimes replaced by measurements of temperature. State variables that are of potential use in rainfall-runoff modeling are, for example, measurements of groundwater levels or soil moisture content.

Measurement errors with respect to streamflow occur owing to underflow and bypassing of gauging structures, and rating curve inaccuracies, especially at very high and very low flows. Sorooshian and Dracup (1980) addressed the problem of heteroscedastic errors in streamflow measurements by deriving a likelihood estimator, which uses a power transformation to stabilize the variance. However, research with respect to data uncertainty and its effect on the predictions of RR models has focused mainly on errors in the precipitation. This focus is based on the assumption that the dominant source of error stems from poor knowledge of the rainfall input. One of the earliest examples in this respect is the work of Crawford and Linsley (1966), who used a rain gauge scaling factor as a calibration parameter in the Stanford Watershed Model, with values up to 1.1 to

account for wind or orographic influences. The use of such a factor can still be found in some of today's modeling exercises. Kavetski *et al.* (2003), for example, included an adjustment coefficient for each rainstorm within a statistical estimation framework.

Much of the error in precipitation measurements is related to the inability of available gauging networks to properly capture the amount and variability of precipitation in space and time. Not surprisingly, Beven and Hornberger (1982) and Obled *et al.* (1994) found that a correct assessment of the global volume of rainfall input in a variable pattern is more important than a rainfall pattern (by itself) for simulating streamflow hydrographs. However, the variability of the rainfall pattern can exert a strong influence on the timing of the hydrograph peak at a downstream gauging station. Initial studies on precipitation error focused on how well networks of rain gages were capable of estimating the actual total rainfall, first using synthetic data (Wei and Larson, 1971; Troutman, 1983; Watts and Calver, 1991) and then real data (Krajewski *et al.*, 1991; Ogden and Julien, 1993, 1994; Shah *et al.*, 1996a). Such studies commonly assume that the highest resolution data available are approximately representative of the real pattern of precipitation behavior. The use of radar rainfall estimates has now become increasingly common and has been tested either individually or in combination with gauged data (e.g. Smith *et al.*, 1996; Moore and Hall, 2000; Morin *et al.*, 2001; Carpenter *et al.*, 2001). Also under investigation is the use of satellite-based remotely sensed information for deriving precipitation estimates (Hsu *et al.*, 1997; Sorooshian *et al.*, 1993, 2000), which has the potential of providing global estimates of precipitation. Satellite-based precipitation estimates enable some knowledge of rainfall over the relatively extensive ungaged portions of the world (including locations that are difficult to access or are blocked from radar coverage owing to topography), and are particularly useful for large (regional and continental) scale hydrologic studies. Both radar and satellite estimates of rainfall, however, are dependent on interpretative models of the recorded signals that also have parameters subject to calibration. It is also important to consider that errors in the precipitation data will also introduce a bias on the parameter estimates that in turn impacts the model predictions (e.g. Troutman, 1983; Andréassian *et al.*, 2001; Kavetski *et al.*, 2003).

The results of the above mentioned studies suggest that the importance of capturing the spatial variability of rainfall depends significantly on whether the catchments are infiltration- or saturation-excess dominated (e.g. Ogden and Julien, 1994; Koren *et al.*, 1999). Spatial variability of rainfall seems to be of particular importance for infiltration-excess dominated catchments. In such catchments, the location of runoff production typically shows a stronger correlation with the location of high rainfall intensity (Michaud and Sorooshian, 1994; Winchell *et al.*, 1998). On the other hand, other factors such as the topography of the catchment can have a stronger influence on the location of runoff production in saturation-excess dominated catchments. The spatial distribution of rainfall can also be of higher importance in cases where the catchment is dry (Shah *et al.*, 1996b). Smith *et al.* (1993) suggest that results related to the importance of estimating precipitation variability should be treated with some degree of caution at this early stage of research, and that it needs to be demonstrated that the sensitivity of the models used in the aforementioned studies is actually representative of the sensitivity of the real catchments.

DISCUSSION AND CONCLUSIONS

This article began with the premise that all rainfall-runoff models are (at some level) lumped and conceptual representations of a real-world system. The main consequences of this premise are that the model structure is defined, prior to any modeling being undertaken, by the modeler's understanding of the natural system, and that estimates of the model parameters must be provided. Such parameter estimates are typically derived through a process of model calibration using observed system behavior. Three necessary conditions for a rainfall-runoff model to be considered as being properly calibrated are that: (i) the input-state-output behavior of the model is consistent with the measurements of catchment behavior, (ii) the model predictions are accurate (i.e. they have negligible bias) and precise (i.e. the prediction uncertainty is relatively small), and (iii) the model structure and behavior are consistent with the hydrologists understanding of reality. With respect to all three aspects, problems have been encountered that are still not satisfactorily solved to this day. Regarding the first point, it has been found that different parameter sets are required to simulate different behaviors of the natural system. This is usually taken to be an indication of model structural problems. Multiobjective approaches can be used to consider this problem, and recursive methods can be applied to more objectively track parameter variation in time. At this time, however, structured approaches to improve model representations are only available for certain simple types of models (e.g. linear). With respect to the second aspect, it is often found that the estimate of prediction uncertainty is relatively large and depends on the type of approach chosen to analyze it. To be blunt, there is currently no unifying framework that properly addresses uncertainty in hydrological modeling. Statistical approaches (such as SCEM and BaRE) require assumptions that are often difficult to justify; alternative approaches (such as GLUE and DYNIA) require subjective decisions about model evaluations that can also be difficult to justify. And finally, the issue of the realism of hydrologic models in current practice is receiving increasing attention. Many modeling approaches

have been based on the powerful mathematics of regression and systems theory with insufficient consideration for the conceptual nature of the model structure and parameters. Recent developments suggest that proper consideration of this issue is required if successful prediction of ungauged catchments or those undergoing land-use changes is to be achieved (Beven, 2002, 2005).

We remain confident, of course, that other strategies to understanding and dealing with the various sources of error, including those arising from model structural deficiencies, will emerge as increasing numbers of intelligent and energetic minds are brought to bear on the problem. If nothing else, history teaches us that the progress of science is inexorable, and that today's "truths" are all too often tomorrow's "mistakes"! However, the nature of hydrological systems is such that even if new measurement techniques become available in the future, uncertainty in hydrological prediction will not be eliminated. Thus, hydrology as science must learn to be realistic about the uncertainties that arise in the modeling process.

Acknowledgments

Partial support for the first and third authors was provided by SAHRA under NSF-STC grant EAR-9876800, and the National Weather Service Office of Hydrology under grant number NOAA/NA06WH0144. The third author also received support from the German Academic Exchange Service (DAAD) under the auspices of its postdoctoral fellowship program. We thank Mary Black for her editing work. We also greatly appreciate the constructive criticism provided by George Kuczera, which resulted in considerable improvements to the manuscript.

SOFTWARE LINKS TEXTBOX

Hydrologic software, including many of the above-described algorithms (including SCE-UA, SCEM-UA, BaRE, etc.), is available for noncommercial use at **`http://www.sahra.arizona.edu/software.html`** (Wagener *et al.*, 2004). Demonstration GLUE software can be downloaded from **`http://www.es.lancs.ac.uk/glue.html`**. The Monte Carlo Analysis Toolbox (MCAT) is a compilation of several techniques to analyze the parameter and output space including the corresponding uncertainties. Any dynamic mathematical model can be analyzed for which a Monte Carlo sampling or a population evolution procedure can be run. The Toolbox includes the DYNIA methodology, elements of the GLUE procedure and multiobjective plots as explained later. Copies of the MCAT can be obtained from **`http://ewre-www.cv.ic.ac.uk/software.`** Other popular optimization packages, not explicitly mentioned in the text, are NLFIT (developed by George Kuczera, **`http://www.eng.newcastle.edu.au/~cegak/`**) and PEST (developed by John Doherty, **`http://www.sspa.com/pest/`**).

132: Rainfall-runoff Modeling for Assessing Impacts of Climate and Land Use Change

AXEL BRONSTERT

Institute for Geoecology, University of Potsdam, Potsdam, Germany

Rainfall-runoff models are frequently used as a tool to assess the impacts of climate and land-use changes on the hydrological cycle. This requires that the applied rainfall-runoff model is able to represent the dynamics of the hydrological cycle of the catchment under study, in particular, if land-use change is of concern, that is, the effects of land-use or land-cover change on the runoff generating processes. This may be accomplished by applying either a process-based model or a conceptual model if the latter's parameters can be regionalized with respect to land-use change. Furthermore, the chosen model must be able to "represent" the influence of different climatic/ meteorological boundary conditions. This implies, of course, that we know the main dynamics of the catchment under consideration.

INTRODUCTION

From the viewpoint of systems-theory, the meteorological conditions and the physiographic characteristics of a landscape are the boundary conditions of the hydrological dynamics of a catchment. For example, rainfall or snowmelt rates serve as the meteorological "Input" into this system and the landscape properties (such as vegetation cover, land-use practice, soil properties, basin and river morphology, and the geological setting) significantly control the relative importance of the different processes of the hydrological cycle. The impacts of any changes in these boundary conditions on the hydrological cycle have been of concern ever since the relationships between external forces (boundary conditions) and the internal dynamics (subprocesses and their interactions) of the hydrological cycle have been known. In this Section, the term "environmental change" is used to summarize changes in climatological and land-use conditions. There are other changes to the boundary conditions which could be included in the term "environmental change", for example, river training measures (see Part 12: Open-channel Flow), water retention in reservoirs, or groundwater use (see Part 13: Groundwater), but those are not discussed in this section. There are specific chapters on land use and climate change in this encyclopedia, for example, Part 16 deals with the topic of land use and water management and Part 17 with the topic of climate change. The reader is therefore referred to these articles for a wide and general discussion of land use and climate change impacts on the water cycle.

The focus of this section is on the possible use of rainfall-runoff models for assessing the impacts of the mentioned environmental changes. Therefore, first a summary of the main issues of climate and land-use change relevant for rainfall-runoff modeling is given. Then, the basic model requirements for modeling the environmental changes, related uncertainties, and possible feedback effects between climate and land use are discussed. This article ends with presentation of a few case studies. There is no attempt to give a comprehensive overview of case studies on this subject nor to list all rainfall-runoff models which have been applied until now for such purposes. Lists of this kind will inevitably be incomplete and pretty soon outdated. It is more important to understand the main model requirements as well as the limitations of such model applications.

THE MAIN ISSUES OF CLIMATE CHANGE FOR RAINFALL-RUNOFF MODELING

What is anthropogenic climate change?

The climate system of our planet is composed of different subsystems, such as the atmosphere, biosphere, cryosphere,

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

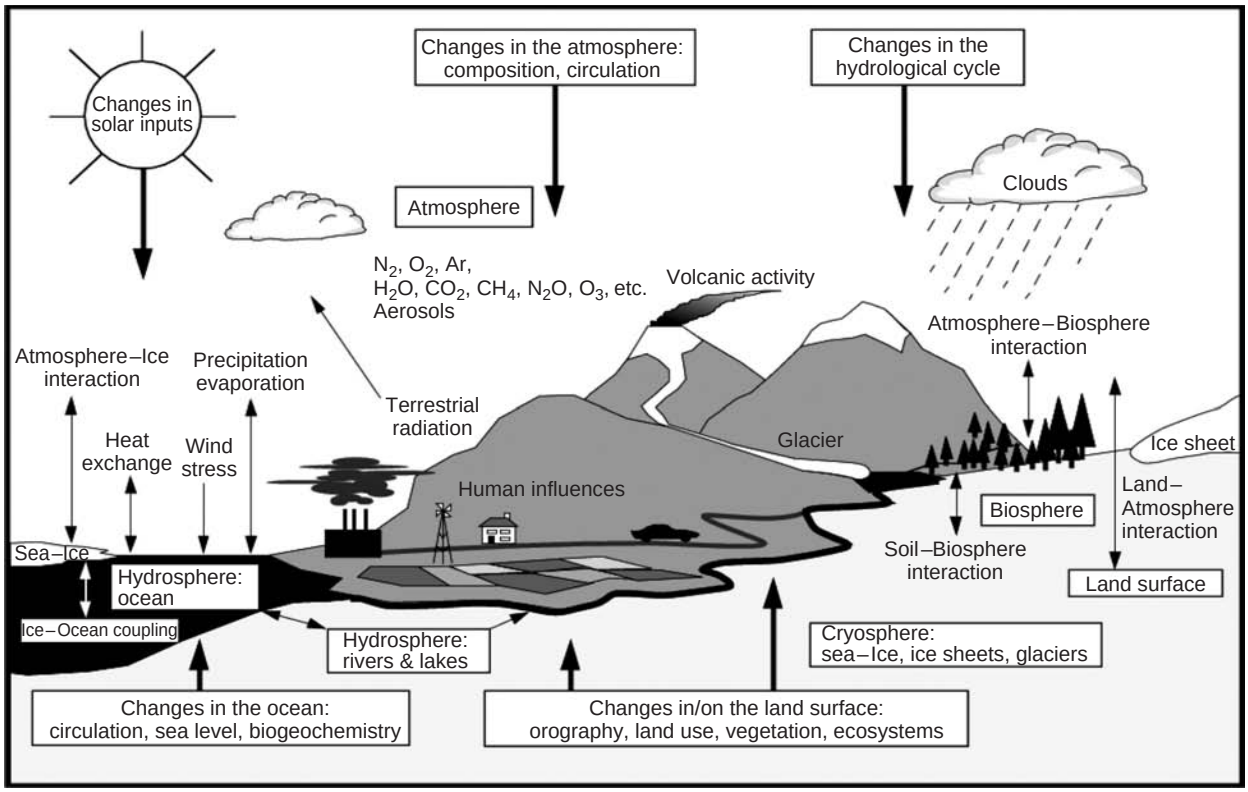

Figure 1 The components of climate system and global change influences (Reproduced by permission of Intergovernmental Panel on Climate Change (IPCC), 2001)

and the terrestrial and maritime hydrosphere. The hydrosphere is one of the most important subsystems, because the hydrological cycle links the energy and water fluxes between the atmosphere, biosphere, and pedosphere (see Figure 1). The climate system was always dynamic, that is, there have always been changes in some of its subsystems or in levels of solar forcing, due to long-term changes of the orbital parameters or the varying activity of the sun. These alterations have caused significant changes in the past in the radiation budget of the atmosphere and the Earth's surface. The changes within the climate system are associated with different scales in space and, more importantly, in time. More details on the climatological timescales can be found in Part 17: Climate Change.

Since the start of industrialization of our Earth (i.e. for about the last 150 years), the use of fossil energy has created a new (additional) source of carbon dioxide (CO_2) emission from the Earth into the atmosphere. Though these emissions are small compared to the natural emissions (mainly from the biosphere), they disturbed the carbon balance of the atmosphere, that is, the CO_2 concentration of the lower atmosphere has increased from a rather stable preindustrial level of 280 ppm to a present level of 360 ppm. Besides CO_2, the concentration of other "greenhouse gases" has increased through human activities. The most important of these increases are for methane (CH_4) which rose from a preindustrial value of 0.7 ppm to a present value of 1.74 ppm, and nitrogen oxide (N_2O), which rose from a preindustrial value of 275 ppb to a present value of 313 ppb. Carbon dioxide and the other "greenhouse gases" affect the atmospheric absorption properties of long-wave radiation, thereby changing the radiation balance. See Part 17: Climate Change for more details on emissions, concentrations, and physical effects off greenhouse gases.

One very important feature of this anthropogenic climate change, compared to natural alterations of the climate system, is the speed of these changes. Never before has the Earth's atmosphere experienced such a rate of change in its chemical composition.

What effects have been observed in recent decades?

Over approximately the last 50 years, a global temperature rise of about 0.6 °C has been observed. Different measurement techniques and data have been used as a basis for this analysis (see IPCC, 2001). The second technical report of the Intergovernmental Panel on Climate Change (IPCC) (IPCC, 1996) concluded, *inter alia*, that the mean summer temperatures in the Northern Hemisphere in the last decade have been the highest experienced since the beginning of

the fifteenth century. On the basis of a wide array of proxy sources (such as ice cores, tree rings, corals, and lake sediments) it has been concluded that the twentieth century was at least as warm as or even warmer than any century of the last millennium. Accordingly, for some places on the earth (especially for high mountain regions), the twentieth century seems to have been the warmest century in several thousand years. Such a trend of temperature increase, as well as an accumulation of warmer years, was not only observed on a global basis, but also in many individual regions of the earth. Higher temperatures are a very important change of the meteorological "input" into rainfall-runoff models. The main point is that higher temperatures will increase calculated evapotranspiration rates, which might cause reduced soil water contents and stronger or earlier water deficit in the root zone. Statistically significant changes of air humidity due to higher temperature (caused by anthropogenic climate change) have not (yet) been monitored. This is the reason why specific air humidity is usually considered unchanged in such modeling studies. Temperature increase can also influence the phenology and composition succession of ecosystems. Such issues are briefly discussed in Section "Interactions of climate change with land-cover conditions".

Regional and long-term observations accompanied by spatial-temporal statistical analysis of precipitation have been carried out in various parts of the globe. Some of them have shown significant trends in precipitation. However, it is very important to realize that differing precipitation trends affect different regions, that is, in some regions there is a notable increase, in some regions there is a decrease, and in other regions no trend has been observed. An example is given in the following text for the Rhine catchment. Measurements over the last 110 years demonstrate an increase in mean precipitation, on a regional scale, in parts of Germany and neighboring areas. According to Engel (1997) the annual precipitation over the Rhine area extending to Cologne has, since 1890, shown a rising overall tendency (increase of ca. 80 mm between 1890 and 1996) with distinctive periodic fluctuations (Figure 2). Apart from the increased amounts of annual precipitation, Engel (1997) also shows a tendency towards a seasonal shift from summer to winter. Combining these trends over the last 100 years, there has been a fairly constant summer precipitation (June–October) and a significant increase in winter precipitation by almost 20% (November–May). The statistical analysis of precipitation trends in Europe between 1891 and 1990 by Rapp and Schönwiese (1996) shows a significant increase in winter precipitation in central and northern Europe and a decrease in southern and southeastern Europe. These results are consistent with the rainfall trends observed in the Rhine basin, which is located in central Europe.

A rather elegant synoptic approach to detect possible regional climatic changes is to analyze the statistics of regional climatic conditions, the so-called *atmospheric circulation patterns* (ACPs), rather than to analyze the different climatic variables independently (Conway and Jones, 1998). For example, Bárdossy and Caspary (1990) and Gerstengarbe *et al.* (2000) have examined the frequency of different types of climate conditions in Europe since 1891 by means of time series derived from daily weather maps. Both studies found a significant increase in the frequency of westerly weather conditions over western Europe, the statistical break point of the time series occurring in the mid-1970s. Because of the lack of earlier weather maps and records, however, it is hardly possible to state to what extent the observed trend (over the past ~120 years) might be explained by longer-term, natural fluctuations.

As an example, the time series of westerly weather conditions and complementary types of weather conditions over western Europe for the months of December and January are shown in Figure 3. The increase of westerly zonal conditions is evident. Since these weather conditions can be considered typical of long-term, large-scale precipitation patterns in western-central Europe, for some catchment areas a correlation has been established between the increase of occurrence of these ACPs and an altered rainfall-runoff behavior of mesoscale catchments. Investigations at many other weather stations in central Europe have confirmed the relationship between westerly/southwesterly weather conditions and heavy precipitation over parts of Europe such as eastern France, Belgium, southwestern Germany, and the western Alps (Bárdossy, 1993).

A similar methodology was applied in a recent study for central Europe by Fricke and Kaminski (2002), who analyzed the ACP frequency of occurrence relevant for heavy summer rainfall over the Danube basin since 1882. They found, for example, for the summer months of June–August, a significant occurrence increase over the past five decades of the ACP "TrM", characterizing atmospheric lows from the Mediterranean to central Europe. This was shown to be associated with an approximate doubling of the probability for heavy and high intensity summer rainfall over the Danube basin.

What development of climatic variables has been projected for the future?

The most relevant climatic variables for rainfall-runoff calculations are precipitation, temperature, air humidity, radiation, and wind velocity, where precipitation and – when snow is melting – temperature are directly relevant for runoff generation at short timescales ("event scale"), and temperature, air humidity, wind velocity, and radiation are relevant for evapotranspiration processes at longer timescales, thus, for example, influencing subsurface runoff and catchment water content preceding a rainfall event.

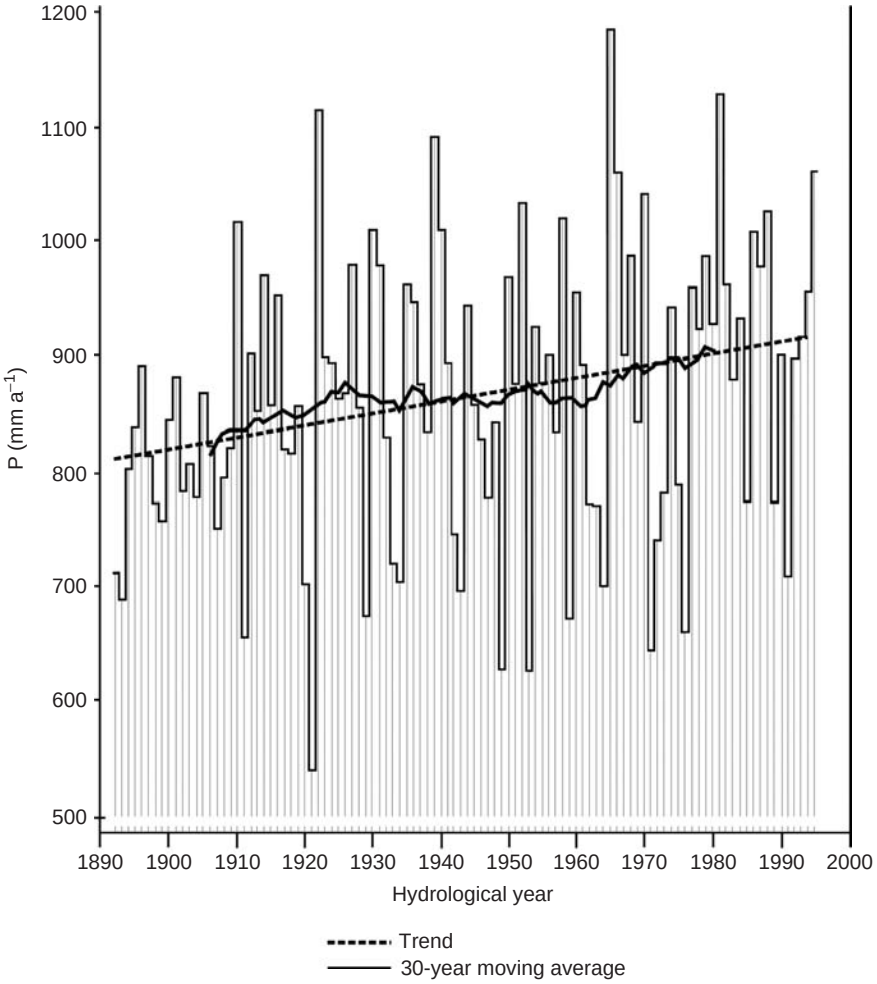

Figure 2 Annual precipitation over the Rhine basin upstream Köln, 1880–1996 (Reproduced from Engel, 1997, Verlag C.F. Müller, Heidelberg)

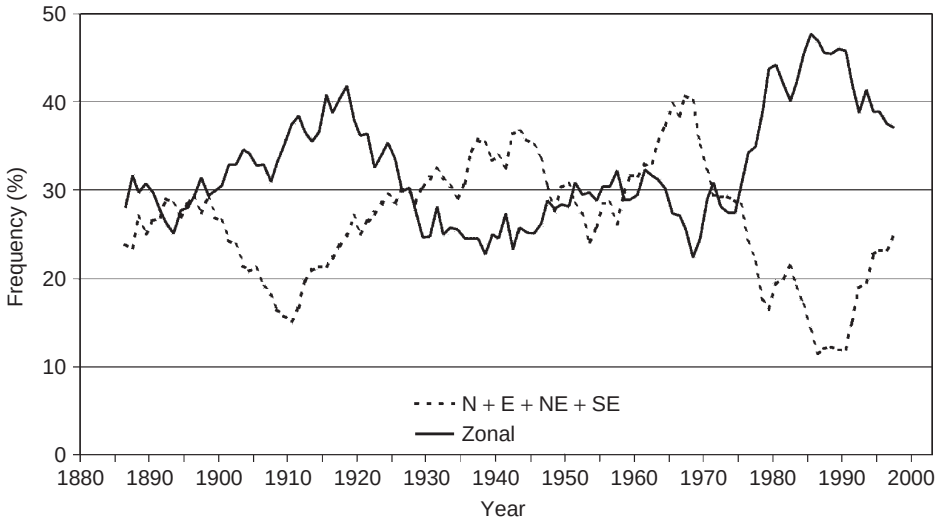

Figure 3 Frequencies of westerly (zonal) weather type and types, north, east, northeast, and southeast (N + E + NE + SE) for December and January from 1881 to 2002 (Bárdossy, personal communication)

The present status of climate change research allows some rather clear statements to be made on the projected global development of radiation and temperature and only a rather vague statement on precipitation, but there is no reliable information on the possible alterations of wind speed and air humidity.

The starting point for an analysis of the development of the global radiation balance is based on scenarios for the emission of greenhouse gases (see Part 17: Climate Change). The third assessment report of the IPCC (IPCC, 2001) lists a range of such scenarios, where the range of emissions varies significantly, depending on the underlying assumptions concerning economic growth, industrial development, and emissions control. On the basis of such emission scenarios it is possible to derive scenarios for the future greenhouse concentration in the atmosphere.

The concentration of greenhouse gases has a direct effect on the atmospheric absorption properties of long-wave (earth) radiation R_{lw}. Shortwave (solar) radiation R_{sw} is almost uninfluenced by these concentrations. Thus, atmospheric absorption of long-wave radiation emitted from the earth increases, resulting in a warming of the lower atmosphere. This yields a reduced long-wave radiation balance at the earth's surface $R_{lw,net}$. For instance, a doubling of the CO_2 concentration is assumed to result in an average reduction of the global long-wave radiation balance ΔR_{lw} of about $3\,W\,m^{-2}$.

According to the projected changes in radiative forcing, a global temperature increase in the range of 1° to 5 °C is to be expected, depending mainly on the emission scenarios; see Figure 4 from IPCC (2001), showing also the range of uncertainty of these projections. IPCC, 2001 also points out that higher latitudes and land surfaces will have to cope with a much higher temperature increase than lower latitudes and sea surfaces. The conclusions are, to some extent, subject to uncertainties, for example, in the prediction of cloud cover and its effects on the global albedo and long-wave radiation.

Predictions of the development of global precipitation are more uncertain than those for temperature. From the viewpoint of global atmospheric energy, one can conclude that an increase of global atmospheric temperature of, say, 3 °C would yield an intensification of the hydrological cycle by about 10%, that is, 10% higher global evaporation and precipitation rates. This is a result of the reduction of net long-wave radiation and an expected decrease of the globally averaged Bowen–Ratio value (see Bronstert *et al.*, 2002 for more details).

The projections of the development of regional precipitation (derived directly from GCM results) are even more uncertain. This is demonstrated by the fact that the results from the different global atmosphere-ocean circulation models (GCMs) show great differences in projected regional precipitation values, and GCMs can rarely reflect the regional precipitation pattern (either spatially or seasonally) for the current, observed climate. Hence, the level of confidence in regional precipitation projections derived directly from GCMs is still rather low. In any case, an assessment of possible changes of rainfall-runoff characteristics resulting from climate change requires reliable

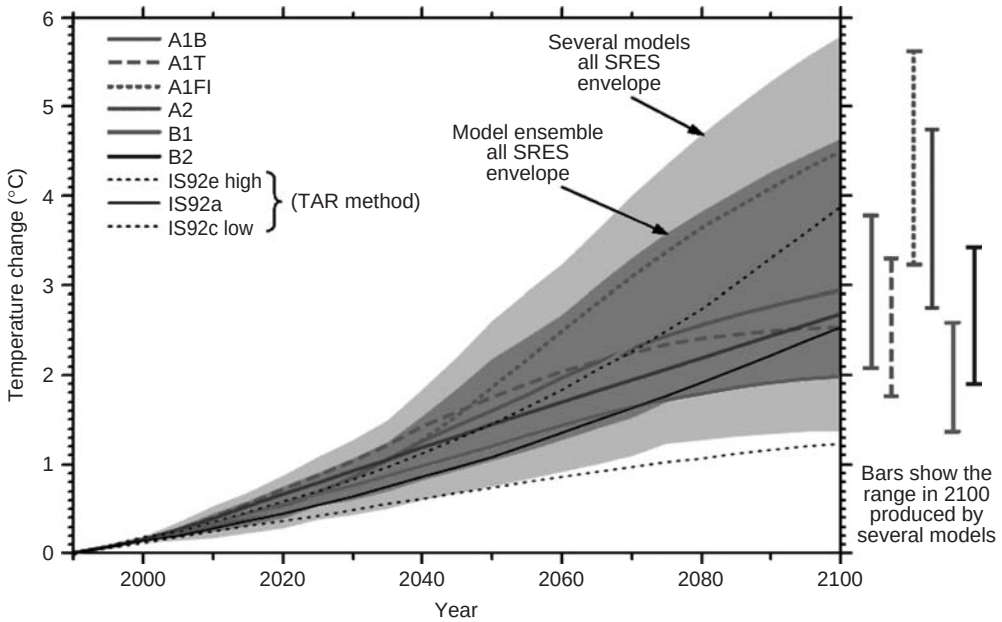

Figure 4 Projections of future development of the global temperature (Reproduced by permission of Intergovernmental Panel on Climate Change (IPCC), 2001). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Table 1 Overview of present knowledge on the projected development of climate variables relevant for rainfall-runoff events. The uncertainty is classified as *very certain, relatively certain, rather uncertain,* and *very uncertain*

Climate variable	Relevance for rainfall runoff	Projected changes due to increase of atmospheric greenhouse gases	Associated uncertainty
Shortwave (solar) radiation balance	Small to moderate	None	Relatively certain
Long-wave (earth) radiation balance	Small to moderate	$-3\,W\,m^{-2}$ (for $2\times CO_2$)	Relatively certain
Air temperature	Moderate	1°–5°	Relatively certain
Precipitation	High	+10% (globally, for $2\times CO_2$)	Globally rather uncertain; regional values very uncertain
Air humidity	Moderate		Very uncertain
Wind speed	Moderate		Very uncertain

information on much smaller scales than the global or continental scale. This is why climate downscaling techniques are an essential tool for climate impact assessment (see Section "Requirements for modeling environmental change impacts on rainfall-runoff events"). Table 1 summarizes present knowledge of the projected development of climate variables relevant for rainfall-runoff events.

Table 1 gives some estimates on the projected changes of climate variables. However, it is important to mention that these numbers are associated with considerable uncertainty and must not be routinely applied in rainfall-runoff modeling for climate impact assessment. Why?

- These numbers show globally averaged values. This scale is not the appropriate one for rainfall-runoff simulations. The regional differences of projected changes of these climate variables are very great and cannot be generalized.
- Furthermore, these numbers show only average values in time. They do not give any information on the extremes (or "anomalies"). The extreme values, however, are of high relevance for rainfall-runoff simulations as the average values.
- The most important variable for rainfall-runoff simulation is precipitation, in particular, precipitation extremes for flood calculations. The associated uncertainty of the statements, however, is especially high for precipitation and highest for extreme values. Even for the simulation of drought events, changes of average (and extreme) precipitation numbers are highly relevant.

THE MAIN ISSUES OF LAND-USE CHANGE FOR RAINFALL-RUNOFF MODELING

Definitions: Land Use, Land Cover, Land Management, River Training

- Land use: According to Mücher *et al.*, (1993), land use can be defined as the human activities that are directly related to land, making use of its resources or having impact on it through interference in ecological processes that determine the functioning of land cover. A very similar definition is given by FAO (1997) and UNEP (1999), who explain land use as "the total of arrangements, activities, and inputs that people undertake in a certain land-cover type".
- Land cover: This term corresponds to a (bio)physical description of the Earth's surface. It is that which overlays or currently covers the ground. This description enables various fundamental biophysical categories to be distinguished, basically areas of vegetation (trees, bushes, fields, lawns), bare soil, hard surfaces (rocks, buildings), and wet areas and bodies of water, for example, watercourses or wetlands (EEA, 2002).
- Land management: This term is directly related to human activities to manage the land's resources. It is influenced by economic, social, environmental, ethical, technological, and other perspectives. This definition sounds similar to the land-use definition given above; however, the various mentioned perspectives may yield categories of land management which have a nonphysical meaning (e.g. "commercial" or "subsistence" land management).
- River training: Human interference with river stretch by means of various river construction measures are summarized by the expression river training. This term is related to the state (including engineering measures) of a river and the corresponding floodplains, that is, it refers only to the river course system and does not include information about the surrounding catchment area. However, river training might be of high importance for the features of rainfall-runoff events.

These definitions are not easily transferable to rainfall-runoff studies. Hence it is proposed to use the following definitions:

- Land use refers to different classes of human activities that are directly related to land (e.g. forest, urban areas,

arable land, meadows). More detailed classifications are possible, for example, distinguishing arable land with/without field drainage or intensively/extensively grazed meadows and so on.
- Land cover refers to the biological and biophysical features of the vegetation covering the land. In this respect, the seasonal dynamics of vegetation or cycles of crop cultivation are of major importance.
- Land management refers to different perspectives, such as economic, social, or technological. There is not always an unambiguous relationship between land management and land use or land cover.
- River training refers to the state of the river and the corresponding floodplains.

With these definitions in mind, it is rather clear that "land use" and "land cover" are of major relevance for rainfall-runoff processes (mainly for runoff-generation processes), river training measures are relevant for the runoff behavior of the river, and land management itself is a less relevant issue in this context.

What is the magnitude of observed land-use change?

The regions of the Earth that are characterized by intense human activity on land resources are almost unavoidably confronted with significant changes of land use. This effect has been proven throughout the entire history of mankind. However, since the era of industrialization and rapid growth of population, land-use change phenomena have accelerated in many regions. Some examples are:

- During the past 50 years, Austria – like almost every other region in Europe – has undergone profound changes in its agriculture, resulting in a reduction of arable land by 14% and an increase of meadows by 24% (Krausmann *et al.*, 2003).
- Between 1938 and 1988, the southwestern German State of Baden-Württemberg underwent a very similar transition: in 1938 58.3% of the land surface was used for agriculture, while 50 years later this figure was only 47.5%. During the same period, urban land use increased from 5.3% to 11.8%.
- Many regions have seen a transition from an agriculturally oriented society to a society dominated by industry. This resulted in an immense increase in urban area. The Ruhr area in Germany, for example, is nowadays one of the most industrialized and most densely populated areas of Europe. The urban area spread over the last century from 6.9% in 1883, to 14% in 1927, to 40% in 1997 (Dosch and Beckmann, 1999).
- Another heavily debated land-use change phenomenon is that of deforestation of tropical forest. For example, DeFries and Achard (2002) reports for the last decade of the twentieth century a deforestation rate of 1.2 million km^2 $year^{-1}$ (0.52×10^6 km^2 in Africa, 0.44×10^6 km^2 in Latin America, and 0.24×10^6 km^2 in Southeast Asia).

Land-use change relevance at what scale and for what climatic conditions?

Part 10: Rainfall-runoff Processes have comprehensively described the different runoff-generation mechanisms and the influence of land-use and land-cover conditions on these. One very important first question for modeling the impact of land-use change on rainfall-runoff processes is the relevance of surface versus subsurface runoff-generation processes in the area under investigation. If the surface runoff processes play an important or even dominant role for rainfall-runoff events, changes on the ground surface may significantly alter those runoff processes. If, however, rainfall-runoff events are characterized mainly by subsurface processes, land-use changes may be of minor importance. This means that for modeling land-use change impacts, it is important that the model represents the main relevant runoff-generation processes, in particular, surface runoff-generation processes.

A second important question is the relevance of surface conditions for the mechanisms by which water produced or triggered by rainfall or snowmelt can travel to a stream ("runoff concentration processes"). These mechanisms (see Part 10: Rainfall-runoff Processes for their explanation) are influenced by the topographic, pedologic–geologic, and vegetational conditions in which they occur. For different climate conditions, different mechanisms of runoff generation and runoff concentration may dominate the rainfall-runoff process. The higher the infiltration-excess overland flow, the greater the importance of ground surface conditions, and therefore the greater the importance of changes to the ground conditions. Infiltration excess is relevant for high intensity rainfall events and/or low conductive soil surfaces. Such conditions are of particular importance (i) in the case of convective rainstorms and (ii) for sealed, crusted, and nonmacroporous soil surfaces. The latter conditions might be exacerbated by removal of vegetation cover. Note that the combination of both conditions is present in many tropical and subtropical regions, while removal of vegetation and the creation of roads and other low permeability surface (e.g. associated with forest logging) is a side effect of land-use change phenomena in the same regions.

In any given catchment, the relative importance of some or all mechanisms of runoff generation and runoff concentration may vary seasonally or even during an individual rainfall-runoff event. Thus the relative importance of land-use changes may vary, too.

As mentioned before, changes in land use and land cover, land management, and river training measures can influence mechanisms of runoff generation, runoff concentration, and

Table 2 Potential impact of land-use changes on surface and near-surface hydrological processes (fluxes or storages) and relevance for runoff components of the hydrological cycle

Process	Potential impact of land-use changes and relevance for components of the hydrological cycle
Interception storage	Greatly affected by vegetation changes (e.g. crop harvest, forest cutting): relevant for evapotranspiration/energy balance
Litter storage	Affected by vegetation changes, in particular, forest cutting: relevant for evapotranspiration/energy balance
Root zone storage	Affected by management practices like tilling method and so on: relevant for evapotranspiration and storm-runoff generation
Infiltration-excess overland flow	Affected by crop cultivation and management practices: relevant for storm-runoff generation in case of high rainfall intensities and low soil conductivity; may be enhanced by soil siltation and crusting and reduced by field drainage and good tillage management
Saturation-excess overland flow	Only slightly affected by land-use changes (process is controlled by topography and subsurface conditions)
Subsurface stormflow	Can be increased by artificial drainage systems, for example, mole or tile drains. Otherwise, subsurface stormflow is only slightly affected by land-use changes (process is controlled by topography and subsurface conditions)
Runoff from urbanized areas	Highly affected by sewer system and sewage retention measures: relevant for storm runoff *from urban areas*
Decentralized retention in the landscape	Affected by landscape structuring and agricultural rationalization of arable land: relevant for storm-runoff concentration *from arable land*

river discharge conditions at different space and timescales. It is evident that a rainfall-runoff event at the catchment scale is a composite of all such mechanisms. Hence, modeling land-use change impacts on such events requires models where the relevant mechanisms are represented by the model. In the following text, the focus is on modeling the impacts on runoff generation and runoff concentration, whereas the impact of river training on discharge conditions is dealt with in Part 12: Open-channel Flow.

As explained before, the influence of land-use practices on runoff generation is most important to the surface or near-surface zones of the soil at least under "normal" conditions; that is, subsurface land uses like mining or underground constructions are not part of these considerations. This means that it is the surface or near-surface fluxes and storages which are mainly affected by land-use changes. This leads to a list of the potential impacts of land-use changes on hydrological fluxes and storages (Table 2).

From Table 2, it is clear that only certain flux and storage processes are *both* affected by land-use changes *and* are primarily relevant for rainfall-runoff events, namely, root zone storage, infiltration-excess overland flow, runoff from urbanized areas, and decentralized retention in the landscape. Artificial drainage of farm land increases subsurface flow velocity but may also increase the storage capacity of the upper soil, which results in a delay or decrease of subsurface storm flow that is, an evaluation of drainage impacts needs to account for both aspects. In any case, an evaluation of land-use change impacts requires identification of the relevant storm-runoff generation mechanisms for the specific *catchment characteristics* and *precipitation conditions*. For different categories of rainstorms (e.g. convective or advective rainstorms), different runoff-generation processes can be relevant and contribute in varying proportions to total runoff. This requires that the modeling of storm-runoff generation has to be both catchment-specific and event-specific. Furthermore, the interactions between precipitation conditions and soil-surface conditions (e.g. soil sealing due to high rainfall intensity) might have to be taken into account.

REQUIREMENTS FOR MODELING ENVIRONMENTAL CHANGE IMPACTS ON RAINFALL-RUNOFF EVENTS

Modeling Climate Change Impacts

Modeling climate change impacts on rainfall-runoff events directly implies that an altered climatic forcing is applied to the rainfall-runoff model. In most climate change impact studies, the mechanisms of the hydrological model remain unchanged, that is, the parameterization of land cover and the algorithms of the hydrological processes remain unchanged. This means that most climate change studies are still based on the assumption that an altered climate system will encounter unmodified land cover and ground surface conditions. Section "Interactions of climate change with land-cover conditions" discusses some examples of effects of climate change on land-cover conditions, that is, for such studies a changed climate forcing *and* changed land-cover parameters have to be applied jointly.

The most important constraint when applying climate change scenarios for hydrological climate change impact analysis is the difference in the spatial scales typical for

climate models and rainfall-runoff models. This means that the best currently available information of future climatic developments, given at a global scale, has to be transformed for use in catchment-scale rainfall-runoff models. This procedure is termed *climate downscaling*.

The most powerful climate models today are coupled GCMs, which carry out three-dimensional calculations of the equations for mass and energy transport, impulse, humidity of the atmosphere, and salt content (of the ocean) for the entire globe. An assessment of possible changes of rainfall-runoff characteristics resulting from climate change requires much smaller scales than the global or continental scale. The following information is required:

- A realistic description of changes in precipitation. This includes both changes of the average value and of the anomalies in space and time. Scenarios that only give changes in the average value are hardly sufficient for an impact analysis, in particular, for flooding conditions;
- A realistic description of changes in temperature. This is particularly important for catchments where rainfall runoff can be composed of *both* rainfall and snowmelt events, which is the case, for example, in many mountainous or high latitude catchments. Besides, temperature may significantly influence evapotranspiration, thereby altering soil water content and long-term characteristics of base flow and low flow periods;
- Information about the uncertainty associated with the climate scenarios. This may form the basis for a thorough uncertainty analysis of the coupled simulations of climate and flood hydrology.

A variety of techniques have been developed to derive climate change scenarios for the catchment scale (or "regional scale" in meteorological terms) required for modeling the hydrological, basin-wide impacts of climate change. The most important of these are regional climate models (or "dynamic downscaling") and "statistical downscaling" methods. In the following paragraph, these methods are summarized, while a more in-depth discussion is given in Part 17: Climate Change.

Regional climate models (RCMs) have been applied for some time. In contrast to general circulation models, they cover only a section of the globe, which can be modeled at a finer spatial resolution. At present, the grid widths used for regional climate models are approximately 50 km or less. In comparison to a GCM resolution, the spatial resolution of an RCM is definitely more adequate for the estimation of runoff-relevant precipitation, particularly with regard to weather conditions connected with large-scale precipitation fields. However, to obtain accurate information on the location, quantity, and intensity of precipitation and on changes in precipitation characteristics caused by climate change, the models are still not sufficiently spatially detailed or accurate for the following reasons (see, e.g. Xu, 1999):

- The boundary conditions of the regional model are obtained from the GCM, and therefore frequently contain a systematic error of atmospheric dynamics, which is transferred to the respective region. Errors in the GCM thus directly limit the capacity of the regional climate model.
- The parameterization of important processes in the RCM, such as the formation of clouds, soil water dynamics, or land-surface interactions, has not yet been resolved in a way that allows for a definition of the natural variability under any weather condition or for the recognition of a possible signal of climate change.
- The resolution of the RCMs is sufficiently detailed to represent large-scale precipitation patterns. However, these resolutions are not sufficient to cover small-scale precipitation, such as convective thunderstorms of local orographic rainfall. Though processes taking place at a smaller scale than represented by the grid box ("subgrid-scale processes") can be parameterized by the subdivision of the grid boxes into a clouded and a cloud-free section, several convective systems cannot be localized within a grid square.
- Regional climate models have not yet been sufficiently tested with regard to how realistically they represent rainfall-runoff events caused by storm rainfall.

Statistical downscaling bridges the two different scales by establishing empirical (statistical) relationships between large-scale features simulated reliably by the GCMs (such as geopotential height fields) and regional or local climate variables (such as temperature and precipitation at a certain location). While dynamic downscaling utilizes physical principles only, the empirical approach is anchored in the observed fact that weather phenomena are often caused by the conditions of the prevailing large-scale atmospheric circulation. The method of GCM downscaling, in its various forms, has by now been well established as an appropriate and necessary tool for impact assessment studies, and the reader is referred for more information to the review article of Wilby & Wigley (1997). Statistical downscaling techniques have been applied in a series of studies (for an overview, see, e.g. Wilby *et al.*, 1999).

There are two main categories of empirical downscaling: deterministic, regression-type methods and weather-type techniques that include stochastic weather generators. Because of the limited correlation between daily circulation and local precipitation, the simulated variability of regression models (including neural networks) is too low, and extreme events cannot be modeled at all (Weichert and Bürger, 1998). Weather-pattern models utilize a finite set of specific circulation patterns, which tend to persist for a certain period of time. Within such a regime, daily precipitation is modeled stochastically using some form of weather generator with regime-dependent parameters. This technique has been successfully applied in a number of studies

(see, e.g., Bárdossy and Plate, 1992; Bárdossy, 1997; Conway and Jones, 1998). Note, however, that the problem of pattern classification introduces subjective elements and the method implicitly assumes that climatic change will not introduce any new weather patterns. *Expanded downscaling* (EDS, Bürger, 1996) is a method midway between the deterministic regression-type models and the stochastic models conditioned on weather types. EDS results from relaxing the unconditional error minimization of regression to allow for the preservation of local variability as a side condition.

As mentioned before, most studies of climate change impacts on hydrology are performed on the basis of the same algorithms for hydrological processes and unmodified land-cover parameterization (see Figure 5). This means that such studies prescribe the altered climate conditions to the same hydrological model and the same land-cover parameterization. This assumption is reasonable as long as the altered climate does not cause significant changes in land-surface conditions (such as a different vegetation cover) or important changes in the dominance of hydrological processes (for example, significant changes of rainfall intensity may change the relevance of infiltration-excess surface runoff). The question of whether the feedback effects between climate, the hydrological conditions of the catchment, and the land cover have to be taken into account is very much related to the timescale of the study (Bronstert *et al.*, 2005). For example, if the study covers short to medium timescales (rainfall-runoff events or event series of a duration, e.g. not longer than a few decades) these feedbacks might be omitted. However, for timescales from a few decades up to centuries, the feedback effects of climate and hydrology may result in significant changes of the land cover. In that case, the alterations of climate, hydrological processes, and land-use conditions have to be analyzed in a coupled manner in order to reflect altered systems conditions of this kind.

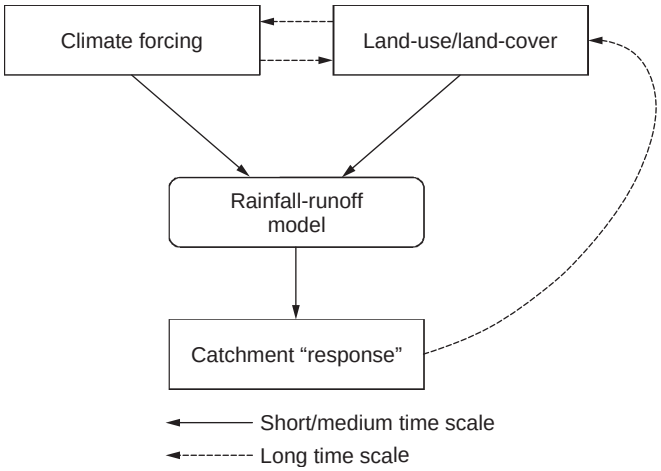

Figure 5 Standard procedure of rainfall-runoff model application for climate and land-use change assessment: the altered hydrological response of a catchment is assessed by application of a hydrological model with altered climatic or boundary conditions. In most cases, the alterations of climate conditions or land-use parameters are performed independently, and the process descriptions of the hydrological model remain unchanged. This approach is appropriate if the modeling study covers short to medium timescales (e.g. not longer then few decades). However, the feedback effects of climate and of the hydrological catchment conditions can result in significant changes in land-cover conditions (e.g. for timescales equal to or longer than a few decades), so that these feedback processes should jointly be taken into account, that is, the alterations of climate, hydrological processes, and land-use conditions have to be analyzed in a coupled manner (indicated by the dotted arrows)

Both climate forcing and hydrological process description may introduce significant uncertainty into the rainfall-runoff modeling. It would therefore be valuable to quantify this uncertainty, or at least, to take this uncertainty into account, (*see* **Chapter 131, Model Calibration and Uncertainty Estimation, Volume 3**). Some remarks on consideration of uncertainty in impact analysis of environmental change are also given in the following text.

Modeling land-use change impacts

As stated before, land-use and land-cover conditions mainly influence surface or near-surface processes; that is, surface or near-surface runoff fluxes are more likely to be affected by land-use changes than the runoff from groundwater. Besides hydrological fluxes (such as infiltration or surface runoff) the capacity of the ground surface to retain water is of importance. In addition to the consideration of fluxes and storage capacity, modeling the effects of land-use change requires that the initial conditions, such as antecedent soil moisture, snow pack, vegetation phenological status, or land cultivation status are appropriately taken into account. Finally, rainfall intensity during the event is of special importance, because it controls the emergence of infiltration excess.

Modeling the impacts of land-use change on rainfall-runoff events requires that the model is able to reflect these surface fluxes, storages, initial and boundary conditions. "Being able" means that the model has to contain algorithms that calculate the relevant processes and storages with model parameters representing the land-use/land-cover conditions and their possible changes.

Hydrological models where fluxes and storage processes are described by equations derived from hydrological process knowledge have been termed *physically based* (e.g. Abbott *et al.* 1986) or *process-based* (e.g. Janssen and Heuberger, 1995) models. Of course, these types of models generally have implicit, empirically derived relations built into them (see e.g. Beven, 2001a). However, compared to empirical or lumped models, these model types bear the

advantage that the different processes can be distinguished and parameterized, which is an essential prerequisite for a model to be able to extract and calculate the effects of land use on hydrological processes.

Thus, assessing land-use change impacts by applying a hydrological model requires a process-based model in which, at least, the hydrological processes on and near the ground surface are included explicitly. However, this does not mean that simplified approaches to describe such processes prohibit the use of this specific model for land-use change impact studies. The necessary and sufficient condition for model selection is the requirement that the relevant rainfall-runoff processes are included and that the specific land-use conditions can be reflected by the model parameters. An overview of some popular hydrological models was put together by, for example, Singh (1995). From the principal requirements stated above, it is possible to specify the features of rainfall-runoff models which are necessary for this kind of impact analysis.

(a) Representation of the soil zone

The condition of the soil surface and the unsaturated zone is crucial for rapid rainfall-runoff processes, for example, infiltration excess, subsurface stormflow, and surface runoff (see Part 10: Rainfall-runoff Processes). Models that do not distinguish different runoff-generation processes (at least, surface, near-surface, and deep-surface processes) and whose parameters do not reflect the state of the soil zone are not advisable, in particular, if effects are to be investigated which may influence the development of a particular process (see Table 2).

(b) Spatial distribution and scale

It is necessary to operate in a spatial resolution of such kind, so that the relevant hydrological processes responsible for the influence of land use on runoff can be represented. This means, that depending on the relevant processes, different spatial resolutions are possible. As an example, if a large-scale change in interception storage is the only relevant process, the spatial resolution can be much coarser compared to a case where small-scale varying Hortonian runoff generation is influenced (amplified or reduced) by the effects of land-use change on the local distribution of soil properties.

A distributed approach is essential if the runoff-generation processes are highly variable in space, especially if this variability can be attributed to soil and vegetation characteristics. A distributed approach is also required if land-use change impacts are to be analyzed in their actual spatial appearance.

(c) Land-use scenarios

While many hydrologists apply rainfall-runoff models with great care and expertise, they tend to be much less aware of the significance of an adequate representation of the boundary conditions controlling the dynamics of the hydrological system. This "representation of the boundary conditions of the systems dynamics" is termed here as *scenario*. Land-use change scenarios need to account for both geophysical and anthropogenic aspects. Designing such scenarios concerning land-use development might consist of two steps: the determination of land-use trends, given as spatially averaged values, and the spatial transformation of these trends into spatially distributed land-use patterns. Many impact studies of environmental changes have neglected neighborhood relationships and the geographic position of land-use features, by adjusting only the proportion of different land-use types. However, if the location of land-use features and changes to these are of importance for the rainfall-runoff model, the land-use change scenario should account for the spatially explicit allocation of land-use change in the landscape, as summarized by for example, Niehoff *et al.* (2002) and described in detail by Fritsch (2002).

(d) Temporal resolution

If rainfall intensity is relevant for runoff generation, this should be reflected in the temporal resolution of both the meteorological data and the modeling time step. This is typically the case in small catchments and/or if Hortonian overland flow contributes significantly to runoff.

(e) Coupling of climate and land cover

If the climate conditions have an *indirect impact on the runoff-generation conditions*, for example, by causing crusting of the soil, altering the characteristics of the vegetation cover and so on, this needs to be taken into account, especially for long-term projections of the development of rainfall-runoff characteristics, see Section "Interactions of climate change with land-cover conditions".

UNCERTAINTY ISSUES

It has to be emphasized that the capability of rainfall-runoff models to forecast the hydrological response of a catchment after changes in land use or climate conditions is severely constrained by the uncertainties involved in the whole rainfall-runoff modeling procedure. In (*see* **Chapter 131, Model Calibration and Uncertainty Estimation, Volume 3**), a methodology to estimate and to take into account uncertainty is presented, where the focus is laid on the uncertainty resulting from difficulties in identifying "optimal" parameter sets. Other sources of uncertainty can be attributed to the model structure and model approaches (due to insufficient knowledge on the physical appearance and the stochastic features of the processes involved) and to data problems (e.g. constrained data availability, insufficient spatial or temporal resolution, measurement or data interpretation errors).

In the case of rainfall-runoff modeling for environmental impact assessment, a very important additional source of uncertainty is introduced by the prescription of the altered land use or climatic boundary conditions, the so-called *land-use change scenarios* and *climate change scenarios*. This will be termed *scenario uncertainty*. In most past rainfall-runoff studies concerned with climate and land-use change, such scenarios have been established in a rather deterministic "if-then" mode, for example, "if" the scenario conditions are prescribed (given, assumed), "then" the altered hydrological response is simulated by the rainfall-runoff model. In most cases the probability of the scenario ("if" case) has not been considered; actually, the probability that the prescribed scenario may become true is usually completely unknown. In rare cases the probability might be estimated from current/observed trends of greenhouse gas concentrations (basis for climate change scenarios) or from socioeconomic development (basis for land-use change), and these trends might be extrapolated in or predicted for the future on the basis of different assumptions with varying probability of the general economic development.

Though knowledge on the scenario uncertainty usually is poor, it is desirable to include it in an integrated uncertainty analysis and estimation. If the purpose of rainfall-runoff model application is to derive standards for design of, for example, water supply schemes, flood protection, or ecological management of floodplains under conditions of environmental change, it is indeed essential to quantify the uncertainty involved in the model application.

In order to assess the uncertainty resulting from model structure and parameterization, a rigorous procedure such as described by Freer *et al.* (1996) can be carried out, *see* **Chapter 131, Model Calibration and Uncertainty Estimation, Volume 3** for details. Cameron *et al.* (2000) applied this approach for a parameter uncertainty estimation for flood frequency simulation under a changing climate and included different emission scenarios from the UK Hadley Centre (Hulme & Jenkins, 1998) into their analysis. Using the General Likelihood Uncertainty (GLUE) procedure, they compared the results obtained by applying different emission scenarios as boundary conditions for TOPMODEL (e.g. Beven, 2001b) while taking account of the parameter uncertainty. This comparison is an important step towards an assessment of the scenario uncertainty, though the shortcoming remains that no probability can be attributed to the different scenarios. From Figure 6, one can extract different kinds of important information:

1. The extrapolation of flood frequency distribution for low probabilities (long return periods), based on observed values (dark solid line), is very uncertain, due to the very limited (or absent) data for such low probabilities and due to the dependence of the chosen distribution function.

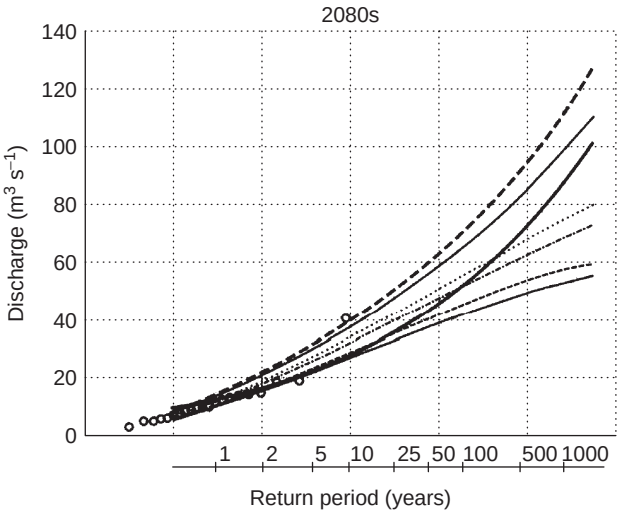

Figure 6 Flood frequency distribution for the Wye catchment (UK) under a changing climate with 90% uncertainty bounds derived from annual maximum peaks obtained by 1000 TOPMODEL-simulations with varying parameter sets. Circles – observed hourly peaks; dark solid line – flood frequency distribution fitted to the observations; dashed lines – 90% uncertainty bounds obtained for climate change scenario (HadCM2 ''medium high'' scenario for 2080s); dotted line – median simulation obtained from climate change scenarios; light solid lines – 90% uncertainty bounds obtained for current conditions; light dash-dot line – median simulation obtained for current conditions, derived from Cameron *et al.* (2000)

2. The median frequencies predicted under current climate conditions (light dash-dot line) yield a distribution which is within the uncertainty bounds for a changed climate (dashed lines) and, of course, within the uncertainty bounds for the current climate conditions.
3. Comparing simulated current climate and changed climate conditions, one can see a slight but notable increase in flood frequency for that particular catchment: for example, from the median results one can derive a return period of 300 years for a flood of 60 m^3 s^{-1} for current climate, and a return period of 200 years under changed climate conditions for the same discharge value.

One has to be aware that, like most other modeling studies of climate change impacts on the hydrological cycle, this study assumed that the functional description of runoff generating processes remains unchanged. That assumption means that an altered climate does not cause a change of the importance of certain specific hydrological processes: if a catchment runoff is fed mainly by saturation-excess overland flow and return flow (a basic TOPMODEL assumption), the same catchment is expected to behave the same under changed climate. Of course, this assumption can be questioned, but for a first step this is acceptable,

because the variations within the existing climate are probably stronger (e.g. between dry and wet years, or between flood and lowflow periods), than the differences between the current and the future climate. In a second step, however, one should check this assumption: does the climate change scenario include altered rainfall intensities, and does this possibly increase the contribution of infiltration-excess overland flow, or may increased evaporation and subsequent dryer soil conditions possibly trigger soil crusting? If so, one can try to introduce such changes into the parameters of the hydrological model, but in doing this, one will definitely introduce a new source of uncertainty.

In general, scenario uncertainty might be dealt with according to the following structure:

- Assessing the overall trend of land use and climate change. In case of climate change, this trend has to be derived from GCM results; in case of land-use change, it might be derived by estimations about the long-term development of the economy, land management, or infrastructure.
- Assessing the uncertainty of the overall trend by evaluating results obtained from different GCMs, or results by one single GCM obtained by using varying initial conditions or varying climate forcing assumptions (multiple scenario ensembles as proposed by, for example, Mitchell & Hulme, 1999), or evaluating the long-term predictions for economic development and land management, respectively.
- Applying a state-of-the-art downscaling method, to express results from GCMs or land-use trends, respectively, on scales more appropriate for rainfall-runoff modeling. Some methods for climate downscaling and for the derivation of spatially distributed land-use scenarios have been mentioned earlier in Section "Requirements for modeling environmental change impacts on rainfall-runoff events".
- Using such "regional scenarios" and the associated uncertainty as climate or land-use boundary conditions in rainfall-runoff modeling.

It should also be noted that uncertainty involved in the assessment of environmental changes is even more pronounced regarding extreme hydrological events (rare events). This is mainly a reflection of the immense natural variability of the climate system, which requires long estimation periods for the statistical derivation of long return periods (= very rare events) and of our restricted hydrological process knowledge for extreme conditions. With the current setting of climate downscaling approaches, using the information of relatively short, observed and simulated circulation fields, one is bound to return to periods in the order of decades. Therefore, Frei *et al.* (2000) suggest that climate impact studies focusing on rare events could profit from analysis of moderately intense events rather than damage-causing extreme events, where the associated uncertainty is very high.

But even for relatively short return periods one must expect that, for a given global emission scenario, different climate models coupled to different subsequent downscaling methods generate a whole spread of local responses. For a thorough uncertainty assessment it is suggested that varying overall trends (of climate or land use) need to be taken into account and that the regional patterns obtained by different downscaling methods should be investigated, which should finally provide a rough guess of the scenario uncertainty.

Additional difficulty arises in modeling land-use change scenarios because, in that case, the parameter set calibrated for observed land-use conditions might be invalid for altered conditions. So, there is the question of assessing if and how the parameter sets will change. The simplest way is to do so entirely deterministically and change the relevant parameters to new estimates. As soon as the parameters are allowed to become uncertain however, this is a lot more difficult because of all the (nonlinear) interactions within the model structure. **Chapter 131, Model Calibration and Uncertainty Estimation, Volume 3** presents uncertainty estimation procedures, such as the GLUE, which is a quite generally accepted method to include the uncertainty associated with model- and scale-specific parameter sets. A way to cope with the uncertainty of the model structure (e.g. of the processes and their interactions represented by the model) is to check if the model structure for a specific land use still holds for a different catchment with different land-use conditions, applying an altered parameter set. If the model does not give plausible results in such a test, one has to check which process approaches have to be adjusted or additionally included to obtain a satisfactory result.

When we consider the many possible sources of uncertainty (scenario uncertainty and model, parameter, and data uncertainty), we might conclude that rainfall-runoff modeling is of little value for environmental impact assessment. However, there are ways to achieve a compromise, such as:

- *Comparison of uncertainty* introduced by data, model, and parameter problems with uncertainty due to the unreliability of scenarios.
- Use of *average and statistical changes* obtained by the GCMs and subsequent downscaling techniques (see Bronstert *et al.*, 1999 for a study example), rather than *absolute values* of climate.
- Testing of model structure by applying the same model structure with an adjusted parameter set to a second catchment with different land-use characteristics and/or different meteorological characteristics and assessing the validity/uncertainty of the model structure (representation of processes and feedbacks).

- Application of rainfall-runoff models *not in a forecast sense or as a predictive* tool but rather as a tool to evaluate the *changes in process dynamics* because of an altered land use or climate.
- Comparing *uncertainty bounds* or confidence intervals obtained by rainfall-runoff models with and without altered climate or land-use conditions, such as shown in the work by Cameron *et al.*, 2000 (see as an example Figure 6 or in a recent paper by Thieken and Merz 2003), rather than comparing single hydrographs only.

INTERACTIONS OF CLIMATE CHANGE WITH LAND-COVER CONDITIONS

Though climate and land-use change are summarized under the notion "environmental change", in most model-based environmental change assessments, climate and/or land-use change impacts are modeled independently, which is an implicit assumption that climate and land-use conditions do not influence each other. However, a changing climate results also in an alteration of the land cover, and, moreover, a changed land cover may influence the local or in part the regional climate. Thus, for assessments with a prospect of long timescales, say several decades, such interactions might become rather important and coupled climate and land-use change scenarios can be of interest.

What are the interactions of climate change and land cover and how can they be parameterized for the purpose of rainfall-runoff modeling?

- The effect of a raised concentration of CO_2 is of particular interest. The results of investigations on the effects of increased CO_2 (mostly from growth-chamber studies or from simulations with vegetation models) are rather complex. Typically, the biomass production increases. Furthermore, the stomatal conductance is reduced as a result of raised CO_2 concentration. One consequence is a greater water use efficiency at leaf level. But this effect is, at least to some extent, counterbalanced at the stand level by the greater biomass and leaf area (Kimball *et al.*, 1993; Norby *et al.*, 1996). So the most interesting hydrological effect seems to be the increased biomass production and leaf area, which leads to a greater interception storage capacity, and the decreased stomata conductance resulting in less transpiration per leaf area. Parameters to account for both leaf area and stomata conductance can be found in most rainfall-runoff models, which include evapotranspiration processes. The adequate quantification of the parameters, however, remains a major research challenge in the coupling of climate and hydrological modeling.
- As well as the greater biomass due to raised levels of $\mathbf{CO_2}$, global warming is expected to lead to a longer growing season in high and midlatitudes, an effect which has been observed during recent decades (e.g. Schaber, 2002). In an analysis over several decades, Sharrat (1992) has observed such a trend over the last 65 years in several regions throughout Alaska. The length of the growing season of course is important for various rainfall-runoff processes and rainfall-runoff modeling. It affects mainly evapotranspiration processes, in which the timing of vegetation growth can be reflected by the seasonal variation of the leaf area index.
- Atmospheric warming directly influences the timing and duration of snowfall, frost, and snowmelt. As long as the change of the temperature conditions are given in the climate scenario, such effects can be accounted for rather easily by most rainfall-runoff models, resulting in, for example, an altered timing and duration of spring floods.
- Furthermore, there is a considerable long-term feedback of the climate on the succession and composition of vegetation and its hydrologic characteristics. However, such effects are at present very difficult to quantify or to transfer into parameters of rainfall-runoff models, particularly on the catchment scale. The long-term effects of vegetation change on the soil-surface conditions (e.g. soil crusting, soil stability) are also still very poorly understood. This points out the need for a stronger integration of hydrological research with climate and soil science.
- Finally, it is worth mentioning that large-scale (e.g. regional or even continental) alteration of land cover (such as deforestation) has an effect on the local or regional climate, due to the changes of the energy exchange between atmosphere and land surface. This may also influence the air humidity, wind profiles, and conditions for rainfall generation over that area. Those mechanisms, however, have not yet been investigated in such depth that this knowledge could be used in coupled regional climate-land-use-change scenarios.

CASE STUDIES

Modeling Climate Change Effects on the Runoff Conditions in Different European Catchments

The project European River Flood Occurrence and Total Risk Assessments System (EUROTAS) was aimed at assessing the risk of current and future flooding for Europe under environmental change, including the effects of climate change. With respect to the latter, climate scenarios were derived for five large European catchments with rather different typical climate conditions, from semi-arid/Mediterranean to maritime: the Pinios, the Jizera, the Mulde, the Saar, and the Thames (see Bürger, 2002). The catchments cover a range of European climates: the Pinios

(area 9450 km^2) runs through a mountainous area in central–northern Greece, with heavy precipitation in winter and persistent droughts in summer. The Jizera (2193 km^2) is an upper Labe/Elbe tributary running through a middle mountain area in the northern Czech Republic, having a climate that is dominated by more continental characteristics. Similar is the situation of the Mulde (6170 km^2) which drains into the middle Elbe first through a mountainous and then through a flat area of eastern Germany. The Saar (7363 km^2) in France and Germany is part of the Rhine basin draining into the river Mosel. Its rainfall regime is dominated by westerly cyclones from the Atlantic. The Thames in south England (about 10 000 km^2 upstream of Kingston), finally, is characterized by maritime conditions without strong seasonality.

Subsequently, these climate scenarios were used as the climate forcing for hydrological models of these catchments to assess the possible impacts of climate change on their runoff regime, with a particular emphasis on the extreme events. In the following, first the climate change information conveyed by the scenarios and an assessment of its statistical significance is presented. Second, as an example of a climate change impact assessment, the runoff response of the Mulde catchment is summarized.

Regional Climate Scenarios

The climate scenarios are derived by a statistical-empirical method developed by Bürger (1996), the so-called *Expanded Downscaling*. EDS has merged both regressional and stochastic approaches. It modifies the classical regression principles (i.e. local climate variable vs. large-scale atmospheric field) by relaxing the condition of absolute error minimization to allow for the preservation of local variability in time. As a consequence, when driven by daily atmospheric fields, EDS simulates, by definition, daily local climate variables (e.g. temperature or precipitation) that have almost complete realistic variability and at the same time are as close as possible to the large-scale atmospheric circulation process. For this work, an improved version of the EDS technique was used which included atmospheric humidity in the set of large-scale variable fields, thus reducing the uncertainty of the statistical relationship between the large-scale fields and local conditions. One advantage of the EDS method is that it offers the possibility to generate local climate time series depending on the type of large-scale atmospheric fields. For example, different large-scale atmospheric fields can be used, such as observed atmospheric fields (supplied by NCEP or ECMWF), or results from a GCM (supplied by, e.g. the UK Hadley Centre or the Max Planck Institute for Meteorology, Germany, MPI). GCM results can be based on a projected increase of greenhouse gases (yielding the large-scale climate change scenario) or on a stationary greenhouse gas concentration (yielding the control simulation). Thus it is possible to compare the results of this downscaling technique for past observed atmospheric, control, and climate change conditions, respectively.

Three different large-scale data sets formed the basis of this study: (i) The MPI Hamburg conducted a climate simulation with the current version of their GCM, ECHAM4/OPYC3, (see Roeckner *et al.*, 1996) for the period 1860–2100, where the greenhouse gas concentrations were taken from observations for the period 1860–1990 and from the IS95a scenario (usually termed *business as usual*) for the remaining period. (ii) With the same GCM, an additional 300-year control simulation without changes of greenhouse gas concentration was conducted. (iii) Finally, a data set of "observed" large-scale atmospheric fields, covering the same selected North Atlantic/European section of the globe was available (reanalysis data of the US National Center of Environmental Prediction, NCEP).

The EDS-downscaling method then was applied for all three large-scale data sets, resulting in three different regional climate scenarios:

1. Regional scenario based on the GCM result given a stationary greenhouse gas concentration (acronym *CTL*).
2. Regional scenario based on GCM results given the above-mentioned IS95a emission trend (acronym *SCA*),
3. Regional scenario based on the reanalysis data of the NCEP (acronym *ANA*).

Table 3 summarizes the results concerning precipitation for four out of the five catchments, showing average values: mean daily precipitation in mm (m), the probability of a daily rainfall larger then 0.1 mm (p), and the mean daily intensity in mm day^{-1} (i). The results are given separately for winter (October–March) and summer (April–September). Here the OBS denotes observed precipitation values. The scenario (SCA) results are based on statistical analysis for the period 2061 to 2090.

One can see that for scenario conditions the intensity (i) increases in all catchments, for both seasons. This can have positive effects on the mean rainfall (Saar), or negative effects on the rainfall probability (Jizera), or both (Thames). The mean rainfall increases for all catchments, besides the Pinios. However, this increase is significant only for the maritime-influenced climates of the Saar and the Thames. It is most interesting that the figures shown for the Pinios indicate a dramatic decrease in rainfall probability, both in winter and summer, meaning less frequent but stronger rainfall events, which would be a dramatic and unfavorable change of the local climate conditions. This is consistent with the tendency of the ECHAM GCM to project a general drying for the eastern Mediterranean area. The design and the analysis of the significance test (mainly the combination

Table 3 Statistics of the precipitation downscaling for four European catchments in winter and summer. Arrows indicate significant departure of the climate change scenarios SCA from the joint statistics of OBS + ANA + CTL, after Kolmogorov–Smirnov (↓: decrease, ↑: increase), from Bürger, 2002

		Winter				Summer			
		OBS	ANA	CTL	SCA	OBS	ANA	CTL	SCA
Pinios	m	2.1	2.1	2.4	2.1	1.0	1.1	1.3	1.2
	p	33.4	32.5	32.7	↓25.8	18.4	17.0	18.3	↓13.9
	i	6.4	6.5	7.4	↑8.3	5.4	6.3	6.9	↑8.6
Jizera	m	2.6	2.6	2.9	3.8	2.9	2.9	3.3	3.7
	p	61.6	61.2	61.7	↓57.4	53.7	55.9	54.2	↓47.0
	i	4.2	4.2	4.7	↑6.7	5.3	5.2	6.2	↑7.9
Saar	m	2.3	2.4	2.8	↑3.5	2.2	2.3	2.5	↑2.7
	p	50.4	47.0	49.0	50.5	43.2	47.1	46.2	43.4
	i	4.6	5.2	5.7	↑6.8	5.0	4.8	5.4	6.2
Thames	m	2.3	2.2	2.6	↑3.5	1.9	1.8	2.2	↑2.4
	p	56.2	56.0	54.9	↓50.7	43.6	44.7	44.1	↓38.3
	i	4.0	4.0	4.7	↑6.9	4.4	4.1	4.9	↑6.2

of ANA, OBS, and CTL) are rather simple and of course the subject of debate. However, it can serve as a rule of thumb for the climate change (given the scenario conditions) impacts on precipitation regimes in different European catchments. More information and in-depth explanations of the results are given by Bürger (2002).

In a subsequent step, the analysis of precipitation time series was conducted looking at the extreme values of daily precipitation. On the basis of the obtained precipitation time series for observed data, downscaled respectively from reanalysis fields from GCM results with constant greenhouse gas concentration, and from GCM results with increasing greenhouse gas concentration (OBS, ANA, CTL, SCA), a classical extreme values analysis was performed, yielding precipitation frequency curves. Return periods larger than 30 years were generally not included into the statistical analysis, because the observed data (OBS) covered a period of only that duration. To utilize the information of the 300 years control run, this series was broken up into ten 30-year subperiods, and their cdfs were calculated separately. Accordingly Figure 7 illustrates a comparison of the probability of annual maximum precipitation values (expressed in return intervals) derived from OBC, ANA, 10 CTL and SCA precipitation series, where Figure 7(a) shows the situation for the winter months (October–March), Figure 7(b) for the summer months (April–September).

One can see from Figure 7 that a great uncertainty stems from the widespread of CTL runs, which is both due to natural variation and to GCM-induced uncertainty. Even with a relatively small return interval of 30 years, the variation within the CTL-cdfs is remarkable. Nevertheless, the precipitation statistics of the scenario (SCA) are significantly different, in particular, with respect to the whole range of return periods, for example, they fall outside the variability of the current climate. They show an intensification of about 10 to 20% for most catchments (in particular, for the Jizera and the Thames) and for both seasons, which indicates an increased flood risk and is in accordance with the results given in Table 3.

Rainfall-runoff Modeling for Climate Change Impact Assessment in the Mulde Basin

Within the framework of large-scale hydrological modeling of the river Elbe and its tributaries (approximately 150 000 km^2 both in Germany and the Czech Republic) the river Mulde has been selected for a detailed analysis of climate change impact on flooding (Menzel *et al.*, 2002; Menzel and Bürger, 2002). The hydrological model applied is the distributed version of the conceptual rainfall-runoff model HBV (Bergström, 1995), called HBV-D (Krysanova *et al.*, 1999). HBV-D consists of three main components: (i) snow accumulation and snowmelt, (ii) the simulation of soil moisture and runoff generation, and (iii) a catchment response and river runoff routine. Continuous simulations of river discharge by use of HBV-D were carried out for the Mulde on a daily time step over the eight successive years 1981–1988. HBV-D was repeatedly applied to simulate discharges with different climate input as follows: first, observed daily data from 75 precipitation and 4 climate stations (OBS), second, regional climatology obtained by applying the EDS method (see the preceding text) on the basis of reanalysis atmospheric fields (ANA), and third regional climatology obtained by applying the EDS method (see the preceding text) on the basis of GCM results with emission scenario IS95a (SCA). This procedure is very similar to the one conducted for the other four catchments. However, the GCM results for a constant greenhouse gas concentration (CTL) were not used here.

Using these three different climate forcings for a historical period enables a direct comparison of simulated runoff and associated uncertainties due to rainfall and temperature for measured data, and for results derived from reanalysis data and from GCM results. Thus, it is possible to test

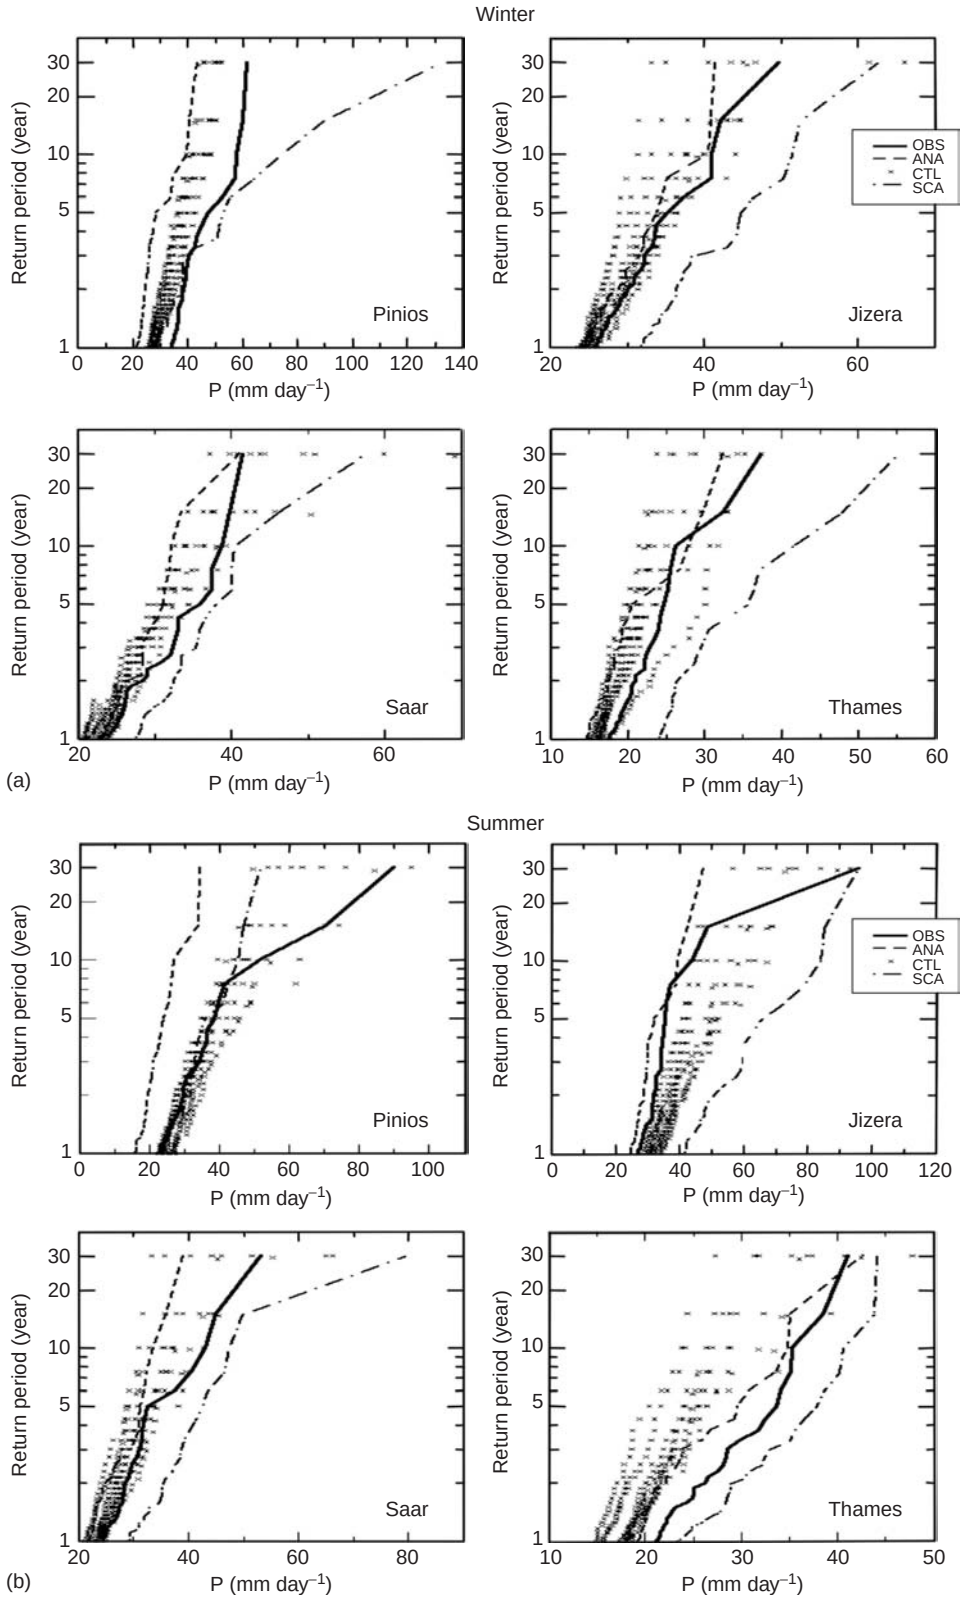

Figure 7 Return periods and associated annual maximum precipitation values for four European catchments (derived from OBS, ANA, CTL, and SCA time series, see text): (a) winter months (October–March); (b) summer months (April–September), from Bürger, 2002. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

the performance of the selected climate forcing for regional rainfall-runoff modeling. Finally, the SCA data were used for a climate change impact assessment for the period up to 2100.

Figure 8 shows a comparison between observed runoff, simulated runoff with measured climatology, and simulated runoff with downscaled climatology (based on reanalysis data) for the period 11/1984 up to 10/1988 at the catchment outlet (Bad Düben gauge). One can see that the applied rainfall–runoff model using observed meteorological conditions is able to capture the runoff dynamics of the Mulde catchment quite well (grey-straight line in Figure 8, yielding a Nash–Sutcliff coefficient 0.8). Use of the climate forcing obtained by EDS based on reanalysis data (ANA) yields somewhat less satisfactory results (black-dashed line), but still gives a surprisingly good performance of runoff dynamics. This shows that a large part of precipitation variability can be attributed to the large-scale circulation. However, some flooding events are not covered by the ANA simulation, in particular, during summer periods (e.g. July 1983), implying that convective rainstorms cannot be derived from large-scale atmospheric data. Finally, Figure 8 shows the rainfall-runoff performance using the climate forcing obtained by EDS based on GCM results (SCA) for the same period (grey-dashed line). It can be seen that the simulated overall runoff dynamics are still similar to the measured and to the simulated ANA results, but, of course, the specific runoff events are not matched, because the SCA conditions cannot reflect the timing of single weather events. Nevertheless, the simulated SCA hydrograph seems to show a lower tendency for high runoff (both in frequency and in peak volume), especially during winter and springtime. This is probably due to the lack of capability to recognize areally restricted storms from large-scale data combined with the simulated underestimation of snow accumulation and related shorter melting periods. Summarizing these findings, one can see the influence of large-scale atmospheric fields on catchment climate and hydrology and the increasing uncertainty if local features of the climate forcing are neglected (ANA) or if no observations at all – neither local measurements nor large-scale fields – are used to derive the climate forcing (SCA, period 1985–1988).

The last step of this case study was the application of the same rainfall-runoff model with projected future climate forcing (SCA, period up to 2100). Menzel and Bürger (2002) reported that this simulation reveals a high uncertainty about the future development of flood risk

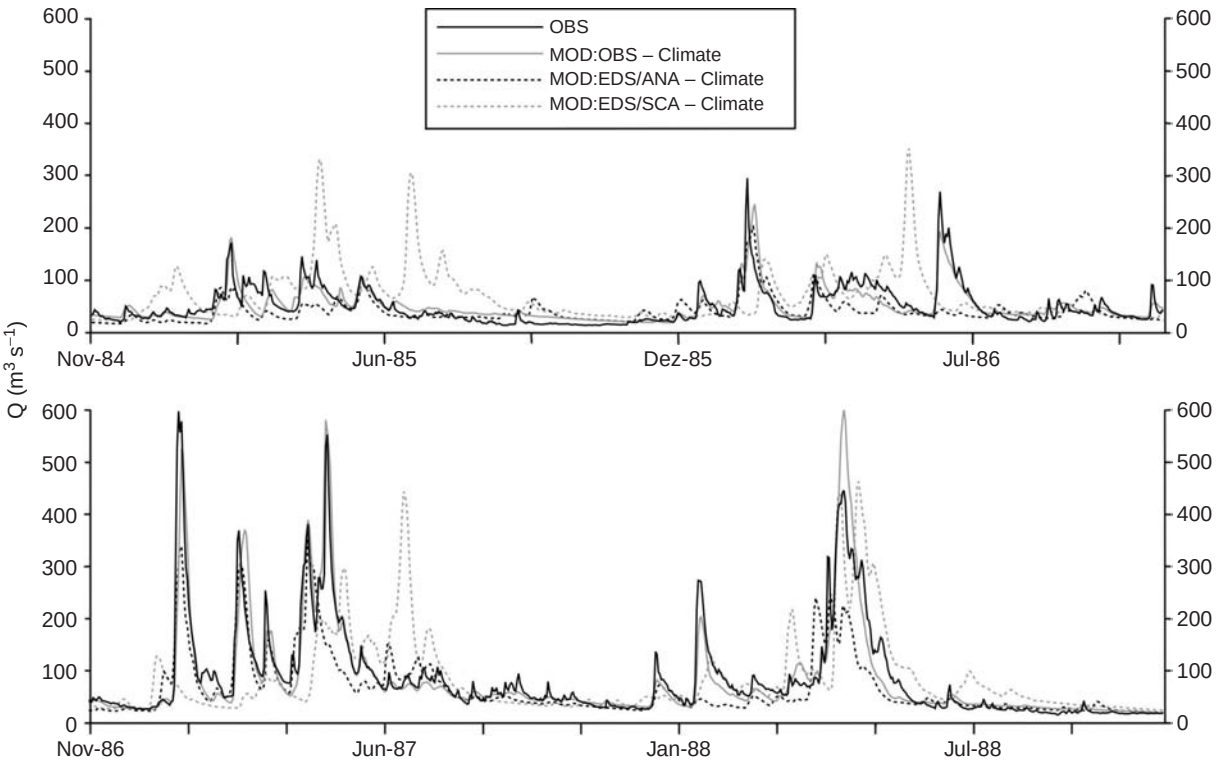

Figure 8 Observed runoff, simulated runoff with measured climatology, and simulated runoff with downscaled climatology (based on reanalysis data and based on GCM results) for the river Mulde at gauge Bad Düben, 11/1984–10/1988, from Menzel *et al.* (2002). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

for catchments. The simulations predict a weak tendency towards reduced peak discharges. This seems to be valid for a major part of the whole Elbe catchment. On the basis of the applied climate change scenario, the simulations indicate that a future problem might arise from reduced water availability in the Elbe catchment. However, it has to be emphasized that such analyses are associated with high uncertainty, in particular, with respect to the probability of very rare events (see also the discussion by Lamb (1999) about difficulties in modeling flood frequency distributions and the detailed elaboration of this issue in Chapter 11.9 of this encyclopedia).

A Comprehensive Modeling Study of Land-use Change Effects on the Runoff Conditions in the Rhine Basin

From 1997 until 2001, an EU-funded project was conducted aiming to quantify flood risk for the Rhine basin under altered environmental conditions. The main focus of the project was on two important questions:

1. To what degree do changes of land cover and river training influence the flood situation in the Rhine basin? and
2. To what degree can flooding be mitigated by water retention measures both in the landscape and along the river courses?

Therefore, the project on the one hand aimed at quantifying the impact of landscape hydrology and river network hydraulics on flooding conditions in the Rhine basin. In this context, the retention capacity of the landscape with its geophysical properties and the river training conditions were of importance. On the other hand, the mitigation potential of specific measures like infiltration ponds, altered agricultural management practices, restoration measures in small tributaries and polders or flooding areas in larger rivers were investigated. The aim was to provide results which could serve as sound scientific figures about a possible increase in flood risk caused by land-use changes or a possible decrease in flood risk induced by specific measures like decentralized water retention or the flooding of polders.

The project required an interdisciplinary and multiscale approach. This was achieved by combining models for different purposes at different spatial scales, allowing the comparison of the impacts of land-cover conditions and the effects of river training activities (including the retention capacity in rivers and floodplains) on the discharge conditions in the river Rhine. The models had either to be adjusted or expanded in order to fulfill the project requirements.

Special attention had to be paid to the coupling of catchment hydrology and flood wave propagation as well as to the linkage between the land-use scenarios and the structure and parameterization of hydrological modeling. The simulations were carried out by process-oriented rainfall-runoff modeling at three different spatial scales covering the Rhine basin from Maxau (southwest Germany) to Lobith (Dutch/German border), which is a total area of more than 110 000 km^2. The mentioned modifications were necessary at the following spatial scales and will be explained hereafter:

1. To include process knowledge at the lower mesoscale (three small catchments covering an area of about 100–500 km^2), which was considered to be relevant for land-use change modeling but was not represented in the original version of the chosen model. This refers in particular to the representation of macropore effects on infiltration conditions and therefore on the possible generation of infiltration-excess overland flow and to the representation of urban storm water processes, such as runoff on impervious areas, retention in sewage systems, and possible transfer to sewage treatment facilities.
2. To transfer process knowledge ("upscaling") simulated at the lower mesoscale to the upper mesoscale (101 larger subcatchments of the Rhine, ranging between 400 and 2100 km^2, covering a total area of 110 000 km^2) where, as a consequence of data scarcity and data management constraints, a rather conceptual modeling approach had to be chosen.
3. To route the runoff from all the different subcatchments of the Rhine catchment in the main river system. This includes possible retention effects within the river corridor and/or in flood polders along the channel system of the Rhine and its main tributaries. This is primarily a matter of hydrodynamic modeling.

The following paragraphs present the models applied and the results achieved at the different scales. The modeling at the lower mesoscale is described more in detail, because at that scale the modeling of land-cover/land-use change effects on runoff processes can be demonstrated best. The other two levels are summarized, followed by an overall discussion of this case study.

Modeling land-cover impact on runoff processes during periods of heavy precipitation at the lower mesoscale

The quantification of the influence of land cover on the runoff process during periods of heavy precipitation at the lower mesoscale was done by applying the process-oriented hydrological model *WASIM-ETH* (Schulla, 1997) on catchments of an area ranging between 100 km^2 to 500 km^2. These were selected because they represent different characteristic land-use patterns with either dominantly urban, agricultural, or forested structure. For these three exemplary catchments, spatially distributed scenarios of future

land use and land cover were generated on the basis of regional analyses of land-use trends.

WASIM-ETH was considered to be an adequate tool for this purpose and this scale, because it includes most of the processes relevant for runoff generation. It considers the spatial distribution of catchment characteristics, and is based on fine-gridded spatial and temporal dynamics of climate variables, topography, soil properties, land use, and vegetation. As mentioned earlier, infiltration and surface runoff-generation processes are crucial processes in modeling land-cover or land-use effects. Particularly under extreme precipitation conditions these processes contribute strongly to the water being transferred to the river system, either directly by generating infiltration-excess overland flow or indirectly by influencing the extent of saturated surface areas, thereby causing saturation-excess overland flow. Therefore, the developed extensions of WASIM-ETH focus on soil and land-cover characteristics, which either increase or reduce the infiltration capacity. Increasing effects are mainly due to the occurrence of macropores (Bronstert, 1999), and reducing effects due to possible siltation at the soil surface. In addition, to account for urban hydrological effects, a model extension was developed, which accounts for the connection of sealed surfaces to the sewer system and the possible diffuse water retention in urban and agricultural areas.

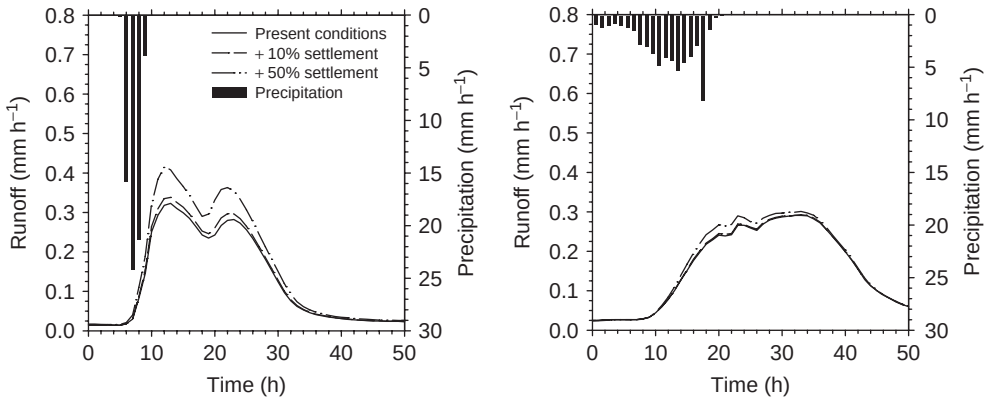
The final model version requires the following parameters to represent the relevant (land-use affected) processes of flood generation:

- soil parameters: soil depth; hydraulic conductivity; saturation content; macroporosity; mean macropore depth; possible reduction of surface conductivity due to siltation
- urban parameters: settlement area; fraction of sealed surface within a settlement; capacity of urban retention reservoirs; controlled discharge from urban retention reservoirs; local catchment area and retention capacity of diffuse storm water control management devices in urban or agricultural areas; maximum seepage rate from these storm water management devices
- land-cover parameters: maximum interception storage; soil cover index; root depth, leaf area index

Niehoff *et al.* (2002) gives an overview of the model and its extensions and Niehoff (2002) provides comprehensive documentation and several application and sensitivity examples for the different extensions.

As an example for the modeling results at the lower mesoscale, the simulated response to a relative increase in urban area of 10% and 50% respectively is described in the following. In the Lein catchment, such an increase corresponds to an absolute growth of these land-use types from 7.4% of the catchment area to 8.1% and 11.1% respectively.

Figure 9 is a comparison of two typical flood events in the Lein catchment, one induced by advective circulation conditions (long lasting but less intense rainfall) and one by convective conditions (i.e. a summer thunderstorm: short rainfall of very high intensity). The figure presents simulation results for present conditions as well as for the two urbanization scenarios. The comparison demonstrates that the increase in flood volume and peak runoff due to urbanization is much more distinct for the *convective* storm event than for the *advective* one, although the precipitation volume as well as the peak flow is in the same order of magnitude for both events and represents a return period of approximately 2 to 3 years in both cases. The markedly less pronounced effect on the advective event is the result of (i) *higher antecedent soil moisture* which levels differences in soil characteristics as well as (ii) *lower precipitation intensities* which prevent an overflow of the sewer system.



(a) June/28/1994, Frankenbach/Lein (b) February/16/1990, Frankenbach/Lein

Figure 9 Simulation of two flood events in the Lein catchment (115 km^2) as a response to (a) a convective storm event (28. 6. 1994) and (b) an advective storm event (15.2.1990) for present conditions and two urbanization scenarios (Reproduced from Niehoff, 2002 by permission of D. Niehoff)

This argument is also supported by a comparison of various advective events with different return periods, as shown in Table 4. The comparison reveals a strong correlation between the impact of urbanization on runoff and the *baseflow contribution* to the flood event, which serves as indicator for high groundwater levels and high soil moisture.

Another comprehensive source of information are the runoff components that are simulated for the different flood events (Figure 10). The two pie charts reveal pronounced differences in the *dominating runoff-generation mechanisms* depending on the event characteristics (rainfall intensities and prestorm moisture conditions). The response to convective storm events is dominated by *sewer overflow* from sealed surfaces as well as a considerable amount of *infiltration excess* mainly from agricultural areas. In contrast to that, for advective events *subsurface flow* processes and *saturation-excess* prevail.

Niehoff and Bronstert (2001) have presented other examples of modeling land-use change impacts at the lower mesoscale, such as urban storm water infiltration, agricultural storm water management, or surface crusting of arable land. The results were similar in the sense that the impacts are generally much more pronounced in case of convective rainstorms than in advective rainstorms.

Upscaling from the lower to the upper mesoscale

In order to simulate land-use change effects at larger scales, the detailed information about the runoff generating processes obtained by applying WASIM-ETH at the lower mesoscale (see the preceding text) has to be transferred to larger subcatchments of the Rhine tributaries (up to 2100 km^2 each) covering the whole Rhine basin between Maxau and Lobith (110 000 km^2). This was approached by applying a rather simple, conceptual hydrological model (extended HBV-model, see the following text) with a generalized parameter set, tailored to represent land-use features. This generalization is achieved by establishing a statistical relationship between the simulated land-use change impacts obtained from the WASIM-ETH model and the HBV parameters.

The HBV-model (Bergström, 1995), is a semidistributed conceptual model. It uses subcatchments as primary hydrological units, and a simple Muskingum flood routing is used

Table 4 Increase in runoff volume and peak due to a 50% increase of settlement and industrial areas in the Lein catchment; the events are sorted by the urbanization impact on runoff volume

Year, month	Increase in runoff compared to present conditions		Simulated baseflow contribution to volume (%)	Duration (h)	Return period approximate (a)
	Peak (%)	Volume (%)			
1990, February	3.4	3.7	19	150	2
1993, December	5.9	2.7	17	250	8
1997, February	3.9	2.7	19	150	7
1982, December	1.7	1.5	27	225	3
1983, May	0.6	0.9	39	300	4
1988, March	0.0	0.0	52	650	3
Mean	2.6	1.8	29	290	4.5

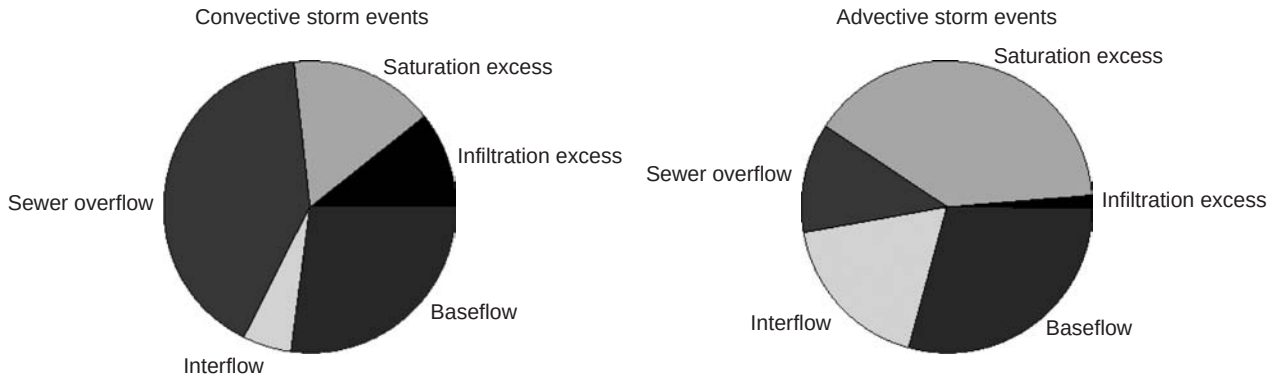


Figure 10 Runoff components simulated with WaSIM-ETH for the Lein catchment for five convective and six advective storm events with return periods between two and eight years (Reproduced from Niehoff and Bronstert, 2001 by permission of Springer)

between the subcatchments to model the runoff from the whole catchment. The subcatchments can further be subdivided into homogeneous zones on the basis of elevation, soil type, vegetation, and so on. The runoff is computed for each zone within the subcatchments using simplified conceptual routines of snow accumulation and snowmelt, soil moisture accounting, and evapotranspiration. The generated runoff is then routed to the outlet of the subcatchments using a lumped runoff concentration model schematized by a series of two reservoirs; a nonlinear upper reservoir that is fed by the runoff generated from the zones and a lower linear reservoir, which is fed by a constant percolation rate from the upper reservoir (Lindström, *et al.*, 1997). The outflow from the upper reservoir simulates the relatively fast runoff from the soil zone near the surface, while the outflow from the lower reservoir simulates the rather slower base flow component. The total outflow from both reservoirs is finally smoothed by a triangular transformation function.

Some extension of the model structure was made to account for the effects of urbanization and possible Hortonian runoff, which is not part of the original model version. A component for impervious area was introduced and runoff generated from such areas is directly routed to the outlet of the subcatchments using the transformation function without entering any one of the reservoirs of the runoff concentration module. Furthermore, at high precipitation intensity, infiltration into (unsealed) soil may be limited by the infiltration capacity of the soil, which might be reduced severely by siltation of the soil surface due to rainfall energy. In order to model this phenomenon, two more parameters were introduced: a threshold precipitation intensity and the fraction of Hortonian runoff contributing area during heavy precipitation intensity. When the intensity of precipitation exceeds the threshold value, part of the precipitation in excess of the threshold produces overland flow. Both parameters are estimated through model calibration. The parameters *impervious area* and *fraction of Hortonian runoff contributing area* are both directly related to the land-use practice. The rainfall intensity is a meteorological parameter, determining the occurrence of Hortonian runoff.

As the HBV-model is a conceptual model, most of its parameters do not have a physical meaning and therefore they have to be estimated through model calibration against observed catchment response. The effect of land-use changes on these parameters can however be estimated only if a relationship between the model parameters and the land-use characteristics of the catchment can be established, which is the main scientific challenge when using a conceptual hydrological model for large-scale (e.g. upper mesoscale) regionalization of process knowledge. In this case, parameters pertaining processes of runoff generation (in each elevation zone of each subcatchment) were estimated as functions of the land-use type or soil type within the zone in question. Parameters of the runoff concentration module were estimated for each subcatchment using a transfer function of the catchment characteristics (see Hundecha and Bárdossy, 2004 for details).

The usual approach of estimating the parameters of the transfer function follows a two-step procedure. The model is first calibrated for many subcatchments independently to obtain "best" model parameter sets, and then the parameters of the transfer function are obtained using optimization. However, this kind of model calibration results in only a single realization among many parameter sets that lead to similar model performance. Therefore, the relationship established between the model parameters and the catchment descriptors is likely to be weak. A different approach was implemented in this study. The model parameters were first expressed in terms of the parameters of the transfer function and thereafter the model was calibrated for many subcatchments with contrasting catchment properties simultaneously. Thus, the model calibration directly yields the parameters of the transfer function, which remain the same for all subcatchments. The lower mesoscale subcatchments modeled by the detailed process-oriented modeling approach (see the preceding text) were also incorporated in the simultaneous model calibration. The calibration for these subcatchments was made against the simulated runoff obtained by the detailed process-oriented model (WASIM-ETH). In order to reproduce the effect of land-use changes obtained by WASIM-ETH, the results obtained for the different land-use scenarios (at the lower mesoscale) were used together with the corresponding land-use distribution. Hundecha and Bárdossy (2004) present details of this regionalization approach and demonstrate simulation results referring land-use change effects on runoff at the upper mesoscale. Some examples of those results are included in the following paragraphs.

Flood routing of the river Rhine and its main tributaries

The macroscale conflation of the tributary subcatchment simulation results was conducted by a flood routing model of the river Rhine and its main tributaries, applying the Muskingum routing model SYNHP (Homagk, 1995) to the main tributaries and the hydrodynamic hydraulic model SOBEK (WL Delft Hydraulics and the Ministry of Transport, Public Works and Water Management, 1997) to the main channel. This allows the river discharge dynamics to be simulated, including impacts of alterations of river channels and retention effects from detention basins and floodplains.

The combined application of these river routing models enables the explicit simulation of changes of cross-section

geometry, river roughness, storage options in floodplains and polders and considers further influencing factors like groundwater exchange. Within the scope of this project, SOBEK was applied to the simulation of the Rhine stretch between Maxau and the Dutch border and the lower parts of the rivers Neckar, Main, and Lahn. SYNHP was applied for the calculation of different retention scenarios in the remaining and upper stretches of the tributaries and furthermore for the upper courses of the relevant Rhine tributaries.

Summary of the modeling results at the large scale

This study is an example of a multiscale process-oriented coupling of different models in order to assess the impacts of land use and river training measures on the runoff of a large catchment. For the first time, it was possible to give quantitative estimates for the impacts of land-use change and river training measures on the flood conditions for the river Rhine. Examples for the process-oriented modeling of land-use change impacts at the lower mesoscale have been demonstrated above; the study as a whole is documented in the Commission for the Hydrology of the River Rhine (CHR) report (Bronstert *et al.*, 2003).

Three different land-use scenarios in the catchment, focussing on urbanization and/or urban storm water treatment, have been taken into consideration:

1. Scenario $D1$ is based on a rather realistic scenario of about a further 10% expansion of urban areas in the Rhine catchment as projected by Dosch and Beckmann (1999),
2. Scenario $D2$ includes the increase of urban area of scenario D1 and, additionally, a planned project for controlled infiltration of urban storm runoff in 2500 km^2 urban areas, as recommended in the flood action plan of the International Rhine Commission (IKSR, 1998), and
3. Scenario $D3$ representing an "extreme scenario" of a 50% increase of urban areas.

All scenarios D1, D2, and D3 also consider the effects of the planned or already constructed flood defense works along the Rhine between Maxau and Lobith. These modeled river training measures include flood polders along the Upper Rhine below Maxau (total volume 79.2×10^6 m^3) and along the Lower Rhine (total volume 65.4×10^6 m^3). However, the planned flood polders along the Upper Rhine upstream of Maxau (207.6×10^6 m^3) have not been assessed in this study.

These three scenarios of land use and/or river training (river retention) measures were simulated driven by *three different scenarios of meteorological forcing*, one observed extreme and large-scale precipitation situation and two designed "extreme meteorological scenarios" in order to test the model system for even more severe meteorological conditions.

1. Scenario $M95$: Meteorological forcing (in its observed spatial and temporal distribution) of January/February 1995, which caused a flood in the Rhine with a return period >100 years,
2. Scenario $M95+$: Meteorological forcing of January/February 1995 *plus* a linear increase of precipitation of 20%,
3. Scenario $M95++$: Meteorological forcing of January/February 1995 *plus* a linear increase of precipitation of 20% *plus* an additional pre-event snow water equivalent of 20 mm over the whole catchment.

In Table 5, a summary of the model results is presented by listing the combined effects of land-use scenarios and meteorological scenarios. The modeled differences in water levels (in cm) at five main gauging stations of the Rhine are given. The values without parentheses are due to the combined effects of land-use change (increase of urban areas) and river training (increase of flood-discharge retention in river polders). The values in parenthesis are due to land-use change only (first value) and due to river training only (second value). Positive numbers imply a decrease in water level and negative numbers imply an increase.

From the differences in water levels listed in Table 5, one can draw several conclusions:

- The increase of flood peak level due to a further moderate (realistic) increase of urbanized areas (D1) is very small (water level increase 2 cm of less) and therefore almost negligible.
- The influence of the proposed management of urban storm water results in a very limited mitigation of flood peaks (water level decrease 2 cm or less) and therefore is almost negligible, too.
- The effects of water retention in flood polders (between Maxau and Lobith) have a stronger but still small effect (water level decrease of 3 cm of less for the M95 scenario, up to 10 cm for the M95+, and up to 17 cm for M95++). It is important to understand that consideration of the possible retention polders upstream of Maxau would yield an additional reduction in the range of 10 cm, in particular, for the Upper Rhine area.
- The unrealistic, extreme land-use scenario (50% increase of urban areas) would result in a water level increase not much more than 10 cm.
- The M95+ and even more the M95++ scenario results in higher reduction of flood levels in the case where the flood polders are active. This is because of the fact that according to the operation rules, the flood polders are to be filled only if flood discharge exceeds the 200-year value. In January/February 1995 (M95) the flood discharge along most stretches of the Rhine was above the 100-year value, but below

Table 5 Modeled changes in water level (cm) at five main gauging stations of the Rhine, due to scenarios of land-use change and river training (river retention) measures for three different meteorological scenarios. Explanations are given in the text (from Bronstert *et al.*, 2003)

Rhine gauging station (km downstream Lake Constance)	Meteorological scenario		
	M95	M95+	M95++
Worms (km 444)			
D1	0 (0/0)	10 (0/10)	16 (0/16)
D2	0 (1/0)	9 (0/10)	16 (−1/17)
D3	0 (−1/1)	−10 (−1/−9)	15 (−1/16)
Kaub (km 546)			
D1	1 (−1/2)	8 (−1/9)	9 (−2/11)
D2	1 (−1/2)	8 (−1/9)	9 (−1/11)
D3	−5 (−7/3)	3 (−6/8)	3 (−9/11)
Andernach (km 614)			
D1	0 (−1/1)	5 (−1/6)	6 (−1/8)
D2	1 (0/1)	6 (−1/6)	7 (−1/8)
D3	−5 (−7/2)	1 (−5/6)	2 (−6/8)
Köln (km 688)			
D1	0 (−2/1)	5 (−1/6)	4 (−2/6)
D2	1 (0/1)	5 (−1/6)	5 (−1/6)
D3	−8 (−9/2)	−1 (−7/6)	−3 (−9/7)
Lobith (km 857)			
D1	2 (−1/3)	2 (−1/3)	2 (−1/3)
D2	2 (−1/3)	3 (−1/3)	2 (−1/3)
D3	−1 (−5/3)	−2 (−6/3)	−5 (−8/3)

D1: Current land-use conditions and a 10% increase of urban area.
D2: Current land-use conditions and increase of urban area (D1) *plus* controlled infiltration of urban storm runoff.
D3: Current land-use conditions and a 50% increase of urban area (''extreme urbanization scenario'').
M95: Meteorological forcing (in its observed spatial and temporal distribution) of January/February 1995.
M95+: Meteorological forcing of January/February 1995 *plus* a linear increase of precipitation of 20%.
M95++: Meteorological forcing of January/February 1995 *plus* increase of precipitation *plus* an increase of snowwater equivalent.

200 years. That is why the polders were used only at a few stretches resulting in small water level reduction only.

Some more general results from the whole study are summarized in the following:

1. At the lower mesoscale level the influence of land use on storm-runoff generation is stronger for convective storm events with high precipitation intensities than for long advective storm events with low precipitation intensities because only storm events associated with high rainfall intensities are at least partially controlled by the conditions of the land cover and/or the soil surface. Convective storm events, however, are of minor relevance for the formation of floods in the large river basins of central Europe because the extent of convective rainstorms is usually restricted to local catchment areas rather than widespread occurrence.
2. An estimated, rather dramatic, further increase of urban areas of about 50% may result in an increase of medium-size flood peak discharge (e.g. return intervals between 2 and 8 years) in catchments of the lower mesoscale (up to ca. 1000 km^2):
   - Between 0% and 4% for advective rainfall events, and
   - Up to 30% for convective rainstorms,
3. The flood impacts due to a more realistic representation of urbanization increase are in the order of 1 cm to 5 cm in the main channel, while the effects are even less for extreme rainfall amounts.
4. The decentralized storage, detention, and infiltration of urban storm water yields reduction of flood peaks in catchments of the lower mesoscale which are about

the same size as the increase due to urbanization (see the preceding text).

5. The superposition of flood waves originating in different subbasins shows that the maximum effect of water retention in the landscape generally occurs in the rising limb of the flood wave in the main channel. The flood mitigation effect at the peak is considerably smaller.
6. Water retention measures in polders along the Upper and Lower Rhine, under the given boundary conditions, yield flood peak attenuation along the Rhine all the way down to Lobith of between 1 cm and 15 cm (see the preceding text). The optimized and coordinated control of the polders can result in a considerably stronger decrease of the peaks.

The results of this study examined the responses to the different scenarios in a purely deterministic way, as a tool to evaluate the changes in process dynamics due to the postulated scenarios of climate and land-use change. A more comprehensive study, as recommended earlier, should also attempt to evaluate the uncertainties in the predictions of change.

CONCLUSIONS

Rainfall-runoff models can be adequate tools to assess the impacts of climate and land-use changes on the hydrological cycle. This implies that the applied rainfall-runoff model is able to "represent" the dynamics of the system to be modeled, that is, the hydrological cycle of the catchment under study, in particular – if land-use change is of concern – the effects of land-use (or land cover) change on the runoff generating processes. This may be accomplished by applying a process-based model (with a rather direct alteration on the model parameter) or by applying a conceptual model if its parameters can be regionalized in connection to land-use change. Furthermore, the chosen model must be able to "represent" the influence of different climatic/meteorological boundary conditions. Like any model, the chosen rainfall-runoff model cannot give a full picture of reality, however, it is important that the model represents the main part of the system dynamics. This implies, of course, that we know (or at least have a well-educated guess) of the main dynamics of the catchment under consideration. The more we know about the catchment to be modeled and the better the model is able to "represent" this knowledge and the more reliable the model results will be.

Different modeling purposes result in different requirements for the rainfall-runoff model to be applied. For instance, before starting the assessment, one has to clearly define the appropriate time and space scale if the focus is on the average water balance or, for example, on hydrological anomalies (floods and droughts). As mentioned above, the boundary conditions are of similar importance to the rainfall-runoff model itself. This means that the whole modeling procedure must contain an adequate, scientifically sound handling of the boundary conditions. A changed climate or an altered land-use condition should not be arbitrarily chosen, instead be based on *reasonable assumptions about the trend of driving forces* influencing climate (e.g. green house gas concentrations) or land use (e.g. economic development), and the *expression of the changed climate or land-use conditions for the space and timescale which is relevant* for the study.

Climate change and land-use change assessment studies using rainfall-runoff models can be treated independently as long as no feedback effects of climate on land use or vice versa are relevant. In most assessment studies, such feedback effects are not on top of the priority list. However, for long-term (decades or centuries) assessment studies the relevance of such feedbacks should be discussed *a priori* and, if necessary, coupled boundary conditions should be defined, or coupled (integrated) models be developed (Bronstert *et al.*, 2005).

Uncertainty assessment is of particular interest for this kind of rainfall-runoff modeling, because both the uncertainty within the rainfall-runoff modeling procedure (data, process, parameter uncertainty), and the uncertainty due to the definition of the scenarios (boundary condition) are relevant. It is an ongoing challenge and an area of present research to reflect the different sources of uncertainty and to quantify it as much as possible.

The ideas presented above are sorted into a few statements yielding – a rather ambitious and often hard to follow – scheme for quality control while modeling the impacts of climate and land-use change:

1. Define the modeling purpose clearly, including the definition of the important hydrological processes, the relevant time and space scale, and the role of hydrological anomalies.
2. Check if the chosen rainfall-runoff model contains/represents the relevant processes of the system to be modeled, under the given purposes.
3. Check model performance, for example, by comparing the model results obtained on the basis of today's-boundary conditions with observed data, and by evaluating model results with several catchments with differing land-use and/or different climate conditions.
4. Define the overall trend of the land use and/or climate change and develop the land use and/or climate scenario in the time and space scale which is relevant for the specific study.
5. Check if feedback effects of climate and land use are important for the specific study, and – if so – develop integrated scenarios.
6. Assess the uncertainty of the whole system modeled, including both the uncertainty within the rainfall-runoff modeling procedure (data, process, parameter

uncertainty), and the uncertainty due to the definition of the scenarios (boundary condition).

Acknowledgments

The author would like to thank Dr. G. Bürger for the downscaling of climate and precipitation scenarios, Dr. Uta Fritsch for her derivation of the land-use scenarios in the Lein catchment and the Rhine basin, Dr. L. Menzel for the climate and land-use change assessment of the Elbe and Mulde catchments, and – last but not least – Dr. D. Niehoff for the rainfall-runoff modeling on the Lein catchment. Thanks are also due to the Commission for the Hydrology of the River Rhine for data provision of the Rhine catchment and the whole LAHOR team for the steady and successful conductance of this project. The work reported here was partly funded by the European Commission (DG XII for the EUROTAS project; DG XVI – IRMA-programme for the LAHOR project) and by the German Federal Environment Agency (UBA).

133: Rainfall-runoff Modeling of Ungauged Catchments

GÜNTER BLÖSCHL

Institute for Hydraulic and Water Resources Engineering, Vienna University of Technology, Vienna, Austria

Catchments where no runoff data are available are termed ungauged catchments. For these catchments, the parameters of rainfall-runoff models cannot be obtained by the calibration on runoff data and hence need to be obtained by other methods. Model parameters that require calibration are usually transposed from similar gauged catchments. This article reviews concepts for identifying hydrologic similarity as well as methods for transposing the parameters of both event models and explicit soil moisture accounting (ESMA) models. Model parameters that are physically based are usually measured or inferred from other data within the ungauged catchment of interest. This article summarizes the most important methods and discusses the issues of using point scale field data in rainfall-runoff models. Alternatives to runoff data for model calibration are suggested. The value of soft data and qualitative field observations is emphasized.

INTRODUCTION

Most catchments of the world are ungauged. Even though more than 60 000 stream gauges are installed worldwide (WMO, 1995), there are a couple of orders of magnitude more catchments where no runoff data are available. These are termed *ungauged catchments*. In these catchments, rainfall-runoff models must be used to calculate runoff and other variables, given rainfall (and other climate variables) as an input. There are both operational and academic drivers for pursuing rainfall-runoff modeling of ungauged catchments. The former include design applications (of spillways, culverts, and embankments), forecasting applications (flood warning and hydropower operation), and catchment management applications (water allocation, climate impact studies), the latter are geared toward understanding the catchment functioning and how the individual processes combine to produce catchment response.

The main challenge with rainfall-runoff modeling in ungauged catchments is the lack of local runoff data that could be used for calibrating model parameters. Parameter calibration is important for a number of reasons. First, with the exception of the water balance equation, there is no unique hydrological equation that can be derived from first principles, so most of the model equations are empirical in nature and tend to depend on the hydrological setting (Chapter 1 On the fundamentals of hydrological sciences. Volume 1). Calibration can account for the effects of the hydrological setting in a particular catchment. Second, hydrological models are very much dependent on their boundary conditions, and these are often poorly defined. Calibration can adjust for biases in the inputs, for example, as a result of orographic effects and instrument biases. Third, and probably most important, the media properties (both soil and vegetation) are highly heterogeneous and essentially always unknown or at least poorly known. Soil properties can change dramatically in space but change very little with time, so parameter calibration can significantly enhance the performance of rainfall-runoff models. This led Beven (2000) to remark that: "However such models are constructed, they will have some parameters that will need to be defined for each application site". While the calibration on runoff data has served hydrology well in the past, this is not an option in ungauged catchments. Alternatives are needed which are the subject of this article.

The most efficient method of addressing the issue of ungauged catchments is to glean the model parameters (and perhaps the model structure) from analogue catchments in

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

the region, that is, from one or more catchments that one can expect to behave similarly to the catchment of interest. This article therefore first discusses hydrological similarity in the context of rainfall-runoff modeling (Section "Hydrological similarity in rainfall-runoff modeling"). Rainfall-runoff models use two broad categories of model parameters: physically based parameters that in principle can be observed or estimated directly from measurements in a catchment; and calibration parameters that appear in empirical relationships and need to be back-calculated from rainfall and runoff data. The calibration parameters need to be transposed from similar, gauged catchments and these methods are reviewed in Section "Transposing calibration parameters from similar, gauged catchments". Physically based parameters, on the other hand, can be observed in the catchment of interest, although with some restrictions. This is discussed in the Section "Measuring or inferring physically based model parameters in an ungauged catchment". Even though in an ungauged catchment no runoff data are available, other hydrologic response data may be available and could be used as an alternative for model calibration and testing. This is dealt with in the Section "Alternatives to runoff data for model calibration".

HYDROLOGICAL SIMILARITY IN RAINFALL-RUNOFF MODELING

If the rainfall-runoff processes in two catchments are similar, their hydrologic responses will be similar too. This is the notion of hydrologic similarity. Similarity of hydrological processes can be defined in various ways. Dunne (1978) suggested that runoff processes are mainly controlled by physioclimatic controls and identified three main types: Infiltration excess runoff which is generated from partial areas where surface hydraulic conductivities are low; saturation excess runoff which is generated in areas with shallow water tables or near-channel wetlands; and subsurface storm flow which is likely to be active and dominant on steep, humid forested hillslopes with very permeable surface soils. In two similar catchments, the relative role of each of these processes would be similar. The characteristics of these processes in natural catchments are never known in full detail so a number of similarity concepts have been proposed in the literature that attempt to represent these processes to various degrees.

1. *Spatial proximity:* In the first concept, catchments that are close to each other are assumed to behave in hydrologically similar manner. The rationale of this concept is that the controls on the rainfall-runoff relationship are likely to vary smoothly in space, so one can expect spatial proximity to be a good indicator of the similarity of catchment response. This has been one of the traditional methods of regionalizing rainfall-runoff model parameters and is usually based on delineating on a map, spatially contiguous regions with approximately homogeneous model parameters. The regions are found from an analysis of a small number of gauged catchments in each of the regions (e.g. Nathan and McMahon, 1990) by exercising expert judgment supported by whatever hydrologic information that is available. Hydrologic information may consist of hydrogeologic maps, climate maps, soil and vegetation maps, and the seasonality of hydrologic response as an indicator of hydrologic processes (e.g. Merz *et al.*, 1999). The regions found in this way will be plausible but it is not straightforward to formalize the procedure. Also, the uncertainty associated with identifying the regions is not usually known. As an alternative to contiguous regions, interpolation methods such as "kriging" have been used more recently as one way of exploiting spatial proximity as a similarity measure (e.g. Merz and Blöschl, 2004, 2005).

2. *Similar catchment attributes:* The second similarity concept consists of using measurable catchment attributes as indicators of hydrological similarity. The assumption is that if catchment attributes such as soil type, vegetation type, and topographic characteristics of two catchments are similar, one would expect the hydrologic response to be similar. Again, this is a plausible assumption, although few studies have conclusively demonstrated the predictive power of catchment attributes. Catchment attributes can be used in different ways. The first method is to use them to define a group of hydrologically similar catchments. The similarity between catchments is usually quantified by a distance measure as a function of the differences of the catchment attributes in the two catchments. The distance measure is zero if the catchment attributes in the two catchments are identical and increases as the attributes get more dissimilar. From the matrix of distance measures, the grouping can then be obtained by a range of statistical methods such as cluster analysis, principal component analysis, and classification trees (Nathan and McMahon, 1990; Bates, 1994; Breiman *et al.*, 1984). One particular variant of this method is the region of influence approach where for each catchment of interest a separate pooling group is formed (Burn and Boorman, 1993). Once the groups are identified, the model parameters (and perhaps the model structure) can be transferred from an analogue gauged catchment to an ungauged catchment within the same group.

The second method of using catchment attributes consists of defining relationships between model parameters and catchment attributes. There is a wide spectrum of methods ranging from multiple regression methods for calibration parameters (see Section "Explicit soil moisture accounting models") to empirical formulae in engineering design (see Section "Event models"). The structure of these relationships is often dictated by parsimony and convenience although some degree of process reasoning can come in. The parameters of the relationships are usually based on the analysis of a large number of gauged catchments. In

multiple regressions, one may encounter problems with multicollinearity if one or more of the catchment attributes is highly correlated with another catchment attribute or with some linear combination of them. Multicollinearity will reduce the reliability of the regression coefficients (Hirsch *et al.*, 1992). One therefore limits the number of catchment attributes used in the regression, sometimes combining a number of attributes into an index that is deemed representative of one particular aspect of the rainfall-runoff model (such as a baseflow index, IH, 1999). Sequential regression may assist in identifying robust parameter estimates (Calver *et al.*, 2004; Lamb and Kay, 2004). The extension of this general approach of using catchment attributes are methods that derive physically based model parameters from landscape or catchment attributes (see Sections "Local scale measurements and relation to landscape attributes" and "Upscaling local measurements to catchment/model element scale"). Sometimes, the first and second methods are combined in using relationships between model parameters and catchment attributes only within regions that are homogeneous with respect to a certain set of catchment attributes (e.g. Burn and Boorman, 1993). A formal way of combining the two methods results in the CART model (Breiman *et al.*, 1984; Laaha and Blöschl, 2005a). In CART models, the independent variables are the catchment attributes and the dependent variables are the model parameters. Regression trees then divide a heterogeneous domain into a number of more homogeneous regions by maximizing the homogeneity of model parameters and catchment attributes within each group simultaneously. Regression trees have a number of advantages over other models. Their structure is nonparametric, small trees are readily interpretable, there is no global sensitivity to outliers, and they are able to handle nonlinear relationships well. However, big trees are difficult to interpret, there is a lack of smoothness, and there are potential problems with overfitting the data, so the trees need to be pruned (see, e.g. Breiman *et al.*, 1984).

The third method of using catchment attributes in defining hydrological similarity has originated from the use of geographical information systems in hydrological modeling. In this method, patches of the landscape are classified into groups of similar topographic slope, aspect, elevation, vegetation type, soil type, and precipitation distribution, for example, by overlaying maps of the different types of information. Each group is termed a *hydrological response unit* (HRU) and all the elements in a group are assumed to exhibit the same hydrological response characteristics (Leavesley and Stannard, 1995). This again is based on the assumption that similar catchment attributes would be associated with similar hydrologic processes. The way the layers of information are combined can have various degrees of process representation. Flügel (1995), for example, combined the layers by reasoning such as "rangeland on gley soil at the valley floor with shallow groundwater over impervious bedrock". HRUs are often the method of choice when inferring physically based model parameters from landscape attributes. The main difficulties with the use of HRUs is that the estimation of parameters for multiple HRUs in a catchment is not simple, either in calibration or for ungauged catchments (*see* **Chapter 122, Rainfall-runoff Modeling: Introduction, Volume 3**), and that measurable landscape attributes and model parameters are often poorly correlated (see Sections "Limitations and challenges" and "Local scale measurements and relation to landscape attributes").

3. *Similarity indices:* Similarity indices are based on some understanding of the structure of runoff generation and runoff routing and are usually defined as a dimensionless number. Two catchments or two parts of the landscape would then behave hydrologically similar if they are associated with the same value of the similarity index (Blöschl and Sivapalan, 1995; Aryal *et al.*, 2002; *see also* **Chapter 3, Hydrologic Concepts of Variability and Scale, Volume 1**). Similarity indices differ in terms of the processes they aim to represent. Similarity in climate can be quantified by the aridity index of Budyko (1974), for example, which is the ratio of long-term potential evaporation to precipitation. Atkinson *et al.* (2002) and Farmer *et al.* (2003) used this type of climatic index for analyzing suitable rainfall-runoff model complexities as a function of timescale and climate characteristics. Similarity in channel flow processes can be quantified by the stream ordering and other characteristics of the map view of the channel topology (e.g. Rodríguez-Iturbe and Valdés, 1979; Rinaldo *et al.*, 1995). Similarity in catchment processes can be quantified by topographic indices (Moore *et al.*, 1991). Examples include the topographic wetness index of Beven and Kirkby (1979), which is a function of the area drained per unit contour length at a given point and the local slope gradient. Catchment characteristics such as soil depths may be incorporated in the index. Each patch in the landscape exhibiting the same value of the index is considered to produce the same hydrologic response. Two catchments are then deemed similar if their distributions of the index are identical. On the basis of this similarity index, Sivapalan *et al.* (1987) identified five nondimensional similarity parameters that represented the interrelationships of topography, soil, and rainfall, which lead to similar catchment responses. Larsen *et al.* (1994) and Robinson and Sivapalan (1995) extended this work concentrating on the relative dominance of the infiltration excess and saturation excess mechanisms. The advantage of this type of index is that they are not purely empirical so their structure may be more defendable than that of the empirical relationships between model parameters and catchment attributes discussed previously. The drawback is that the inputs needed for the indices are often difficult to specify in ungauged catchments. Also, tests of some

of these indices against spatial soil moisture data have given mixed results, as their applicability depends on catchment conditions and climate (e.g. Lamb *et al.*, 1998; Western *et al.*, 1999; Blazkova *et al.*, 2002). Similarity indices are therefore currently not widely used in practice although they constitute an active and promising area of research.

The various concepts of hydrological similarity are potentially useful for inferring a suitable model structure in ungauged catchments, but their main application lies in transposing model parameters in space. The following section focuses on the case of calibration parameters.

TRANSPOSING CALIBRATION PARAMETERS FROM SIMILAR, GAUGED CATCHMENTS

Methods

Calibration parameters are those that cannot be measured or inferred from measurements but need to be transposed from gauged catchments in the region. These gauged catchments should be hydrologically similar to the catchment of interest in the sense discussed earlier. Rainfall-runoff models can be either event models or ESMA models (*see* Beven 2001a and **Chapter 122, Rainfall-runoff Modeling: Introduction, Volume 3**). Event models require initial conditions on the soil moisture status of the catchment and are usually run over several hours. ESMA models, in contrast, account for the changes of soil moisture stores in a catchment through taking stock of evapotranspiration, precipitation, and runoff and are usually run over several years. Different model parameters exist in each type of model: runoff coefficient (or loss) parameters and lag time (or time to peak) parameters in the case of event models; and evaporation parameters, runoff generation parameters and storage coefficients in the case of ESMA models. The procedures for transposing these parameters from similar, gauged catchments in the region to an ungauged catchment are, however, similar for the two model types. The transposition typically involves the following steps:

1. Delineation of homogeneous regions and/or identification of one or more gauged catchments, termed *donor catchments*, based on any of the similarity measures discussed in Section "Hydrological similarity in rainfall-runoff modeling".
2. Estimation of model parameters for the donor catchments by manual or automatic calibration on observed runoff data (*see* **Chapter 131, Model Calibration and Uncertainty Estimation, Volume 3**).
3. Selection of catchment attributes that are deemed to affect catchment response to rainfall. This is either based on an *a priori* understanding of what attributes may be relevant to a particular model parameter or on some goodness-of-fit measure.
4. Setting up models relating each rainfall-runoff model parameter to a set of catchment attributes. In this step, commonly, multiple linear regressions are used (see Section "Hydrological similarity in rainfall-runoff modelling"), and some or all of the catchment attributes are (e.g. logarithmically) transformed.
5. Testing the strength of the relationship of (4), for example, by some goodness-of-fit measure such as a correlation coefficient.
6. Estimating each parameter of the rainfall-runoff model for the ungauged catchment from the (regression) model.
7. Simulating runoff for the ungauged catchment of interest by applying the same model as in (2), using the regionally transposed model parameters.
8. Testing the transposition by cross-validation. A gauged catchment is assumed to be ungauged, runoff is simulated as in (7) and then compared with the locally observed runoff.

Some of these steps can be skipped depending on the data availability and the similarity concept chosen. In the simplest case of using model parameters from one or more donor catchments directly in the ungauged catchment, steps (3 – 6) can be skipped. Alternatively, results from the literature can be used for any of the steps. The less the information available in the region of interest, the fewer the steps that can be carried out, but this is likely at the cost of decreasing model performance. In each of these steps it is prudent to not only find the "best" relationships or parameters but also to find some measure of the uncertainty associated with the estimates. In step (1) alternative regions and/or donor catchments can be examined and their suitability can be tested by cross-validation (step 5); in step (2) formal methods of parameter uncertainty analysis can be used or less formal sensitivity analyses and split sample methods (*see* **Chapter 131, Model Calibration and Uncertainty Estimation, Volume 3**); in step (3) alternative catchment attributes or combinations of catchment attributes can be used and tested in a similar way; and in step (4) alternative transposition models can be tested. The advantage of the cross-validation test in step (5) over other methods of assessing uncertainty, such as sensitivity analyses, is that it examines a combination of a number of sources of uncertainty including the data, the model parameters, and the structure of both the runoff model and the transposition model.

Event Models

As an example for estimating model parameters for event-based rainfall-runoff models, the procedure recommended in the UK Flood Estimation Handbook (FEH) (IH, 1999: `http://www.nwl.ac.uk/ih/feh/`) will be very briefly summarized. The general recommendation in the FEH is to

use runoff data wherever possible including records as short as a year. In ungauged catchments, this is obviously not possible. The preferred method for ungauged catchments is to use the parameters from a similar (donor) catchment in the region. As a last resort, relationships between model parameters and catchment attributes can be used. These involve the largest errors. It is also recommended to combine the last two methods and scale the parameters from the donor catchment by the ratio of the parameter estimates from catchment attributes in the catchment of interest and those in the donor catchment. It is suggested to estimate the time-to-peak parameter, if needed, from the following catchment attributes: mean drainage path slope, mean drainage path length, extent of urban land cover, and a parameter representing the proportion of time when soil moisture deficit was below 6 mm during a standard period. The runoff coefficient can be estimated as the sum of three terms. The first represents the normal capacity of a catchment to generate runoff. It varies between catchments but does not vary between storms and is estimated from the Hydrology of Soil Types (HOST) soil classes (Boorman *et al.*, 1995). The second term represents the variation in runoff depending on the antecedent soil moisture and can be estimated from mean annual precipitation. The third term depends on the storm rainfall depth and represents the nonlinearity in runoff generation. There is also a correction for urbanization.

There are numerous recommendations in the engineering hydrology literature of how to obtain model parameters in ungauged catchments, but they all fall into one of the two categories of transpositions from similar, gauged catchments and empirical formulae (e.g. USACE, 1994; Bates, 1994). In the empirical formulae, lag time parameters are often a function of morphometric parameters such as topographic slope, stream slope, and flow length (e.g. USACE, 1994). Loss parameters are often a function of land cover, soil type, and antecedent soil moisture (such as in the Curve Number method of the US Soil conservation service (SCS, 1973; Mishra and Singh, 2003; Merz *et al.*, 2005). There is also the option of making use of the structure of the empirical equations and adjusting their coefficients by analyzing runoff data in the region which, from a practical perspective, is probably more meaningful than applying any of the (black box) regression equations in use. In most studies, the emphasis is on finding a best-fit curve between the runoff model parameters and their controls. The uncertainty around these best-fit curves is often immense (Cordery and Pilgrim, 1983). Because of this, similar to the suggestion of the FEH, the general recommendation is to analyze runoff data from similar gauged catchments in the region whenever possible and use them by one method or another for estimating the model parameters in the ungauged catchment of interest.

Explicit Soil Moisture Accounting Models

Little is known on the process relationships between the parameters of conceptual ESMA models and the measurable catchment attributes. Because of this, the most widely used method of estimating ESMA model parameters is either by using uniform zones or regions (e.g. lithological zones in Drogue *et al.*, 2002), or by multiple regressions from catchment attributes. However, most of the case studies published in the literature have found rather low correlations. Sefton and Howarth (1998), for example, compared calibrated parameters of the IHACRES model with attributes of 60 catchments in England and Wales. The best correlations they obtained were $R^2 = 0.59$ between a routing parameter and percentage of aquifers, and $R^2 = 0.69$ between an evaporation parameter and mean annual precipitation. For the storage parameters no significant correlations were obtained. Seibert (1999) related the model parameters of the HBV model (Bergström, 1976) to attributes of 11 Swedish catchments within the NOPEX area. The relationships between forest percentage and snow parameters could be interpreted on hydrological grounds but other relationships could not. The rank correlation coefficient between a nonlinearity parameter of runoff generation and catchment area was $R^2 = 0.87$ but most other parameters exhibited hardly any significant correlations with catchment attributes. These typically low correlations are likely to translate into rather low model performances for the ungauged catchment case. In Seibert's (1999) study, the median Nash and Sutcliffe (1970) model efficiency decreased from 0.81 to 0.79 when moving from calibrated parameters to regionalized parameters for the same set of 11 catchments, but the median efficiencies decreased to 0.67 for a separate set of 7 catchments. A model efficiency of 1 indicates a perfect fit while smaller values indicate poorer fits. In a Norwegian study, Beldring *et al.* (2002) used 141 catchments for calibrating a version of the HBV model. They then treated 43 additional catchments as ungauged and regionalized the model parameters as a function of land use classes. For both sets of catchments they found median Nash–Sutcliffe efficiencies of 0.68 and concluded that the regionalization method represented the main features of the landscape well. However, for 20% of the second set of stations the efficiencies were less than 0.3.

In a recent study, Merz and Blöschl (2004) simulated the water balance dynamics of 308 catchments in Austria using a lumped ESMA model involving 11 calibration parameters. The parameters were calibrated separately on two nonoverlapping 11 year periods of daily runoff data to assess the reliability of the calibrated model parameters. Figure 1 shows two of the parameters. Figure 1(a) gives the calibrated *beta* parameter, which is the nonlinearity parameter in the function relating runoff generation to the soil moisture state. There are distinct patterns of low values in the West and high values in the East. The regional

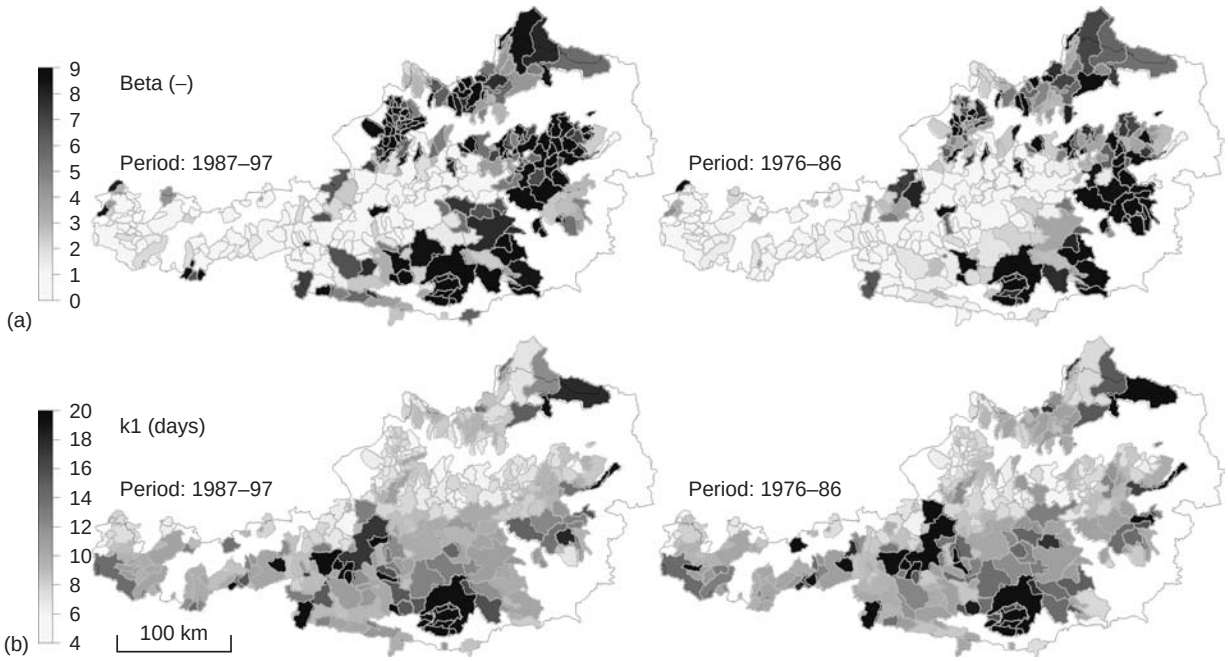

Figure 1 Patterns of calibrated model parameters (left: calibration period 1987–1997, right: calibration period 1976–1986). (a) Nonlinearity parameter, *beta* (–). (b) Fast storage coefficient k1 (days) (From Merz and Blöschl, 2004 by permission of Elsevier). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

differences in *beta* imply a relatively linear rainfall-runoff relationship and large runoff coefficients in the wetter alpine catchment in the West, and a nonlinear rainfall-runoff relationship and small runoff coefficients in the dryer lowland catchments in the East. Figure 1 (b) shows the spatial patterns of the fast storage coefficient. There is a tendency for faster responses in the prealpine catchments of the North than in the alpine catchments of the South. The regional patterns of the parameters for the two periods are similar although large local differences occur. This suggests that the calibrated parameters are able to represent the regional or large-scale differences in the hydrological conditions. One would therefore assume that it is possible to derive regional relationships between the calibrated parameter values and catchment attributes. Merz and Blöschl (2004), however, found that the correlation coefficients were relatively low with maximum values of $R^2 = 0.27$. They then compared various methods for estimating the model parameters in ungauged catchments in terms of their ability of simulating runoff, judged against runoff data (i.e. a cross-validation; Table 1, Figure 2). The regionalization methods significantly increased the predictive performance from the cases of preset parameters (Figure 2a) and global average parameters (Figure 2b). The increase in performance depended on the regionalization method. Average parameters of immediate upstream and downstream neighbors (Figure 2f) and regionalization by kriging (Figure 2 g) performed somewhat better than multiple regressions with catchment attributes (Figure 2d). For the calibration period, the median of the Nash–Sutcliffe model efficiency decreased from 0.67 to 0.57 when moving from gauged to ungauged catchments (Table 1, using kriging for regionalization). For the verification period, the median decreased from 0.63 to 0.56. This means that the uncertainty introduced by moving from gauged to ungauged catchments is about twice the uncertainty of moving from the calibration to the verification period. Of particular interest is the change in the bias of simulated runoff (i.e. volume errors). While the median values are always small, the scatter between catchments (quantified by the difference of the 75% and 25% quantiles) doubles when moving from the calibration to the verification period, but increases by a factor of 5 when moving from gauged to ungauged catchments. This illustrates the value of model calibration in reducing bias in gauged catchments and the uncertainties in ungauged catchments where calibration is not an option Parajka *et al.* 2005a extended the analysis of Merz and Blöschl (2004) by modifying the model structure and testing additional regionalisation methods. Their model efficiencies were higher than those of Merz and Blöschl (2004) but their main findings remained similar.

Limitations and Challenges

There are three potential explanations of the relatively poor correlations between model parameters and catchment attributes, and the relatively poor performance of both event-based and ESMA models when parameters estimated from catchment attributes are used.

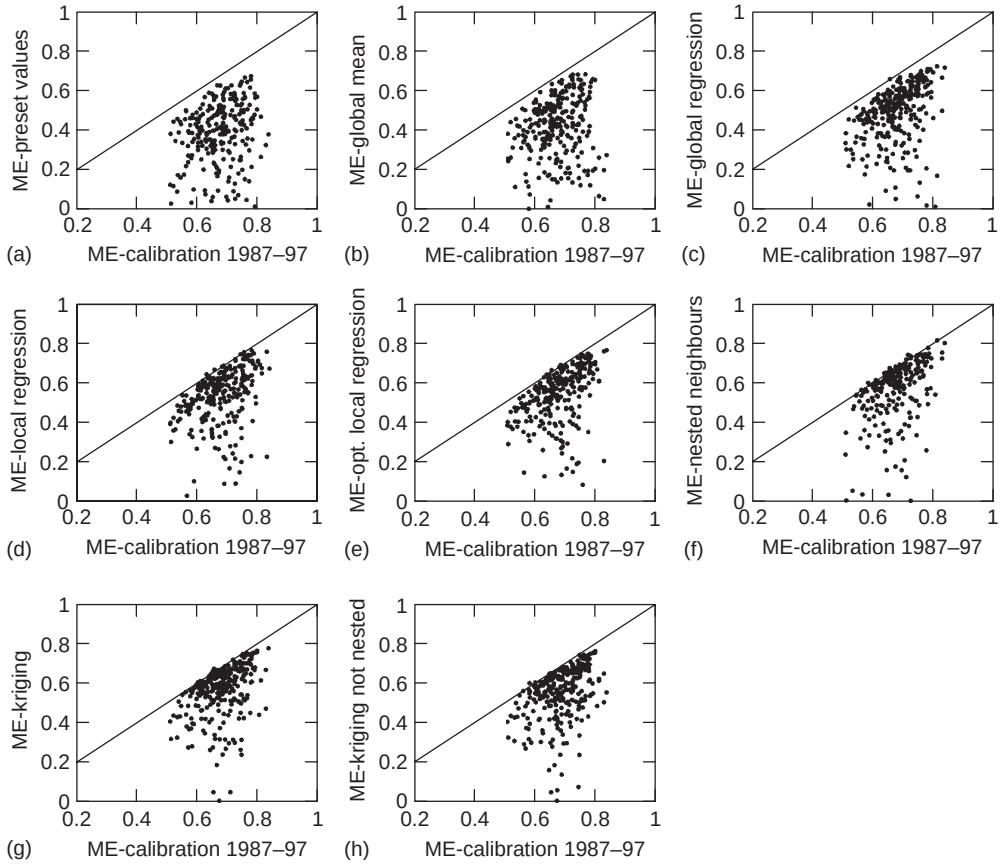

Figure 2 Nash–Sutcliffe model efficiencies of regionalized versus calibrated parameters for the period 1987–1997. (a) preset parameters, (b) global mean of all catchments, (c) global regression with catchment attributes using all catchments, (d) local regression within a 50 km neighborhood, (e) optimized local regression, (f) average parameters of immediate upstream and downstream (nested) neighbours, (g) kriging, (h) kriging without nested neighbours (From Merz and Blöschl, 2004 by permission of Elsevier)

Table 1 Model performance for gauged catchments and ungauged catchments (kriging regionalization) by cross-validation, both for the calibration and the verification periods. ME: median Nash–Sutcliffe efficiency of runoff plus or minus difference of 75% and 25% quantiles of efficiencies, that is, a measure of scatter. Bias: Median relative volume errors of runoff plus or minus difference of 75% and 25% quantiles of relative volume errors. Statistics are for 308 catchments in Austria. (From Merz and Blöschl, 2004 by permission of Elsevier)

	Gauged catchment	Ungauged catchment
ME–Calibration period	0.67 ± 0.10	0.57 ± 0.18
ME–Verification period	0.63 ± 0.11	0.56 ± 0.18
Bias–Calibration period	0.00 ± 0.04	0.04 ± 0.21
Bias–Verification period	-0.01 ± 0.10	0.04 ± 0.21

1. One explanation is that the measurable catchment attributes may not be very relevant for catchment response. This is certainly the case for soil type as reflected by the usually low predictive power of pedotransfer functions (see Section "Local scale measurements and relation to landscape attributes"). Catchment attributes are usually static indicators and may therefore not be very representative of the hydrologic functioning of catchments. Also, much of what is of interest in rainfall-runoff modeling happens beneath the surface while most measurable catchment attributes (such as topographic characteristics and vegetation) may be representative of the surface but are not normally representative of the hydrologically active zone in the subsurface. This will be expanded in Section "Measuring or inferring physically based model parameters in an ungauged catchment" of this article. One avenue to proceed would be to identify catchment attributes that are more representative of the processes relevant to rainfall-runoff modeling, perhaps based on similarity indices, but so far it is not quite clear how to define them at the regional scale.
2. The second explanation is that there may be significant uncertainty in the calibrated parameter values,

which may cloud the underlying relationship between calibrated model parameters and catchment attributes (e.g. Gottschalk, 2002). There are methods of accounting for parameter uncertainty in the regionalization of model parameters (see, e.g. Campbell and Bates (2001), in the case of an event scale rainfall-runoff model illustrated on 39 catchments in southwestern Australia). The examples in Figure 1 suggest that the uncertainty is not very large in this case, but it does seem important to better constrain model parameters in the calibration process. There are two possibilities. The first is to use additional data on state variables in the calibration procedure (Gupta *et al.*, 1998; Mroczkowski *et al.*, 1997; also see **Chapter 131, Model Calibration and Uncertainty Estimation, Volume 3**). For the study area of Figure 1, Parajka *et al.* (2005b) used snow depth measurements in a multiobjective calibration procedure which lead to better constrained parameters. The second possibility is regional calibration in which the model parameters of a number of catchments are calibrated simultaneously (e.g. Fernandez *et al.*, 2000; Szolgay *et al.*, 2002; Engeland and Gottschalk, 2002). Regional calibration will provide more robust parameters that are likely to translate into a reduction in uncertainty when transposing them to ungauged catchments. Merz *et al.* (2004) also showed that regional calibration may increase the correlations between calibrated model parameters and catchment attributes.

3. The third explanation is that the structure of the model relating catchment attributes and model parameters may not be suitable. Indeed, the choice of a linear regression model is one of convenience rather than one based on know relationships. An additional complication with the linear regression model is that it is an unbiased linear estimator of the model parameters but because the rainfall-runoff models are nonlinear, the regression model results in biased runoff simulations in the ungauged catchment. Also, estimating the model parameters independently from catchment attributes may lead to parameter combinations that are not very realistic. Nonlinear models (such as CART models, Section "Hydrological similarity in rainfall-runoff modelling") exist, and thresholds or bounding conditions may be introduced. For example, in the United Kingdom, the baseflow index (IH, 1999) may take on a full range of values in low rainfall areas of the country but is always low in high rainfall areas of the country. There have been a number of other attempts to include process reasoning into the estimation of calibration parameters of ESMA models. Schumann *et al.* (2000), for example, imposed the structure on some of the equations of estimating the model parameters. Another attempt is that of Koren *et al.* (2003) who derived parameters of the Sacramento model from catchment attributes on the basis of hydrologic reasoning.

There are additional sources of uncertainty including errors in the structure of the rainfall-runoff model and data errors. These are discussed in more detail in Beven (2001a) and also in **Chapter 122, Rainfall-runoff Modeling: Introduction, Volume 3**, **Chapter 131, Model Calibration and Uncertainty Estimation, Volume 3**.

MEASURING OR INFERRING PHYSICALLY BASED MODEL PARAMETERS IN AN UNGAUGED CATCHMENT

Methods

Physically based parameters are those that can be observed in the field or estimated directly from measurements of catchment or channel characteristics without the use of runoff data. They possess a physical meaning beyond the particular model used. Examples include roughness parameters such as Manning's n, hydraulic conductivity, soil depth, and surface albedo. There are, however, two types of difficulties with using measured parameters in rainfall-runoff models that are related to scale (Western and Blöschl, 1999; Blöschl, 1999). The first difficulty is that the measurement volume (or *support scale*) is usually much smaller than the model element size. The second is that in most cases there are only a few measurement locations within a catchment and the spacing between the measurements (the *spacing scale*) is hence large. This means that the measured parameter is not defined in exactly the same way as in the model even if it shares the same name (Beven, 1989). In principle, both scale disparities can be addressed by upscaling procedures. In practice, there is no generally accepted upscaling theory (see Section "Upscaling local measurements to catchment / model element scale") and one often neglects the incompatibility related to the support and addresses the incompatibility related to the spacing by some sort of interpolation procedure (see Section "Upscaling local measurements to catchment / model element scale"). In many instances, particularly when remote sensing data are used, model parameters are inferred from surrogates (e.g. roughness from land use). As the model parameters are often not very well correlated with the surrogate, this introduces additional uncertainties.

Because of these difficulties, in gauged catchments physically based parameters are often allowed some degree of calibration within a physically justifiable range to adjust some of the measurement or estimation biases. For ungauged catchments, it may therefore be of value to transfer physically based parameters from similar catchments in the region by one of the methods outlined in Section "Transposing calibration parameters from similar, gauged catchments", in addition to measuring the parameters in the field (or estimating them from remote sensing

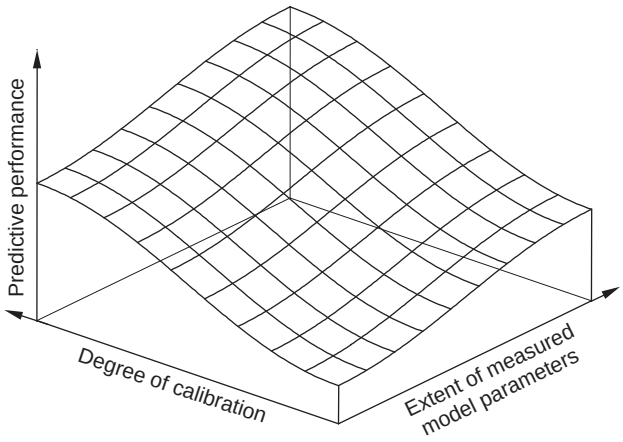

Figure 3 Schematic of the value of calibration model parameters versus measuring model parameters for a typical rainfall-runoff application

data). In fact, estimating the parameters from two or more different sources will always increase their reliability. The distinction between calibration parameters and physically based parameters is hence not a sharp one, there is a gradual transition from what one would call a calibration parameter and a physically based parameter, depending on the type and extent of information available in any particular case. Figure 3 shows a schematic of the relative value of the calibration and the measurement of model parameters for a typical rainfall-runoff model application. Both calibrating and measuring a model parameter tend to enhance the predictive performance of the model. Ideally one should pursue both avenues. The schematic also indicates that, while it is useful to measure physically based parameters, it is even more useful to have access to runoff data in a particular catchment to calibrate or adjust one or more of the model parameters. The following section reviews methods of inferring model parameters from measurements in the catchment of interest.

Local Scale Measurements and Relation to Landscape Attributes

Physically based model parameters can be inferred from field measurements or from remote sensing data. The former are usually local scale measurements and hence best suited for small catchments while the latter are more appropriate for large catchments. Often, parameters are inferred from qualitative information or surrogates. In the following, a brief summary is given of the three main categories of model parameters as used in rainfall-runoff models and how they can be related to surrogates that are more widely available than the model parameters themselves. A practical discussion of some of the parameter estimation methods is given in Duan *et al.* (2001) and Vieux (2001).

1. *Soil hydraulic characteristics*: Soil hydraulic characteristics such as the saturated conductivity, porosity, and soil water release characteristics are usually estimated from infiltration experiments at the plot scale in the field or, alternatively, from laboratory core tests. If no or only a few measurements are available, they are sometimes estimated from relationships to soil type (often defined by % sand, silt, clay, organic matter, and perhaps bulk density). These relationships are termed *pedotransfer functions*. An excellent review of pedotransfer functions and their use in hydrology is given in Wösten *et al.* (2001). The appeal of pedotransfer functions is that soil texture data are now widely available in databases such as the State Soil Geographic Data Base (STATSGO) in North America (USDA, 1991) and the European soil database (Jamagne *et al.*, 2002). The justification of using pedotransfer functions is that the grain-size distribution (defined by the soil type) should also be relevant to the pore-size distribution (which in turn is related to soil hydraulic properties). Unfortunately, this is not often the case because peds and cracks, rather than the grain-size distribution, tend to dominate the hydraulic properties. It is therefore not uncommon for the soil properties to vary as much between soil types as within a soil type (e.g. Warrick *et al.*, 1990) and for other influences such as terrain to be important to soil hydraulic properties (Gessler *et al.*, 1995). This makes Wösten *et al.* (2001) conclude that pedotransfer functions are sufficiently accurate for interpolation purposes between soil hydraulic measurements in the catchment of interest whereas they are not recommended to be used in catchments where no measurements are available. If no measurements are available, a minimum requirement for the use of pedotransfer functions would seem to be that the conditions in the catchment of interest are similar to those in the catchments in which they were derived (see Section "Hydrological similarity in rainfall-runoff modeling"), though it is worth noting that the pedotransfer functions are generally derived from measurements on small soil cores or samples.

2. *Surface roughness*: Surface roughness parameters such as Manning's n are usually determined by *in situ* experiments on irrigation plots (e.g. Hessel *et al.*, 2003). If no measurements are available, tabulated values in the literature are often used, which are a function of land cover and sometimes topographic slope (Engman, 1986). Land-cover type can be obtained either from field surveys or from analyses of satellite data. Roughness can also change with the flow rate (e.g. Sepaskhah and Bondar, 2002). Again, ideally, the conditions of the application should be similar to those where the roughness values were measured.

3. *Vegetation characteristics*: The Leaf Area Index (LAI), the Fraction of Green Vegetation (FGV), and the Fraction of Absorbed Photosynthetic Active Radiation (f_{APAR}) are vegetation characteristics that can be used in rainfall-runoff

models to estimate evapotranspiration. These vegetation characteristics can be related to land-cover classes although the relationships are not always unique (Hall *et al.*, 1995; Gorte, 2000; Kite and Droogers, 2000). Land-cover classes, in turn, can be estimated from a range of satellite data on the basis of indices such as the normalized difference vegetation index (ndvi). There exist numerous satellite-(e.g. AVHRR and Landsat) based land-cover maps such as the European CORINE land-cover data set (Büttner *et al.*, 2002), data sets for North America (see, e.g. Gallo *et al.*, 2001), as well as global data sets (e.g. Hansen *et al.*, 2000; Tucker *et al.*, 2004). Scale incompatibilities may be less stringent with satellite data than with ground data although scale issues do remain (e.g. Brunsell and Gillies, 2003).

Upscaling Local Measurements to Catchment/Model Element Scale

As mentioned previously, the *support* scale incompatibility is usually neglected but some sort of interpolation is often used to bridge the *spacing* scale incompatibility (Blöschl and Sivapalan, 1995; *see also* **Chapter 6, Principles of Hydrological Measurements, Volume 1**). The interpolation procedures usually build on the surrogate variables, discussed in the section "Local scale measurements and relation to landscape attributes", either based on different classes of the surrogates (land-cover class, soil type class, etc.) or on regression relationships or a combination of the two. The classification approach is closely related to the Hydrologic Response Unit concept (Section "Hydrological similarity in rainfall-runoff modeling") where each HRU is a unique combination of attribute classes (land cover, soil type, terrain slope, etc.). Both regressions and classifications based on HRU concepts are widely used in the literature to upscale measurements (see, Blöschl and Grayson, 2000; *see also* **Chapter 11, Upscaling and Downscaling – Dynamic Models, Volume 1**). Examples include Busch *et al.* (1999) and Bormann *et al.* (1999) who identified HRUs based on a cluster analysis of actual evapotranspiration, groundwater recharge, and surface runoff, and then performed one single simulation for each HRU. Upscaling methods based on remotely sensed data are summarized in Stewart *et al.* (1996). Upscaling methods based on geostatistical concepts are reviewed in Bierkens *et al.* (2000) and also in **Chapter 9, Statistical Upscaling and Downscaling in Hydrology, Volume 1**.

There is considerable uncertainty associated with any of these upscaling methods and the magnitude of the uncertainty is not always clear. While the standard procedure is to relate the model parameters to landscape attributes either by classification or regression methods (which are both black box methods), there are also initial attempts at incorporating hydrological understanding. An excellent example is presented in Peschke *et al.* (1999a,b) who, based on many years of field experience, mapped the *type* of runoff generation mechanism that occurred for a given catchment state in the 4.6 km^2 Wernersbach catchment in Germany. They then developed an expert system, known as *FLAB*, that estimates the dominant runoff mechanism for a given point in the landscape and a given event size. The mechanisms included were Hortonian overland flow, saturation area overland flow, interflow, recharge, and storage. The expert system is based on rules. For example, potentially contributing areas are identified on the basis of connectivity to the stream, terrain slope, and soil characteristics including layering. If, for a given event, the saturation deficit is exceeded, these areas become active saturation areas and contribute to saturation area overland flow. The rules are based both on hydrologic reasoning and field mapped runoff mechanisms for certain event types. Figure 4 shows a test of the FLAB model against the field mapped areas for two runoff mechanisms, saturation area runoff (Figure 4 (a)), and interflow (Figure 4 (b)). Each figure is a composite of the observed and FLAB simulated binary pattern of the presence/absence of the given runoff mechanism. Black indicates areas where both model and field observations identify the mechanism, grey indicates areas where presence of the mechanism is modeled but not observed, and light grey indicates areas where the presence of the mechanism is observed but not modeled. Overall, there is a close match. Saturation areas mainly occur close to the stream, interflow occurs at some distance from the stream, and this general pattern is modulated by soils and terrain slope. The strength of the FLAB approach is that the rules are based on *field scale* observations rather than on laboratory-scale measurements. This general method has the potential of being used in ungauged catchments for identifying runoff mechanisms and hence upscaling local measurements. Although the rules are not likely to be universal, identifying these rules for certain catchment regime types seems a promising area of research (Scherrer and Naef, 2003; Woods, 2003).

Soft Data and Qualitative Field Observations

Strategies of upscaling such as those of Peschke *et al.* (1999a,b) are partly based on qualitative information which one may term *"soft data"*. In addition to upscaling local measurements, this type of soft information can be used for estimating or, at least, for making an educated guess on the magnitude of model parameters in ungauged catchments. Clearly, site visits will be instrumental in this type of assessment. The value of qualitative information is illustrated by an example from the Austrian Alps. Wienerbruck and Mitterbach are two adjacent catchments that are similar in size and are similar in terms of their catchment attributes as available at the regional scale (Table 2). Wienerbruck is slightly steeper which would suggest somewhat faster response but the channel lengths are slightly larger, so most empirical equations suitable for ungauged catchments would give similar estimates of time-to-peak model

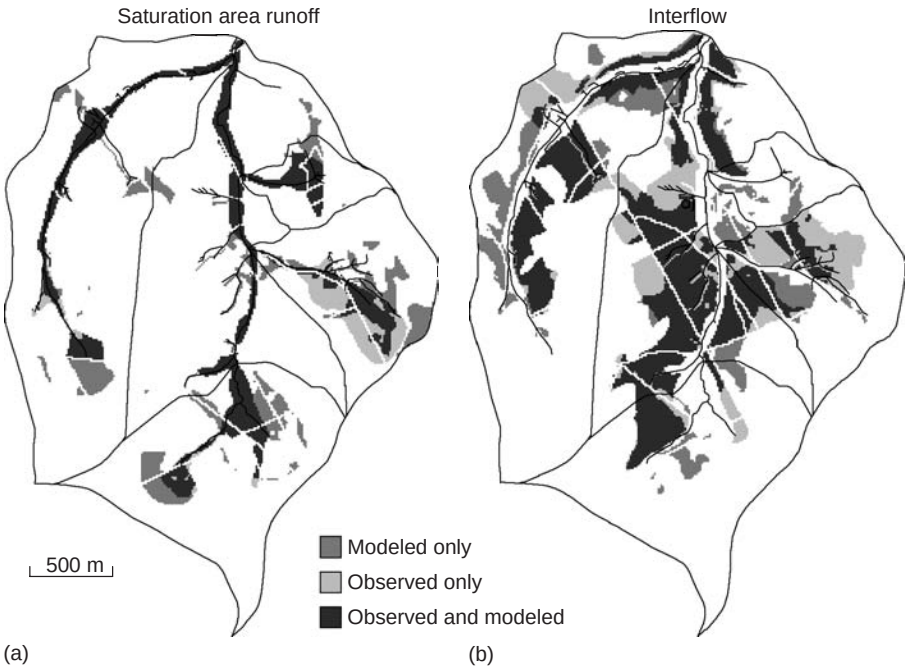

Figure 4 Comparison of the FLAB model estimates against field mapped areas of the presence of two runoff mechanisms (a): saturation area runoff, (b): interflow, for a 5 h, 25 mm event and wet antecedent soil moisture status (Peschke *et al.,* (1999b). Reproduced with permission of IHI Zittau). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

parameters in the two catchments. Similarly, surrogate-based estimates of physically based model parameters would give similar values, as land use and soil types are similar. Since these two catchments are gauged, one can test this assessment. Table 3 shows the event characteristics of the largest event on record (August 2, 1991). While runoff coefficients in the two catchments were similar, the response time (here in terms of the recession constant near peak) in the Mitterbach was almost 10 times that of the Wienerbruck catchment. It would be clearly impossible to predict the differences in catchment response between the two catchments on the basis of the quantitative catchment attributes. In contrast, soft information obtained through a visual examination of the catchments during site visits may help tremendously. Figure 5 shows photographs that are representative of the landforms in each of the catchments. In the slow response catchment (Mitterbach, (a)) the stream channel is mossy. Quite clearly, there is very little hydrologic activity. In contrast, the fast-response catchment (Wienerbruck, (b)) exhibits signs of erosion rills and deeply incised channels, that is, this is a hydrologically highly active catchment. From the visual assessment it would not be impossible to predict the magnitude differences in response timing. It is clear that physical controls do lead to these differences in catchment response but these are not apparent in the quantitative catchment attributes usually available in rainfall-runoff analyses. The geologic database available at the regional scale indicates limestone as the dominant geologic formation in both catchments. A more detailed survey indicates that the difference in response is likely a function of a number of factors, including topography, geology, and the valley bottom infill. In both catchments, dolomites from the Upper Trias prevail although in slightly different variants (Dachsteindolomit in Mitterbach and Wettersteindolomit in Wienerbruck). In Mitterbach, moraines have accumulated on some of the valley bottoms while in Wienerbruck the valley bottoms are narrow without infill. In a small part of the upper Mitterbach catchment, karstic limestone appears to exist giving rise to karstic springs. Soils tend to be deeper in Mitterbach than in Wienerbruck. In a *post hoc* analysis one can speculate that the steeper slopes along with more rainfall have lead to feedback effects between runoff processes, soil development, and vegetation development through some sort of coevolution (see e.g. Hoosbeek and Bryant, 1993; Lucas, 2001; *see also*, **Chapter 12, Co-evolution of Climate, Soil and Vegetation, Volume 1**). In an *a priori* mode, as needed in ungauged catchments, there is clearly a very important role of this type of field assessment.

There have been few attempts at formalizing the soft information from an expert assessment of the catchment functioning of the type in the above example. One notable exception is presented in Seibert and McDonnell (2002). They proposed a method where qualitative knowledge from field surveys is made useful through defining a fuzzy membership function that can be used in calibrating a

Table 2 Catchment attributes of two adjacent catchments in the Austrian Alps

	Ötscherbach at Wienerbruck	Große Erlauf at Mitterbach

rainfall-runoff model. Seibert and McDonnell tested their method in the Maimai research catchment in New Zealand. They achieved very good fits for a three-box model when optimizing the parameter values with only runoff data, but parameter sets obtained in this way showed in general a poor goodness of fit for other criteria such as the simulated new water contributions to peak runoff. Inclusion of soft data criteria in the model calibration process resulted in lower runoff model efficiency values but led to a better overall performance, as interpreted by the experimentalist's view of catchment runoff dynamics. One of the difficulties with this type of analysis is that normally it will be necessary to introduce additional parameters to make use of tracer data (be it artificial tracers or natural tracers including geochemical data) because wave velocities and flow velocities are not necessarily the same as assumed in their study. However, this general approach of including soft information does appear to have considerable potential for application in ungauged catchments provided soft information in the catchment of interest is available.

ALTERNATIVES TO RUNOFF DATA FOR MODEL CALIBRATION

So far this article has focused on methods of parameter estimation that do not use any runoff data for calibration in the catchment of interest as the article is concerned with the case of ungauged catchments. Even if no runoff data are available there may exist other hydrologic response data that can be used to calibrate some or all of the model parameters. In the following, two examples are given to illustrate the potential of hydrologic response data. The first example is set in the 90 km^2 Schneealpe area in the Austrian Alps (Blöschl *et al.*, 2002). In this study, calibration of model parameters on runoff data was not possible because the catchment was highly Karstic and it was unclear what the hydrologic catchment area was. The catchment was therefore treated as ungauged and the model parameters were calibrated on alternative response data. The main interest in the study was on snow processes, so snow cover patterns were deemed to be suitable response data. Snow cover patterns for the years 1998–2000 were derived from Systeme Probatoire pour l'Observation de la Terre SPOT XS images based on an unsupervised isodata technique (Jensen, 1996), separately for different illumination classes. The classification produced three class patterns of snow, no-snow, and partial coverage. The rainfall-runoff model focused on the snow component and simulated the snow pack evolution and snow melt for each grid cell on the basis of an energy balance approach. Wind drift of snow was represented by a wind drift factor, which was a function of terrain elevation, slope, and curvature. For the calibration of the model parameters, four SPOT-derived cover patterns were chosen from each of the years 1998 and 1999. These eight patterns were compared with the simulated patterns for the same dates. The calibration proceeded in two steps. In the first step, snow albedo and the threshold air temperature for separating snowfall and rainfall were calibrated. The objective function was based on differences in the snow-covered area of simulation and observation, both lumped for the entire study area and stratified by terrain slope and aspect. This made it possible to separate the effects of albedo from those of the threshold temperature through differential melting on north and south facing slopes. In the second step, the wind drift factor was refined. To this end, a combined error map of cover for the eight patterns was calculated (Figure 6a). This map represents the average percent error in snow cover estimation and it was assumed that this error stemmed largely from the representation of snow drift. The parameters of the snow-drift model were then individually calibrated for each pixel to minimize the error. Figure 6(b) shows the error pattern for the calibrated model and illustrates the significant improvement over the pattern in Figure 6(a). Remaining error is due to sources other than wind drift, or that cannot be explained by the structure

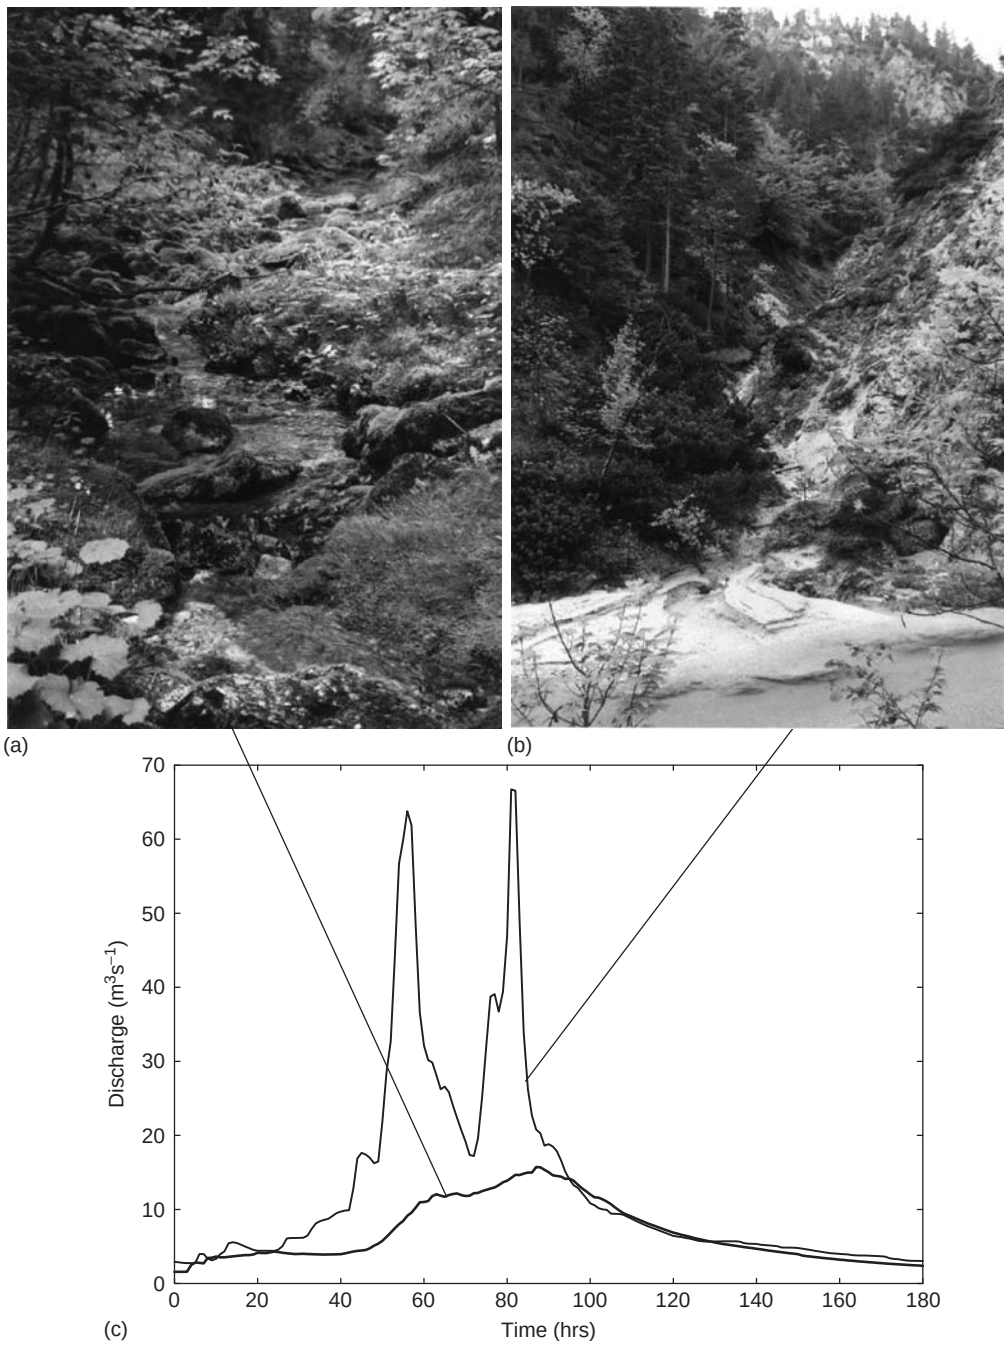

Figure 5 (a) Photographs that are representative of the landforms in the Mitterbach (a) and the Wienerbruck (b) catchments (Tables 2 and 3). (c) Hydrograph of the largest flood on record (thick line: Mitterbach; thin line: Wienerbruck). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

of the wind drift representation. The model was then applied to a different snow season (2000) in a classical split sample test. Figure 6(c) shows the error map for this year and illustrates that, while there is some deterioration in simulation compared to the fully calibrated year, the revised snow-drift model is a major improvement over the original form (Figure 6a). While subsurface parameters of the rainfall-runoff model cannot be estimated from a comparison with observed snow patterns, the snow related parameters clearly can.

The second example is taken from Bauer (2004). His study is set in the Okavango Delta which is a large alluvial fan situated in northwestern Botswana. This wetland is fed by the Okavango River, which flows from the tropical

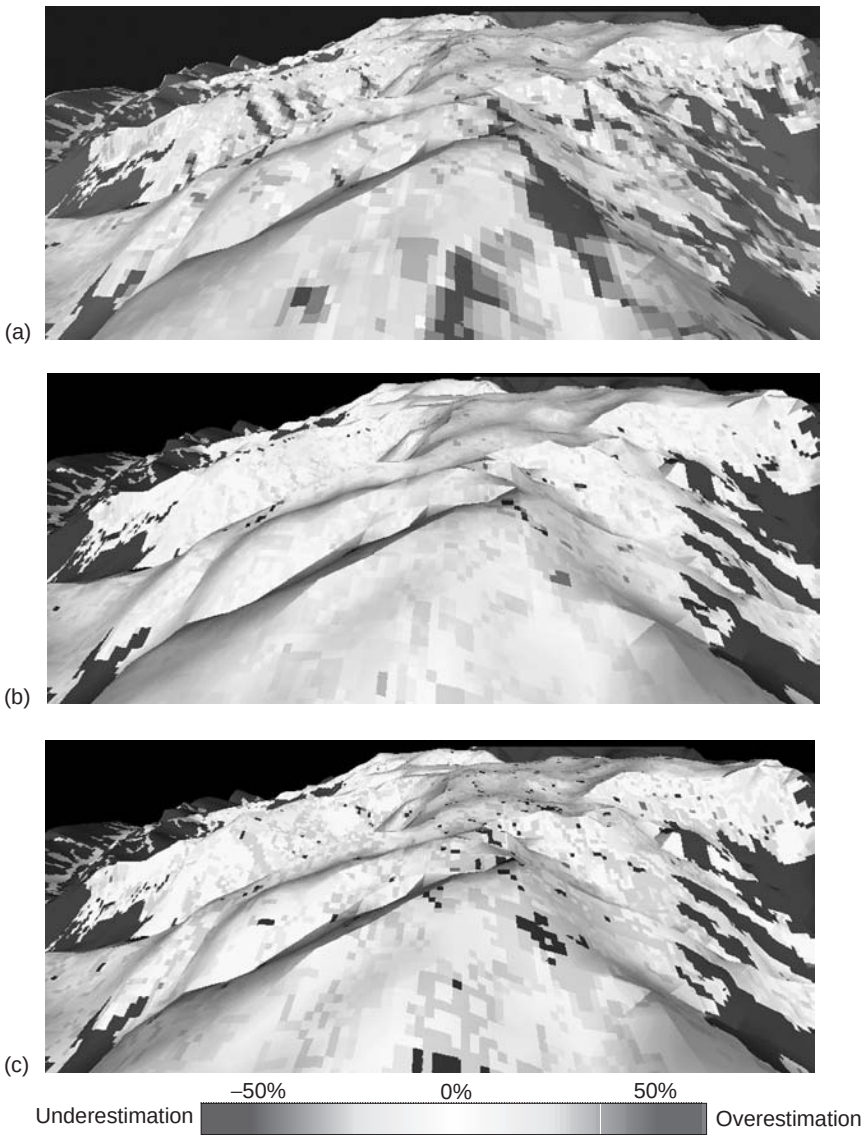

Figure 6 Bias in snow cover patterns based on residuals of comparisons between observed and simulated patterns for the Schneealpe region. (a) precalibration using eight observed patterns in 1998–1999, (b) postcalibration using eight observed patterns in 1998–1999, (c) validation using four observed patterns in 2000 (Blöschl *et al.* (2002). Reproduced with permission of Spinger-Verlag Wien). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

highlands of Angola into the Kalahari basin. The core wetland, which is permanently flooded, is around 6000 km^2 in size; the surrounding seasonal floodplains add another 6000 km^2. Runoff data would be extremely difficult to acquire as the flow occurs in numerous channels and on the marsh land. The catchment was therefore treated as ungauged and the model parameters were calibrated on alternative response data. The main interest in the study was on the runoff processes in the wetland, so inundation patterns were deemed to be suitable response data. The inundation patterns (either land or water) were derived from National Oceanic and Atmospheric Administration (NOAA), Advanced Very High Resolution Radiometer (AVHRR), and Landsat satellite images by unsupervised classification (McCarthy *et al.*, 2003). A total of 150 inundation patterns over the period of 1970–2000 was available for calibration. The hydrological model used was physically based and represented surface routing by Manning's equation, infiltration into the unsaturated and saturated zones by a simple leakage approach, two-dimensional regional groundwater flow, and evaporation from the saturated and unsaturated zones. The main calibration parameters were Manning's roughness of surface flow, the hydraulic conductivity of the swamp cells, the transmissivity of the sand

aquifer, and the vertical leakance between the surface and the subsurface layer (i.e. an infiltration parameter). Three objective functions were used in a manual calibration procedure and they all involved a comparison of simulated and observed inundation patterns for the same date. The first objective function was based on the total size of the flooded area, the second on a pixel-by-pixel comparison, and the third attempted to match the number of fringe points of the observed and simulated inundation patterns. Resulting parameters were all within a physically plausible range.

There are more alternatives to runoff that can be used for calibrating rainfall-runoff models in ungauged catchments. Suitable variables depend on the type of hydrological process of interest (Grayson *et al.*, 2002). Observed soil moisture would be an obvious choice for explicit soil moisture accounting models, but it is difficult to obtain spatially representative soil moisture measurements in catchments (Western *et al.*, 2002, 2004). Ground measurements may be representative of the entire root zone but are usually limited to a few spots in a catchment. Spaceborne estimates of soil moisture can be retrieved for large areas (e.g. Wagner *et al.*, 2003) but their main limitations are the shallow penetration depths, which are much smaller than the root depth represented in many hydrologic models. Although there are methods of dealing with this incompatibility in a simplified way (Houser *et al.*, 2000; Walker *et al.*, 2001; Schuurmans *et al.*, 2003), challenges remain. Various types of field based soft data, as discussed in Section "Soft data and qualitative field observations", are also potentially useful for assisting in model calibration as demonstrated in Seibert and McDonnell (2002). Soft data include saturation areas as mapped in the early work of Dunne and Black (1970) and Dunne *et al.* (1975). There is renewed interest in saturation patterns as illustrated by a number of mapping projects occurring (e.g. Kirnbauer *et al.*, 2005) and their application in constraining parameter estimation in rainfall-runoff modeling (e.g. Franks *et al.*, 1998).

CONCLUDING REMARKS

In ungauged catchments, no runoff data are available for calibrating model parameters, so alternative methods are needed. This article has reviewed numerous methods that depend on the type of parameters, whether they are calibration parameters associated with one particular model, or physically based parameters with some meaning beyond the model used. Calibration parameters are preferably transposed from similar, gauged catchments in the same region. Estimating calibration parameters from catchment attributes is generally not recommended for a number of reasons. Physically based parameters can be inferred from measurements, often based on widely available surrogates such as land use and soil type but, again, there are significant uncertainties and comparisons with adjusted parameters from similar, gauged catchments in the same region are extremely useful. As an alternative, or in addition to these parameter estimation methods, hydrologic response data other than runoff may be available in the catchment of interest and these may assist in calibrating model parameters.

Some guidance for selecting the model structure may also be needed in ungauged catchments. Similar to gauged catchments, model structure choice depends on the problem at hand, data availability, and the runoff processes one is to represent (see **Chapter 122, Rainfall-runoff Modeling: Introduction, Volume 3**). An analysis of similar, gauged catchments in the same region can provide some assistance in the latter step. Acquiring confidence in the model through model tests is not straightforward in the ungauged catchment case but pursuing more than one avenue of parameter estimation can be of assistance. For example, transposing parameters from similar gauged catchments, inferring them from measurements in the ungauged catchment, and testing the model against hydrologic response data that may be available in the ungauged catchment may provide some indications on model reliability through complimentary information. Cross-validation is also useful as it tests a number of uncertainties in a combined way. Additionally, some of the methods of uncertainty assessment reviewed in **Chapter 131, Model Calibration and Uncertainty Estimation, Volume 3** are applicable to the ungauged catchment case. In all these steps there is a very important role of qualitative field observations, if only by visual examination of the landforms. Qualitative field observations may greatly assist in judging the catchment functioning and hence in testing the plausibility of model parameters and the model structure.

It may seem strange to end a review of rainfall-runoff modeling in ungauged catchments with a note on the value of runoff data, but that in my opinion is the state of the science. As highlighted throughout this article, there are methods for dealing with rainfall-runoff modeling in ungauged catchments, but significant uncertainties remain. Short-runoff data series may contain very valuable information (Vogel and Kroll, 1991; Laaha and Blöschl, 2005b) so the single best recommendation on the issue of rainfall-runoff modeling of ungauged catchments may be to install a stream gauge!

Acknowledgment

I am grateful to Ralf Merz for providing valuable comments on an early draft of this manuscript and to Keith Beven and an anonymous reviewer for comments that helped improve the manuscript. I would also like to thank Dieter

Gutknecht, Rodger Grayson, and Siva Sivapalan for the numerous insightful discussions on the subject matter over the years. Financial assistance from the Austrian Academy of Sciences and the Austrian Science Foundation (project no P14478-TEC) is gratefully acknowledged.

134: Downward Approach to Hydrological Model Development

MURUGESU SIVAPALAN[1] AND PETER C YOUNG[2,3]

[1]Centre for Water Research, The University of Western Australia, Crawley, Australia
[2]Centre for Research on Environmental Systems and Statistics, Lancaster University, Lancaster, UK
[3]Centre for Resource and Environmental Studies, Australian National University, Canberra, Australia

This article presents the top-down or downward approach to hydrological model development as an alternative to the bottom-up, reductionist approach, which is the current, dominant paradigm in the hydrological sciences. It discusses the philosophical underpinnings as well as the pros and cons of each approach, and illustrates the application of the downward approach through several examples. These examples variously emphasize three key elements in the application of the downward approach. First, the analysis of identifiable "signatures" or "features" in the available data including the definition of a generic model form that can accommodate these features; second, model development including model structure identification and parameter estimation; and last, model refinement or "fingering down" (Klemes, 1983; Jarvis, 1993), in which the model is improved by the use of additional information or by adding more causal factors. Two main approaches to downward modeling are identified and discussed: the classical stochastic systems approach and the deterministic, conceptual modeling approach. The advantages of the downward approach are highlighted, particularly as they relate to the development of models that have sufficient causal basis to make predictions in basins other than those on which the model was developed.

INTRODUCTION

Hydrologists are under considerable pressure to provide answers to questions concerning the effects of future climatic and land-use changes on the quantity and quality of streamflows. Understanding changes of hydrological processes in relation to human-induced climatic and landscape changes and the ability to predict these ahead of time are essential for sustainable catchment management. Hydrologists are, therefore, concerned with the development of hydrological models of various kinds for these purposes. These may include, amongst others: models of long-term water balance needed for integrated water resources management; models of stream water quality (i.e. sediments, nutrients, heavy metals, etc.) to manage the environmental health of receiving water bodies such as lakes, estuaries, and coastal oceans; and models of flood response for the purposes of flood warning and forecasting.

If a model is able to reflect the essence of how a catchment functions hydrologically (for the full range of its possible states), then it may be possible to extrapolate with some confidence beyond the observed conditions and come up with reliable predictions. The issue of obtaining adequate predictive power for future states is, therefore, tantamount to acquiring, and then utilizing, adequate understanding of how the catchment system functions over the full range of states. But just how do we obtain this understanding? Ideally, modeling approaches that are adopted for prediction must be based on a combination of *a priori* theoretical understanding of climate, soil, vegetation, and topography controls on catchment behavior, as well as an insightful interpretation of observed catchment response data. In other words, modelers must rely on accepted knowledge about

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

general catchment behavior, combined with information on actual ground conditions and data collected in real, *specific* catchments.

The current debate on the development of hydrological models that can be used for future predictions centers on the relative merits of two major modeling philosophies (Klemes, 1983; Jarvis, 1993; Sivapalan *et al.*, 2003a). First, the "upward" or "bottom-up" approach, the dominant paradigm at present, leads to models that are invariably based on small-scale theories of hydrologic responses. They often result in large, complex models because of the perceived need to capture, in full, all of the heterogeneities and process complexities known or observed at small space-time scales. In contrast, the "downward" or "top-down" approach concentrates on extracting parametrically efficient or "parsimonious" model forms that successfully reproduce key "signatures" or "features" of observed hydrological variability; or can describe dominant modes of dynamic system behavior that are "identifiable" from available input–output and other (e.g. internal) response data. The objective of this article is to present an overview of the latter "top-down", or "downward approach" to hydrological modeling; to set it apart from the currently more popular "bottom-up" or "upward approach"; to illustrate its application using a number of relevant examples; and, finally, to discuss its relevance to current hydrologic research and practice.

BOTTOM-UP OR UPWARD APPROACH TO MODEL DEVELOPMENT

The defining feature of the bottom-up or upward approach is the attempt to predict the overall catchment response on the basis of understanding and process knowledge acquired on smaller spatial and temporal scales. The consequent "up-scaling" is through an integration or aggregation of the smaller-scale process descriptions up to the catchment scale. In hydrology, the upward approach has been championed by Freeze and Harlan (1969) in their "Blueprint for a physically based, digitally simulated hydrologic response model" and, since then, many other modeling studies have followed this dominant paradigm (see e.g. Abbott and Refsgaard, 1996).

The resulting models are often labeled as "process-based" or "physically based", with the approach to such model development being known variously as *upward, bottom-up, reductionist*, and so on. Klemes (1983) defines the "upward approach" as "the route that attempts to combine, by mathematical synthesis, the empirical facts and theoretical knowledge available at a lower level of scale, into theories capable of predicting events to be expected at a higher, in our case hydrological, level". One can gain further insights into this approach from a description offered by Jarvis (1993), who defines "bottom-up" models as "deterministic, state-of-the-art, mechanistic, process-based models that provide a statement of how a system may function on its spatial and temporal scale, on the basis of knowledge acquired on smaller spatial and shorter temporal scales".

Development of these distributed, process-based or physically based models over the past 25 years has been fueled by the explosion in knowledge about various hydrological processes and the development of theories and models that are able to describe them to a high level of sophistication. It has also been influenced by several other factors: the rapid growth in certain types of data availability (e.g. terrain attributes such as topography, soils, vegetation); the enormous increases in computational power; and the development of advanced statistical methods of data analysis and model parameter/state estimation.

The common argument, indeed abiding hope, of developers of distributed, physically based models has always been that, if a model mirrors in detail how individual parts of a catchment function hydrologically, the resulting predictions at the catchment scale will be reliable, particularly for unobserved states. Unfortunately, this hope has been deceptive, as illustrated by Beven (1989) and Grayson *et al.* (1992), among others, as already anticipated by Freeze and Harlan (1969) themselves.

The main problem seems to be that processes important at one scale (either space or time or both) may not necessarily be important at other, larger or smaller, scales (Blöschl and Sivapalan, 1995). Indeed, because of the change of dominant processes with changing scales, it can be argued that, at large scales, not all the complexity embedded in small-scale models is actually necessary (Sivapalan, 2003). For example, soil heterogeneity may average out as we aggregate from the patch to the catchment scale. Conversely, as we go up in scale, processes not observed at the small scale may become important, such as large-scale, preferential flow paths in the subsurface. Similarly, in the time domain, the way one models an individual event may need to be different from the way one models a population of events occurring over a long period, in view of the multiplicity of timescales and processes, and the changes in the relative dominance of the variety of processes, over that longer period. For example, one frequently comes across such changes in dominant processes when developing models for extreme flood estimation (Jothityangkoon and Sivapalan, 2003). An *a priori* perception of what small-scale processes are important and how they interact, either in the temporal or spatial domain, can be grossly misleading unless underpinned by catchment response data over a broad range of time and space scales, or by some larger-scale process understanding.

Another, equally important, problem is excessive model complexity relative to data availability, and the associated

difficulties in identifying the chosen model structure and estimating its parameters. While in the 1970s and 1980s it was sometimes argued that the more complex models may be appropriate in situations with limited data availability because of their basis in physical representation of the processes (Abbott *et al.*, 1986), the opposite now seems to be true: the more complex a model, the more data are needed to calibrate it and to have confidence in using it in predictive mode (Grayson and Blöschl, 2000). Because of nonexistent or inadequate data for comprehensive model validation exercises, many models of this type tend to be overparameterized, with arbitrary and overly complex model structures.

From a systems perspective, model overparameterization is intimately connected to the question of model "identifiability". A defined model structure is only considered identifiable if its parameters can be estimated uniquely from a given set of data, without ambiguity. In this sense, overparameterized models have more parameters than are required to explain the data, and there is, therefore, a basic ambiguity in the model, leading to multiple model solutions. Because of the possibility of obtaining such multiple model solutions when using large models, Beven (2000) has introduced the term "equifinality" to describe this situation, based on an analogy with the use of this term in geomorphology. The implications of this on model identification and estimation are far reaching. For instance, Young (1978) has argued that, because large and complex models have enormous explanatory power, they can usually be fitted easily to the meager time-series data that often confronts the modeler: many of the "estimated" parameters tend to be ill-defined, and a smaller subset is often sufficient to explain or mimic the observed system behavior (see also, Jakeman and Hornberger, 1993). Not surprisingly, therefore, the converse is also possible: Young *et al.* (1996), for instance, show how a simple, low-order linear model, identified and estimated on the basis of data obtained from experiments on a very large, nonlinear simulation model, is able to mimic almost perfectly the response of the large simulation model.

TOP-DOWN OR DOWNWARD APPROACH TO MODEL BUILDING

As outlined in the previous section, there are considerable difficulties in the application of the bottom-up or reductionist modeling approach to the prediction of catchment behavior. In response to difficulties of this kind, there has been a paradigm shift in scientific thinking regarding descriptions of the natural world, away from the mechanistic or reductionist perspective to a more holistic or systems perspective (Capra, 1996). This shift is supported by experience from numerous examples in nature, including many from hydrology, where one finds apparently complex systems behaving in a simpler manner than might be expected, (e.g. Young, 1978, 1983, 2003; Young *et al.*, 1996; Sivapalan, 2003).

Whereas the bottom-up, reductionist approach emphasizes individual components or processes that make up the whole, the systems approach places more emphasis on whole system behavior, as inferred from appropriate data. It recognizes that the nature of the whole system is different from the sum of its parts, and that properties of individual processes or components are not intrinsic properties of the whole system, and so any study of the individual processes or components is carried out only from the point of view of understanding the whole system. Consequently, the focus is much more on the interactions, feedbacks, and functional relationships amongst various parts, and their relationship to the whole system behavior. In a hydrological context, a holistic approach to spatial processes focuses more on the patterns of connectivity between various parts of the catchment system, such as paddocks, hillslopes, soil catena, stream network structure, downstream hydraulic geometry, and so on, and less on the details of the responses of individual components. Similarly, in the temporal domain, a holistic approach will focus less on individual events, and more on the population of events, and the connectivity between these events over a long period of time through the combined climate-catchment system.

The downward approach, as discussed here, is a holistic approach but with a specific sharper focus. Klemes (1983) defines the downward approach as the "route that starts with trying to find a distinct conceptual node directly at the level of interest (or higher) and then looks for the steps that could have led to it from a lower level". The downward approach is an empirical or data-based approach involving the interpretation of, or learning about, a catchment's functioning from data obtained *at the catchment scale*. This is in contrast to the bottom-up approach, which relies on *a priori* available small-scale theories and/or process understanding, where the role of data is in the validation of model predictions. The defining feature of the downward approach is that any explanation and generalizations are achieved *by fingering down into the (smaller-scale) processes from above* (i.e. at the catchment scale), and this is why models developed in this way are also called *top-down* models (in the hydrological literature, see for example, the papers by Silvert, 1981; Jarvis, 1993).

In other words, starting from available data, the downward approach attempts to identify the processes directly at the scales of interest, and interprets them in terms of properties and processes that may be occurring at the same or finer scales, as required by the objectives of the modeling study. In this sense, the downward approach is different from the classical systems approach to hydrology pioneered by the work of Dooge (1973), for example. In his "Linear theory of hydrologic systems" Dooge (1973, pp. 5–6) states: "In systems analysis, we are concerned only with the way in which

the system converts input to output. If we can describe this system operation, we are not concerned in any way with the nature of the system – with the components of that system, their connection with one another, or with the physical laws which are involved". This is only one "black-box" interpretation of the systems approach – the downward approach to model building is a holistic or systems approach that goes further by emphasizing the need to explain the internal mechanisms of the identified input-output system in a physically meaningful manner.

METHODOLOGIES FOR APPLICATION OF THE DOWNWARD APPROACH

The defining feature of the downward approach to hydrological modeling is the attempt to predict the overall catchment response, as well as the catchment's functioning, based on interpretation of the observed responses directly at the catchment scale. Blöschl and Sivapalan (1995) present the most generally accepted sequence of steps that are involved in the development of hydrological models (see also Mackay and Riley, 1991; O'Connell, 1991): (i) collecting and analyzing data; (ii) developing a conceptual model that describes the important characteristics of a catchment; (iii) translating the conceptual model into a mathematical model; (iv) calibrating (optimizing, estimating) the model to fit a part of the historical data by adjusting the various coefficients in some manual or automatic manner; and (v) evaluating the model by predictive validation, that is, ensuring that it continues to predict the data satisfactorily on data other than that on which it was calibrated. In essence, this is a *hypothetico-deductive* approach to model building that follows from the ideas of the philosopher Popper (1959); see also Young (2002).

In contrast to the hypothetico-deductive approach, a top-down model is normally inferred from the data using an *inductive* process (see Young, 2002). This can be achieved in various ways. For instance, it can involve formal, data-based, statistical *identification* of an appropriate generic model structure (normally differential equations or their discrete-time equivalents, often, in the systems case, considered in stochastic terms), followed by *estimation* of the parameters that characterize this structure, and the *interpretation* of the identified model in physically meaningful terms. Or, less formally, it can involve simulation modeling (usually deterministic) accompanied by judicious selection of the model based on its ability to explain the data in the simplest manner. These procedures help avoid the imposition of too many preconceived ideas about the hydrologic mechanisms involved *prior* to modeling. Depending on the objectives of the model building exercise, however, the downward approach can proceed further – not satisfied with extracting a model structure and parameters from data, it can seek to refine the model by enabling it to use other information available at the same or lower level of scale.

Three main stages can be discerned in previous applications of the downward approach to the development of hydrological models. (Here we have tried to unify the procedures used in stochastic and deterministic top-down modeling into a common strategy that should be acceptable to the proponents of both strategies.)

Signature Analysis and Model Identification

The exploration of signatures in the available information is an attempt to quantify the functional transformation, or "filtering" that takes place during the catchment's response to climate inputs, and helps postulate an appropriate transfer function or conceptual model. Note that filtering is used here in a broad sense. This includes the more specific, systems meaning of the word, namely, the effect of passing a signal though a dynamic system (e.g. a real system or a model) such that it is filtered in frequency domain terms: that is, components at some frequencies are attenuated more than at others. An example is rainfall-flow, where the high frequency components in the rainfall are attenuated as the rainfall leads to changes in the flow of river water down the catchment: as a result, the measured flow becomes progressively smoother (and easier to forecast). Depending on the objectives of the modeling, the key aspects of the input-output transformation that we may be interested in can include, amongst others, time delay, attenuation of flood peaks, the dispersion of the input signal, and loss of mass (due to infiltration losses, evaporation, chemical transformations). In systems and statistical terms, the process of defining an appropriate model is termed "identification" and is normally seen as a method of defining not only a generic model form that is most appropriate but also the best defined dynamic model structure (e.g. dynamic order, time delay).

Model Development

Model Development refers to the *identification* of appropriate models on the basis of signatures extracted from the data, or the *choice* of appropriate conceptual models that can reproduce these signatures. This is followed by the *estimation* of model parameters, either from the data itself (using statistical or less formal methods), or from known catchment characteristics, depending on the type of model chosen. In describing models, we use the two terms, "transfer function models" and "conceptual models" somewhat interchangeably. Essentially, both refer to the mathematical or functional form of the input–output transformation. They differ in their origins in different scientific disciplines, in the way they are identified, and in the way they are parameterized.

The term "transfer function" (*see* **Chapter 128, Rainfall-runoff modeling: Transfer Function Models, Volume 3**) represents the dynamic relationship between the input and output of a linear, dynamic system represented, in continuous-time terms, as the ratio of polynomials in the Laplace operator. (Note that in the case where initial conditions on variables are zero, the Laplace operator is equivalent to the derivative operator, so the Laplace transform transfer function is simply a useful shorthand representation of an input–output relationship described by a differential equation.) However, transfer function (TF from hereon) models can also be formulated in discrete-time terms and are then ratios of polynomials in the backward shift operator. TFs, expressed as Laplace transforms or as convolution integrals, have made a considerable impact in hydrology, as can be seen in the seminal work of Dooge (1973). The Nash cascade model (Nash, 1959), consisting of a number of identical, linear reservoirs in series, is a very well-known hydrological model and can be expressed in the form of a continuous or discrete-time TF model (Dooge, 1973; Dooge and O'Kane, 2003). There have also been extensions of such mathematical representations to include nonlinear transformations, through the work of Ven Te Chow and his coworkers in the 1960s, as described in detail in Chow (1964). More recently, Young (2000, 2001a) has extended TF representations to handle a wide class of "state-dependent parameter" nonlinear stochastic systems by allowing the parameters in the transfer function to be dependent on other variables or states in the system (see later example).

The attractive aspect of TF models is that, because of the direct connection between the signatures and model structure, the model structure can be *identified* by careful analysis of the hydrological data. However, there is no pretense that these can be automatically estimated (without further analysis) from observable catchment characteristics. Following the early work of Dooge and others, therefore, subsequent developments in hydrology tended to move away from formal representations of TFs and their estimation from data, in favor of so-called *conceptual models*. Conceptual models tend to be based on how the modeler perceives the nature of the catchment and its behavior, and not on the analysis of data. With the proliferation of conceptual models such as these, however, the moderating step of learning from data has tended to be forgotten and model structures are not often chosen on the basis of these data (i.e. signature or model identification analysis). Recent work on the downward approach by Sivapalan and his coworkers has partially addressed this problem and examples of this work are presented later. In these examples, because of the claimed hydrological basis of the model, the parameters of the chosen model structure may come directly from response data, as well as from observable catchment physical characteristics, which may help toward the "regionalization" (e.g. Kokkonen *et al.*, 2003) of at least some of the parameters to other, ungauged catchments.

Model Refinement (Fingering Down)

An important element of the downward approach, particularly when it is carried out within a deterministic, conceptual framework, is the emphasis placed on the use of model refinement based on additional information. This can relate directly to the input–output transformation and can involve various approaches, such as the establishment and estimation of causal links between the parameters of the identified or chosen model structure with catchment physical characteristics, or through the use of additional response information or surrogate data. This is the hardest part of the methodology and is done in an evolutionary manner. While no formal procedure exists, clearly the work on model refinement must be motivated by the success or otherwise of the model predictions as quantified, for example, by measures of predictive uncertainty.

EXAMPLES OF APPLICATION OF THE DOWNWARD APPROACH IN HYDROLOGY

The terms "top-down" or "downward" represent a general philosophical approach to model building that can be interpreted and used in a variety of different ways, often depending on the background of the hydrologist. On the basis of the three stages in the general methodology outlined previously, three main interpretations can be discerned in current hydrologic practice. First, a *stochastic approach* that exploits advanced statistical and systems methods of modeling to identify model structure and estimate parameters directly by data analysis (e.g. Young, 2001b, and the prior references therein; Schulz and Beven, 2003). Second, a *deterministic conceptual approach* that relies on considerable hydrological expertise in the choice of model structure on the basis of detailed analysis of available data, puts more emphasis on physically based model refinement, but places less emphasis on formal procedures for the extraction of model structure or parameters from the data directly. Because of its deterministic basis, at least some of the parameters in this approach to downward modeling can be estimated from the observable catchment characteristics (e.g. Wittenberg and Sivapalan, 1999; Jothityangkoon *et al.*, 2001). Finally, there is another *deterministic conceptual approach*, that is concerned with models that help in the understanding of interesting phenomena, rather than making predictions in the traditional sense: this is an approach that focuses much more on model refinement or "fingering down" (Milly, 1994; Rodríguez-Iturbe and Valdés, 1979; Jury *et al.*, 1982). Of course, the methodologies utilized in each of these cases are not mutually exclusive and there is hope (Young, 2003) that they can be combined

to form an integrated, top-down approach to hydrological modeling that gains through formalized procedures for data analysis, model development, parameterization, and model refinement. In this section, we discuss a number of different top-down modeling exercises that help exemplify the wide variety and applicability of this approach to model building.

The Aggregate Dead Zone Model: a Data-Based Mechanistic Model of Pollutant Transport in a River

This example and the one that will be discussed in the next subsection "A data-based mechanistic model of the rainfall-runoff process" are illustrations of *Data-Based Mechanistic* (DBM) modeling (see e.g. Young and Lees, 1993; Young, 1998 and the prior references therein). The systematic stochastic approach to the application of the downward approach within this DBM setting is illustrated well by the *Aggregate Dead Zone* (ADZ) model for the transport and dispersion of a dissolved pollutant in a defined reach of a river channel, with the flow rate denoted by Q. For simplicity, let us assume that Q is constant and there is "complete mixing" within an *Active Mixing Volume* (AMV: see Young and Lees, 1993) of defined volume V less than the volume of water in the reach and non-dispersive, purely advective (plug flow) elsewhere. Note that the mixing processes in the reach as a whole are normally imperfect, so that AMV is normally of considerably less volume than the total volume of water Vr in the reach at any time. The ratio V/Vr is called the dispersive fraction (Wallis *et al.*, 1989). The relationship between the measured concentration $C_o(t)$ of a pollutant at the output (or downstream) location in the reach, to the measured concentration $C_i(t)$ at the input (or upstream) location can then be obtained from dynamic mass-conservation considerations. Assuming, again for simplicity, that the loss of pollutant in the reach (i.e. both within the AMV *and* during advection) is proportional to the mass of pollutant in the reach, this mass balance equation takes the following ordinary differential equation form:

$$\underset{\substack{\text{rate of}\\ \text{change of}\\ \text{mass}}}{\frac{\mathrm{d}\{VC_o(t)\}}{\mathrm{d}t}} = \underset{\substack{\text{mass in}\\ \text{per unit}\\ \text{time}}}{Q\mathrm{e}^{-k\tau}C_i(t-\tau)} - \underset{\substack{\text{mass out}\\ \text{per unit}\\ \text{time}}}{QC_o(t)} - \underset{\substack{\text{mass lost}\\ \text{per unit}\\ \text{time}}}{k[VC_o(t)]} \tag{1a}$$

or,

$$\frac{\mathrm{d}C_o(t)}{\mathrm{d}t} = -\left(k + \frac{Q}{V}\right)C_o(t) + \frac{Q}{V}\mathrm{e}^{-k\tau}C_i(t-\tau) \tag{1b}$$

This simple description is the basis of the ADZ model (Beer and Young, 1983; Wallis *et al.*, 1989), and it can be rewritten in the form of the following first-order, stochastic TF model (*see* **Chapter 128, Rainfall-runoff modeling: Transfer Function Models, Volume 3**):

$$C_o(t) = \frac{\beta_0}{s+\alpha_1}C_i(t-\tau)\ ;\ C_o^m(t) = C_o(t) + \xi(t) \tag{1c}$$

where $\beta_0 = (Q/V)\mathrm{e}^{-k\tau}$, $\alpha_1 = k + (Q/V)$ and s is the Laplace transform operator, interpreted loosely here as the derivative operator, that is, $s = \mathrm{d}/\mathrm{d}t$. In the above equations, k is the decay rate and τ is the advective time delay introduced to allow for the translational effects associated with the unidirectional river flow. Because we are assuming that the model has been obtained from the analysis of measured data, $C_o^m(t)$ in equation (1c) denotes the *measured* downstream concentration of the solute and $\xi(t)$ represents the combined effect of all unmeasurable stochastic inputs to the system, including measurement noise, unmeasured inputs and errors arising from any limitations in the assumed model structure ("modeling errors").

Often in TF modeling, the TF is represented in its discrete-time, sampled data form, since most data these days are sampled over time at some sampling interval (*see* **Chapter 128, Rainfall-runoff modeling: Transfer Function Models, Volume 3**). In this case, the TF equation (1c) becomes:

$$x_k = \frac{b_o}{1+a_1z^{-1}}u_{k-\delta}: \quad x_k = C_o(k\Delta t); \quad y_k = x_k + \xi_k;$$
$$u_{k-\delta} = C_i(k\Delta t - \delta) \tag{1d}$$

where z^{-1} is the backward shift operator, that is, $z^{-r}y_t = y_{t-r}$, and the subscripted variables denote the value of the variable at the kth sampling instant. If the sampling interval is Δt (in appropriate units: hours, days, etc.), then $k = t/\Delta t$ is the sampling index, $k = 1, 2, \ldots, N$ and N is the total number of samples. Also, δ is the pure advective time delay in sampling intervals, defined as the nearest integral value of $\tau/\Delta t$. Note that this is normally an approximation to the time delay, which is the price paid for using the discrete-time rather than the continuous-time TF model. The discrete-time ("difference" or "finite difference" equation) model associated with equation (1d) is obtained by simple cross multiplication and application of the z^{-1} operator, to yield:

$$y_k = -a_1y_{k-1} + b_ou_{k-\delta}: \quad a_1 = \exp(-\alpha_1\Delta t);$$
$$b_o = \frac{\beta_o}{\alpha_1}\{1 - \exp(-\alpha_1\Delta t)\} \tag{1e}$$

The definitions of a_1 and b_0 given here are based on an assumption that the input concentration remains approximately constant over the sampling interval Δt. Equation (1e) shows that in these discrete-time terms, the downstream concentration of the solute at the kth sampling

instant is equal to a fraction ($-a_1$ where a_1 is negative and less that unity) of the concentration measured at the previous $(k-1)$th sampling instant, plus a fraction b_0 of the upstream concentration measured δ samples previously.

In the case of the first-order ADZ models such as (1a–e), there is little that can be deduced about the internal structure of the system other than the quantification of the overall advective and dispersive effects. However, suppose that analysis of the experimental data results in the statistical identification and estimation of an ADZ model in the form of the following second-order TF:

$$C_o(t) = \frac{\beta_0 s + \beta_1}{s^2 + \alpha_1 s + \alpha_2} C_i(t-\tau) \; ; \; C_o^m(t) = C_o(t) + \xi(t) \tag{2a}$$

or in discrete-time TF form:

$$x_k = \frac{b_0 + b_1 z^{-1}}{1 + a_1 z^{-1} + a_2 z^{-2}} u_{k-\delta} : \quad x_k = C_o(k\Delta t);$$
$$y_k = x_k + \xi_k; \quad u_{k-\delta} = C_i(k\Delta t - \delta) \tag{2b}$$

In most practical situations, the TF in equation (2a) can be factorized into the following parallel connection (*see* **Chapter 128, Rainfall-runoff modeling: Transfer Function Models, Volume 3**) of two first-order TFs of the form (1b):

$$C_o(t) = \left(\frac{b_q}{s + a_q} + \frac{b_s}{s + a_s} \right) C_i(t-\tau) = \frac{G_q}{1 + T_q s} C_i(t-\tau) + \frac{G_s}{1 + T_s s} C_i(t-\tau) \tag{3}$$

Since, in practice, the residence times of the two parallel, first-order processes almost always are of quite different magnitudes, the subscripts q and s denote "quick" and "slow" processes, respectively. Of course, for any physical interpretation of the parameters in the parallel TFs (e.g. to compute V and k, given a measurement of Q), one must take account of the mass partitioning down the two parallel pathways. The parameters of the TF model (3) are the ADZ residence times or time constants, T_q and T_s, and the steady state gain, G_q and G_s, which account for any gain ($G_q + G_s > 1.0$) or loss ($G_q + G_s < 1.0$) of solute in the ADZ reach. The "travel time" in each parallel pathway is the sum of the associated residence time and the advective time delay τ.

A typical practical example of ADZ modeling is the analysis of data obtained from a dye tracing experiment on the River Conder, near Lancaster in northwest England (Young, 1999). This river is fairly small, with a "cobbled" bed, and the experiment involved the injection of 199 mg of the dye tracer Rhodamine WT, with the measurement locations situated 400 m apart, some way downstream of the injection location to allow for initial mixing. The measurements were taken at regular sampling interval of 0.25 min, and the river flow rate was measured at a constant 1.3 $m^3\,sec^{-1}$. Identification and estimation of an ADZ model from these data does not require any prior assumption about the order of the system and the advective time delay: these properties of the model are identified directly from the data. In this example, a continuous-time, second-order TF model, with a pure advective time delay of 3 min, is identified from the sampled data using the continuous-time *Simplified Refined Instrumental Variable* (SRIV) algorithm in the CAPTAIN Toolbox. This Toolbox is a collection of computational algorithms written for use in the Matlab software environment (see `http://www.es.lancs.ac.uk/cres/captain/`). Such a continuous-time TF estimation involves no approximations (see previous discussion) and seems more appropriate in this example. In any case, discrete-time TF estimation did not yield such good results.

The SRIV-estimated second-order model is of the same form as equation (2a) and it explains the downstream concentration changes very well indeed, as shown in Figure 1, with a *Coefficient of Determination* based on the simulated output (normally equivalent to *Nash-Sutcliffe Efficiency*) of $R_T^2 = 0.998$ (i.e. 99.8% of the measured output variance is explained by the model). Not surprisingly, this model can be decomposed into the parallel pathway form of equation (3) and the resulting ADZ models in the two pathways are defined as follows:

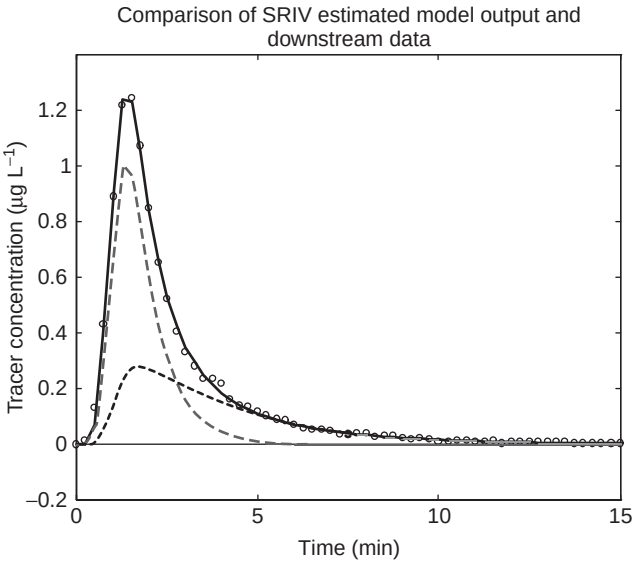

Figure 1 Comparison of the SRIV identified and estimated ADZ model output (full line) and the measured concentration of tracer at the downstream location (circular points). Also shown: inferred quick-flow pathway (dashed) and slow-flow pathway (dash-dot) concentrations

A. Slow Pathway: $x_s(t) = (0.475/1 + 2.818s)u(t-3)$ $G_s = 0.475$; $T_s = 2.818$ mins; $P_s = 42.9\%$
B. Quick Pathway: $x_q(t) = (0.608/1 + 0.590s)u(t-3)$ $G_q = 0.608$; $T_q = 0.590$ mins; $P_q = 57.1\%$

where *u(t)* is the upstream tracer concentration, while $x_s(t)$ and $x_q(t)$ are the inferred tracer concentrations at the output of the slow and quick pathways, respectively.

If it is assumed that the flow is partitioned in the same way as the dye, then the acting mixing volumes associated with the two pathways can be calculated by reference to the flow rate and residence times as $V_q = 26.3\,m^3$ and $V_s = 94.1\,m^3$, respectively. The associated dispersive fractions are then calculated as $DF_q = 0.12$ and $DF_s = 0.56$ (i.e. the acting mixing volumes are 12% and 56% of the total volume of water in each pathway, respectively). In other words, the slow pathway results in a considerably greater dispersion (and longer term detention) of the dye than the quick pathway, as one might expect.

The most obvious physical interpretation of the parallel flow decomposition in this example, as required in DBM modeling, is a form of "two-layer flow", with the slow pathway representing the dye in the water moving in, or adjacent to, the cobbled bed and banks of the river, which is being differentially delayed in relation to the quick pathway, which is associated with the more freely moving surface layers of water. The aggregated effect of each pathway is then an advective transportation delay of 3 min, associated with nondispersive plug flow, and an ADZ, defined by the associated active mixing volume and dispersive fraction in each case, which are the main mechanisms for dispersion of the dye in its passage down the river. Further details of this example, including full discussion of the stochastic aspects of the model, are given in Young (1999). Another ADZ modeling example is described in **Chapter 128, Rainfall-runoff modeling: Transfer Function Models, Volume 3**.

In this ADZ case, model development and refinement are fairly straightforward. Given single reach ADZ models such as (1c), (2a), or the above model, it is possible to synthesize a water quality model for a complete river system from serial and parallel (and even feedback) interconnections of these elements. The nature of the interconnections in this situation will be defined by the physical characteristics of the river catchment. In such applications, the ADZ models obtained from conservative tracer experiments, such as that described previously, effectively provide a "calibration" of the *physical* aspects of solute transport and dispersion in the river. This information can improve the identifiability of other chemical and biological factors that may affect a nonconservative solute as it undergoes physical transport. For example, in the case of the simple decay process in equation (1a), it is clear that estimation of the decay rate k is facilitated by prior and independent estimation of the ADZ model parameters. And the advantages are even more pronounced in more complex situations where chemical and biological interactions are taking place (e.g. *Dissolved Oxygen-Biochemical Oxygen Demand* (DO-BOD) models, as in Beck and Young, 1975).

A Data-Based Mechanistic Model of the Rainfall-Flow Process

Much has been written on the important topic of rainfall-runoff and rainfall-flow modeling (e.g. Beven, 2001 and the prior references on this topic given therein). A typical top-down, DBM model of a rainfall-flow process is shown in the multiple storage element block diagram of Figure 2 (see Young, 2003). Here, the two linear storage elements or "buckets" A and B are first-order, linear TF models of a generic form similar to those used in the water quality model (1d) but, of course, with different physical interpretations. The block marked $f(s_k)$ is a nonlinearity, which is a function of an estimated "catchment soil water storage state" s_k. This storage state is generated from the measured rainfall r_k via the linear soil water storage TF that constitutes the storage element C; and it modulates r_k to yield the input u_k. The model in this form was identified and estimated on the basis of 360 samples of hourly rainfall and flow data from the River Hodder, at Hodder Place in northwest England, using the discrete-time *Refined Instrumental Variable* (RIV) algorithm in the CAPTAIN Toolbox mentioned above. The model was validated over a further, independent set of 120 hourly samples.

Full details of the DBM analysis that leads to the model in Figure 2 are given in Young (2003). In this example, the initial generic modeling stage is carried out in discrete-time terms (although it could equally well be based on a continuous-time model, as in the case of the ADZ model) and it identifies the following second-order, nonlinear TF model that consists of a nonlinearity in series with a linear second-order TF model (a "Hammerstein" model in systems terminology):

$$x_k = \frac{b_0 + b_1 z^{-1}}{1 + a_1 z^{-1} + a_2 z^{-2}} u_{k-\delta} \tag{4a}$$

$$u_k = f(s_k).r_k \tag{4b}$$

where,

$$\hat{a}_1 = -1.821(0.017);\ \hat{a}_2 = 0.822(0.016);$$
$$\hat{b}_0 = 0.13(0.011);\ \hat{b}_1 = -0.135(0.010)$$

In equation (4b), the nonlinearity $f(s_k)$ is estimated by considering the model in *State-dependent Parameter* (SDP) terms (see Young, 2000, 2001a,b). In particular, SDP estimation applied to the measured rainfall-flow time series (x_k, r_k) shows that, if the rainfall r_k is multiplied by a state-dependent parameter, identified from the data

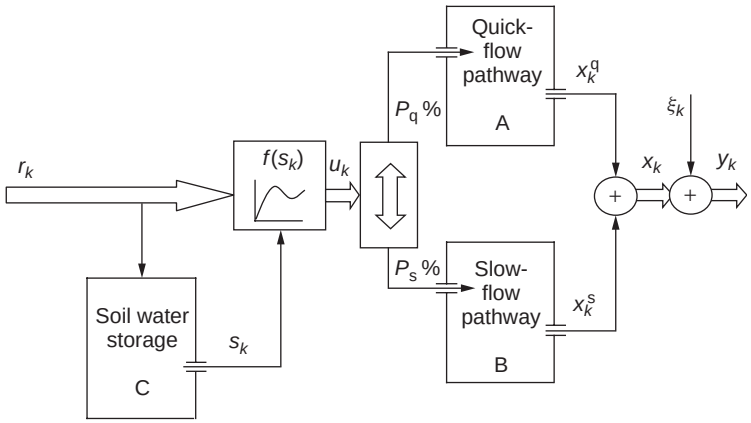

Figure 2 Block diagram of DBM rainfall-runoff model for the River Hodder at Hodder Place

as a power law in s_k (i.e. the nonlinearity $f(s_k) = s_k^\gamma$, where γ is the power law coefficient), then the complete model in equation (4) is able to predict very well the nonlinear flow variations x_k on the basis of the variations in the "effective rainfall" input $u_k = s_k^\gamma . r_k$ (see the following text). And because the introduction of this effective rainfall nonlinearity accounts for most of the nonlinear dynamics in the rainfall-flow data, the relationship between u_k and x_k can be represented quite simply by a linear, constant coefficient, discrete-time TF (the discrete-time equivalent of a linear differential equation).

As mentioned later in Section "Other examples of the downward approach", equation (4a) is the direct equivalent of the discrete-time convolution equation and the pulse response of this discrete-time TF (the response to a unit-volume pulse input of effective rainfall, u_k) can be interpreted in hydrological terms as the discrete-time *Unit Hydrograph* (UH) or, more strictly, the unit-volume pulse response (TUH) of the system. Note that this TUH is invariant in shape because the TF parameters $(\hat{a}_1, \hat{a}_2, \hat{b}_0, \hat{b}_1)$ that define this shape are all constant over time: the variation in the magnitude of the TUH that controls the changes in the nature of the output flow response is a consequence of the gain changes associated with the SDP, as it affects the effective rainfall nonlinearity $f(s_k)$. It is clear, therefore, that by estimating the rainfall-flow model in this manner, one is led naturally to the calibration of an underlying, *invariant* TUH that controls the shape of the storm events occurring over the whole data set.

As in the ADZ modeling example discussed in the previous subsection, the subsequent and very important hydrological interpretation stage of DBM modeling is relatively straightforward in this case. The nonlinearity is clearly associated with the "effective rainfall" dynamics: it accounts for the effect of antecedent rainfall on the soil water storage in the catchment; and this storage is modeled by the TF in block C. The second-order linear TF then defines the unit hydrograph response of the model and it nicely decomposes into a parallel connection of "quick" and "slow" flow pathways, similar to those discussed previously in relation to the ADZ model (3). Each of these is modeled as a first-order TF with estimated gains and residence times that define the quick "storm runoff" and slow "baseflow", which constitute the two major estimated components, or "dominant modes" (Young, 1999), of the *total* gauged flow.

The model in Figure 2 explains the data very well over the validation data set, as we see in Figure 3(a), which compares the model output (full line) with the measured flow in the validation part of the data set (dashed line). The *Coefficient of Determination* (see the preceding text) based on the simulated model output is $R_T^2 = 0.94$ (i.e. 94% of the measured flow variance is explained by the simulated model output); while the more normal coefficient of determination, based on the one-hour-ahead prediction errors is $R = 0.98$. In addition, the physical properties of the two pathways make good practical sense for the Hodder catchment. For instance, the parallel decomposition of the linear transfer function part of the model yields the following description of the two linear storage elements:

C. Slow Flow: $x_k^s = (0.0023/1 - 0.996z^{-1})u_{k-4}$ $G_s = 0.53$; $T_s = 230$h; $P_s = 41\%$
D. Quick Flow: $x_k^q = (0.134/1 - 0.825z^{-1})u_{k-4}$ $G_q = 0.77$; $T_s = 5.2$h; $P_q = 59\%$

where x_k^s and x_k^q are, respectively, the partitioned quick and slow-flow components; G denotes the steady state gain; T the residence time and P the partition percentage (i.e. the inferred percentage flow of water down the pathway in question), with the subscripts differentiating between the slow and quick pathways. The flow components generated by this parallel decomposition are shown in Figure 3(b) and (c). It is clear that the very long term baseflow behavior is being modeled by the slow-flow component (c), which has a very long 230-h residence time. The soil water storage TF also has physically meaningful characteristics, with a

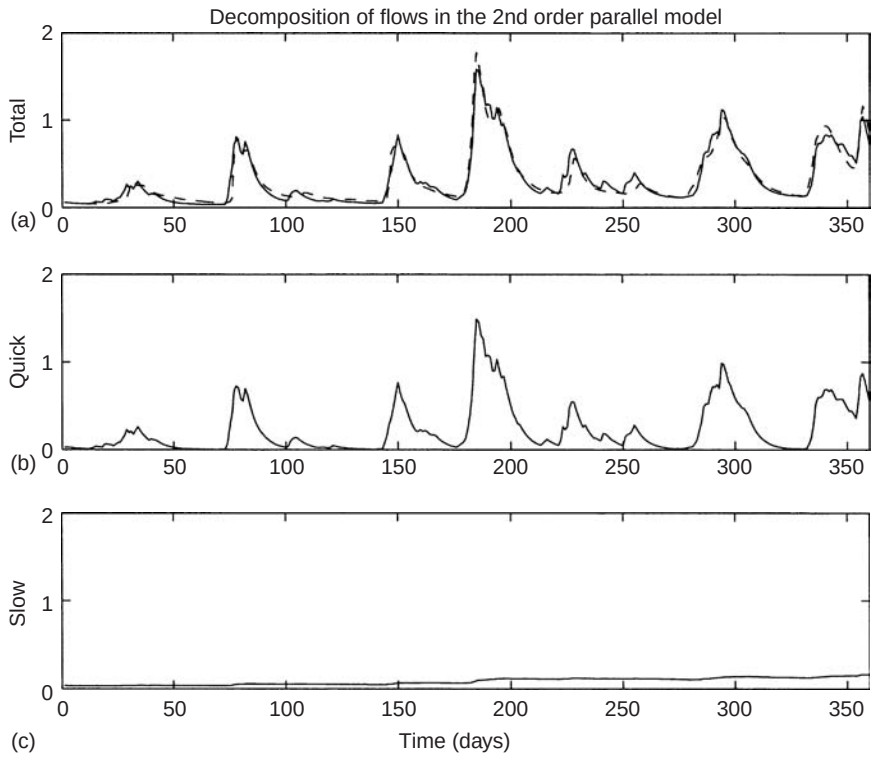

Figure 3 Parallel decomposition of the DBM rainfall-flow model for the River Hodder at Hodder Place, with all components plotted to the same scale for comparison

residence time of 9.1 h that is about twice the residence time of the quick-flow TF. And, finally, the nonlinearity acts as an effective rainfall coefficient that is zero when $s_t = 0$ and rises to a maximum of 0.87 at higher soil water storage level: that is, 87% of the gauged rainfall becomes effective rainfall when the storage is at this higher level (see Figure 8 in Young, 2003). Of course, since the model is stochastic, all of these parameters have associated uncertainties that are quantified in the estimation process (*see* **Chapter 128, Rainfall-runoff modeling: Transfer Function Models, Volume 3**). However, in order to simplify the presentation of the results, they have not been reported here.

As in the previous example, model development and refinement are fairly straightforward because of the modular nature of the rainfall-flow model and the fact that a similar DBM/TF approach can be used for flow routing, that is, modeling the relationship between flow (or level) at adjacent gauge locations on the river (which could include man-made elements such as weirs). Depending on the application, the main river catchment will be modeled by suitably interconnected routing modules, while the rainfall-flow modules will provide inputs to this system. If information is required at a finer scale, for instance flows between gauge locations, then the routing modules can be replaced by a physically appropriate connection of smaller routing modules chosen so that the combined response mimics that of the single module (see the discussion concerning the combined response of serial and parallel processes in **Chapter 128, Rainfall-runoff modeling: Transfer Function Models, Volume 3**).

Water Balance Estimation Through Streamflow Recession Analysis and Baseflow Separation

Wittenberg (1999) and Wittenberg and Sivapalan (1999) present an example of the downward approach to water balance model development that uses an empirical, deterministic methodology, involving analyzing key signatures in the data, proposing simple models capable of reproducing these signatures, and then refining these systematically to capture more aspects of the variability in the observed data. Their work is a forerunner to the approaches adopted in much of the subsequent work in this area (see later) and offers hope that much more information can be extracted from data than can be obtained in the usual model calibration exercises. Wittenberg and Sivapalan present a method of analysis of observed rainfall and streamflow time series with a view to identifying and quantifying the underlying groundwater balance. In a recent effort, Wittenberg (2003) extends this work to include further analyses to decipher the effects of human impacts.

Through the analysis of numerous streamflow recession curves Wittenberg and Sivapalan obtained a nonlinear relationship between groundwater discharge and reservoir

storage in shallow unconfined aquifers. This analysis is similar to methods previously adopted by Brutsaert and Nieber (1977) and Troch *et al.* (1993). Depletion of groundwater by evapotranspiration losses through the uptake of trees was found to bias the recession curves and the estimated reservoir parameters. This biasing was found to be strongly seasonal, due to the reinforcing seasonality of both rainfall and potential evaporation. Analysis of the recession curves, stratified according to time of year, allowed the quantification of evapotranspiration loss as a function of calendar month and stored groundwater storage.

Using the nonlinear storage-discharge relationships, they then separated the subsurface flows from the observed time series of streamflows, and subsequently inferred the corresponding time series of storage and the rates of recharge to groundwater through a numerically stable, inverse routing procedure. Comparison of the computed groundwater recharge hydrographs with measured daily rainfalls revealed an approximately time-invariant travel time (to the water table) distribution of infiltrated water. Using traditional unit hydrograph methods, unit recharge responses to rainfall (i.e. unit hydrographs) were computed by least squares fitting. These estimated unit response functions were found to be comparable to those found in previous work based on theoretical approaches that used assumed soil properties, and others based on lysimeter data.

It can be seen that the work of Wittenberg and Sivapalan (1999) involves systematically analyzing rainfall and streamflow data, and nothing more; and then piecing together the components, such as surface and subsurface runoff, evapotranspiration, groundwater storage, and recharge. The method is very good at identifying the key transformations, and extracting the appropriate transfer functions based on the data, without utilizing anything more than the basic mass balance concept. Clearly, it is an empirical method and yet produces a simple model of the system and involves no subsequent calibration. Of course, the drawback of such a model is that, first, the methodology itself is rather *ad hoc* and can benefit from the use of more standardized methodologies. Second, in the absence of any inferred relationship between the mechanistic interpretation of the model and geographical or other physical aspects of the catchment ("regionalization analysis"), it is difficult to extrapolate to ungauged catchments.

Hierarchical Approach to Development of Conceptual Water Balance Models

Following on from the lead of Wittenberg and Sivapalan (1999), Sivapalan and a number of his coworkers (Jothityangkoon *et al.*, 2001; Atkinson *et al.*, 2002; Farmer *et al.*, 2003; Atkinson *et al.*, 2003a; Atkinson *et al.*, 2003b; Struthers *et al.*, 2003; Eder *et al.*, 2003) extended the deterministic approach further to look at water balance variability at the annual, monthly, daily, and hourly timescales, and through these to develop a more formalized procedure for the development of continuous water balance models of appropriate complexity. The methodology was applied to catchments in a variety of climatic and soil settings, in New Zealand, various parts of Australia, Austria, and Germany.

The similarity with the Wittenberg and Sivapalan (1999) approach is that the adopted methodology remains a hydrologically oriented, deterministic approach to the analysis of the observed data. However, the main difference is that the analysis goes beyond the analysis of individual storms to the comprehensive analysis of a population of storm events and is designed to make inferences about hydrological variability not only at the event scale, but also at longer, intra-annual (seasonal), and interannual variability.

In terms of transformations that one then looks for in the data, the approach is now considerably different since the focus is on a population of storms. Whereas the event response analysis looked for signs of "filtering" behavior at that scale in the traditional sense, the analysis of a population of storms, covering a range of scales of variability, looks for signs of such filtering at longer timescales including, for example, threshold filtering, whereby only those storms that exceed an intensity or depth threshold pass through the system, thus generating an output time series which is a truncated version of the input time series. In order to further the application of the downward approach, Sivapalan and his coworkers invoked a number of *discrete signatures* that characterize water balance variability at these timescales. These are, in sequential order:

- interannual (i.e. year to year) variability of annual runoff;
- mean monthly variation of runoff (also known as the *regime curve*);
- flow duration curve based on daily flows, describing the variability of streamflow within the year;
- streamflow recession curves, limited to deciphering the nature of subsurface flows within the catchment and as a measure of associated time delays.

The downward approach to model development then takes the view that these signatures of the transformation can be extracted from the observed data, and model development can then be pursued with the idea of incorporating the climate, soil, vegetation controls that underpin an explanation of these transformations. One continues with the idea that relatively simple models need to be found that explain and reproduce these signatures of variability.

A basic assumption in the above approach is of an evident hierarchy of controlling influences relating climate-landscape interactions to the prediction of hydrologic responses at various space-timescales of interest. Relatively simple models were often found to be adequate to capture the water balance at large time and space scales, provided they took into account the primary controlling

variables of precipitation, potential evaporation, and soil storage capacity.

When greater levels of prediction are required (i.e. at smaller spatial and/or temporal scales), then consideration must be given to the inclusion of additional variables and processes, in order to address the more subtle causes of variability. For example, when one changes from the annual to the monthly timescale, then the systematic time delay between precipitation and streamflows is an important feature that must be captured, and this is done through the incorporation of subsurface flow pathways. Such features that come into play at a smaller timescale are deemed as *emergent properties*, because they may not have been important to separately capture, if the objective was to reproduce interannual variability alone. Testing of hypotheses with respect to climate and landscape controls on these emergent behaviors are carried out in respect of the key signatures of variability at the monthly, daily, and hourly timescales. Typically, model complexity increases as timescale decreases, since it is increasingly important to introduce additional processes and parameterizations to reproduce these emergent behaviors. The various signatures (interannual variability, mean monthly flows, flow duration curve at the daily timescale, etc.) thus serve as guideposts in the development of models of increasing complexity.

Figure 4 presents an example of a hierarchy of models of increasing complexity explored for Australian catchments by Farmer *et al.* (2003), ranging from simple overflow or Manabe-type buckets, to multiple-bucket models that include both shallow subsurface flow and deep groundwater discharge, as well as explicit treatment of unsaturated zone time delays. An example of such an application of the downward approach to a specific catchment from Australia is presented in Figure 5, also from Farmer *et al.* (2003), while a summary of the levels of model complexity required to reproduce the signatures of water balance variability with changing timescales is presented in Figure 6, confirming an evident hierarchy with respect to timescale. Atkinson *et al.* (2002) found that the required model complexity increased with increasing aridity of the catchment, which is nicely illustrated by the schematic presented in Figure 7. This is also confirmed by the relative ease with which a simple parsimonious model was developed (Eder *et al.*, 2003) for a humid catchment in Austria.

Through the application of the downward approach, Jothityangkoon *et al.* (2001) developed a distributed model of water balance (based on subcatchments) for a large, heterogeneous catchment in semiarid Western Australia. This systematic procedure led to a model with just 6 parameters, most of which could be estimated *a priori* either from landscape properties or through prior analysis of observed streamflow records.

While conceptual models of the type developed by Sivapalan and his coworkers abound in the literature, their modeling approach differs from previous ones in a number of respects: (i) the appropriate model structure is obtained through systematic analysis of the data, (ii) the model is parsimonious for the data that are used in the model development, and (iii) many of the model parameters are estimated from the data. In addition, the systematic analysis of the data also enables the hydrologist/modeler to learn from the data as part of the process of model development.

While the signatures signify the transformations that the modeler attempts to reproduce, there is considerable flexibility in the choice of models that can be adopted to achieve these transformations. In the above examples, "bucket" models of varying degrees of complexity and nonlinearity are used, the parameters of which are estimated from the observed streamflow data, but other model types can likewise be employed. Indeed, Struthers *et al.* (2003) used the downward approach to model deep drainage underneath a large lysimeter in Germany, through the use of a nonlinear bucket model. They found that the bucket model did an excellent job in reproducing long-term (seasonal and multiannual) variability of recharge.

Other Examples of the Downward Approach

Mean Annual Water Balance and the Budyko Curve

It is well known that annual evapotranspiration approaches annual precipitation in regions where the water equivalent of the energy supply greatly exceeds precipitation (arid regions), whereas in regions where the water equivalent of energy supply is only a small fraction of precipitation (humid regions), annual evapotranspiration is commensurate with the energy supply. On the basis of these considerations, and water balance data obtained from a number of catchments around the world, Budyko (1974) derived a simple relationship describing annual evapotranspiration as a function of annual energy supply (i.e. net radiation) and precipitation. The resulting *Budyko curve*, as the universal relationship is known, represents a simple pattern at the annual timescale and watershed (space) scale, a pattern that is often hidden behind considerable scatter in the observed data but is, nevertheless, extremely critical and not yet fully understood.

Milly (1994) presented a simple mathematical framework to explore the climate, soil, vegetation controls on the shape of the Budyko curve, which is an excellent example of the application of the "downward approach". Milly hypothesized that long-term water balance is determined by interactions of fluctuating water supply and demand, mediated by water storage in the soil. He showed that a simple bucket model based on these considerations was able to

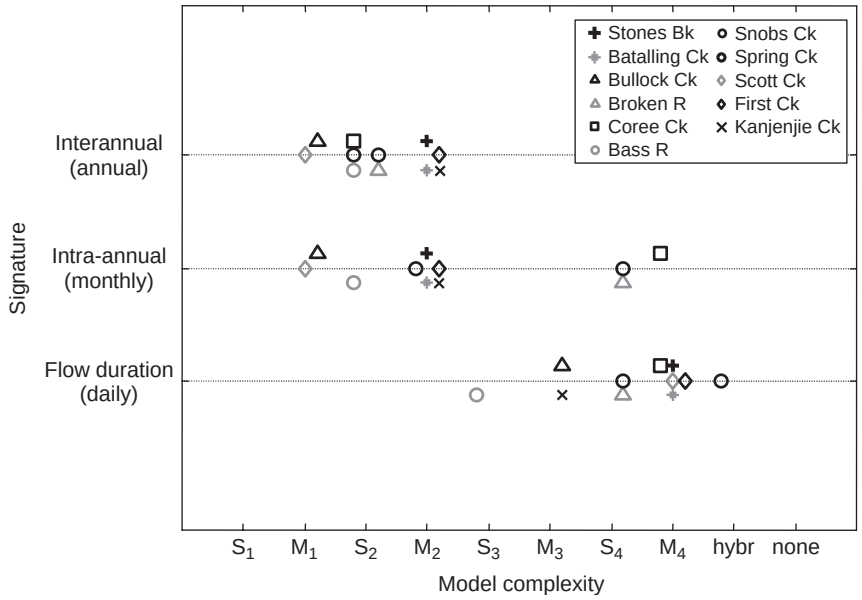

Figure 6 Minimum model complexity required to capture signatures: interannual variability, mean monthly variability, and daily flow duration curve (Reproduced from Farmer *et al.* (2003) by permission of American Geophysical Union)

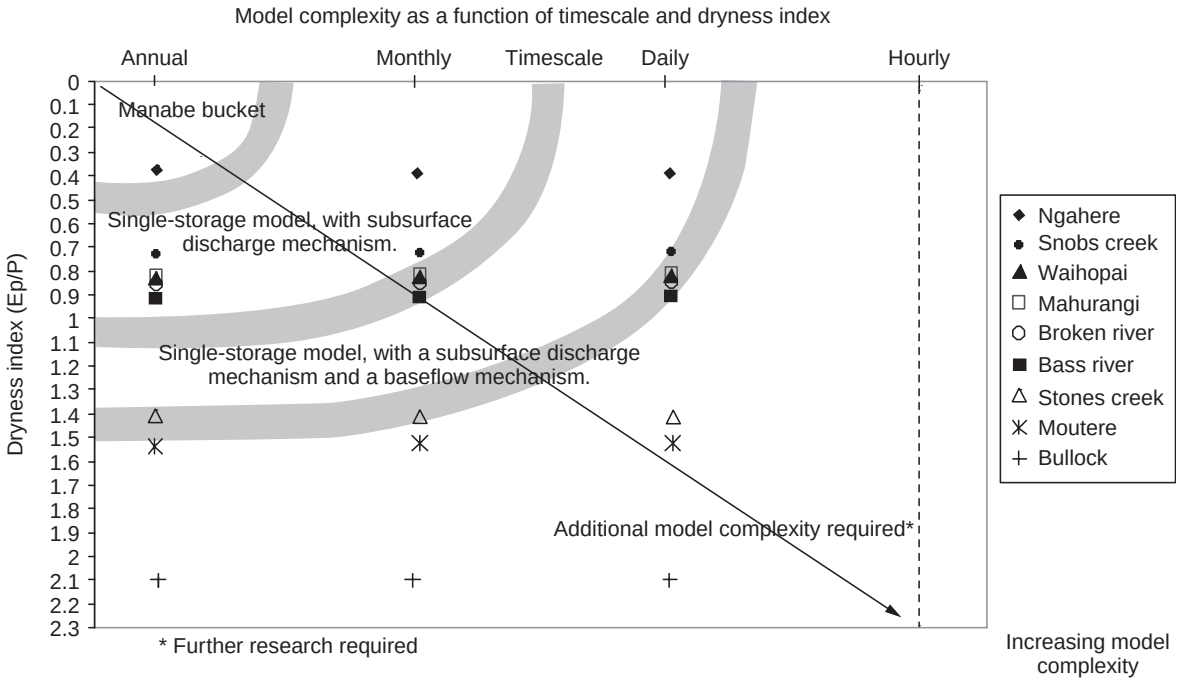

Figure 7 Required model complexity as a function of timescale and climatic dryness index. Model complexity increases with decreasing timescale and increasing aridity of the catchment (Reproduced from Atkinson *et al.* (2002) by permission of American Geophysical Union)

capture over 80% of the spatial variability of annual water balance for that part of the USA east of the Rocky Mountains. Choudhury (1999) proposed an alternative explanation that attributes the Budyko curve to the effects of spatial variability of precipitation and energy supply. In an attempt to quantify the effects of vegetation changes on annual water balance, Zhang *et al.* (2001) developed a simple two-parameter model that related mean annual evapotranspiration to rainfall, potential evapotranspiration, and to plant-available water capacity. This model related

average annual evapotranspiration under the same climatic conditions to vegetation characteristics, and attributed any differences therein to the way different kinds of vegetation use soil water.

Geomorphologic Instantaneous Unit Hydrograph (GIUH)

The unit hydrograph concept is one of the earliest building blocks of hydrologic theory, the one concept that separates hydrology from hydraulics. In place of resorting to the use of established theories of hydraulics (e.g. St. Venant equations) to the entire network of channels (and hillslopes) comprising the catchment, the unit hydrograph concept permits the formulation (through a convolution integral or equivalent linear transfer function relationship) of the catchment's storm response in terms of an (integrated) unit response, called the *instantaneous unit hydrograph* (IUH). Yet, until the work of Rodríguez-Iturbe and Valdés (1979) and the introduction of the geomorphologic instantaneous unit hydrograph (GIUH), the physical basis of the IUH was not explored, nor understood. The GIUH work has been driven by a desire to understand the pattern of hydrologic response at the event scale, and to interpret instantaneous unit hydrographs (IUHs) obtained from observed streamflow data in terms of the elements of catchment structure and functioning "that could have led to it" (Klemes, 1983). The GIUH of Rodríguez-Iturbe and Valdés (1979) made an explicit connection between the IUH and the geometry of the catchment, especially the topology of its channel network as represented by Horton order ratios. The physics of flows in the river network was, however, represented by simple storage routing, through a set of interconnected linear reservoirs, the mean residence times of which were governed by a common velocity parameter.

Subsequent work on interpretations of the GIUH have shed considerable light on the geometric features and component processes operating at lower scales that govern the shape of the IUHs, especially the relative roles of channel network topology, at-site and downstream hydraulic geometry, channel network hydraulics, and the nature of hill slope responses. An alternative scheme to incorporate network geometry was introduced by Lee and Delleur (1976) and Kirkby (1976) on the basis of the catchment's so-called *width* or *area function*. The width or area function is a mechanism to represent the distribution of catchment area along a length dimension. Various models of water transport motivated by hydraulic considerations have been proposed as alternatives to the use of linear reservoirs: (i) pure translation routing based on a constant velocity assumption (Gupta *et al.*, 1980), (ii) linearized diffusion wave routing (Rinaldo *et al.*, 1991), based on the assumption of constant velocity and hydrodynamic diffusivity, and (iii) based on spatially variable velocity and hydrodynamic dispersion (Saco and Kumar, 2002). This body of literature illustrates the use of the downward approach to "finger down" in search of improved physical meaning and realism of a concept established at the catchment scale. Whether the additional process details can be justified against data remains an open question.

Finally, it is interesting to compare this deterministic approach to GIUH analysis with the equivalent stochastic systems approach discussed in Section "A Data-Based Mechanistic Model of the Rainfall-Flow Process". There, the underlying shape of the discrete-time unit hydrograph (TUH) is represented by the pulse response of the estimated linear TF model (4); the changes of the magnitude (but not the shape) of the TUH under different flow and catchment storage conditions is defined by the effective rainfall nonlinearity $f(s_k)$ (a function of the catchment storage variable, s_k); and the interconnected linear reservoirs derive from the TF decomposition into the parallel pathway structure of Figure 2. Similar comments apply to the equivalent, continuous-time TF model, although there the impulse response is precisely the IUH, since it is the response to an instantaneous impulsive input.

Solute Transport in Heterogeneous Media

Transfer function modeling has been pursued within groundwater hydrology area in the 1980s for describing vertical percolation of water and solute transport in heterogeneous soils. Use of models based on deterministic description of the system, such as Richards equation, is the standard approach and has shown encouraging results under homogeneous conditions. However, in heterogeneous media, the success of such models has been rare because of the difficulty in parameterizing both vertical and lateral heterogeneity of soil hydraulic properties and the complicated internal dynamics of such a system. Instead of trying to provide an exact and detailed representation of the system, Jury (1982) developed an alternative modeling approach based on a transfer function model. In the case of solute transport within soils, the transfer function model is able to simulate the average solute concentrations at any depth and time based on the so-called *lifetime density function* (Jury *et al.*, 1982; Jury *et al.*, 1986; White *et al.*, 1986). As in the case of solute transport in river channels discussed above, the form of the TF model is not dictated by the detailed mechanisms of solute transport and the structural properties, and all small-scale processes that lead to an observed solute mass loss rate are implicitly imbedded into this lifetime density function.

Beven and Young (1988) and Young and Beven (1993) describe a rather different stochastic DBM approach to modeling solute transport in heterogeneous soils. Here the TF model is obtained by direct identification and estimation from tracer experiment data (similar to the approach used in

Section "The Aggregate Dead Zone Model: a Data-Based Mechanistic Model of Pollutant Transport in a River") and this is then interpreted in dynamic mass-conservation and dispersion terms.

DISCUSSION AND CONCLUSIONS

In this article, we have given a broad introduction to the downward or top-down approach to model development, distinguishing it from the current dominant paradigm that is the upward or bottom-up approach. We have illustrated its application to hydrological problems through two sets of examples based on the deterministic and stochastic approaches to downward modeling. The deterministic approach focuses more on drawing hydrological inferences from the analysis of the data; whereas the stochastic approach uses much more formal procedures of data-based analysis, drawn from the systems theory and statistics literature. While each of these methodologies may have come from different disciplines and may appear to be superficially different, there are significant similarities between them, as demonstrated by Quimpo (1971), O'Connor (1976), and Young (2003). Therefore, in the future, we believe that the two methodologies should be combined together to yield a common, formalized procedure for the analysis of data and the development of parsimonious, data-based mechanistic models. This will considerably enhance the acceptability of models developed by the downward approach, helping to streamline and make more efficient the required analysis of data and associated statistical inference.

Predictions in Ungauged Basins (PUB) remains one of the most difficult, yet practically important problems in hydrology, and is the focus of a major, new decade-long international initiative (Sivapalan *et al.*, 2003b). Extension of models developed through the systems approach to predict in ungauged basins requires that the model structure and parameterizations have a mechanistic basis, in order that their parameters can be connected to routinely observable climate and landscape properties, thereby enabling their extrapolation (so-called *regionalization*) to other, neighboring catchments. The enhancement of the mechanistic basis naturally requires "fingering down" to seek connections to processes and features operating at a lower level, which is a defining feature of the downward approach.

Klemes (1983) stated 20 years ago: ". . . the most promising route to significant new discoveries in hydrology is to combine the upward and downward search based on the existing facts and knowledge as well as on imagination and intuition, to form testable hypotheses – i.e. to apply the time-honored scientific method". However, there is a limit to how far we can refine or "finger down" the top-down models without changing over completely to the upward approach, and introducing assumptions not justified by, nor identifiable from, the data. This limit is usually reflected in a limit on the model complexity justified by the data. This is in line with the principle of *Occam's Razor*, which is consistent with the concept of parsimonious modeling discussed in this article: this states that one should not make any more assumptions than the minimum needed: that is, when choosing from among models with equal explanatory power, the simplest model is more likely to be correct (Young, 1978; Forster, 2000).

One way of addressing this problem is to move beyond the notion of "trying to model everything" and develop methods that are able to identify the dominant processes that control hydrological response in different environments (landscapes and climates) and at different scales, and then develop models that focus on these dominant processes (Grayson and Blöschl, 2000; Young, 1999; Young *et al.*, 1996, 2004). This may involve the development of some sort of classification or typological system (Woods, 2002) to precede the modeling effort, which is consistent with a downward avenue to hydrologic prediction. It would also be worth adopting the downward approach in a comparative mode in many catchments around the world under different climatic and hydrologic settings. This should allow both the methodology and the insights gained by the top-down modeling to be shared around the world and, hopefully, this will result in top-down models that apply in different climatic or hydrologic settings. Ideally, the order of these settings may be governed by a catchment classification or typology system, such as that proposed by Woods (2002) and McDonnell and Woods (2004).

Open-channel Flow

135: Open Channel Flow – Introduction

WALTER H GRAF AND MUSTAFA S ALTINAKAR

Laboratoire de Recherches Hydrauliques, Ecole Polytechnique Fédérale, Lausanne, Switzerland

The introduction begins with a presentation of the different types of channels as well as with the corresponding flow regimes. Subsequently, the notions of the distribution of velocity and of pressure are exposed.

INTRODUCTION

Treated will be the flow and flow-related phenomena in artificial and natural channels of simple geometry with a free surface subjected to the atmospheric pressure.

CHANNELS

A channel is a transport system where water flows and where the free surface is subject to atmospheric pressure. Channels are important and integral parts of any hydrologic system.

Two categories of channels are to be distinguished: (i) natural channels and (ii) artificial channels (see Figure 1).

Natural channels are watercourses that exist naturally on (or under) the earth, such as gullies, brooks, torrents, rivers, streams, and estuaries. The geometric and hydraulic properties are generally rather irregular.

Artificial channels are watercourses developed by men on (or under) the earth, such as open channels (navigation channels, power canals, irrigation and drainage channels) or closed channels where flow does not fill the entire section (hydraulic tunnels, aqueducts, drains, sewage canals). The geometric and hydraulic properties of such channels are generally rather regular.

Geometry of Channels

The (transversal) section of a channel is a section in the cross-sectional plane being normal to the direction of flow (see Figure 2). The section, or better the wetted (cross-sectional) surface, A, is the portion of the cross section occupied by the liquid.

A channel whose section does not vary and whose longitudinal slope and roughness remains constant – however, the flow depth may vary – is called a *prismatic* channel; otherwise the channel is a nonprismatic one.

The geometric elements of a section or wetted surface, A, are the following:

The wetted perimeter, P, of the channel, being formed by the length of the line of contact between the wetted surface and the bed and the side walls. The wetted perimeter can be composed of a fixed or immobile bed (concrete, rock) or of a mobile bed (granulates of sediments).

The hydraulic radius, R_h, being the ratio of wetted surface to its wetted perimeter, or

$$R_h = \frac{A}{P} \tag{1}$$

The width, B, of the channel being the width at the free surface.

The hydraulic depth, D_h, of the channel being defined by $D_h = A/B$.

The flow depth, h, or the water height – if not defined otherwise – is considered to be the maximum depth.

Formulas for the geometric elements for different types of channel sections are given in Chow (1959), p. 21. A natural watercourse might have a rather irregular geometric form, but often it can be rather well approximated by a trapezoidal or parabolic section.

Besides the geometric elements, the longitudinal slopes are also to be considered, namely,
the slope of the bed (bottom or floor), S_f,
the slope of the water surface (piezometric), S_w.

The value of the bottom slope depends essentially on the topography of the terrain, being generally weak; it may be expressed by $S_f = tg\alpha \cong \sin\alpha$.

FLOW IN CHANNELS

Flow in open channels is essentially due to the inclination (slope) of the bed, while flow in closed conduits (see Graf and Altinakar, 1991, 1995, Chapter PP.1), is due to a difference in the charge between the sections.

Types of Flow

A classification of open channel flow may be done according to the change of the flow depth, h or D_h, with respect to time and space:

$$D_h = f(t, x) \tag{2}$$

Time variation: Flow is steady (stationary or permanent), if the average velocity of flow, U, but also the flow depth, h or D_h, remain invariable with time. Consequently, the discharge remains constant:

$$UA = Q \tag{3}$$

between the different sections of the channel, supposing there is no lateral inflow or outflow. Flow is unsteady if the flow depth, $D_h(t)$, as well as the other parameters vary with time. Consequently, the discharge is no more constant. Strictly speaking, open channel flow is rarely steady. However, the temporal variations are often sufficiently slow and the flow may be assumed to be steady.

Space variation: Flow is uniform if the flow depth, h or D_h, as well as the other parameters, remain unchanged at every section of channel. The line of the bottom slope is thus parallel to the one of the free-water surface, or $S_f \equiv S_w$. Flow is nonuniform or varied if the depth, $D_h(x)$, as well as the other parameters, vary along the length of the channel. The bottom slope is thus different from the slope of the water surface, or $S_f \neq S_w$. Nonuniform flow can be steady or unsteady. Varied flow can be accelerating, $dU/dx > 0$, or decelerating, $dU/dx < 0$, depending on the variation of velocity in the direction of flow. If the flow is a gradually varied one, the depth, $D_h(x) \cong D_h$, varies slowly from one section to another. If the flow is a rapidly varied one, the depth, $D_h(x)$, changes abruptly over a comparatively short distance, sometimes with a discontinuity. This happens generally in the neighborhood of a singularity, such as at a weir or at a change of channel width, and also at a hydraulic jump or a hydraulic drop.

Flow Regimes

The physics of open channel flow is governed basically by the interplay of the inertia forces, the gravity forces, and the friction (viscosity and roughness) forces.

The (reduced) equations of motion (see Graf and Altinakar, 1991, 1995, Section FR.7.2), which bring these forces into play, involve the following dimensionless numbers:

The Froude number, being the ratio of gravity to inertia forces, or

$$\frac{\rho g}{\rho U_c^2 / L_c} = Fr^{-2} \quad \text{and} \quad Fr = \frac{U_c}{\sqrt{g L_c}} \tag{4}$$

The Reynolds number, being the ratio of friction to inertia forces, or

$$\frac{\mu (U_c / L_c^2)}{\rho U_c^2 / L_c} = Re^{-1} \quad \text{and} \quad Re = \frac{U_c L_c}{\nu} \tag{5}$$

Added to these two numbers is still the relative roughness, being the ratio of the roughness height, k_s, to a characteristic length, or

$$\frac{k_s}{L_c} \tag{6}$$

Here, U_c and L_c are the characteristic velocity and length; one takes often $U_c = U$ and $L_c = R_h$ or $L_c = D_h$.

In the hydraulics of open channel flow, one generally defines these dimensionless numbers as

$$Fr = \frac{U}{\sqrt{g D_h}};\ Re = \frac{4 R_h U}{\nu} \quad \text{or} \quad Re' = \frac{R_h U}{\nu};\ \frac{k_s}{D_h} \tag{7}$$

The Reynolds number is used to classify the flow (see Graf and Altinakar, 1991, 1995, Chapter FR.3) as follows:

Laminar flow	$Re' < 500$
Turbulent flow	$Re' > 2000$
Transition flow	$500 < Re' < 2000$

From numerous experiments with different artificial channels (see Chow, 1959, p. 10), it results that flow is turbulent if the Reynolds number, Re', reaches a value of 2000. In general, flow in open channels is a turbulent and often rough flow.

The Froude number is used to classify the flow as follows:

Subcritical (fluvial) flow	$Fr < 1$
Supercritical (torrential) flow	$Fr > 1$
Critical flow	$Fr \equiv Fr_c = 1$

In general, flow in open channels can be thus of the three types.

DISTRIBUTION OF VELOCITY

In flow along a wall (the bottom of a channel), a distribution of velocity (see Graf and Altinakar, 1991, 1995, Chapter FR. 6) is encountered. Being zero at the wall, the point velocity, u, increases towards the free surface; its maximum value is often found slightly below this free surface. The velocity profile is approximately logarithmic.

Steady flow depends in general on the three variables, x, y, and z; this is called three-dimensional flow. If such a channel has a large width, B – large in comparison with the depth, $B > 5\,h$ – flow is considered two-dimensional, with the exception of a small distance close to the vertical side walls. Hydraulic calculations are considerably simplified, if one assumes the flow to be one-dimensional. The average velocity, $U(x)$, in a vertical or in a section, is expressed by

$$U = \frac{1}{h}\int_0^h u(z)\,\mathrm{d}z \quad \text{or} \quad U = \frac{1}{A}\int_0^B \int_0^h u(z)\,\mathrm{d}z\,\mathrm{d}y \tag{8}$$

In open channels of simple geometry, one encounters generally turbulent flow where the point velocity, $u(x, z)$, differs little from the average velocity, $U(x)$. In the steady state, such an hypothesis allows to consider the flow as one-dimensional.

DISTRIBUTION OF PRESSURE

A general expression for the relative (with respect to the atmospheric pressure) pressure on a curved bottom of the channel is given (see Graf and Altinakar, 1998, Chapter 1.4) by

$$p_f = \gamma h' + \rho\frac{U^2}{r}h + \cancel{p_a} = 0 \tag{9}$$

having an hydrostatic and an accelerating component (see Figure 3).

For uniform flow, when the average velocity, U, remains constant and the streamlines are reasonable rectilinear (with $r \to \infty$) , the distribution of pressure is hydrostatic in a section, normal to the bottom (see Figure 4). The expression for the pressure, relative to the bottom, can now be given as

$$p_f = +\gamma h' = \gamma h \cos\alpha \tag{10}$$

For the usually encountered open channels, the inclination, α, is rather weak, that is, $\alpha < 6°$; or $S_f < 0.1$, implying that $\cos\ \alpha \simeq 1$. Consequently, equation (10) reduces to

$$\left(\frac{p}{\gamma}\right)_f = h \tag{11}$$

where h is the flow depth in the channel.

For flow, being (slightly) nonuniform, thus having a curvilinear current of converging or diverging type, there exists an acceleration component caused by the inertia

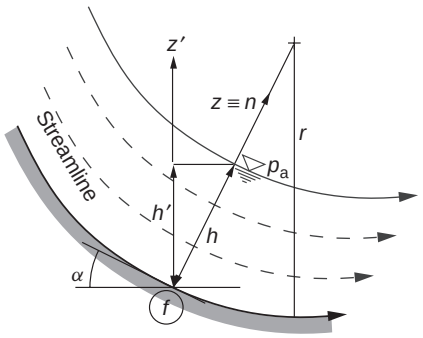

Figure 3 Flow over a concave bottom. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

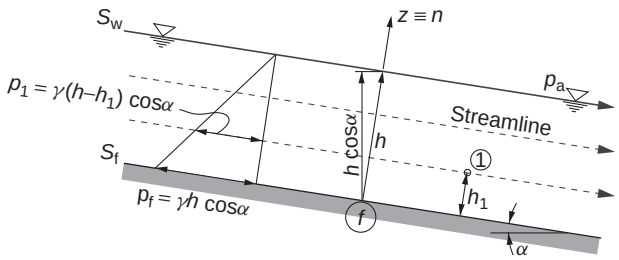

Figure 4 Flow with a uniform current

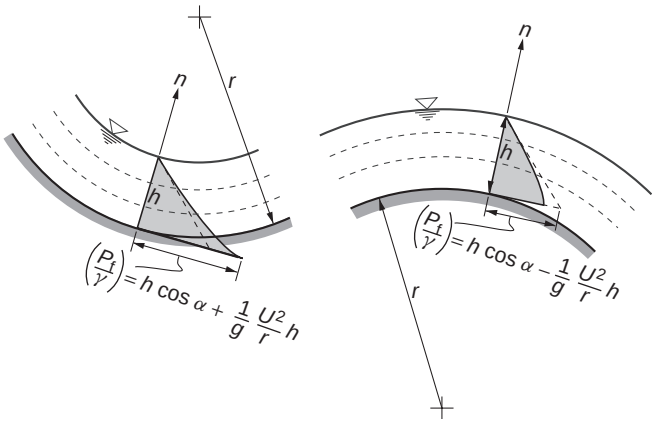

Figure 5 Flow over a concave and a convex bottom. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

forces. The expression for the pressure relative to the bottom is given by

$$p_f = \gamma h' \pm \rho\frac{U^2}{r}h = \gamma h\cos\alpha \pm \rho\frac{U^2}{r}h \qquad (12)$$

being (+) for a concave and (−) for a convex bottom. The distribution of pressure is no more hydrostatic (see Figure 5). For an external concave current, the centrifugal force increases the pressure; while for a convex current, this force decreases the pressure. In the latter case, the pressure could get below the atmospheric pressure, thus causing separation of flow on the channel bed.

136: Hydrodynamic Considerations

WALTER H GRAF AND MUSTAFA S ALTINAKAR

Laboratoire de Recherches Hydrauliques, Ecole Polytechnique Fédérale, Lausanne, Switzerland

The equations of continuity and of energy are developed for the general case. Subsequently, the specific energy, a concept useful for the understanding of different problems, is introduced.

INTRODUCTION

Some fundamental notions of hydrodynamics, being the basis of open-channel hydraulics, shall be presented.

EQUATION OF CONTINUITY

The equation of continuity, one of the basic equations of fluid mechanics, is an expression of the conservation of mass.

A flow of an incompressible fluid, being steady, uniform and almost rectilinear, in an open channel with a free surface and a weak bed slope (see Figure 1) will be studied. Two channel sections are considered. The volume, entering by the first section is $Q\,\mathrm{d}t$; the volume leaving by the second section is $[Q + (\partial Q/\partial x)\mathrm{d}x]\mathrm{d}t$. The variation of the volume between these sections during the time, $\mathrm{d}t$, is consequently $(\partial Q/\partial x)\ \mathrm{d}x\ \mathrm{d}t$. This variation is the result of a modification of the free surface, $\partial h/\partial t$, between the two sections during the time, $\mathrm{d}t$; it is expressed by $(B\mathrm{d}x)\ (\partial h/\partial t)\ \mathrm{d}t$, where $B(h)$ is the width of the channel, $h(x, t)$ is the flow depth and $\mathrm{d}A = B\mathrm{d}h$. Assuming the fluid incompressible, the above two expressions are made equal (see Chow, 1959, p. 525) and one obtains:

$$\frac{\partial Q}{\partial x} + \frac{\partial A}{\partial t} = 0 \tag{1}$$

For a rectangular channel, defining $q = Q/B$ as the unit discharge, equation (1) is:

$$\frac{\partial q}{\partial x} + \frac{\partial h}{\partial t} = h\frac{\partial U}{\partial x} + U\frac{\partial h}{\partial x} + \frac{\partial h}{\partial t} = 0 \tag{2}$$

For steady flow, $\partial A/\partial t = 0$, the equation of continuity, equation (1), reduces to:

$$\frac{\partial Q}{\partial x} = 0 \tag{3}$$

If a supplementary discharge leaves (or enters) the channel between the two sections, equation (1) can be written as:

$$\frac{\partial Q}{\partial x} + \frac{\partial A}{\partial t} \pm q_\lambda = 0 \tag{4}$$

where q_λ is the supplementary discharge per unit length.

EQUATION OF ENERGY

The equation of energy is an expression of the first principle of thermodynamics. The energy for an element of incompressible fluid, written in homogeneous quantities of length (see Figure 2) – here as the height of a liquid with specific weight $\gamma = \rho g$ – in almost rectilinear and one-dimensional flow, taken with respect to the plane of reference (PdR), is given by:

$$\frac{u^2}{2g} + \frac{p}{\gamma} + z_p = \frac{p_t}{\gamma} = \mathrm{Cte} \tag{5}$$

The different terms represent: the velocity head, $u^2/2g$, the pressure head, p/γ, the elevation (position) of a point P, z_P, and the (mechanical) energy head or the total head, $p_t/\gamma = H$.

Consider the following reasonable assumptions:

1. The piezometric head, $p*/\gamma = p/\gamma + z_P$, is supposed to be constant over a normal to the bed, implying that the distribution of pressure is hydrostatic.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

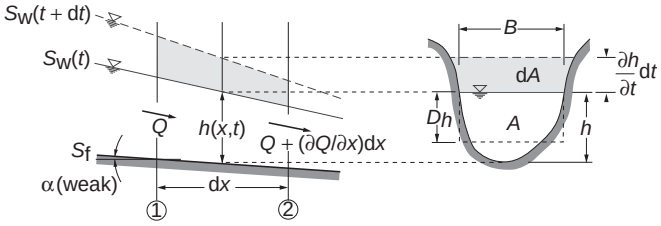

Figure 1 Scheme for the equation of continuity. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

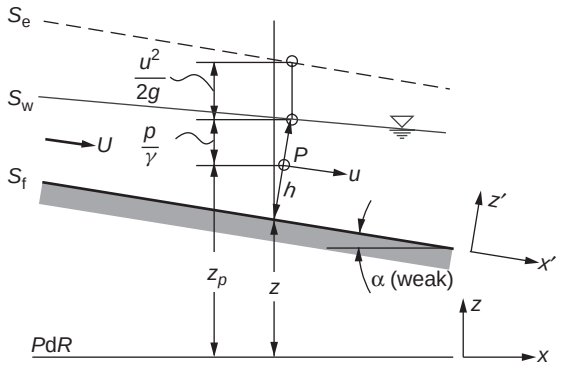

Figure 2 Scheme for the equation of energy in a cross section. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

2. The slope (weak) of the channel is given by: $S_f = tg\alpha = -dz/dx \cong \sin\alpha$;
3. If h is the flow depth, the pressure head at the bed of the channel (see equation (10) in **Chapter 135, Open Channel Flow – Introduction, Volume 4**) is: $(p/\gamma)_f = h\cos\alpha$, but for weak slopes, $\alpha < 6°$, where $S_f < 0.1$, one may take $\cos\alpha \cong 1$. The system of the coordinates, xz, is thus almost identical with the one of the coordinates, $x'z'$, (see Figure 2).
4. In a perfect fluid, each fluid element moves with the same velocity, being identical with the average velocity in the section, U.

Making use of these assumptions, the total head in a section is now given by:

$$\frac{U^2}{2g} + h + z = H \tag{6}$$

The equation of energy, equation (6), is a manifestation of the principle of energy if the fluid is *perfect*. From one to another section, each of the three terms in equation (6) can take a different value, but the sum, H, remains constant.

For flow of a *real* fluid with a free surface, being unsteady and nonuniform, the difference of the total head

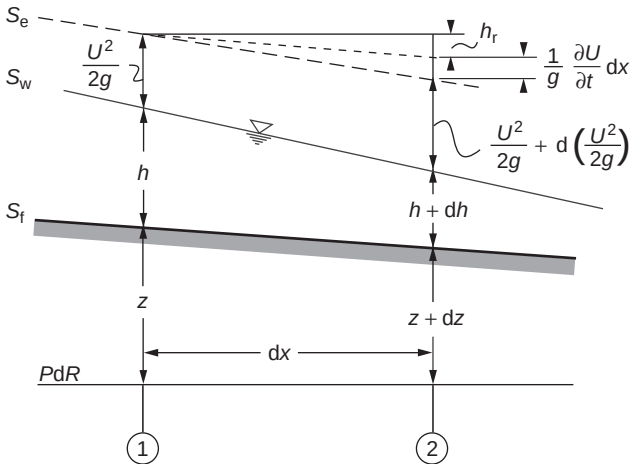

Figure 3 Scheme of the equation of energy, between two sections. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

between two sections, separated by a distance, dx, (see Figure 3) is given as:

$$\alpha_e\frac{U^2}{2g} + h + z = \left[\alpha_e\frac{U^2}{2g} + d\left(\alpha_e\frac{U^2}{2g}\right)\right] + [h + dh] + [z + dz] + \frac{1}{g}\frac{\partial U}{\partial t}dx + \frac{1}{g}\frac{\tau_o}{\rho}\frac{dP}{dA}dx \tag{7}$$

Here $(1/g)\ (\partial U/\partial t)\ dx$ is the term of energy due to unsteady flow, and $(1/g)\ (\tau_o/\rho)\ (dP/dA)\ dx$ is the term of energy or head loss due to friction (see Graf and Altinakar, 1991, 1995, p. 138); where τ_o is the shear stress due to the frictional forces acting on the wetted surface, $dP\ dx$. This last term is usually written as h_r. The kinetic energy correction coefficient, α_e, results from the distribution of the velocity in the section. Its numerical values (see Chow, 1959, p. 28), notably for turbulent flow, are very close to unity, $\alpha_e \cong 1$.

Dividing by the distance, dx, and using partial differentials, the equation of energy, equation (7), can thus be written:

$$\frac{1}{g}\frac{\partial U}{\partial t} + \frac{U}{g}\frac{\partial U}{\partial x} + \frac{\partial h}{\partial x} - S_f = -S_e$$

steady, uniform
steady, non-uniform
unsteady, non-uniform

(8)

where $h_r = S_e\ dx$, with S_e as the energy slope, and $S_f = -(dz/dx)$ as the bottom slope. Equation (8) is the dynamic equation for unsteady and nonuniform flow.

The head loss, h_r, must be evaluated with a formula such as the one of Weisbach–Darcy, equation (7), of Chézy,

equation (8) in **Chapter 137, Uniform Flow, Volume 4**, or of other experimenters. Such relations are only valid for steady, uniform flow; however – for lack of better information – they are also used (see Chow, 1959, p. 217) for unsteady and nonuniform flow.

The equation of continuity, equation (1), and the equation of motion, equation (8), form together the *equations of Saint-Venant* (see Chow, 1959, p. 528). Despite the various simplifications made to obtain these equations, their solutions are often rather complicated. In some cases, which are simple but still realistic, explicit solutions are possible. For flow, which is steady but nonuniform or steady and uniform, equation (8) is used in a reduced form.

The equation of motion, equation (8), can also be obtained by applying the momentum equation. The resulting equation is almost the same (see Chow, 1959, p. 51).

SPECIFIC ENERGY

The total head, H, in a given cross section was defined with respect to an arbitrary horizontal plane. If the plane of reference is placed into the bed slope, S_f, a fraction of the total head, called the *specific energy*, H_s, is defined; one writes now (see Figure 4):

$$\frac{U^2}{2g} + h = H_s \quad \text{or} \quad \frac{Q^2/A^2}{2g} + h = H_s \tag{9}$$

The notion of the specific energy is often very useful; it helps to understand and to solve different problems of free-surface flow.

For a given section in the channel, the area of flow, A, is a function of the flow depth, h, and equation (9) gives a relation of the following form:

$$H_s = f(Q, h) \tag{10}$$

which allows a study of the variation of h with H_s for $Q = \text{Cte}$ or h with Q for $H_s = \text{Cte}$ (see Graf and Altinakar, 1998, Chapter 2.3).

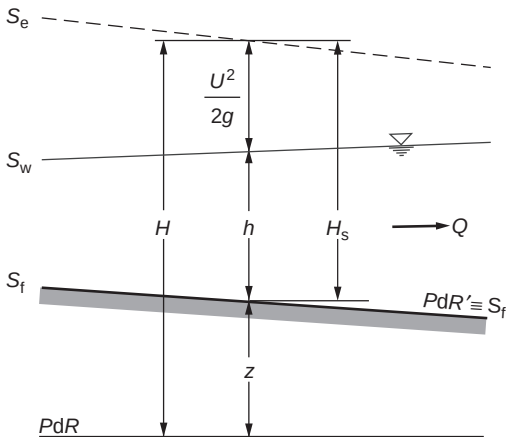

Figure 4 Definition of the total head, H, and the specific energy, H_s. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Specific-energy Curve

Equation (9) gives the evolution of the specific energy, H_s, as a function of the flow depth, h, for a given discharge, $Q = UA$. This curve (see Figure 5) has a horizontal asymptote for $h = 0$ and is asymptotic to the line $h = H_s$ for $h = \infty$. In addition, the curve has a minimum, H_{s_c}, for:

$$\frac{dH_s}{dh} = -\frac{Q^2}{gA^3}\frac{dA}{dh} + 1 = 0 \quad \text{or} \quad \frac{Q^2}{g}\frac{B}{A^3} = \frac{U^2}{gD_h} = 1 \tag{11}$$

since dA/dh is equal to the width of the channel, B, at the free surface, and the hydraulic depth is defined as $D_h = A/B$.

For a channel with a rectangular cross section, one takes $D_h = h$. The flow depth, h, which corresponds to the minimal specific energy, H_{s_c}, is called *critical depth*, h_c.

Following the curve (see Figure 5) one notices that for a given discharge $Q = \text{Cte}$, and for an arbitrary value of

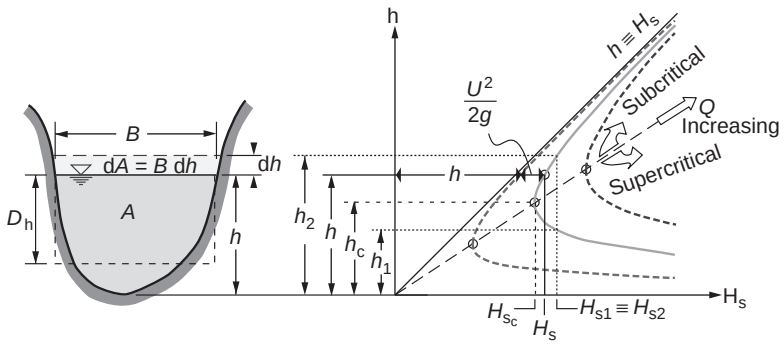

Figure 5 Specific-energy curve, $H_s = f(h)$, for $Q = \text{Cte}$. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

specific energy, H_s, – if flow can take place – there are always two solutions for the flow depth, h_1 and h_2. They are called the *corresponding (alternate) depths*; one of which, h_1, is smaller and the other one, h_2, is larger than the critical depth, h_c. Both of these depths are indications of different regimes of flow, thus:

$h < h_c$ supercritical (torrential) regime
$h > h_c$ subcritical (fluvial) regime
$h \equiv h_c$ critical regime

Each curve (see Figure 5) has thus two branches. Consequently, a steady flow in a channel can exist in two different ways, both having the same specific energy, H_s; namely in supercritical regime, where the flow depth is small and the velocity large, and in subcritical regime, where the flow depth is large and the velocity small. For a variation of the discharge, Q, the corresponding curves have the same form; they follow each other for an increase in the discharge, starting at the origin, (see Figure 5).

Discharge Curve

Equation (9) shows also the evolution of the discharge, Q, as a function of the flow depth, h, for a given specific energy, H_s, such as:

$$Q = A\sqrt{2g(H_s - h)} \tag{12}$$

From such a curve (see Figure 6) one obtains a discharge of $Q = 0$ for $h = 0$ and $h = H_s$. The curve has a maximum value, Q_{max}, for:

$$\frac{dQ}{dh} = \frac{2g(H_s - h)(dA/dh) - Ag}{[2g(H_s - h)]^{1/2}} = \frac{gB[2(H_s - h) - D_h]}{[2g(H_s - h)]^{1/2}} = 0 \tag{13}$$

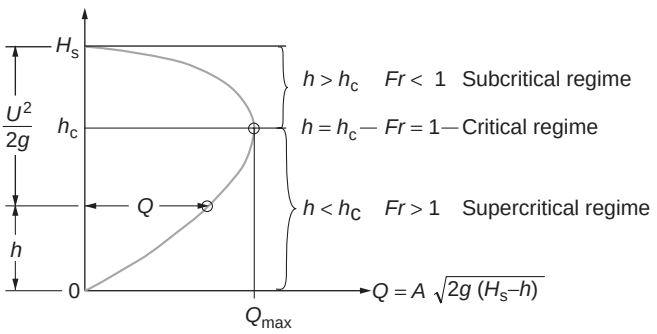

Figure 6 Discharge curve, $Q = f(h)$, for $H_s = \text{Cte}$. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

using the definitions $dA/dh = B$ and $D_h = A/B$. Its derivative becomes zero, if:

$$2(H_s - h) - D_h = 0 \tag{14}$$

The values, h and D_h, which do correspond to the maximum discharge, Q_{max}, represent the *critical depth*, h_c and D_{h_c}. For flows smaller than Q_{max}, one finds again the two different flow regimes (see Figure 6 and also Figure 5).

Equation (14) can be used to obtain the critical depth ($h \equiv h_c$ and $H_s \equiv H_{s_c}$). For a channel with a rectangular cross section, $D_h \equiv h$, the critical depth is:

$$h_c = \tfrac{2}{3} H_{s_c} \tag{15}$$

while for channels with a triangular or parabolic cross section, one obtains respectively:

$$h_c = \tfrac{4}{5} H_{s_c} \quad \text{and} \quad h_c = \tfrac{3}{4} H_{s_c} \tag{16}$$

Critical Depth

In summary, the critical depth, h_c, in a channel is the flow depth at which the specific energy is minimal, H_{s_c}, for a given discharge (see Figure 5), and at which the discharge is maximal, Q_{max}, for a given specific energy (see Figure 6).

Between equation (14) and equation (12), the maximum discharge, Q_{max}, is obtained as:

$$Q_{max} = A\sqrt{g D_{h_c}} \tag{17}$$

The average velocity, which corresponds to the critical hydraulic depth, D_{h_c}, is:

$$U_c = \sqrt{g D_{h_c}} \quad \text{or} \quad \frac{U_c^2}{2g} = \frac{D_{h_c}}{2} \tag{18}$$

In critical regime, the velocity head is thus equal to half of the hydraulic depth. Both equation (18) and equation (11) could also be expressed as:

$$\frac{U_c}{\sqrt{g D_{h_c}}} = 1 \tag{19}$$

being precisely the definition of the Froude number (see equation (4) **Chapter 135, Open Channel Flow – Introduction, Volume 4**) in critical regime; here the Froude number is equal to unity, $Fr_c = 1$. Consequently, the Froude number classifies also the different flow regimes, such as:

$Fr > 1$ supercritical regime $U > U_c$
$Fr < 1$ subcritical regime $U < U_c$
$Fr = 1$ critical regime $U \equiv U_c$

The average velocity, U_c, corresponding to the critical depth, h_c, is given by:

$$U_c = \sqrt{g D_{h_c}} = c \tag{20}$$

being equal to the celerity, c, of the propagation of (superficial) infinitesimal gravity waves in a channel of hydraulic depth, D_{h_c} (see Graf and Altinakar, 1998, Chapter 2.4).

Using equation (15) and equation (18), the critical depth for a rectangular channel, $D_h \equiv h$, with a unit discharge, $q = Uh$, is now given by:

$$\frac{h_c}{2} = \frac{q^2}{2gh_c^2} \quad \text{or} \quad h_c = \sqrt[3]{\frac{q^2}{g}} \tag{21}$$

The maximum unit discharge, q, which may produce itself in a channel of rectangular section is equal to:

$$q = \sqrt{g h_c^3} = \sqrt{g \left(\tfrac{2}{3} H_{s_c}\right)^3} \tag{22}$$

According to equation (17) and equation (22), the critical hydraulic depth, D_{h_c}, or the critical flow depth, h_c, depend only on the discharge. Thus it is interesting to use this information for metering flow in open channels; such as is done with the free overfall and the Venturi channel (see Graf and Altinakar, 1998, Chapter 2.3).

137: Uniform Flow

WALTER H GRAF AND MUSTAFA S ALTINAKAR

Laboratoire de Recherches Hydrauliques, Ecole Polytechnique Fédérale, Lausanne, Switzerland

The equation of continuity and of motion will be developed. The different relationships for the determination of the coefficients of friction for fixed and mobile channel beds are subsequently presented. The calculation of discharge is elaborated. Elementary knowledge about flow in curves as well as instabilities at the free-water surface are exposed.

INTRODUCTION

Flow in a channel is considered as uniform and steady, if the flow depth remains invariable in the flow direction as well as in time. In fluvial hydraulics, uniform flow is taken as the base (reference) for all other considerations, and this despite the fact that truly uniform flow is rarely encountered in reality.

HYDRODYNAMIC EQUATIONS

Equation of Continuity

If the flow is uniform and steady, the wetted cross section of the flow, A, remains the same in direction, x, and in time, t. The equation of continuity is given as:

$$\frac{\partial(UA)}{\partial x} = 0 \tag{1}$$

where $Q = UA$ is the discharge and U is the average velocity. Consequently, the discharge remains constant, $Q = Cte$. Between two cross sections (see Figure 1), one has:

$$A_1 U_1 = Q = A_2 U_2 \tag{2}$$

and with $U_1 = U_2$ and $A_1 = A_2$, one writes: $Q = U\,A$.

Equation of Motion

Consider a prismatic channel (see Figure 1). The liquid in motion provokes a friction force at the wetted perimeter, $F_F = \tau_o P\,dx$, by the action of the longitudinal component of the gravity force, $F_G = \gamma A\,dx \sin\alpha = W \sin\alpha$. In uniform flow, there exists an equilibrium between these forces, $\tau_o P\,dx = \gamma A\,dx \sin\alpha$. Consequently, one obtains:

$$\tau_o = \gamma \frac{A}{P} \sin\alpha = \gamma R_h S_f \tag{3}$$

where τ_o is the tension due to the friction forces, called the *shear stress*, which acts on the wetted surface (wall and bed).

The quotient of the wetted cross section, A, and its wetted perimeter, P, defines the hydraulic radius, R_h. The inclination is usually very small; thus one may write $\sin\alpha \cong tg\alpha = S_f$.

In hydrodynamics, one defines, $\tau_o/\rho = u_*^2$, where u_* is the friction velocity. Thus one can also write:

$$u_* = \sqrt{g R_h S_f} \tag{4}$$

Instead of the shear stress, $\tau_o = \rho u_*^2$, one may also use the definition of the *friction coefficient* (see Graf and Altinakar, 1991, p. 433) which is given by:

$$f = \frac{\tau_o}{\rho U^2/8} = 8\left(\frac{u_*}{U}\right)^2 \tag{5}$$

Subsequently one obtains:

$$\left(\frac{f}{8}\right)\rho U^2 = \tau_o = \rho g R_h S_f \quad \text{or} \quad S_f = f\,\frac{1}{4R_h}\frac{U^2}{2g} \tag{6}$$

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

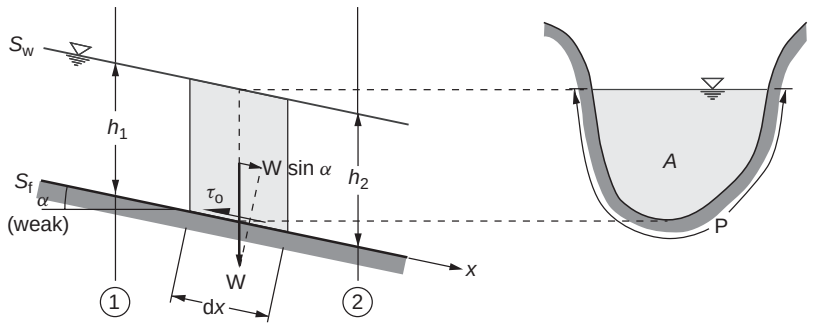

Figure 1 Scheme of uniform flow. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

This relation, which is known as the equation of *Weisbach–Darcy* (see Graf and Altinakar, 1991, sect. FR. 2.1 and sect. PP.2), is also used for calculating flow in pipes. The coefficient, $\boldsymbol{f}$, of friction (head loss) depends on the Reynolds number and the relative roughness, and also on the form of the cross section. The equation of Weisbach–Darcy can also be written as:

$$U = \sqrt{\frac{8g}{\boldsymbol{f}}}\sqrt{R_h S_f} \tag{7}$$

an expression which is frequently given in the form of:

$$U = C\sqrt{R_h S_f} \tag{8}$$

This is called the *relationship of Chézy*, where C is the resistance coefficient of Chézy.

In uniform regime (see equation 7 and equation 8), the flow depth, h, which corresponds to the hydraulic radius, R_h, is defined as being the *normal flow depth*, $h \equiv h_n$.

Different formulae have been elaborated over the years to render expressions for the friction (resistance) coefficients. Herewith some more common formulae will be presented, namely the:

1. coefficient of Weisbach–Darcy,
2. coefficient of Chézy,
3. coefficient of Manning–Strickler,
4. coefficient of friction for mobile bed.

COEFFICIENT OF FRICTION

The two relations, equation (7) and equation (8), give satisfactory results, notably for practical problems in channel flow, if applied correctly and respecting their possible limitations. The ASCE (see Silberman *et al.*, 1963) recommended, however, the use of the equation of Weisbach–Darcy.

Artificial and, particularly, natural channels have all types of the cross-sectional shapes. No parameter exists which would well take care of the variability in form; the use of the hydraulic radius is often not sufficient. An estimation of the friction coefficient for a fixed or immobile bed is already difficult; but still more difficult will be an estimation for a mobile bed.

Coefficient of Weisbach–Darcy

In the above relation, equation (7), the definition of friction coefficient, $\boldsymbol{f}$, is analogous to the one given for circular pipes. For pipes having an industrial roughness, a universal formulation is given by the diagram of Moody–Stanton or the relation of Colebrook–White, for turbulent flow. For cross sections, which are geometrically close to circular sections, one may readily use the experiments performed on pipes. However, some modifications are necessary; the hydraulic radius (see Graf and Altinakar, 1991, p. 439) should be expressed by $4R_h = 4$ (A/P). Thus $4R_h$ becomes the characteristic length to be used in the definition of the Reynolds number, the relative roughness and in the equation of Weisbach–Darcy. For the roughness, k_s, in artificial channels, the equivalent roughness, established for industrial pipes, may be taken (see Graf and Altinakar, 1998, Table 3.1).

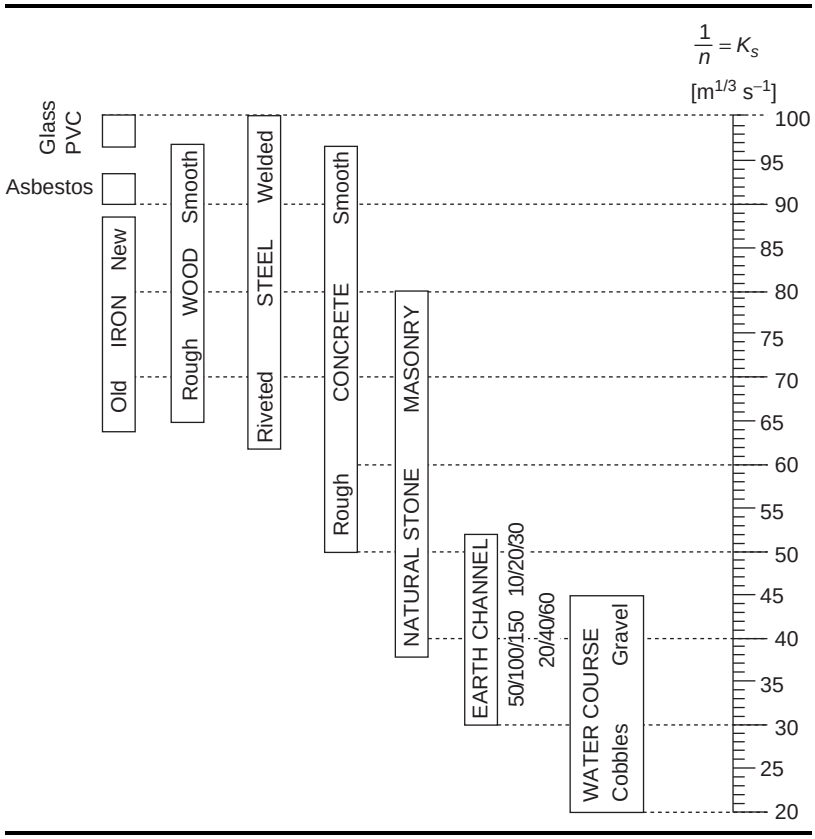
The use of the diagram of Moody–Stanton (see Graf and Altinakar, 1991, Fig. PP.9) with $\mathrm{Re} = 4R_h U/\nu$ and $k_s/4R_h$ gives values for $\boldsymbol{f}$ for laminar and turbulent flow. Subsequently, one obtains the average velocity, U, using equation (7), or the bed slope, $S_f = S_w$, of the channel, using equation (6).

Instead of using the diagram of Moody–Stanton, one may also take the semiempirical *relation of Colebrook–White* (see Graf and Altinakar, 1991, p. 436), valid only for turbulent flow, which is written for channels as follows:

$$\sqrt{\frac{1}{\boldsymbol{f}}} = -2\log\left(\frac{k_s/R_h}{a_f} + \frac{b_f}{Re\sqrt{\boldsymbol{f}}}\right) \tag{9}$$

with $12 < a_f < 15$ and $0 < b_f < 6$, established for different kinds of cross sections, as well as for different types of roughness (see Silberman *et al.*, 1963, p. 104).

Table 1 Coefficients of roughness of Manning and of Strickler



For channels or watercourses whose bed is made up of a granulate, one generally takes $k_s \cong d_{50}$; d_{50} being the diameter equal to 50% of grains in the granulometric curve.

Coefficient of Chézy

For turbulent, rough flow the *formula of Chézy*, equation (8), can be used. However, it cannot be used for laminar or turbulent smooth flow. The coefficient of Chézy, C [m$^{1/2}$/s], is a dimensional expression. Different formulae, being all of empirical nature, have been advanced for the determination of the coefficient of Chézy, C; all of which make use of the hydraulic radius, R_h.

In the practice, one prefers presently exponential relations and one uses commonly the *formula of Manning–Strickler* in the form of:

$$U = K_s R_h^{2/3} S_f^{1/2} \quad \text{with} \quad C = K_s R_h^{1/6} = \frac{1}{n} R_h^{1/6} \quad (10)$$

Here K_s [m$^{1/3}$ s^{-1}] is the coefficient of *Strickler* and n [m$^{-1/3}$ s^1] is the coefficient of *Manning*. The above relation, equation (10), was elaborated using numerous measurements, performed in both natural and artificial channels. The values of n and K_s are given in Table 1. More detailed tables are available in the literature.

Coefficient of Manning

The most popular formula is presently the one of *Manning–Strickler*, often called shortly the *formula of Manning*:

$$U = \frac{1}{n} R_h^{2/3} S_f^{1/2} \quad (11)$$

This is a rather simple relationship, but it must be used only for turbulent rough flow, thus for flow at large Reynolds numbers. In such a case, the coefficient of Manning, n, stays constant for a given roughness, while the coefficient of Chézy, C, depends on the relative roughness, $(R_h^{1/6}/n)$.

Complete tabulations of the coefficient of Manning, n, have been presented by Chow (1959, pp. 110–113) and Graf (1984, pp. 306–309). Furthermore, Chow (1959, pp. 115–123) and Barnes (1967) provide photos of different natural and artificial channels as a visual support, to facilitate the choice of the coefficient of Manning in the range of $0.012 < n < 0.15$. Indicative values are summarized in Table 1. The influence of vegetation on the coefficient of friction is extensively treated by Chow (1959).

It must be pointed out that the values of the coefficient of Manning are the same both in the metric and in the English system. In the latter case, one has to use the following

relation:

$$C = \frac{1.48}{n} R_h^{1/6} \tag{10a}$$

For watercourses, where the bed and walls are made up of a noncohesive granulate, the *formula of Strickler* (see Strickler, 1923, pp. 11–15) may be used:

$$K_s = \frac{21.1}{d_{50}^{1/6}} \quad \text{or} \quad K_s = \frac{26}{d_{90}^{1/6}} \tag{12}$$

where d_{50} or d_{90} [m] are the diameters, being equal to 50 or 90% of the grains in the granulometric curve.

Composite Roughness

The coefficients of friction, $\boldsymbol{f}$, n and C, are valid as long as the entire wetted perimeter has the same roughness; thus the wetted section is homogeneous. In sections where the wetted perimeter is *not homogeneous*, the bed and the sidewalls have different roughness; thus it becomes necessary to compute an equivalent coefficient of friction.

According to *Einstein* (see Chow, 1959, p. 136), one divides – in a reasonable way – the wetted surface, A, in N parts, each one having its wetted perimeter, P_1, $P_2 \ldots\ldots P_N$, and its coefficient of friction, n_1, $n_2 \ldots . n_N$. Furthermore, one assumes that the average velocity of each particular section, A_1, $A_2 \ldots . A_N$, is the same and thus also the same as the average velocity of the entire section, U. Using, for example, the formula of Manning, equation (11), the equivalent coefficient of friction for a composite roughness is given by:

$$n = \left[\frac{\sum_1^N (P_N n_N^{3/2})}{P} \right]^{2/3} \tag{13}$$

Bed Forms

Natural, but also artificial channels may have a *mobile bed*, being a channel bed composed of solid particles (noncohesive granulate), which displace themselves by the action of the flow. The bed may become covered with *bed forms*, commonly called *dunes*.

The geometry of a dune (idealized, since sometimes they are not well apparent) is approximated by a triangular form of length, λ, and of height, ΔH. Indicatives relations (see Graf, 1984, p. 283), made dimensionless by the flow depth, are given as:

$$\frac{\Delta H}{h} < \frac{1}{6}; \quad \frac{\lambda}{h} \approx 5 \tag{14}$$

The presence of bed forms causes an increase in the flow resistance. For the calculation of the total shear stress on the bed, τ_o, one assumes (see Graf, 1984, p. 303) that the contribution of the roughness due to the particles, τ', and the one due to the bed forms, τ'', is additive, namely:

$$\tau_o = \tau' + \tau'' \tag{15}$$

Using the definition of the friction velocity and of the coefficient of friction, one writes:

$$u_*^2 = (u_*')^2 + (u_*'')^2 \quad \text{or} \quad \boldsymbol{f} = \boldsymbol{f}' + \boldsymbol{f}'' \tag{16}$$

but also:

$$n^{3/2} = (n')^{3/2} + (n'')^{3/2} \quad \text{and} \quad \frac{1}{C^2} = \frac{1}{(C')^2} + \frac{1}{(C'')^2} \tag{16a}$$

The total shear stress, τ_o, (see equation 15) varies with the Froude number, Fr.

Coefficient of Friction, Mobile Bed

A quantification of friction coefficients for flow over a mobile bed has, up to now, not been very successful over a large range of flow parameters. Nevertheless, there exist methods, where one calculates the coefficient of friction due to the grain roughness, $\boldsymbol{f}'$ or n', using the formulae presented above; subsequently one determines the coefficient of friction due to the bed forms, $\boldsymbol{f}''$ or n'', using other types of formulae. There exist also methods where one determines directly the *entire* coefficient of friction, $\boldsymbol{f}$ or n.

Different empirical relationships have been elaborated for the calculation of the friction velocity and of the coefficient of friction, u_*'' and $\boldsymbol{f}''$, being due to bed forms, for example, the relation proposed by *Einstein–Barbarossa* which is given usually in graphical form (see Figure 2). Many observations from American rivers, having $0.19 < d_{35}$ [mm] < 4.3 and $1.49 \times 10^{-4} < S_w < 1.72 \times 10^{-3}$ were used. This relationship is expressed (see Graf, 1984, p. 310) by:

$$\frac{U}{u_*''} = f\left(\frac{\rho_s - \rho}{\rho} \frac{d_{35}}{R_h' S_f} \right) = f(\Psi') \tag{17}$$

where R_h' is the hydraulic radius attributed to the grain roughness.

More relations have been presented in Graf (1984, pp. 303–320), Raudkivi (1976, chap. 6) and Graf and Altinakar (1998, p. 84).

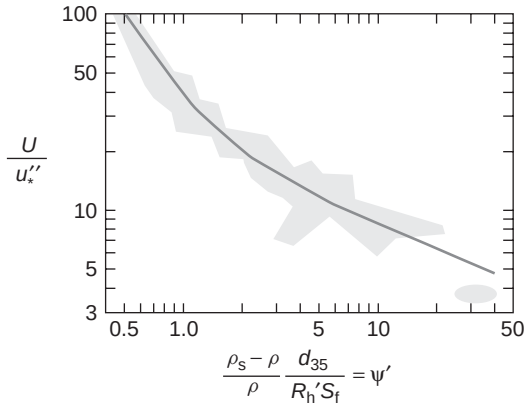


Figure 2 Friction velocity, u_*'', due to bed forms; after Einstein–Barbarossa. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

DISCHARGE CALCULATION, FIXED BED

Determination of the discharge, Q, in a channel with a fixed bed requires the knowledge of the channel geometry, of the roughness coefficient and of the bed slope. Assumed will be that the walls (bed and side walls) of the channel are fixed or immobile, thus not subject to erosion.

Conveyance

The discharge, Q, at uniform flow, given by equation (2), using the corresponding velocity, given by equation (11), can be expressed as:

$$Q = UA = \frac{1}{n} R_h^{2/3} S_f^{1/2} A \tag{18}$$

An expression can be formed such as, $K(h) = (1/n) R_h^{2/3} A$, known as the *conveyance* of the channel (see Bakhmeteff, 1932, p. 13), being only a function of the flow depth, $h \equiv h_n$, known as the *normal depth* for the given discharge, Q. Thus, above expression yields:

$$Q = K(h)\sqrt{S_f} \quad \text{or} \quad \frac{Q}{\sqrt{S_f}} = f(h) \tag{19}$$

For a given form (shape) of the section, this relation can be obtained and plotted point by point (see Figure 3). One can readily calculate the conveyance, K, for geometrically simple sections; for complex ones, a graphical solution is necessary. The normal depth, h_n, increases with the discharge, Q. For identical channels, but having different slopes, S_f, the normal depth increases if the bed slope decreases.

The conveyance, K, characterizes the channel; it represents a measure of the capacity of water transport through the cross section. The curve of the normal depths (see Figure 3) is rather useful in solving different kinds of problems: if two of the three parameters, h_n, Q and S_f, (see equation 19) are known, the third one can be found; *a priori*, the roughness of the walls, n, is taken to be known.

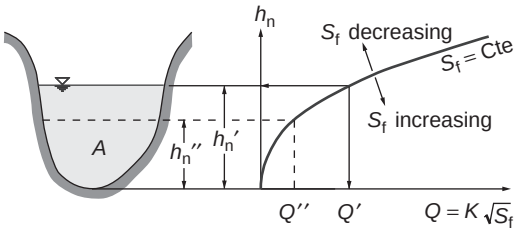

Figure 3 Curve of conveyance or of normal depth. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Normal Depth

The normal depth, h_n, is the flow depth at uniform flow of discharge, Q, at a given bed slope, S_f. (All geometric elements of the cross section, which correspond to the normal depth, h_n, are known as *normal elements*, such as: R_{h_n}, A_n, or P_n)

The normal depth of a channel of a given geometry is calculated using the relation for the discharge, equation (18). This relation shows that uniform flow is only possible in a channel whose bed slope is descending, $S_f > 0$. In a horizontal channel, $S_f = 0$, the normal depth would be infinite.

For a natural watercourse and for rectangular channels whose width, B, is very large ($B \gg h$), one takes $R_h \approx h$ as the hydraulic radius. Subsequently, one obtains for the normal or uniform depth:

$$h_n = \left(\frac{q^2}{C^2 S_f}\right)^{1/3} \quad \text{where } q = \frac{Q}{B} \tag{20}$$

Composite Section

A cross section of a channel can be composed of different subsections (see Figure 4), of which each one can have a different roughness and a different bed slope. This

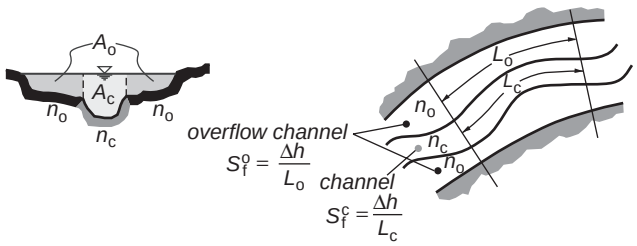

Figure 4 Composite section. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

is frequently the case during flooding, when the flow leaves the channel and enters into the overflow section of the channel.

Such a case can be approximately treated by applying the formula of discharge for each subsection:

$$Q = Q_c + Q_o = \frac{1}{n_c} A_c R_{h_c}^{2/3} \left(\frac{\Delta h}{L_c}\right)^{1/2} + \frac{1}{n_o} A_o R_{h_o}^{2/3} \left(\frac{\Delta h}{L_o}\right)^{1/2} \qquad (21)$$

Note that the wetted perimeters, P_c and P_o, should be calculated for the lines of contact between water and bed.

DISCHARGE CALCULATION, MOBILE BED

Artificial and natural channels, whose flow moves in an alluvium, composed of a granulate, are channels of *mobile bed*. The discharge can be calculated using the coefficient of roughness for a mobile bed.

In such channels, the velocity (in the vicinity of the bed) should:

1. not be superior to a certain critical value, otherwise there is a risk of erosion of the solid particles on the bed: this is the permissible maximum velocity or *velocity of erosion*, also called the *critical velocity*;
2. not be inferior to a certain critical value, otherwise there is a risk of deposition of the solid particles: this is the permissible minimum velocity or *velocity of sedimentation*.

The flow velocity, U, to be selected for a "good functioning" of the channel, must lie between the velocity of erosion, $U_E \equiv U_{cr}$, and the one of sedimentation, U_D:

$U_D < U < U_E$. As is evident in Figure 5, the two velocities, U_D and U_E, will have distinctly different values.

Sedimentation Velocity

The velocity of sedimentation, U_D, is the minimum velocity which is necessary to transport the flow containing solid particles in suspension. A diagram (see Figure 5) which was established by *Hjulstrom* (see Graf, 1984, p. 88) delimits the zone of sedimentation as a function of the diameter of the (monodispersed) granulate.

Critical Velocity

There will be erosion of the bed (and the walls), if one exceeds a certain critical value, expressed with:

1. the average critical velocity, U_{cr}, or the critical velocity, $u_{b_{cr}}$, at or close to the bed, or
2. the critical shear stress, $\tau_{o_{cr}}$.

From a hydraulic view point, it is more reasonable to use the shear stress, τ_o, as a criterion of erosion. Using the definition of shear stress:

$$\tau_o = \gamma R_h S_f \qquad (3)$$

and of the average velocity:

$$U = C\sqrt{R_h S_f} \qquad (8)$$

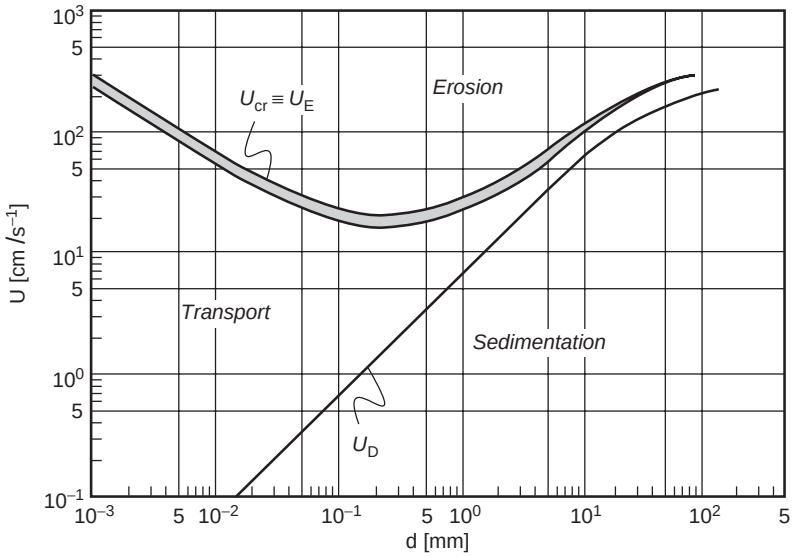

Figure 5 Velocity of sedimentation and of erosion, U_D and U_{cr}, for a uniform granulate, after Hjulstrom

the following ratio is obtained:

$$\frac{U}{\sqrt{\tau_o/\rho}} = \frac{C}{\sqrt{g}}$$

In fluvial hydraulics, one usually uses (see Graf, 1984, p. 91) a dimensionless form of the shear stress, τ_*, or:

$$\frac{\tau_o}{(\gamma_s - \gamma)d} \equiv \tau_* = \frac{\gamma R_h S_f}{(\gamma_s - \gamma)d} \tag{22}$$

where d is the diameter of the granulate (to be specified); γ_s and γ are the specific weight of the granulate and of water, respectively. With this relation, one compares the flow parameters, R_h and S_f, with the granulometric parameters, d and $(\gamma_s - \gamma)$.

Amongst the different formulae for prediction of the critical condition, found in the literature (see Graf, 1984, chap. 6), only the one by *Shields* will be presented. Relying on concepts of the hydrodynamics, *Shields* developed a relation between the dimensionless shear stress, τ_* (see equation 22), and the friction/particle Reynolds number, $Re_* = u_* d/\nu$, such as:

$$\tau_* \equiv \frac{\tau_o}{(\gamma_s - \gamma)d} = f\left(\frac{u_* d}{\nu}\right) \tag{23}$$

where $u_* = \sqrt{\tau_o/\rho}$. The form of this relation using experimental data was determined. An average curve, reasonably well defined, characterizes the begin of erosion, expressed by $\tau_{*_{cr}}$. For the particle diameter, one takes usually $d \equiv d_{50}$. It is to be seen (see Figure 6) that the critical values fall roughly in the range of $0.03 < \tau_{*_{cr}} < 0.06$. The determination of $\tau_{*_{cr}}$ is done using the above relation, equation (23), by successive approximations. The criterion of *Shields* is of great importance for the hydraulic engineer.

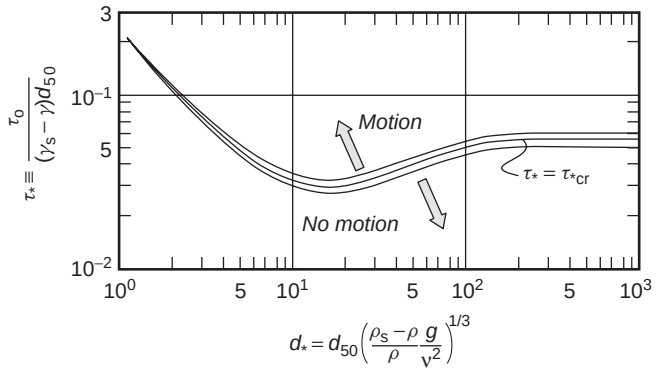

Figure 6 Dimensionless shear stress, τ_*, as a function of the dimensionless diameter, d_*, after Shields–Yalin. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Since a direct use of the relation of *Shields* is laborious, Yalin (1972, p. 82) proposed to use a dimensionless diameter of the granulate, $d_* = d\{[(\rho_s - \rho)/\rho](g/\nu^2)\}^{1/3}$ Consequently, the above relation, equation (23), can be written as:

$$\tau_* = f(d_*) \tag{23a}$$

which is given with Figure 6; one usually takes $d = d_{50}$. If the properties of the fluid, ρ and ν, and of the granulate, ρ_s and d, are known, one can readily determine the corresponding value of $\tau_{*_{cr}}$ and subsequently of τ_{cr}.

For cohesive material, the determination of the critical values, U_{cr} or $\tau_{*_{cr}}$, represents a difficult task; the specialized literature (see Graf, 1984, chap. 12, and Raudkivi, 1976, chap. 9) should be consulted.

Distribution of Shear Stress

The shear stress, τ_o, is given by equation (3). For a channel of large width one may take $R_h \equiv h$.

However, it must be remarked that the shear stress, τ_o, is distributed over the wetted perimeter, P. A typical distribution for a trapezoidal channel (see Chow, 1959, p. 169) is given with Figure 7.

An expression for the critical shear stress on the channel side walls, $(\tau_{o_{cr}})^w$, was proposed by *Lane* (see Graf, 1984, p. 116), being of the following form:

$$(\tau_{o_{cr}})^w = \tau_{o_{cr}}\left[\cos\theta\left(\frac{1 - tg^2\theta}{tg^2\varphi}\right)^{1/2}\right] \tag{24}$$

$\tau_{o_{cr}}$ is the critical shear stress on the bed – given for example, with Figure 6, θ is the inclination of the side wall(s), and φ is the angle of repose. The latter depends on the granulometry and on the cohesion (see Graf, 1984, p. 115); it varies such as $20° < \varphi < 40°$. Evidently: $(\tau_{o_{cr}})^w < \tau_{o_{cr}}$, and for stable side walls: $\theta < \varphi$.

FLOW IN CURVES

A curve or bend, positioned in a rectangular channel, causes a change in the flow direction. If the discharge, Q, remains constant along the curve, the flow velocity, U, as well as the wetted section, A, remain also constant. The sectional

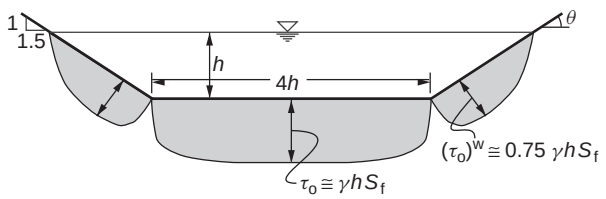

Figure 7 Distribution of the shear stress in a trapezoidal channel. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

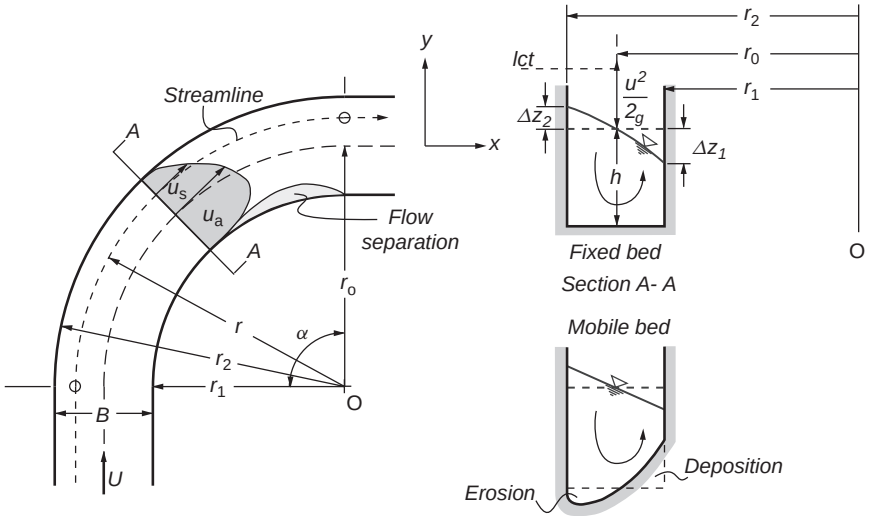

Figure 8 Flow in a curve. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

distribution of the flow depth, $h(y)$, will be responsible for a transversal water slope and a superelevation, Δz, at the outside of the curve.

The distribution of velocity in the curve can be approximated by the one of a free vortex (see Graf and Altinakar, 1991, p. 196). The velocity has a maximum at the inside of the curve (see Figure 8).

Superelevation

In a curve, the streamlines will no longer stay parallel and the flow becomes three-dimensional. This is a complex physical phenomenon, for which an adequate analysis seems difficult. It was proposed (see Kozeny, 1953, p. 223) that the superelevation can be calculated by:

$$\Delta z = \frac{B r_o}{r_1 r_2} \frac{U^2}{2g} \tag{25}$$

If the channel width, $B = r_2 - r_1$, is small compared to the radius of the curve, r_0, one gets the simplified expression of:

$$\Delta z = \frac{B}{r_o} \frac{U^2}{2g} \tag{25a}$$

The transversal water profile is convex; the superelevation, $\Delta z = \Delta z_2 + \Delta z_1$, has its maximal value, $\Delta z = \Delta z_{max}$, usually observed for fluvial flow, $Fr < 1$, at the entrance of the curve and for supercritical flow, $Fr > 1$, at the exit of the curve.

The superelevation at the outside of the curve (see Figure 8) causes a vertical downward current, which comes back to the water surface at the inside of the curve. Such a secondary current will superpose itself on the primary flow and result in helicoidal flow over the entire reach of the curve. If the outside side wall is of mobile material, erosion will take place; on the inside there will be deposition (see Figure 8).

Supercritical Flow

Gravity waves (see Graf and Altinakar, 1998, sect. 3.5.2 and sect. 2.4.3) will establish themselves in a curve, notably if the flow is supercritical, $Fr > 1$. For a rectangular channel, the resulting maximum superelevation, $(\Delta z' + \Delta z)$, due to the gravity waves, can be twice the superelevation, Δz, obtained with equation (25). It is given by:

$$\Delta z' = \frac{B}{r_o} \frac{U^2}{2g} \tag{26}$$

If the superelevations get very large, methods are available to suppress it, like the construction of transition curves or the installation of steps on the channel bed.

Head Loss

In flow over a curve, one encounters not only a head loss due to friction, h_r, but also one due to the curvilinear flow, $h_r{}^c$. This additional head loss is usually expressed by:

$$h_r{}^c = \zeta_c \frac{U^2}{2g} \tag{27}$$

where ζ_c is a coefficient which depends on $\zeta_c = f$ (*Fr, Re,* r_0/B, h/B, α); α being the angle of the curve, *Fr* and *Re* are the number of Froude and of Reynolds, respectively. According to numerous experiments, one takes (see Chow, 1959, p. 443):

$$0.1 \leq \zeta_c \leq 1.1$$

where the larger values of ζ_c are for curves of $r_0/B = 0.5$.

INSTABILITY AT SURFACE

If the channel slope is substantial and/or if the flow is supercritical, the water surface can become unstable. The normal flow depth, h_n, must now be considered as an average value. Such an instability is characterized by a series of gravity waves of small flow depth, called *roll waves*, progressing downstream, and a breaking of these waves, causing an *air entrainment*.

Roll Waves

An instability at the water surface is evidenced by the formation of roll waves. The uniform steady flow becomes locally an unsteady one. The roll waves are superposed on the uniform flow (see Figure 9). They displace themselves towards the downstream – increasing in height and then collapsing – with an absolute celerity, c_w, being larger than the flow velocity, U, or $c_w = U + \sqrt{gh} > U$.

There is no simple criteria available to determine the geometrical dimensions of this type of waves. Their height can, however, attain dimensions of the order of magnitude of the prevailing flow depth (see French, 1986, p. 625). The crests of the roll waves are zones of strong turbulence, while the rest of the waves remains remarkably smooth. Some theoretical considerations for a determination of the (in)stability of uniform flow are presented in Liggett (1975, Chap. 6).

Air Entrainment

For large channel slopes, S_f, – such as exist also on the downstream face of a weir – the flow is usually supercritical and gravity waves appear at the water surface. These waves will break and entrain air into the water. The turbulence will diffuse (mix) the air bubbles across the entire flow depth; and water droplets will escape into the air. In flow of such an air–water mixture, it becomes rather difficult to define the flow depth; the water surface is often covered by *white water*.

A schematic distribution of the concentration, C(z), of air is given with Figure 10. Two regions are to be distinguished: bubbles in the water and droplets in the air.

The equivalent flow depth of water (without the air) is defined by:

$$h = \int_0^\infty (1 - C)\,\mathrm{d}z \cong h_a(1 - \overline{C}) \tag{28}$$

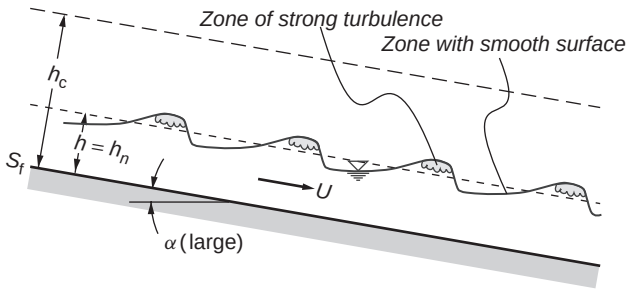

Figure 9 Roll waves. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

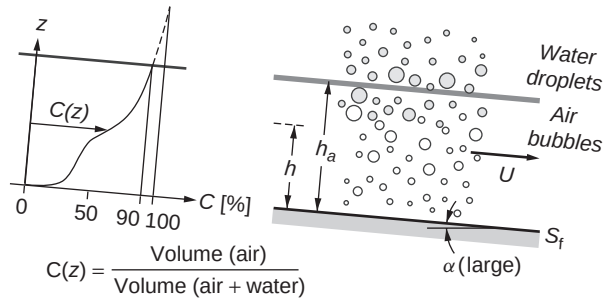

Figure 10 Flow with air entrainment. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

and the average velocity of water by $U = q/h$, where q is the unit discharge of the water. The depth of the mixture, h_a, is the depth where the concentration is equal to $C = 90\%$ (see Wood, 1985, p. 21) and $\overline{C}$ is the average concentration in the cross section, given (see Henderson, 1966, p. 185) by the relation:

$$\overline{C} = 0.7 \log\left(\frac{\mathrm{S_f}}{\mathrm{q}^{1/5}}\right) + 0.9 \tag{29}$$

which was obtained from experimental studies performed by *Straub* et *Anderson* for $0.14 < q[\mathrm{m^2/s}] < 0.93$. Usually (see Wood, 1985, p. 21) one takes:

$$\overline{C} = 0.14 \quad \text{for slopes of } \mathrm{S_f} = 7.5°$$
$$\overline{C} = 0.71 \quad \text{for slopes of } \mathrm{S_f} = 75°$$

138: Unsteady Flow

WALTER H GRAF AND MUSTAFA S ALTINAKAR

Laboratoire de Recherches Hydrauliques, Ecole Polytechnique Fédérale, Lausanne, Switzerland

Flow is unsteady, if the flow depth as well as other hydraulic parameters vary with time. An unsteady flow is usually also nonuniform. The one-dimensional hydrodynamic equations, known are the equations of Saint-Venant, are developed. The simplified equations of Saint-Venant are used to treat the kinematic wave as well as the diffusive wave. The flood wave is also briefly discussed. Numerical solutions to unsteady flow will be treated in a subsequent chapter (see ***Chapter 139, Numerical Modeling of Unsteady Flows in Rivers, Volume 4****).*

HYDRODYNAMIC EQUATIONS

Equations of Saint-Venant

We (see Figure 1) will consider a channel with flow, having a free water surface, and that is one-dimensional, unsteady, nonuniform (gradually varied) and almost rectilinear. The bed slope, S_f, is fixed and permanent, but also weak; the discharge of the incompressible fluid is given by $Q = UA$, with $U(x, t)$ as the velocity averaged over the cross section, $A(x, t)$. There is no lateral inflow or outflow.

The *equation of continuity* is given (*see* **Chapter 136, Hydrodynamic Considerations, Volume 4**, Figure 1) by

$$\frac{\partial Q}{\partial x} + \frac{\partial A}{\partial t} = A\frac{\partial U}{\partial x} + U\frac{\partial A}{\partial x} + B\frac{\partial h}{\partial t} = 0 \qquad (1)$$

For a rectangular, prismatic channel, the above equation reads

$$h\frac{\partial U}{\partial x} + U\frac{\partial h}{\partial x} + \frac{\partial h}{\partial t} = 0 \qquad B = Cte \qquad (2)$$

The *dynamic equation* for an unsteady and gradually varied flow is given (*see* **Chapter 136, Hydrodynamic Considerations, Volume 4**, Figure 3) by

$$\frac{1}{g}\frac{\partial U}{\partial t} + \frac{U}{g}\frac{\partial U}{\partial x} + \frac{\partial h}{\partial x} + \frac{\partial z}{\partial x} = -S_e \qquad (3)$$

where $S_f = -(\partial z/\partial x)$ is the bed slope, $h_r = S_e\,dx$ is the head loss, and S_e is the energy slope. As an approximation, it is assumed that the energy slope, S_e, can be expressed by a relation established for uniform, steady flow of the Weisbach-Darcy type (*see* **Chapter 137, Uniform Flow, Volume 4**):

$$S_e = \boldsymbol{f}\frac{1}{4R_h}\frac{U^2}{2g} \qquad (4)$$

or of the type of Chézy:

$$S_e = \frac{8g}{C^2}\frac{1}{4R_h}\frac{U^2}{2g} \qquad (5)$$

Where $\boldsymbol{f}$ is the friction coefficient, defined with equation 5 in **Chapter 137, Uniform Flow, Volume 4**. The friction coefficient of Chezy, C, is defined as

$$U = K_s R_h^{2/3} S_f^{1/2} \qquad \text{with} \qquad C = K_s R_h{}^{1/6} = \frac{1}{n} R_h{}^{1/6} \qquad (6)$$

where K_s is the coefficient of Strickler, n the coefficient Manning, and R_h, is the hydraulic radius.

For a river with a weak bed slope, S_f, the two terms due to acceleration can readily be neglected (see Henderson, 1966, p. 364). Consequently, one may write equation 3 as:

$$\frac{\partial h}{\partial x} + \frac{\partial z}{\partial x} = -S_e \qquad \text{where} \qquad -S_w = \frac{\partial h}{\partial x} + \frac{\partial z}{\partial x}$$
$$\text{or} \quad S_e = S_w \qquad (7)$$

If the variation of the flow depth is weak compared to the bed slope, $\partial h/\partial x < \partial z/\partial x$ – this may be the case in

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

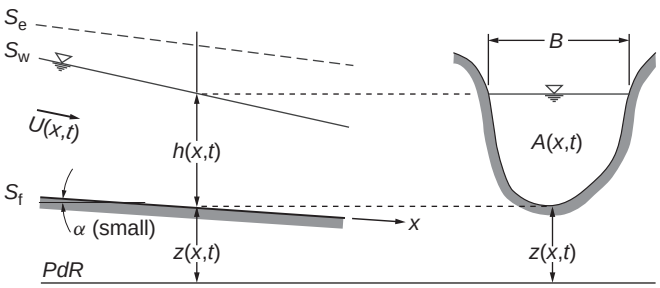

Figure 1 Scheme of an unsteady and nonuniform flow over a slope of a fixed bed, $z(x)$. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

waterways of more or less steep bed slopes – the dynamic equation, equation (7), reduces to

$$\frac{\partial z}{\partial x} = -S_e \qquad \text{where} \qquad -S_f = \frac{\partial z}{\partial x} \qquad \text{or} \quad S_e = S_f \tag{8}$$

Using the relation of Chézy, the dynamic equation, equation (3), can also be expressed as

$$U = C\sqrt{R_h S_e} = C\sqrt{R_h\left(S_f - \frac{\partial h}{\partial x} - \frac{U}{g}\frac{\partial U}{\partial x} - \frac{1}{g}\frac{\partial U}{\partial t}\right)} \tag{9}$$

which for a steady and uniform flow becomes

$$U = C\sqrt{R_h S_f} \tag{10}$$

The relation between the velocity, U, or the discharge, Q, and the flow depth, h, or the hydraulic radius, R_h, (see Figure 2a) is given by

- a unique relation for equation (10),
- a nonunique relation with a *loop* for equation (9), where the width of the loop is an indication of the importance of the terms of inertia and of pressure.

The relation, $Q = f(h)$, (Figure 2a), called the *gauging (or rating) curve of the section*, will provide the following information (see Forchheimer, 1930):

- For unsteady flow, the discharge, Q, has two different values for the same flow depth, h, depending on the increase or decrease of the water level.
- If the flow depth, h, increases, the term $\partial h/\partial t$ is positive and the term $\partial U/\partial t$ is negative; consequently the velocity, U, decreases.
- At a given section, one observes (see Figure 2b) the maximum of the average velocity, U_{max}, then the maximum of the discharge, Q_{max}, and finally the maximum of the flow depth, h_{max}.

The equations, equation (1) and equation (3), established first by Saint-Venant (1870), render solutions to problems of unsteady flow, if integration is possible. They constitute a system of two equations of partial derivatives – of the hyperbolic type – in x and t, introducing two unknown functions, h and U. The initial and boundary conditions must be selected to describe adequately the physical problem. An exact integration of the equations of Saint-Venant is, however, very complicated; analytical solutions are rare (see Sobey, 2001, and MacDonald *et al.*, 1997). Nevertheless, there exist different numerical (and graphical) techniques making solutions possible.

It happens that a problem, where flow is unsteady and gradually varied, can be formulated in a way that one or more of the terms in the dynamic equation can be neglected. Considering the different terms in the dynamic equation, equation (3), one usually distinguishes the following types

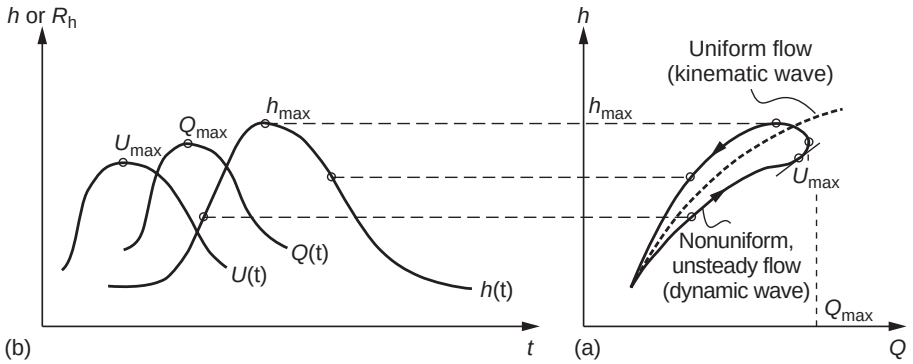

Figure 2 Schematic representation of the relation of $Q = f(h)$ and of $h = f(t)$ for an unsteady and nonuniform flow

of unsteady flow, here called *waves*:

$$\frac{1}{g}\frac{\partial U}{\partial t} + \frac{U}{g}\frac{\partial U}{\partial x} + \frac{\partial h}{\partial x} = S_f - S_e \qquad (3)$$

- kinematic wave (11)
- diffusive wave (12)
- dynamic, quasi-steady wave (13)
- dynamic wave (3)
- simple wave (14)

The equation of continuity, equation (1), remains of course valid for all these waves.

Numerical methods exist to solve the equations of Saint-Venant. The following ones could be mentioned:

- the method of characteristics,
- the explicit method,
- the implicit method.

Usually a *scheme of finite differences* – also schemes of *finite element* and *finite volume* – is employed. The numerical methods can well be dealt with the use of computers. These methods are presented in detail in the books of Liggett and Cunge (1975), Cunge *et al.* (1980) and Abbott and Basco (1989). Practical aspects dealing with fluvial hydraulics are treated by Cunge *et al.* (1980).

KINEMATIC WAVE

Hydrodynamic Equations

The kinematic wave represents a special and simple case of unsteady flow. The equations of Saint-Venant, equation (1) and equation (3), can be simplified, when considering the kinematic wave. The equation of continuity remains valid:

$$\frac{\partial Q}{\partial x} + \frac{\partial A}{\partial t} = A\frac{\partial U}{\partial x} + U\frac{\partial A}{\partial x} + B\frac{\partial h}{\partial t} = 0 \qquad (1)$$

but the equation of motion can be considerably simplified:

$$S_f = S_e \qquad (11)$$

This implies, that in the complete equation of motion, equation (3), the terms due to the variations in velocity, U, and in depth, h, are negligible.

This equation, equation (11), can also be written, using the relation of Chézy, as

$$S_f = \frac{U^2}{C^2}\frac{1}{R_h} \qquad \text{or} \qquad U = C\sqrt{R_h S_f} \qquad (10)$$

The discharge is thus given by: $Q = UA = CA\sqrt{R_h S_f}$, implying that $Q = f(A)$ or $A = f(Q)$. Thus, a single-valued function (Figure 2a) exists between the discharge, Q, and the wetted surface, A, in a cross section at a given abscissa, $x = x_o$. The term, $\partial A/\partial t$, in above equation, equation (1), can be expressed as

$$\frac{\partial A}{\partial t} = \left(\frac{\partial A}{\partial Q}\right)_{x_o} \cdot \frac{\partial Q}{\partial t} \qquad (15)$$

Consequently, the equation of continuity, equation (1), can be written (see Forchheimer, 1930) as follows:

$$\frac{\partial Q}{\partial t} + \left(\frac{\partial A}{\partial Q}\right)_{x_o} \cdot \frac{\partial Q}{\partial x} = \frac{dQ}{dt} = 0 \qquad (16)$$

This is the equation of the *kinematic wave*, where the term

$$\left(\frac{\partial Q}{\partial A}\right)_{x_o} = c_k \qquad \text{or} \qquad c_k = -\frac{\partial Q/\partial t}{\partial Q/\partial x} \qquad (17)$$

is the *celerity of propagation* (or the *wave speed*) of the kinematic wave for a given discharge; it will be different for each section of abscissa, $x = x_o$. According to equation (17), the discharge, Q, is convectively displaced with the celerity, c_k.

The kinematic wave is a type of wave, whose properties follow essentially from the law of conservation of mass, namely, the equation of continuity, equation (1).

Since a variation in flow depth, $\partial h/\partial x$, (see equation 3 and equation 11) is not accounted for, the kinematic wave will not subside (attenuate). The geometric form of a kinematic wave, namely its wave profile – being of limited interest for the engineer – is given by Henderson (1966).

For a numerical simulation of kinematic waves, the methods presented in literature can readily be used

- the explicit method, as given by Jansen *et al.* (1979) and Abbott and Basco (1989);
- the implicit method, as given by Chow *et al.* (1988), Jansen *et al.* (1979) and Abbott and Basco (1989).

For the numerical simulation, one generally assumes (see Dingman, 1984), that the kinematic wave, equation (11), is a good approximation to the complete dynamic wave, equation (3), if

$$\frac{g\ L\ S_f}{U^2} > 10$$

where L is the length of the channel under investigation and, U is the average velocity of the uniform flow.

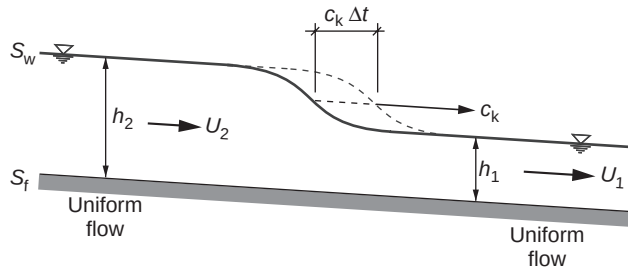

Figure 3 Monoclinal wave (front of a kinematic wave). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Celerity of Propagation

Take a wide rectangular channel (Figure 3) where the flow is uniform, having a flow depth, h_1, and an average velocity, U_1; the discharge, Q_1, is initially constant.

The flow increases suddenly to another discharge, Q_2; it stabilizes itself at another uniform flow, h_2, and U_2. This step-increase in discharge propagates downstream and forms a translatory wave of stable shape, called the *monoclinal* (rising) wave. During an interval of time, Δt, the wave displaces itself over a distance of $\Delta x = c_k \Delta t$. The celerity of this propagation is given as

$$c_k = \frac{Q_2 - Q_1}{A_2 - A_1} = \frac{dQ}{dA} = \frac{1}{B}\frac{dQ}{dh} \tag{18}$$

implying that the celerity of propagation of a kinematic wave is proportional to the rate of change of discharge, Q, with the surface area, A, or the flow depth, h. The above equation can also be expressed (see Lighthill and Whitham, 1955) by

$$c_k = \frac{d(UA)}{dA} = U + A\frac{\partial U}{\partial A} \tag{19}$$

This equation shows that

- in absence of an initial flow, $Q_1 = 0$, implying $U_1 = 0$ and $A_1 = 0$, one has

$$c_k = U_2 \tag{20}$$

- in presence of an initial flow, $Q_1 > 0$, one has

$$c_k > U_1, \quad c_k > U_2$$

The celerity of the kinematic wave, c_k, is always larger than the flow velocities, U_1 and U_2, upstream and downstream of the wave front.

If the flow in a wide rectangular channel is turbulent, the average velocity can be obtained, using the relation of Chézy, equation (10). The above equation (19), can thus been expressed (see Forchheimer, 1930) by

$$c_k = U + h\frac{\partial U}{\partial h} = U + h\frac{C S_f^{1/2}}{2h^{1/2}} = U + \frac{U}{2} = \frac{3}{2}U \tag{21}$$

For a parabolic or triangular channel, one gets, respectively

$$c_k = \frac{4}{3}U \qquad \text{or} \qquad c_k = \frac{5}{4}U \tag{22}$$

Should the same reasoning be done, by using the relation of Manning, equation (6), one obtains for a wide rectangular channel

$$c_k = \frac{5}{3}U \tag{23}$$

The celerity of propagation of a kinematic wave is 3/2 or 5/3 times the flow velocity, U. This conclusion was arrived at using only two relations, namely the equation of continuity, equation (1), and the momentum equation, equation (11), expressed with a relation of friction.

DIFFUSIVE WAVE

Hydrodynamic Equations

The diffusive wave represents another special and simple case of unsteady flow. The equations of Saint-Venant, equation (1) and equation (3), can be simplified, when considering the diffusive wave. While the equation of continuity remains valid,

$$\frac{\partial Q}{\partial x} + \frac{\partial A}{\partial t} = A\frac{\partial U}{\partial x} + U\frac{\partial A}{\partial x} + B\frac{\partial h}{\partial t} = 0 \tag{1}$$

the equation of motion can be simplified:

$$S_f - \frac{\partial h}{\partial x} = S_e \tag{12}$$

This implies, that in the complete equation of motion, equation (3), the terms of inertia are negligible.

The diffusive wave undergoes attenuation (subsidence) due to a (possible) variation of the flow depth, $\partial h/\partial x$; this is not possible for the kinematic wave which cannot subside, but will deform, changing its curvature (see Figure 4).

Above equation, can be written (see equation 9), using the relation of Chézy, equation (10), as:

$$U = C\sqrt{R_h\left(S_f - \frac{\partial h}{\partial x}\right)} \tag{24}$$

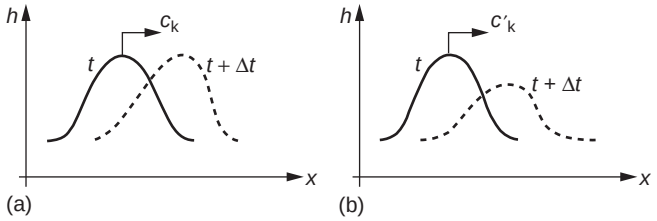

Figure 4 Attenuation of a wave; successive positions

The dynamic equation, equation (12), can also be written as

$$\frac{\partial h}{\partial x} + \frac{\partial z}{\partial x} + \frac{Q|Q|}{K^2} = 0 \tag{25}$$

whereby the conveyance of the channel is taken as

$$K(h) = \frac{1}{n} {R_h}^{2/3} A \tag{26}$$

which in turn gives $Q = K\sqrt{S_f}$ (*see* **Chapter 137, Uniform Flow, Volume 4**, equation 19).

Suppose the channel is rectangular of width $B = Cte$. Upon mathematical manipulation (see Graf and Altinakar, 1998, Section 5.4 and Cunge *et al.*, 1980) the above two equations, equation (1) and equation (25), render a single equation, such as

$$\frac{\partial Q}{\partial t} + \left(\frac{Q}{BK}\frac{\mathrm{d}K}{\mathrm{d}h}\right)\frac{\partial Q}{\partial x} - \left(\frac{K^2}{2B|Q|}\right)\frac{\partial^2 Q}{\partial x^2} = 0 \tag{27}$$

This is the equation of the *diffusive wave*. This partial differential equation is parabolic, having only one dependent variable, $Q(x,t)$. The discharge, Q, is convected with the celerity (see also equation 17) of

$${c_k}' = \left(\frac{Q}{BK}\frac{\mathrm{d}K}{\mathrm{d}h}\right) = \frac{1}{B}\frac{\mathrm{d}Q}{\mathrm{d}h} \tag{28}$$

and is diffused (or attenuated) with a coefficient of

$$C_D = \left(\frac{K^2}{2B|Q|}\right) = \frac{Q}{2BS_f} \tag{29}$$

The equation of the diffusive wave, equation (27), can now be written as

$$\frac{\partial Q}{\partial t} + {c_k}'\frac{\partial Q}{\partial x} - C_D\frac{\partial^2 Q}{\partial x^2} = 0 \tag{30}$$

Assuming that the bottom slope remains constant, Henderson (1966) gives the following relation (see also equation 21) for the celerity, using the relation of Chézy, or

$${c_k}' = \frac{3}{2}U = \frac{3}{2}C\sqrt{R_h\left(S_f - \frac{\partial h}{\partial x}\right)} \tag{31}$$

and for the coefficient of diffusion

$$C_D = \frac{{c_k}' h}{3[S_f - (\mathrm{d}h/\mathrm{d}x)]} \approx \frac{{c_k}' h}{3\ S_f} \tag{32}$$

For a numerical simulation of diffusive waves, the solution methods presented in the literature can readily be used:

- the explicit method, as given by Abbott and Basco (1989);
- the implicit method, as given by Abbott and Basco (1989) and Jansen *et al.* (1979).

The diffusion term in the above equation, equation (27), may be neglected if $\partial^2 Q/\partial x^2$ or/and $Q/(2BS_f)$ (see equation 29) are small. The last condition implies that

$$Q \ll 2BS_f \tag{33}$$

or, when using the Manning relation, equation (6), for a wide rectangular channel:

$$h^{5/3} \ll 2n{S_f}^{1/2} \tag{34}$$

The latter relation shows, that for bottom slopes, S_f, being

- sufficiently *steep*, the diffusion term can be eliminated; the diffusive wave is thus well approximated by a kinematic wave;
- *gentle*, the diffusion term must remain; the diffusive wave is maintained.

In steady state, the discharge, Q, can be calculated according to equation (24), which gives a non-single-valued relation, with a loop (see Figure 2a). The size of this loop is due to the diffusion coefficient, C_D (equation 29), in the equation of the diffusive wave, equation (27).

FLOOD WAVE

Flood waves are phenomena of great importance for the hydraulician. A flood is a type of unsteady flow, whose theoretical study must be deduced from the complete equations of Saint-Venant; methods of solution have been presented in the literature.

The displacement – rising and falling – of such a flood is generally very *slow*; thus certain terms in equation of

motion, equation (3), can be neglected. Consequently the equations of Saint-Venant can be simplified. Usually one makes a distinction (see Henderson, 1966) between

- floods in channels on *steep slopes*, Fr < 1;
- floods in channels on *weak slopes*, Fr $\ll 1$.

A flood wave is thus considered as being a slowly variable flow.

Floods in channels on *steep* slopes, Fr < 1, can be approximated by *kinematic waves* (see Section on "Kinematic Wave"). The *in situ* observations by Seddon in 1900 as well as theoretical considerations by Kleitz in 1858 have this confirmed; it is *known as* the principle of Kleitz-Seddon (see Chow, 1959).

One supposes that a flood rises gradually to a (unique) maximum, and subsequently descends till the initial uniform flow is reached again. Before the rise and after the fall of the flood, the flow is in permanent regime and has the same discharge in all cross sections. This wave, being a kinematic one, is characterized by

- a relation of $Q = f(h)$ being single-valued (Figure 2a);
- the celerity of propagation, given by:

$$c_k = \frac{3}{2}U = \frac{3}{2}C\sqrt{hS_f} \tag{21}$$

  for a wide rectangular section, using the relation of Chézy;
- a geometric form, being invariable and without attenuation.

For such type of a flood (see Figure 5), the major part – the main body of the flood – is well described by a kinematic wave, equation (18). In front and behind the main body of the flood wave, there travel gravity waves (*see* **Chapter 136, Hydrodynamic Considerations, Volume 4**, equation 20). According to Henderson (1966), if Fr $<$ $3/2$ (or Fr < 2), these gravity waves are usually of little importance, since they subside rapidly.

Floods in channels on *weak* slopes, Fr $\ll 1$, can be approximated by *diffusive waves*, being characterized (see Section on "Diffusive Waves") by

- a relation of $Q = f(h)$ that is not single-valued (Figure 2a);
- the celerity of propagation, given by

$$c_k' = \frac{3}{2}C\sqrt{h\left(S_f - \frac{\partial h}{\partial x}\right)} \tag{31}$$

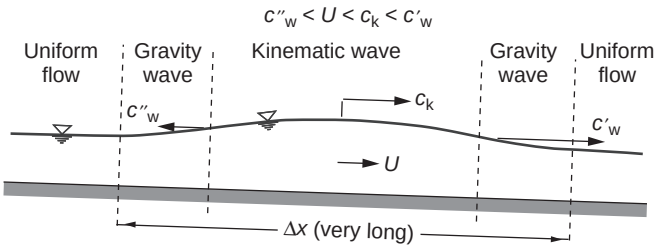

Figure 5 Flood wave (Fr $< 3/2$). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

where C is the Chézy coefficient;
- a geometric form, being variable; thus an attenuation is present.

Various aspects of such waves are presented by Henderson (1966).

Solution methods to solve the unsteady flow equations are reviewed in this article. The basis of the method of characteristics is outlined. Some of the commonly used finite difference schemes are reviewed. A detailed description of an unsteady flow model called MOBED is given to highlight the various assumptions and simplifications that are involved in the development of an unsteady flow model. Testing of the model using a laboratory data set measured by Treske is described. Such a data set can serve as a benchmark data for the testing of unsteady flow models. Integral form of governing equations and their properties are introduced. High-resolution conservative finite-volume schemes for modeling flows with discontinuities are briefly discussed. Examples of numerical solutions using a robust one-dimensional upwind finite-volume code are presented.

GOVERNING EQUATIONS

In **Chapter 5, Fundamental Hydrologic Equations, Volume 1**, the governing equations for unsteady flows (i.e. the St. Venant equations) were presented, and their properties were analyzed. In this section, the numerical techniques that have been used to solve these equations are reviewed. The St. Venant equations describe the unsteady flow characteristics in channels, which are prismatic, and which do not have any lateral inflows. If the river is nonprismatic and contains lateral inflows, then the governing equations have to be modified to include additional terms to take into account these extra features. The numerical methods that are reviewed in this section are capable of treating these additional features. The governing equations that are discussed in this section are listed below (Krishnappan, 1981):

$$\frac{\partial Q}{\partial x} + B\frac{\partial h}{\partial t} = q \tag{1}$$

$$\frac{\partial Q}{\partial t} + 2\frac{Q}{A}\left(\frac{\partial Q}{\partial x}\right) - B\frac{Q^2}{A^2}\left(\frac{\partial h}{\partial x}\right) + gA\left(\frac{\partial h}{\partial x}\right) = gA(S_x - S_f) + q\left(U_q - \frac{Q}{A}\right) + \frac{Q^2}{A^2}A_x^y \tag{2}$$

where x is the longitudinal axis placed along the thalweg of the river, t is the time axis, Q is the flow rate, h is the flow depth, B is the top width of the river, A is the flow cross-sectional area, S_x is the slope of the river bed, S_f is the friction slope, q is the lateral inflow rate, U_q is the downstream component of velocity of the lateral inflow, g is the acceleration due to gravity, and A_x^y is the rate of change of A with respect to x when the distance from the bed is held constant. This derivative goes to zero for prismatic channels. A schematic representation of the profile and the cross section of a river that can be modeled using the above equations is shown in Figure 1.

The first equation expresses the conservation of mass while the second equation is based on the conservation of momentum. In the derivation of these equations, a number of simplifying assumptions have been introduced. A good understanding of the underlying assumptions is important to gauge the applicability and the usefulness of the equations to practical problems. For example, the equations were derived on the basis of first – order shallow

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

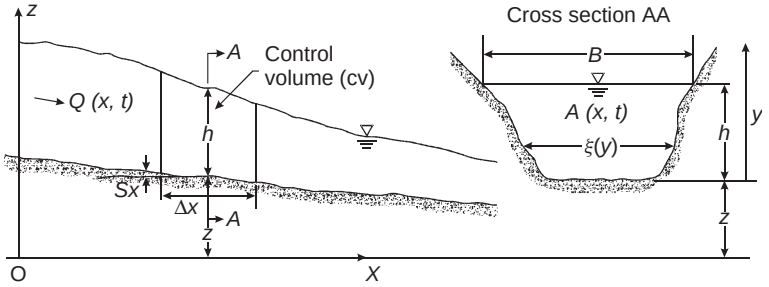

Figure 1 Schematic representation of the longitudinal profile and a flow cross section in a river reach considered for modeling

water theory with the assumption that the wave surface varies gradually. Such an assumption leads to a condition that the pressure distribution in the vertical direction is hydrostatic and the vertical accelerations are small. This implies that the equations are valid, strictly speaking, for long waves only. For the treatment of hydraulic jumps and bores, where the vertical accelerations are substantial, these features are treated as discontinuities of the water surface of infinitesimal length and use the moving hydraulic jump relations to link the upstream and downstream regions where the hydrostatic pressure distribution assumption is not violated (see Cunge *et al.*, 1980). Second assumption used in the derivation of the governing equations deals with the bed friction loss. It is assumed in the derivation that the friction loss in unsteady flows is not significantly different from those in the steady flow and the steady flow friction factor equations such as Chezy and Manning equations are used to evaluate the friction losses in unsteady flows. The other assumptions invoked were: (i) slope of the bed is small so that the sine of the angle that the x axis makes with the horizontal is equal to the tangent of the angle and therefore, the angle itself; (ii) velocity distribution within the cross section does not have appreciable impact on the wave propagation.

The governing equations are partial differential equations of hyperbolic type, and hence can be solved either by the method of characteristics or by approximating the equations using the finite difference equations. A review of these methods is presented in the following subsection.

SOLUTION METHODS

Method of Characteristics

In the method of characteristics, the two partial differential equations are replaced by a system of four ordinary differential equations. To illustrate this method, the simplest case of uniform rectangular channel flow without the friction and lateral inflow, and so on, is considered (see Abbott, 1975). In this case, the mass and momentum conservation equations become

$$\frac{\partial h}{\partial t} + \frac{\partial (uh)}{\partial x} = 0 \tag{3}$$

and

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + g\frac{\partial h}{\partial x} = 0 \tag{4}$$

where u is the average flow velocity. Multiplying equation (3) by g and substituting $gh = c^2$, we get the following two equations:

$$2\frac{\partial c}{\partial t} + 2u\frac{\partial c}{\partial x} + c\frac{\partial u}{\partial x} = 0 \tag{5}$$

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + 2c\frac{\partial c}{\partial x} = 0 \tag{6}$$

Adding equations (5) and (6) and subtracting equation (5) from equation (6), the following two equations are obtained:

$$\frac{\partial (u+2c)}{\partial t} + (u+c)\frac{\partial (u+2c)}{\partial x} = 0 \tag{7}$$

$$\frac{\partial (u-2c)}{\partial t} + (u-c)\frac{\partial (u-2c)}{\partial x} = 0 \tag{8}$$

Comparing the form of equation (7) and equation (8) with the total variation (total differential) of any quantity A that is a function of x and t, that is,

$$\frac{\mathrm{d}A}{\mathrm{d}t} = \frac{\partial A}{\partial t} + \frac{\mathrm{d}x}{\mathrm{d}t}\frac{\partial A}{\partial x} \tag{9}$$

we get from 5.7,

$$\frac{\mathrm{d}x}{\mathrm{d}t} = u + c \tag{10}$$

and

$$\frac{\mathrm{d}(u+2c)}{\mathrm{d}t} = 0 \tag{11}$$

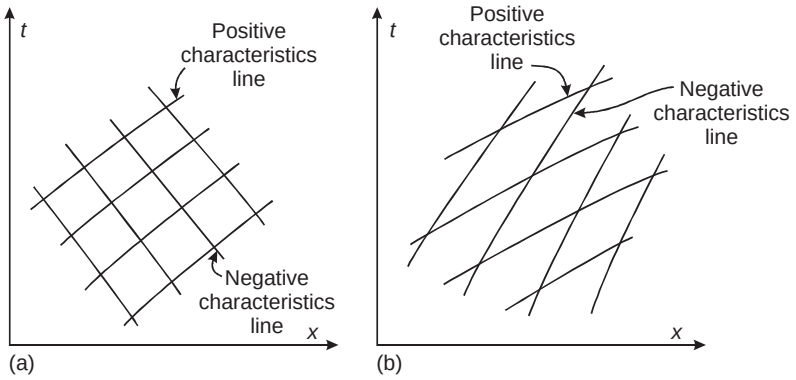

Figure 2 Schematic representation of characteristic lines for subcritical (a) and (b) supercritical flows

From equation (8), we get:

$$\frac{dx}{dt} = u - c \tag{12}$$

and

$$\frac{d(u - 2c)}{dt} = 0 \tag{13}$$

Equation (10) gives the slope (direction) of a line (characteristics) at a point in the $x-t$ plane, while equation (11) expresses the relationship between the dependent variables that is valid along the line. Similarly, equation (12) gives the direction of the second characteristic at the same point in the $x-t$ plane and equation (13) gives the relationship between the variables along this characteristics. Thus, the four ordinary differential equations (i.e. equations 10–13) are equivalent to the two partial differential equations (i.e. equations 3 and 4), and they provide a basis for solving for u and h as a function of x and t at all the intersection points of the characteristics in the $x-t$ plane.

In $x-t$ plane, the line passing through the directions specified by equation (10) is called the *positive characteristics* (see Figure 2), and the line passing through the directions specified by equation (12) is called *the negative characteristics*. For subcritical flows, $|u| < c$, the positive characteristics have positive slopes, and negative characteristics have negative slope (Figure 2a). For supercritical flows, u is greater than c, and therefore, both positive and negative characteristic lines have a positive slope as shown in Figure 2(b). The solution technique based on the method of characteristics involves constructing the positive and negative characteristic lines in the $x-t$ plane and determining the flow parameters u and h at the intersection points of these characteristics. At the boundaries, the boundary conditions needed to calculate the values at the boundary nodes depend on the number of characteristics emanating from the boundaries at a single point. For example, in subcritical flows at the upstream boundary, only one of the characteristics, namely the positive characteristics emanate from the boundary node at a point and the negative characteristics intersecting the boundary at that point emanate from the downstream sections of the flow. Therefore, one boundary condition involving either the flow velocity or the flow depth has to be specified at the upstream boundary. Similarly, at the downstream boundary only one condition has to be specified involving flow velocity or the flow depth. In the case of supercritical flows flowing from left to right, both positive and negative characteristics can emanate from a single point on the upstream boundary. Therefore, two boundary conditions involving both the flow velocity and the flow depth have to be specified at the upstream boundary. There is no need to specify a condition at the downstream boundary for the supercritical flows.

When the governing equations include additional terms to reflect the complexities such as irregular cross sections, nonprismatic channel, friction, lateral inflows, and so on, such as in equations (1 and 2), Liggett (1968) had proposed a generalized method to transform the governing equations into the characteristic form. Liggett (1968) had also considered the off channel storage in his derivation of the characteristic equations. Liggett (1968) solved the characteristic equations using numerical methods because of the complex nature of the equations. The points at which the equations are solved are spaced at uneven time and space intervals. This fact has often been used as a criticism of the method, but in some cases it is an advantage because the net becomes denser in the region of rapid change, where more points need to be calculated. Solution methods based on the method of characteristics had been proposed by other investigators as well. The notable ones are Stoker (1957), Fletcher and Hamilton (1967), and Lai (1965).

Finite Difference Approximations

The numerical methods based on finite difference approximations of the governing equations allow the computation of the flow variables (flow velocity and depth) at fixed grid points in the $x-t$ plane. There are two types of finite difference schemes, namely, Explicit Schemes and Implicit

Schemes. In Explicit Schemes, the finite difference equations are set up in such a way that the solution at a single point in the $x-t$ plane is calculated at a time. In the Implicit Schemes, on the other hand, solutions at all points at a new time level are calculated simultaneously knowing the solutions at the previous time step. Some of the commonly used finite difference schemes are reviewed here. For a comprehensive description of the available schemes, the references Liggett and Cunge (1975) and Cunge *et al.* (1980) can be consulted.

Explicit Schemes:

1. *The leap-frog scheme:*

This scheme was a widely used explicit scheme. It employs the central difference approximations for both time and distance derivative terms as shown below:

$$\frac{\partial f}{\partial t} = \frac{f_i^{j+1} - f_i^{j-1}}{2\Delta t} \tag{14}$$

$$\frac{\partial f}{\partial x} = \frac{f_{i+1}^{j} - f_{i-1}^{j}}{2\Delta x} \tag{15}$$

The function $f(x,t)$ is approximated as follows:

$$f(x,t) \approx f_i^j \tag{16}$$

The subscript i in the above equations denotes the numerical grid points in the x direction and the superscript j denotes the numerical grids along the time axis. Substitution of the equations (14) to (16) in the St. Venant equations results in algebraic equations expressing the values of the variables at a single grid point in the new time level in terms of the variables in the old time level in the vicinity of the grid, and hence can be solved for the variables in the new time level explicitly without having to solve a system of simultaneous equations.

Stability and accuracy of the numerical schemes determine the suitability of the schemes for practical applications. The stability analysis for the leap-frog scheme was carried out by Liggett and Cunge (1975) for the linearized equation without the resistance term using the spectral method. This analysis indicated that the scheme is stable only when the Courant condition,

$$\frac{\Delta t}{\Delta x} \leq \frac{1}{|u \pm c|} \tag{17}$$

is satisfied. If the Courant condition is not satisfied, then the perturbations grow indefinitely making the scheme unsuitable for computational purposes. The analysis further showed that when the LHS of equation (17) is *equal* to the RHS, then the amplification factor of the scheme is unity implying that the perturbations are neither amplified or damped, and the perturbations are propagated with the celerity of the analytical solution, that is, without dispersion. But, when the LHS is less than the RHS, the scheme is stable but dispersive.

2. *Lax scheme:*

This scheme was applied to the homogeneous part of the St. Venant equation expressed in the conservation form. The derivation of the St. Venant equation in the conservation form is given in Cunge *et al.* (1980). The conservation form of the St. Venant equation is specially suited for tackling discontinuities. Details of modeling discontinuities are taken up in Section "Modeling Flows With Discontinuities". The homogeneous part of the conservation form of St. Venant equation is given by

$$\frac{\partial f}{\partial t} + \frac{\partial F(f)}{\partial x} = 0 \tag{18}$$

where $f(x,t)$ is the vector of the variables and F is the flux vector. Lax scheme approximates the derivatives as follows:

$$\frac{\partial f}{\partial t} \approx \frac{f_i^{j+1} - \left[\alpha f_i^j + (1-\alpha)\dfrac{f_{i+1}^j + f_{i-1}^j}{2}\right]}{\Delta t} \tag{19}$$

$$\frac{\partial F(f)}{\partial x} \approx \frac{F_{i+1}^j - F_{i-1}^j}{2\Delta x}; \qquad 0 \leq \alpha \leq 1 \tag{20}$$

Substitution of equations (19) and (20) into equations (18) gives an explicit expression for the unknown vector function *f(x,t)* at the computational points. This scheme yields exact solution of the linearized equation when α is zero and the time and distance steps satisfy the Courant condition. The scheme is first – order accurate for arbitrary values of α, Δx, and Δt.

Implicit Schemes:

1. *Preissmann implicit scheme:*

This has been a very popular scheme. It has been implemented in many operational models such as DWOPER/DAMBRK (US-NWS), CARIMA (SOGREAH), and MOBED (NWRI-EC). In this scheme, the dependent variable and its derivatives are approximated as follows:

$$f(x,t) = \frac{\theta}{2}\left[f_{i+1}^{j+1} - f_i^{j+1}\right] + \frac{1-\theta}{2}\left[f_{i+1}^{j} + f_i^{j}\right] \tag{21}$$

$$\frac{\partial f}{\partial x} = \theta\left[\frac{f_{i+1}^{j+1} - f_i^{j+1}}{\Delta x}\right] + (1-\theta)\left[\frac{f_{i+1}^{j} - f_i^{j}}{\Delta x}\right] \tag{22}$$

$$\frac{\partial f}{\partial t} = \frac{1}{2}\left[\frac{f_{i+1}^{j+1} - f_{i+1}^{j}}{\Delta t}\right] + \frac{1}{2}\left[\frac{f_i^{j+1} - f_i^{j}}{\Delta t}\right] \tag{23}$$

where θ is a weighting coefficient that can assume values from 0 and 1. Substitution of these approximations into

the St. Venant equations gives rise to a system of algebraic equations, which have to be solved simultaneously. When θ is equal to 0, the scheme becomes fully explicit, and when θ is equal to 1, the scheme is fully implicit. The stability and the accuracy of the scheme had been investigated by Cunge (1961), who concluded that the scheme is unconditionally stable for θ values between 0.5 and 1.0 and the accuracy is second order with respect to Δx when θ is equal to 0.5 and first – order for any other value between 0.5 and 1.0. Cunge (1961) further observed that for θ, some oscillations occurred in the solution resembling the phenomenon of numerical instability, and suggested a practical range for θ to be between 0.6 and 1.0. With respect to the computational celerity, it was found to differ from the analytical celerity and the deviation was a function of θ, $\Delta x/L$ and $\Delta t/\Delta x$. When $\Delta x/L$ is small (long waves), the deviation is small as long as $\Delta t/\Delta x$ is closer to 1.

2. *Gunaratnam–Perkins scheme:*

This is a six-point scheme developed by Gunaratnam and Perkins (1970). In this scheme, the derivatives of the variables are approximated as follows:

$$\frac{\partial f}{\partial t} \approx \frac{1}{6}\frac{f_{i-1}^{j+1} - f_{i-1}^{j}}{\Delta t} + \frac{2}{3}\frac{f_{i}^{j+1} - f_{i}^{j}}{\Delta t} + \frac{1}{6}\frac{f_{i+1}^{j+1} - f_{i+1}^{j}}{\Delta t} \tag{24}$$

$$\frac{\partial f}{\partial x} \approx \frac{f_{i+1}^{j+1} - f_{i-1}^{j+1}}{2\Delta x} \tag{25}$$

The scheme, therefore, is fully implicit, and it involves six nodes, namely, three consecutive distance nodes in two consecutive time levels. Substitution of the approximations in the St. Venant equations leads to system of $2N-4$ algebraic equations for $2N$ unknowns, where N is the total number of grid points. With two boundary conditions and two characteristic equations written for the boundary points, the system of equations becomes a closed system and can be solved for the unknowns simultaneously.

AN EXAMPLE OF AN UNSTEADY FLOW MODEL AND ITS TESTING

An unsteady flow model called *MOBED* developed by the first author is described here in detail to highlight the various assumptions and simplifications that have to be introduced in the development of an unsteady flow model. The description also includes a testing of the model using laboratory channel data that can serve as benchmark data for testing of unsteady flow models.

Description of the MOBED Model

The MOBED model is based on the governing equations (1) and (2). These equations were discretized using the implicit finite difference scheme of Preissmann (1961), that is, using equations (21) to (23). The model, therefore, cannot handle discontinuities and is valid only for subcritical flows. The value of θ used in the model was 0.667.

Expressing the value of f at $(j+1)$th time level as a sum of the value at the jth time level and a difference Δf, that is,

$$f^{j+1} = f^{j} + \Delta f \tag{26}$$

the relationships given by equations (21)–(23) can be rewritten as:

$$f(x,t) = \frac{1}{2}[\theta(\Delta f_{i+1} + \Delta f_i) + (f_{i+1} + f_i)] \tag{27}$$

$$\frac{\partial f}{\partial x} = \frac{1}{\Delta x}[\theta(\Delta f_{i+1} - \Delta f_i) + (f_{i+1} - f_i)] \tag{28}$$

$$\frac{\partial f}{\partial t} = \frac{1}{2\Delta t}[\Delta f_{i+1} + \Delta f_i] \tag{29}$$

The superscript for f in the equations (27)–(29) was dropped because all values of f correspond to the time level j. When these equations were substituted in the continuity equation, that is, equation (1), and after linearization we get:

$$a_i \Delta h_{i+1} + b_i \Delta Q_{i+1} = c_i \Delta h_i + d_i \Delta Q_i + e_i \tag{30}$$

where

$$a_i = \left[\frac{B_{i+1} + B_i}{2\Delta t}\right] - \frac{2\theta}{\Delta x}\left[\frac{Q_{i+1} - Q_i}{B_{i+1} + B_i}\right]\frac{\mathrm{d}B}{\mathrm{d}h_{i+1}} + \theta\left[\frac{q_{i+1} + q_i}{B_{i+1} + B_i}\right]\frac{\mathrm{d}B}{\mathrm{d}h_{i+1}} \tag{31}$$

$$b_i = \frac{2\theta}{\Delta x} \tag{32}$$

$$c_i = -\left[\frac{B_{i+1} + B_i}{2\Delta t}\right] + \frac{2\theta}{\Delta x}\left[\frac{Q_{i+1} - Q_i}{B_{i+1} + B_i}\right]\frac{\mathrm{d}B}{\mathrm{d}h_i} - \theta\left[\frac{q_{i+1} + q_i}{B_{i+1} + B_i}\right]\frac{\mathrm{d}B}{\mathrm{d}h_i} \tag{33}$$

$$d_i = \frac{2\theta}{\Delta x} \tag{34}$$

$$e_i = -\frac{2}{\Delta x}[(Q_{i+1} - Q_i) + (q_{i+1} + q_i)] + \theta[(\Delta q_{i+1} + \Delta q_i)] \tag{35}$$

When equations (27)–(29) were substituted in the momentum equation and the resulting equation linearized, we get:

$$a_i' \Delta h_{i+1} + b_i' \Delta Q_{i+1} = c_i' \Delta h_i + d_i' \Delta Q_i + e_i' \tag{36}$$

where

$$a_i' = \frac{\theta}{\Delta x}\left[\frac{Q_{i+1}B_{i+1}}{A_{i+1}^2}(Q_i - Q_{i+1})\right] + \frac{g\theta}{\Delta x}[(h_{i+1} - h_i)B_{i+1} + A_{i+1} + A_i] + \frac{\theta}{2\Delta x}\left[\left(\frac{2B_{i+1}^2Q_{i+1}^2}{A_{i+1}^3} - \frac{Q_{i+1}^2}{A_{i+1}^2}\frac{\mathrm{d}B}{\mathrm{d}h_{i+1}}\right) \times (h_{i+1} - h_i) - \frac{B_{i+1}Q_{i+1}^2}{A_{i+1}^2} - \frac{B_iQ_i^2}{A_i^2}\right] - \frac{g\theta}{2\Delta x} \times [B_{i+1}(z_i - z_{i+1})] + \frac{g\theta}{2}const\left(\frac{R_{i+1}}{D_{65}}\right)^m Fr_{i+1}^n \times \left(B_{i+1}(m - 3n) - \frac{A_{i+1}}{P_{i+1}}\frac{\mathrm{d}P}{\mathrm{d}h_{i+1}}(m - n) + B_{i+1}\right) + \theta\frac{Q_{i+1}^2B_{i+1}}{A_{i+1}^3}A_{x\ i+1}^y \quad (37)$$

$$b_i' = \frac{1}{2\Delta t} + \frac{\theta}{\Delta x}\left[\frac{Q_{i+1}}{A_{i+1}} + \frac{Q_i}{A_i} + \frac{(Q_{i+1} - Q_i)}{A_{i+1}}\right] + \frac{\theta}{2\Delta x}\left[\frac{2Q_{i+1}B_{i+1}}{A_{i+1}^2}(h_i - h_{i+1})\right] + gn\theta const\left(\frac{R_{i+1}}{D_{65}}\right)^m \times Fr_{i+1}^n\frac{A_{i+1}}{Q_{i+1}} - \theta\frac{Q_{i+1}}{A_{i+1}^2}A_{x\ i+1}^y \quad (38)$$

$$c_i' = \frac{\theta}{\Delta x}\left[\frac{Q_iB_i}{A_i^2}(Q_i - Q_{i+1})\right] + \frac{g\theta}{2\Delta x}[(h_{i+1} - h_i)B_i - A_{i+1} - A_i] + \frac{\theta}{2\Delta x}\left[\left(\frac{2B_i^2Q_i^2}{A_i^3} - \frac{Q_i^2}{A_i^2}\frac{\mathrm{d}B}{\mathrm{d}h_i}\right) \times (h_{i+1} - h_i) + \frac{B_{i+1}Q_{i+1}^2}{A_{i+1}^2} + \frac{B_iQ_i^2}{A_i^2}\right] - \frac{g\theta}{2\Delta x} \times [B_i(z_i - z_{i+1})] + \frac{g\theta}{2}const\left(\frac{R_i}{D_{65}}\right)^m Fr_i^n\left(B_i(m - 3n) - \frac{A_i}{P_i}\frac{\mathrm{d}P}{\mathrm{d}h_i}(m - n) + B_i\right) + \theta\frac{Q_i^2B_i}{A_i^3}A_{x\ i}^y \quad (39)$$

$$-d_i' = \frac{1}{2\Delta t} + \frac{\theta}{\Delta x}\left[\frac{(Q_{i+1} - Q_i)}{A_i} - \frac{Q_{i+1}}{A_{i+1}} - \frac{Q_i}{A_i}\right] + \frac{\theta}{2\Delta x} \times \left[\frac{2Q_iB_i}{A_i^2}(h_i - h_{i+1})\right] + gn\theta const\left(\frac{R_i}{D_{65}}\right)^m \times Fr_i^n\frac{A_i}{Q_i} - \theta\frac{Q_i}{A_i^2}A_{x\ i}^y \quad (40)$$

$$-e_i' = \frac{1}{\Delta x}\left[\left(\frac{Q_{i+1}}{A_{i+1}} + \frac{Q_i}{A_i}\right)(Q_{i+1} - Q_i)\right] + \frac{g}{2\Delta x} \times [(A_{i+1} + A_i)(h_{i+1} - h_i)] + \frac{1}{2\Delta x}\left[\left(\frac{B_{i+1}Q_{i+1}^2}{A_{i+1}^2} + \frac{B_iQ_i^2}{A_i^2}\right)(h_i - h_{i+1})\right] + \frac{g}{2\Delta x}[(A_{i+1} + A_i)(z_{i+1} - z_i)] + \frac{g}{2}const\left(\frac{R_{i+1}}{D_{65}}\right)^m Fr_{i+1}^n A_{i+1} + \frac{g}{2}const\left(\frac{R_i}{D_{65}}\right)^m \times Fr_i^n A_i - \frac{1}{2}\frac{Q_{i+1}^2}{A_{i+1}^2}A_{x\ i+1}^y - \frac{1}{2}\frac{Q_i^2}{A_i^2}A_{x\ i}^y \quad (41)$$

In deriving the above relations, the following linearization expressions were utilized:

$$\frac{1}{f_i + \Delta f_i} = \frac{1}{f_i\left(1 + \frac{\Delta f_i}{f_i}\right)} \approx \frac{1}{f_i}\left[1 - \frac{\Delta f_i}{f_i}\right] \quad (42)$$

$$\frac{1}{(f_i + \Delta f_i)^2} = \frac{1}{f_i^2\left(1 + \frac{\Delta f_i}{f_i}\right)^2} \approx \frac{1}{f_i^2}\left(1 - \frac{2\Delta f_i}{f_i}\right) \quad (43)$$

$$(f_i + \Delta f_i)^2 \approx f_i^2 + 2f_i\Delta f_i \quad (44)$$

The friction slope appearing in equations (2) was evaluated using a generalized friction factor relationship proposed by Krishnappan (1985) and it is valid for both rigid and mobile boundary flows. This form of the equation is as follows:

$$S_f = const.\left(\frac{R}{D_{65}}\right)^m\left(\frac{U^2}{gR}\right)^n \quad (45)$$

For rigid boundary flows considered in this review, the value of the first exponent m becomes zero and the value of the second exponent n is equal to one. The value of the const is related to the Chezy's coefficient. The finite difference form of S_f, that is, ΔS_f was evaluated as follows:

$$\Delta S_{f_i} = \frac{2nS_{f_i}\Delta Q_i}{Q_i} + \left[S_{f_i}\frac{B_i}{A_i}(m - 3n) - S_{f_i}\frac{1}{P_i}\frac{\mathrm{d}P}{\mathrm{d}h_i}(m - n)\right]\Delta h_i \quad (46)$$

For any time level, the coefficients appearing in equations (30) and (36) can be evaluated using equations (31)–(35) and (37)–(41) knowing the flow properties Q and h, geometric parameters A, P, R, $\mathrm{d}B/\mathrm{d}h$ and $\mathrm{d}P/\mathrm{d}h$, and the friction parameters const, m and n. Therefore, when equations (30) and (36) are applied to the first $(N-1)$ grid points along the length of the river (N is the total number of grid points) is a system of two $(N-1)$ linear equations involving $2N$ unknowns, namely, ΔQ_1, ΔQ_2, ΔQ_3, …, ΔQ_N and Δh_1, Δh_2, Δh_3, …, Δh_N result. With two boundary conditions (one at the upstream boundary and the other at the downstream boundary in the case of subcritical

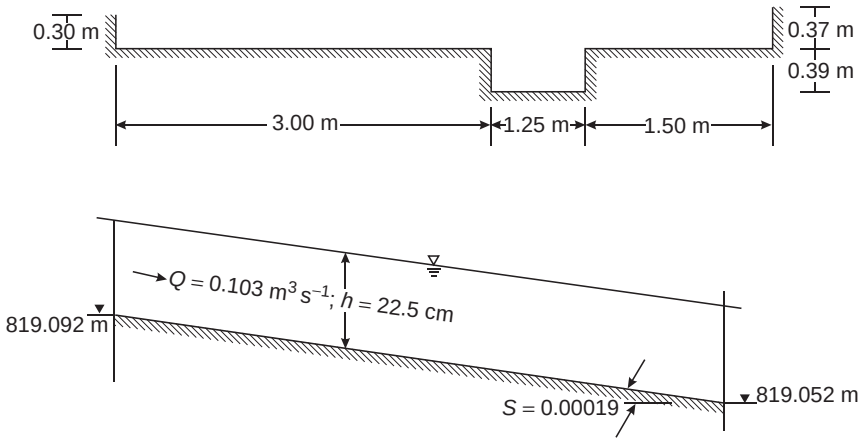

Figure 3 Schematic representation of a cross section and a profile of the compound channel used in Treske's experiments (1980).

flows) the number of equations matches the number of unknowns and hence the system of algebraic equations can be solved to obtain the solution at the next time level. The system of linear algebraic equations was solved using the double sweep method in the MOBED model. The details of the method can be found in Krishnappan (1981).

Testing of MOBED Model

The MOBED model was tested using unsteady flow experiments carried out by Treske (1980) in a laboratory channel. The channel used by Treske is a straight compound channel. The channel is 224 m long. The cross section and the profile of the channel are shown schematically in Figure 3. The main channel section is 39.0 cm deep and 125.0 cm wide. The floodplains on either side of the main channel are of different dimensions. The right side (looking downstream) floodplain is 150.0 cm wide and 37.0 cm deep whereas the left side floodplain is 300.0 cm wide and 30 cm deep. The working length of the channel is 210 m. The slope of the channel bed is 0.019% and the Manning's roughness coefficient was estimated to be 0.012 from uniform flow experiments. Unsteady flow experiments were carried out

by first running a steady flow for a period of time and then introducing a predetermined flow hydrograph at the head box. There were two measurement stations. The first one was at an upstream station located at 14.0 m from the head box and the second one was at the downstream end that was located at 224.0 m from the head box. At each measurement station, the flow rate and the flow stage were measured as a function of time. Altogether, 10 different hydrographs were tested in this channel. Out of these, four hydrographs produced flows that were confined to the main channel and the remaining six hydrographs produced flows in the floodplains. For testing the MOBED model two hydrographs were selected. The first one was a main channel flow (test no. 1) and the second one was a compound channel flow (test no. 10). The measured data for these two tests are shown in Figures 4 and 5, and listed in Tables 1 and 2.

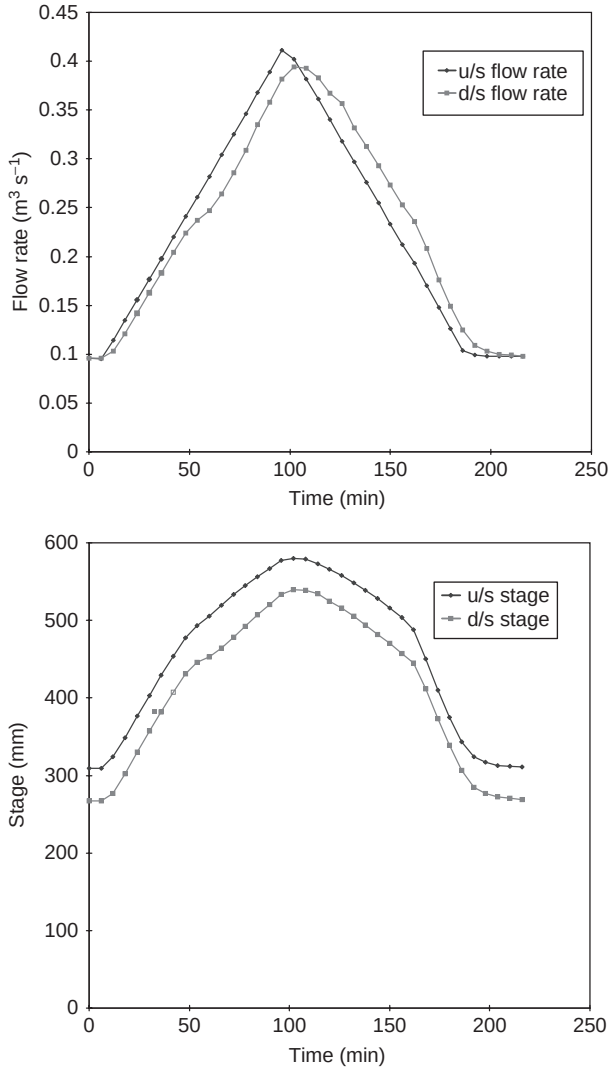

Figure 5 Measured data for test no. 10. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

For simulating the experimental conditions in the model, the reach between the two measurement stations was modeled. The flow rate measured at the upstream station was used as the upstream boundary condition and a stage-discharge relationship established from the measured data at the downstream boundary was used as the downstream boundary condition. This type of boundary condition specification is appropriate for the flows tested as the regime of the flow is subcritical at all times. For test no. 1, a time step of one minute and a distance step of 10 m were used. The stage-discharge relationship was expressed in the following functional form:

$$Q\left(\frac{\mathrm{m}^3}{\mathrm{sec}}\right) = 0.740h(\mathrm{m}) - 0.064 \tag{47}$$

For test no. 10, a time step of three minutes and a distance step of 10 m were used. For this test, a composite stage-discharge relationship established from the measured data was used. The forms of the relationships are shown below:

$$Q\left(\frac{\mathrm{m}^3}{\mathrm{sec}}\right) = 0.833h(\mathrm{m}) - 0.090 \quad \text{for} \quad h < 0.39 \tag{48}$$

$$Q\left(\frac{\mathrm{m}^3}{\mathrm{sec}}\right) = 1.583h(\mathrm{m}) - 0.383 \quad \text{for} \quad h > 0.39 \tag{49}$$

Results

Figure 6 shows a comparison of MOBED's prediction of upstream stage and the measured stage as a function of time for test no. 1. As can be seen from this figure, the model

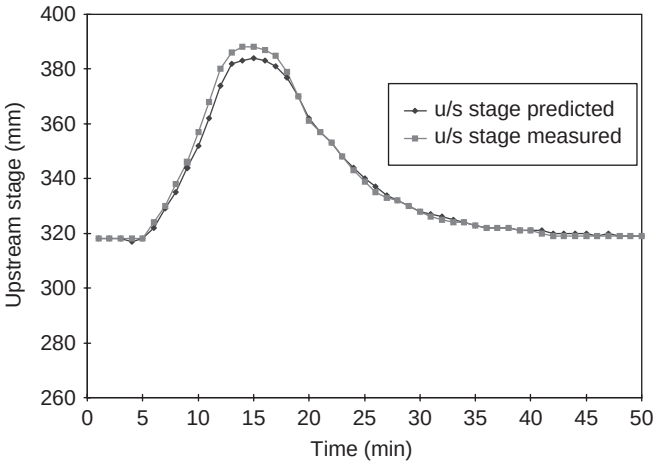

Figure 6 Comparison of predicted and measured upstream stage for test no. 1. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

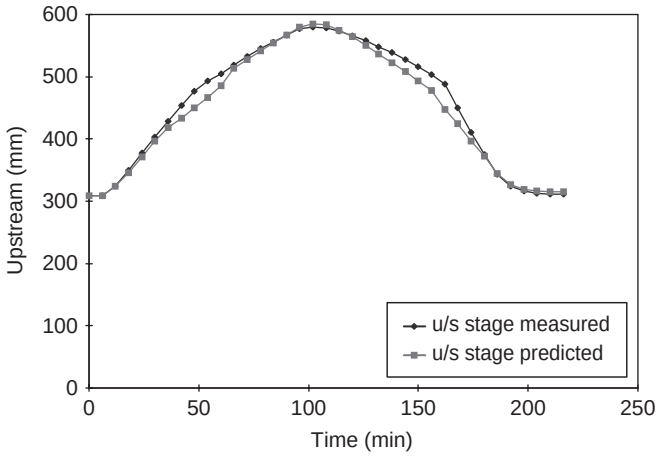

Figure 7 Comparison of predicted and measured upstream stage for test no. 10. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

prediction agrees reasonably well with the measurement, except for the peak stage. The model underestimates the peak stage by about 1%. It should be pointed out that for this test in which the flow is confined to the main channel, no adjustment of the friction factor was made. The measured friction factor under uniform flow conditions was used in the model without any adjustment. Under such condition, the prediction of peak stage within 1% can be considered as a significant result.

Figure 7 shows the agreement between the MOBED's prediction and the measurement for test no. 10. In this test, the flow spilled over into the floodplains when the stage exceeded 482 mm. When simulating the floodplain flow, the friction factor of the flow during the period when the flow was in the floodplain was increased by 25%. Such an increase was necessary to match the predicted peak stage with the measured peak stage, but it failed to match the stages during the rising and falling near the transition. Nevertheless, the agreement between the model prediction and the measurement can be considered satisfactory.

MODELING FLOWS WITH DISCONTINUITIES

Integral (Conservative) Forms of Governing Equations

The governing equations, equations (1) and (2) as well as equations (3) and (4), are written in a differential form. They are only valid in the case of smooth solutions and do not accept discontinuities. These equations, therefore, cannot be used to model flows involving mixed flow regimes of subcritical and supercritical flows, hydraulic jumps, and translatory waves, such as bores and dam-break fronts.

The governing equations for unsteady flows (i.e. the St. Venant equations), however, can be cast in an integral form that accepts discontinuous solutions. To illustrate the ideas for numerical modeling of discontinuities in unsteady flows, let us rewrite the differential form of simplified one-dimensional unsteady open-channel flow equations for rectangular channels (equations 3 and 4) in a slightly different form:

$$\frac{\partial h}{\partial t} + \frac{\partial hU}{\partial x} = q_\lambda \tag{50a}$$

$$\frac{\partial hU}{\partial t} + \frac{\partial}{\partial x}\left(hU^2 + \frac{1}{2}gh^2\right) = -gh(S_o - S_e) \tag{50b}$$

where h is the water depth, U is the average velocity, q_λ is the lateral discharge, and S_o and S_e represent the bed slope and slope of the energy line. These equations can be conveniently cast in a vector form as follows:

$$\mathbf{\Phi}_t + \mathbf{F}(\mathbf{\Phi})_x = \mathbf{S}(\mathbf{\Phi}) \tag{51a}$$

with

$$\mathbf{\Phi} = \begin{bmatrix} \phi_1 \\ \phi_2 \end{bmatrix} = \begin{bmatrix} h \\ hU \end{bmatrix}; \mathbf{F}(\mathbf{\Phi}) = \begin{bmatrix} f_1 \\ f_2 \end{bmatrix} = \begin{bmatrix} hU \\ hU^2 + \frac{1}{2}gh^2 \end{bmatrix};$$
$$\mathbf{S}(\mathbf{\Phi}) = \begin{bmatrix} S_1 \\ S_2 \end{bmatrix} = \begin{bmatrix} q \\ -gh(S_o - S_e) \end{bmatrix} \tag{51b}$$

where $\mathbf{\Phi}$ is the vector of conserved variables, $\mathbf{F}(\mathbf{\Phi})$ the flux vector, $\mathbf{S}(\mathbf{\Phi})$ the vector of source terms, and the subscripts x and t represent derivation with respect to x and t, respectively. Bold characters denote a vector or a matrix.

To present the general ideas behind conservative methods for modeling flows with discontinuities, we will consider only the homogeneous part of the equation (51a).

$$\mathbf{\Phi}_t + \mathbf{F}(\mathbf{\Phi})_x = 0 \tag{52}$$

The inclusion of the source terms will be discussed later. Consider the solution space x–t shown in Figure 8, which is discretized by dividing it into cells of size $\Delta x \times \Delta t$. Integral form of equation (52) can be obtained by integrating it over the control volume $[x_{i-1/2}, x_{i+1/2}] \times [t^n, t^{n+1}]$, represented by the shaded rectangle shown in Figure 8, and making use of Green's theorem:

$$\int_{x_{i-1/2}}^{x_{i+1/2}} \mathbf{\Phi}(x, t^{n+1})\,\mathrm{d}x = \int_{x_{i-1/2}}^{x_{i+1/2}} \mathbf{\Phi}(x, t^n)\,\mathrm{d}x - \left[\int_{t^n}^{t^{n+1}} \mathbf{F}(\mathbf{\Phi}(x_{i+1/2}, t))\,\mathrm{d}t - \int_{t^n}^{t^{n+1}} \mathbf{F}(\mathbf{\Phi}(x_{i-1/2}, t))\,\mathrm{d}t\right] \tag{53}$$

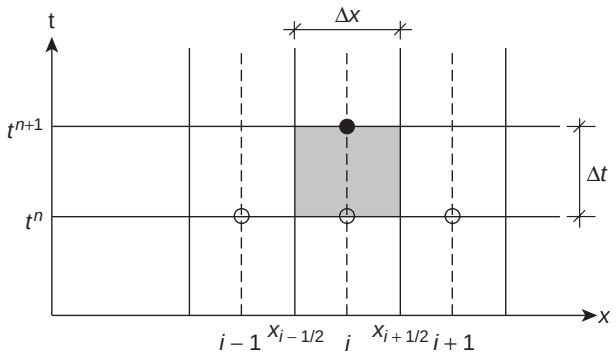

Figure 8 Solution domain x-t, and the control volume used for integration of equation (52)

By making the following definitions:

integral average of $\mathbf{\Phi}(x,t)$ at time $t = t^n$

$$\mathbf{\Phi}_i^n = \int_{x_{i-1/2}}^{x_{i+1/2}} \mathbf{\Phi}(x, t^n)\,\mathrm{d}x \tag{54a}$$

integral average of $\mathbf{\Phi}(x,t)$ at time $t = t^{n+1}$

$$\mathbf{\Phi}_i^{n+1} = \int_{x_{i-1/2}}^{x_{i+1/2}} \mathbf{\Phi}(x, t^{n+1})\,\mathrm{d}x \tag{54b}$$

integral average of flux $\mathbf{F}(\mathbf{\Phi})$ at $x = x_{i-1/2}$

$$\mathbf{F}_{i-1/2} = \int_{t^n}^{t^{n+1}} \mathbf{F}(\mathbf{\Phi}(x_{i-1/2}, t))\,\mathrm{d}t \tag{54c}$$

integral average of flux $\mathbf{F}(\mathbf{\Phi})$at $x = x_{i+1/2}$

$$\mathbf{F}_{i+1/2} = \int_{t^n}^{t^{n+1}} \mathbf{F}(\mathbf{\Phi}(x_{i+1/2}, t))\,\mathrm{d}t \tag{54d}$$

mesh size and time step, respectively

$$\Delta x_i \equiv x_{i+1/2} - x_{i-1/2}; \Delta t \equiv t^{n+1} - t^n \tag{54e}$$

the integral form of one-dimensional unsteady flow equations is obtained as:

$$\mathbf{\Phi}_i^{n+1} = \mathbf{\Phi}_i^n - \frac{\Delta t}{\Delta x}[\mathbf{F}_{i+1/2} - \mathbf{F}_{i-1/2}] \tag{55}$$

It should be noted that so far the derivation of equation (55) does not involve any approximations. This integral form of governing equations accepts discontinuous solutions.

Properties of Integral Governing Equations

An equivalent but nonconservative form of equation (52) can be written as:

$$\mathbf{\Phi}_t + \frac{\partial \mathbf{F}(\mathbf{\Phi})}{\partial \mathbf{\Phi}}\mathbf{\Phi}_x = \mathbf{\Phi}_t + \mathbf{A}(\mathbf{\Phi})\mathbf{\Phi}_x = 0 \tag{56}$$

where $\mathbf{A}(\mathbf{\Phi})$ is called *the associated Jacobian matrix*, given as:

$$\mathbf{A}(\mathbf{\Phi}) = \frac{\partial \mathbf{F}(\mathbf{\Phi})}{\partial \mathbf{\Phi}} = \begin{bmatrix} \partial f_1/\partial \phi_1 & \partial f_1/\partial \phi_2 \\ \partial f_2/\partial \phi_1 & \partial f_2/\partial \phi_2 \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -U^2 + gh & 2U \end{bmatrix} \tag{57}$$

The system is hyperbolic and has two distinct eigenvalues, which can be determined by setting $|\mathbf{A}(\mathbf{\Phi}) - \lambda \mathbf{I}| = 0$:

$$\lambda_1 = \frac{\mathrm{d}x}{\mathrm{d}t} = U + c;\ \lambda_2 = \frac{\mathrm{d}x}{\mathrm{d}t} = U - c \quad \text{with} \quad c = \sqrt{gh} \tag{58}$$

These eigenvalues are the same as given by equations (10) and (12). The Figure 9 shows the characteristics families for different flow regimes, as has been shown earlier in Figure 2 for the general case. Equations (11) and (13) hold along the characteristic lines λ_1 and λ_2, respectively. The shaded area is the *domain of dependence* for point x_3^{n+1}. The area between two characteristics emanating from a given point is the *domain of influence* for that point.

Equation (52), is written in terms of conserved variables h, and (hU). A quasi-linear form of equations can also be written using primitive variables, h and U:

$$\mathbf{W}_t + \mathbf{E}(\mathbf{W})\mathbf{W}_x = 0 \tag{59}$$

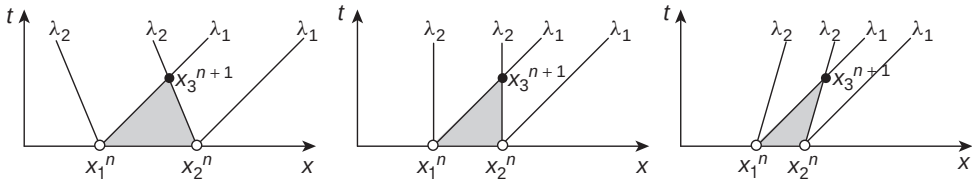

Figure 9 Characteristic lines for various uniform flow regimes

with

$$\mathbf{W} = \begin{bmatrix} w_1 \\ w_2 \end{bmatrix} = \begin{bmatrix} h \\ u \end{bmatrix}; \quad \mathbf{B}(\mathbf{W}) = \begin{bmatrix} u & h \\ g & u \end{bmatrix} \tag{60}$$

The $\mathbf{W}$ is the vector of primitive variables, and $\mathbf{E}(\mathbf{W})$ the associated Jacobian matrix. By setting $|\mathbf{E}(\mathbf{W}) - \lambda\mathbf{I}| = 0$ it can be shown that this system has the same two eigenvalues given by equation (58). The right and left eigenvectors can be determined by writing, $\mathbf{E}\mathbf{R}^{(i)} = \lambda\mathbf{R}^{(i)}$ and $\mathbf{L}^{(i)}\mathbf{E} = \lambda\mathbf{L}^{(i)}$, where $i = 1, 2$, respectively:

$$\mathbf{R} = [\mathbf{R}^{(1)}\mathbf{R}^{(2)}] = \begin{bmatrix} \mathrm{r}_1^{(1)} & \mathrm{r}_1^{(2)} \\ \mathrm{r}_2^{(1)} & \mathrm{r}_2^{(2)} \end{bmatrix} = \begin{bmatrix} h & h \\ c & -c \end{bmatrix};$$
$$\mathbf{L} = \begin{bmatrix} \mathbf{L}^{(1)} \\ \mathbf{L}^{(2)} \end{bmatrix} = \begin{bmatrix} \mathrm{l}_1^{(1)} & \mathrm{l}_2^{(1)} \\ \mathrm{l}_1^{(2)} & \mathrm{l}_2^{(2)} \end{bmatrix} = \begin{bmatrix} c & h \\ c & -h \end{bmatrix} \tag{61}$$

Each eigenvalue describes a wave family. The *generalized Riemann invariants* define relationships that hold true across the wave structure. They relate the ratio of the change of dependent variables to the respective component of the eigenvector:

$$\frac{\mathrm{d}w_1}{\mathrm{r}_1^{(i)}} = \frac{\mathrm{d}w_2}{\mathrm{r}_2^{(i)}} \qquad \text{with} \quad i = 1, 2 \tag{62}$$

Using the two right eigenvectors, one can write:

$$\text{For} \quad i = 1 \quad \frac{\mathrm{d}h}{h} = \frac{\mathrm{d}U}{c} \Rightarrow \mathrm{d}U = \frac{c}{h}\,\mathrm{d}h = \frac{\sqrt{g}h^{1/2}}{h} \times \mathrm{d}h = \sqrt{g}h^{-1/2}\,\mathrm{d}h \tag{63a}$$

$$\text{For} \quad i = 2 \quad \frac{\mathrm{d}h}{h} = \frac{\mathrm{d}U}{-c} \Rightarrow \mathrm{d}U = -\frac{c}{h}\,\mathrm{d}h = -\frac{\sqrt{g}h^{1/2}}{h} \times \mathrm{d}h = -\sqrt{g}h^{-1/2}\,\mathrm{d}h \tag{63b}$$

Integrating these equations in the phase plane w_1-w_2 (i.e. u-h), one obtains the following relationships:

$$\text{For } i = 1 \quad \lambda_1 = U + c \Rightarrow U + 2c = const. \tag{64a}$$

$$\text{For } i = 2 \quad \lambda_1 = U - c \Rightarrow U - 2c = const. \tag{64b}$$

These are equivalent to equations (11) and (13), respectively.

Discontinuous Solutions and Riemann Problem

The Riemann problem is an initial-value problem whose formal definition is given as:

$$\mathbf{\Phi}_\mathrm{t} + \mathbf{F}(\mathbf{\Phi})_x = 0$$
$$\mathbf{\Phi}(x, 0) = \begin{cases} \mathbf{\Phi}_\mathrm{L} & \text{if} \quad x < 0 \\ \mathbf{\Phi}_\mathrm{R} & \text{if} \quad x > 0 \end{cases} \tag{65}$$

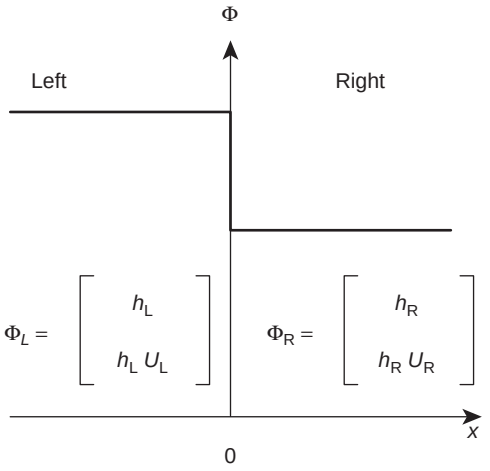

Figure 10 Initial data for the Riemann problem

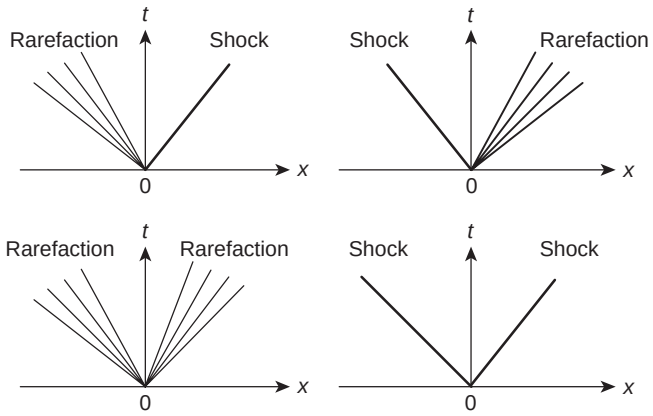

Figure 11 Possible wave patterns for a Riemann problem with both sides containing water

As shown in Figure 10, the initial data represent a discontinuity at $x = 0$, which separates left and right constant states. The Riemann problem is in fact a generalization of the dam-break problem in which the velocities in the left and right constant states are identically zero. The *exact* solution of this problem can be studied in terms of basic wave types which can be either a shock wave or a rarefaction wave. Figure 11 shows four possible wave combinations arising from a Riemann problem.

As shown in Figure 12, the left and right waves, which can be either shock or rarefaction, divide the solution domain into three distinct regions. Left and right states are the undisturbed initial constant data states. The region between the left and right waves is called *star region.* Depending on the type of the wave (shock or rarefaction), functions f_L and f_R, which relate constant values of depth, h_*, and velocity, U_*, in the star region to the values in the undisturbed left and right states, can be derived

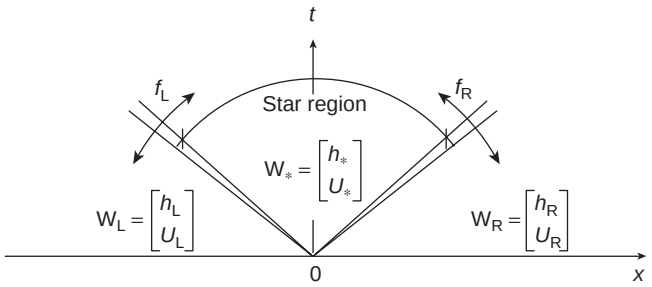

Figure 12 Solution domain used for solving Riemann problem when left and right initial states both contain water. Left and right waves can be either shock or rarefaction. The region between the two waves is called *star region*

using either Riemann invariants, equations (40a,b), or the Rankine–Hugoniot condition for shocks:

$$\mathbf{F}_R - \mathbf{F}_L = a\ (\mathbf{\Phi}_R - \mathbf{\Phi}_L) \tag{66}$$

where "a" is the propagation speed of the shock. Following Toro (2001), the solution for h_* is given by the root of a nonlinear algebraic equation (in terms of f_L, f_R, U_L and U_R) by an iterative numerical method such as Newton–Raphson method. Once h_* is known, the U_* is calculated from a simple algebraic formula. This computational procedure is only valid when the initial left and right constant states have both water ($h_L > 0$ and $h_R > 0$). If one side is dry, then there is no star region and the solution procedure must be modified. The detailed discussion of the solution of Riemann problems for wet–wet and wet–dry type discontinuities can be found in LeVeque (1999), Toro (1999) and Toro (2001). The last reference contains a sample FORTRAN code for the exact solution of Riemann problem for both wet–wet and wet–dry discontinuities.

First – order Numerical Schemes for Modeling Flows with Discontinuities

Nonconservative forms of governing equations are not suitable for dealing with discontinuous solutions. In the presence of discontinuities, nonconservative equations written in primitive variables lead to wrong jump conditions and give erroneous results for shock speed, strength, and position. Moreover, Hou and LeFloch (1994) have shown that nonconservative schemes do not converge to correct solution if the solution involves a shock wave.

Lax and Wendroff (1960) have shown that convergent conservative methods do converge to the *weak solution* of the conservation law. The weak solution is a solution that satisfies the integral form (conservative form) of conservation laws, equation (55), and the Rankine–Hugoniot condition, equation (66). It is, however, important to mention that the uniqueness of a weak solution is not always guaranteed. The weak solution may converge to a physically nonrelevant result. In such cases additional constraints, called *entropy function*, need to be imposed to ensure convergence to a physically relevant solution.

When modeling flows with discontinuities, special attention must be paid not only to the form of equations but also to the numerical scheme to be used. In this respect, the conservative form given by equation (55) constitutes an excellent starting point for developing conservative numerical schemes. Equation (55) admits discontinuous solutions, and also provides a direct link for the development of numerical methods when the flux terms are replaced by their numerical approximations over a solution domain discretized with a step size of $\Delta x = x_{i+1/2} - x_{i-1/2}$. Since information propagates with finite speed, it can be assumed that numerical approximations to flux terms $\mathbf{F}_{i+1/2}$ and $\mathbf{F}_{i-1/2}$ can be devised in terms of the initial data to the left and right of the respective interfaces, provided that the time step is chosen appropriately.

The general idea in selecting a correct time step is that the fastest wave should not travel more than one cell length, Δx, during the time Δt. On the basis of the values known at time $t = t^n$, let the propagation speed of the fastest wave be $a^n_{\max}$. The constraint for the time step can be given as $a^n_{\max} \le \Delta x/\Delta t$, where $\Delta x/\Delta t$ can be interpreted as grid speed. This constraint can be cast in the following convenient form:

$$\Delta t = \frac{C_{CFL}\Delta x}{a^n_{\max}} \quad \text{with} \quad 0 < C_{CFL} \le 1 \tag{67}$$

Table 3 Some centered (symmetric) schemes and their properties

Scheme	Flux term in equation (55)	Properties	
Forward time-centered space (FTCS)	$\mathbf{F}^{FTCS}_{i+1/2} = \frac{1}{2}(\mathbf{F}^n_i + \mathbf{F}^n_{i+1})$	Unconditionally unstable	
Lax–Friedrichs (LF)	$\mathbf{F}^{LF}_{i+1/2} = \frac{1}{2}(\mathbf{F}^n_i + \mathbf{F}^n_{i+1}) + \frac{\Delta x}{2\Delta t}(\mathbf{\Phi}^n_i - \mathbf{\Phi}^n_{i+1})$	Monotone and stable for	$0 < \lvert CFL\rvert \le 1$
Godunov-centered (GODC)	$\mathbf{F}^{GODC}_{i+1/2} = \mathbf{F}(\mathbf{\Phi}^{GODC}_{i+1/2})$, with $\mathbf{\Phi}^{GODC}_{i+1/2} = \frac{1}{2}(\mathbf{\Phi}^n_i + \mathbf{\Phi}^n_{i+1}) + \frac{\Delta t}{\Delta x}(\mathbf{F}^n_i - \mathbf{F}^n_{i+1})$	Stable for monotone for oscillatory for	$\lvert N_{CFL}\rvert \le \sqrt{2}/2$ $1/2 \le \lvert N_{CFL}\rvert \le \sqrt{2}/2$ $0 \le \lvert N_{CFL}\rvert \le 1/2$

where C_{CFL} is the Courant-Friedrichs-Levy (CFL) coefficient, or the Courant number. It is generally taken as $C_{CFL} \cong 0.9$.

Centered numerical schemes provide the simplest approach for expressing fluxes at the cell interfaces. These schemes do not explicitly take into account the wave nature of the solution and the direction of propagation of the information. Table 3 summarizes the flux expressions of some important centered schemes and their properties. First – order schemes are generally highly diffusive and the stability condition is defined by the Courant number.

The centered (symmetric) schemes do not make use of the wave-propagation characteristics of conservation equations. Godunov (1959) devised a first – order upwind method on the basis of the forward-time solution of Riemann problem. Consider the discretized solution domain illustrated in Figure 13(a). The solution $\mathbf{\Phi}^n$ at time $t = t^n$ is known (Figure 13b). A piecewise continuous representation of the initial data is obtained by calculating the integral averages $\mathbf{\Phi}_i^n = \int_{x_{i-1/2}}^{x_{i+1/2}} \mathbf{\Phi}^n \, dx$. To obtain the Godunov intercell fluxes $\mathbf{F}_{i\pm1/2}^{GOD}$, first the exact Riemann initial-value problem is solved at each cell interface using a local coordinate system with $x = 0$ centered at the interface (Figure 13c). If the time interval is chosen sufficiently small, such that $|C_{CFL}| \leq 1$, the solutions $\mathbf{\Phi}_{i-1/2}(x/t)$ and $\mathbf{\Phi}_{i+1/2}(x/t)$ emanating from left and right sides of the cell do not reach the other side of the cell. The Godunov intercell fluxes can then be simply computed as the physical flux function $\mathbf{F}(\mathbf{\Phi})$ evaluated along the t-axis used for the Riemann problem, which in terms of the local coordinate system corresponds to $x/t = 0$. The results of Riemann problems at the cell interfaces are sampled to obtain:

$$\mathbf{F}_{i+1/2}^{GOD} = \mathbf{F}(\mathbf{\Phi}_{i+1/2}(0)) \quad \text{and} \quad \mathbf{F}_{i-1/2}^{GOD} = \mathbf{F}(\mathbf{\Phi}_{i-1/2}(0)) \tag{68}$$

The conservative form equation (55) is then used for marching the solution to the time $t = t^{n+1}$:

$$\mathbf{\Phi}_i^{n+1} = \mathbf{\Phi}_i^n - \frac{\Delta t}{\Delta x}\left[\mathbf{F}_{i+1/2}^{GOD} - \mathbf{F}_{i-1/2}^{GOD}\right] \tag{69}$$

The exact solution of Riemann problem at each interface involves an iterative solution for h_* and is time consuming. Moreover, the detailed flow field information given by the exact solution of the Riemann problem is not used by the Godunov method. Several methods have, therefore, been proposed for approximate solution of the Riemann initial-value problem. Approximate Riemann solvers can lead to considerable reduction in computational time.

Roe's approximate solver (Roe, 1981) is the earliest and most popular approximate solver. It is based on the idea of replacing the associated Jacobian matrix $\mathbf{A}$ in equation (56), by a linear system with constant coefficients (obtained by freezing $\mathbf{A}$ at some intermediate time step). Roe's approximate solver fails, however, in case of wet-dry discontinuities. This can be avoided by imposing a very small water depth even when there is no water. This solution, however, may sometimes lead to an error in the estimation of the true wave speeds. Roe's approximate Riemann solver also produces an entropy-violating rarefaction shock when the rarefaction wave (negative wave) forms around the local t-axis (sonic or critical conditions). This problem can be cured by imposing an appropriate entropy function. Another important approximate solver is the HLL (Harten *et al.*, 1983) approximate Riemann solver which computes the numerical flux using estimated values of left and right wave speeds. HLL Riemann solver, however, relies on another suitable approximate Riemann solver for computing h_*. A detailed discussion of the approximate solvers is beyond the scope of this article. The interested readers are referred to LeVeque (1999), and Toro (1999) and Toro (2001).

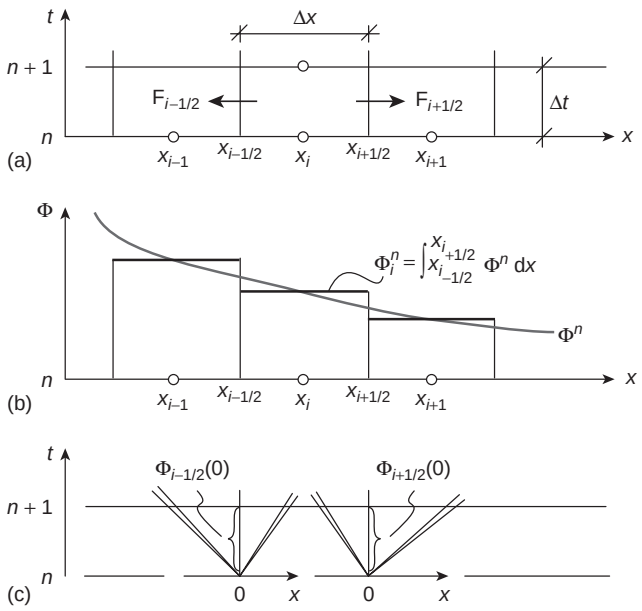

Figure 13 Principles of Godunov upwind scheme for one-dimensional flow: (a) control volume in solution space x–t, and the Godunov fluxes; (b) initial solution at time $t = t^n$ and its piecewise constant representation; (c) Riemann problems are solved in local coordinates with the origin located at the cell interfaces (adapted from Toro, 2001). Higher – order Numerical Schemes for Modeling Flows with Discontinuities

On the basis of the leading term of their local truncation error, it can be seen that the centered schemes and the Godunov upwind scheme presented above are all first – order accurate. These first – order schemes are

very diffusive and the discontinuities smear out as they propagate. One way of fixing this problem is to construct higher – order schemes.

A second – order accurate (in space and time) version of Godunov scheme can be constructed using Weighted Average Flux (WAF) method. The WAF method also relies on the piecewise constant representation of the initial data. Without going into the details, the WAF flux at a cell interface can be regarded as a weighted average of the fluxes at the cell centers on both sides see Toro (1999) and Toro (2001).

$$\mathbf{F}_{i+1/2}^{\mathrm{WAF}} = \frac{1}{2}(\mathbf{F}_i - \mathbf{F}_{i+1}) - \frac{1}{2}\sum_{1}^{N} C_{\mathrm{CFL}}^{(k)} \Delta \mathbf{F}_{i+1/2}^{(\mathrm{k})} \quad \text{with}$$

$$\Delta \mathbf{F}_{i+1/2}^{(\mathrm{k})} = \mathbf{F}_{i+1/2}^{(\mathrm{k}+1)} - \mathbf{F}_{i+1/2}^{(k)} \tag{70}$$

The term $\Delta \mathbf{F}_{i+1/2}^{(k)}$ is the flux jump across the wave k, N the number of conservation equations (two in the present case). The courant number for the wave k is represented by $C_{\mathrm{CFL}}^{(k)} = \Delta t a_{\max}^{(k)}/\Delta x$, where $a_{\max}^{(k)}$ is the maximum propagation speed of the wave k.

Monotone Upstream-centered Scheme for Conservation Laws (MUSCL) (MUSCL or MUSCL-Hancock), applies a different approach for the derivation of a scheme second – order accurate in space and time. MUSCL-Hancock method uses a piecewise linear representation of the initial data as opposed to piecewise constant representation used by the original Godunov method. As a result, the left and right states are not constant but linearly varying. This leads to a so-called *Generalized Riemann Problem* (GRP), which is defined as

$$\mathbf{\Phi}_t + \mathbf{F}(\mathbf{\Phi})_x = 0$$
$$\mathbf{\Phi}(x,0) = \begin{cases} \mathbf{\Phi}_{\mathrm{L}}(x) & \text{if} \quad x < 0 \\ \mathbf{\Phi}_{\mathrm{R}}(x) & \text{if} \quad x > 0 \end{cases} \tag{71}$$

When compared with equation (65) it is seen that the left and right states are now functions of x. The resulting characteristic lines are no longer straight lines but curves in the x–t plane. Without going into the details, one way of solving GRP is to compute left and right states at the half-step ($\Delta t/2$) using a formula involving the values of $\mathbf{\Phi}_{\mathrm{L}}(x)$ and $\mathbf{\Phi}_{\mathrm{R}}(x)$ evaluated at the interface. These intermediate $\mathbf{\Phi}_{\mathrm{L}}(x)$ and $\mathbf{\Phi}_{\mathrm{R}}(x)$ values are then treated as constant left and right states of a piecewise constant data, and the intercell fluxes are computed using an appropriate Riemann solver, the same way it is done in the first–order upstream method of Godunov. In fact, the approach used by MUSCL-Hancock method can be used to construct even higher – order schemes by using other piecewise representations of the data. The piecewise parabolic method of Colella and Woodward (1984), for example, is a scheme third – order accurate in space and time.

The higher – order methods presented above are not monotone and suffer from spurious oscillations near the sharp discontinuities. Total variation diminishing (TVD) methods provide a way to cure this problem. TVD methods are in a way similar to the use of artificial viscosity in some traditional centered schemes. The difference being that in TVD methods artificial viscosity is built into the scheme and is activated in a rather sophisticated way. TVD schemes were first introduced by Harten (1984) for solving the Euler equations in gas dynamics. The TVD schemes are second – order accurate and oscillation free at the discontinuities. A complete discussion of TVD class schemes would be too lengthy to describe here. It will suffice to mention that there are two general approaches to construct TVD schemes: *flux limiter approach* and *slope limiter approach*. The details of these approaches and TVD versions of higher – order upwind schemes can be found in LeVeque (1999), Toro (1999), and Toro (2001).

Treatment of Source Terms

The conservative methods described in the preceding sections dealt exclusively with the homogeneous form of the governing equations given by equation (52). Using fractional step method, these numerical schemes can be easily extended to solve the complete version with source terms as given by equation (51a). The fractional step (or splitting) method requires the solution of two separate equations at each step:

$$\mathbf{\Phi}_t + \mathbf{F}(\mathbf{\Phi})_x = 0 \tag{72a}$$

and

$$\mathbf{\Phi}_t = \mathbf{S}(\mathbf{\Phi}) \tag{72b}$$

First, using the initial data $\mathbf{\Phi}_i^n$ at time t, the equation (72a) is solved to obtain an intermediate solution, $\mathbf{\Phi}_i^{\mathrm{int}}$ at time $t + \Delta t$. This intermediate solution is then used as the initial data for solving equation (72b) to find the final solution $\mathbf{\Phi}_i^{n+1}$ at time $t + \Delta t$. Any appropriate numerical method can be used at this step to solve the ordinary differential equation, equation (72b). The entire solution can be written as:

$$\mathbf{\Phi}_i^{n+1} = \mathbf{\Phi}_i^n - \frac{\Delta t}{\Delta x}(\mathbf{F}_{i+1/2} - \mathbf{F}_{i-1/2}) + \Delta t \mathbf{S}(\mathbf{\Phi}_i^{\mathrm{int}}) \tag{73}$$

The fractional step (or splitting) methods do not give good results for problems involving steady flows or stagnant water. This is because of their inability to correctly model the delicate balance between flux terms and the source terms in each cell.

Recently methods have been developed to incorporate the source terms into the wave-propagation algorithm and thereby to avoid the use of fractional step methods. A

discussion of these methods can be found in LeVeque (1998) and Sanders *et al.* (2003).

AN EXAMPLE OF A CONSERVATIVE UPWIND MODEL AND ITS TESTING

Some of the high – order conservative upwind methods presented above may still present entropy glitches and may not perform well with arbitrary cross sections and bottom variations. For solving practical problems, it is desired to have a computationally efficient robust scheme, which will perform well under a wide range of conditions. The relatively simple upwind scheme proposed by Ying *et al.* (2003) and Ying *et al.* (2004) is very robust and computationally very efficient. The governing equations solved are:

$$\frac{\partial \mathbf{\Phi}}{\partial t} + \frac{\partial \mathbf{F}(\mathbf{\Phi})}{\partial x} = \mathbf{S}(\mathbf{\Phi}) \tag{74}$$

with

$$\mathbf{\Phi} = \begin{bmatrix} A \\ Q \end{bmatrix} \quad \mathbf{F}(\mathbf{\Phi}) = \begin{bmatrix} Q \\ \dfrac{Q^2}{A} \end{bmatrix}$$

$$\mathbf{S}(\mathbf{\Phi}) = \begin{bmatrix} 0 \\ -gA\dfrac{\partial Z}{\partial x} - \mathrm{g}\dfrac{Q|Q|}{C^2 R_\mathrm{h} A} \end{bmatrix} \tag{75}$$

where A is the cross-sectional area; Q is the discharge; g the gravitational acceleration; Z the water-surface elevation with respect to a reference datum; C the Chezy coefficient, and R_h is the hydraulic radius. Referring to Figure 8, the conservative form of equation (74) is obtained by integrating it over the control volume $[x_{i-1/2}, x_{i+1/2}] \times [t^n, t^{n+1}]$:

$$\mathbf{\Phi}_i^{n+1} = \mathbf{\Phi}_i^n - \frac{\Delta t}{\Delta x_i}(\mathbf{F}_{i+1/2} - \mathbf{F}_{i-1/2}) + \Delta t \mathbf{S}_i \tag{76}$$

The intercell flux term is given by

$$\mathbf{F}_{i+1/2} = \begin{bmatrix} Q_{i+k}^n \\ \dfrac{(Q_{i+k}^n)^2}{A_{i+k}^n} \end{bmatrix} \text{ where } k = \begin{cases} 0 & \text{if} \quad Q \geq 0 \\ 1 & \text{if} \quad Q \leq 0 \end{cases} \tag{77}$$

and the source term is calculated using

$$\mathbf{S}_i = \begin{bmatrix} 0 \\ -gA_i^{n+1}\left[\omega_1\left(\dfrac{Z_{i+1-k}^{n+1} - Z_{i-k}^{n+1}}{x_{i+1-k} - x_{i-k}}\right) + \omega_2\left(\dfrac{Z_{i+k}^{n+1} - Z_{i-1+k}^{n+1}}{x_{i+k} - x_{i-1+k}}\right)\right] - g\dfrac{Q_i^n|Q_i^n|}{(C_i^n)^2 R_i^n A_i^n} \end{bmatrix} \tag{78}$$

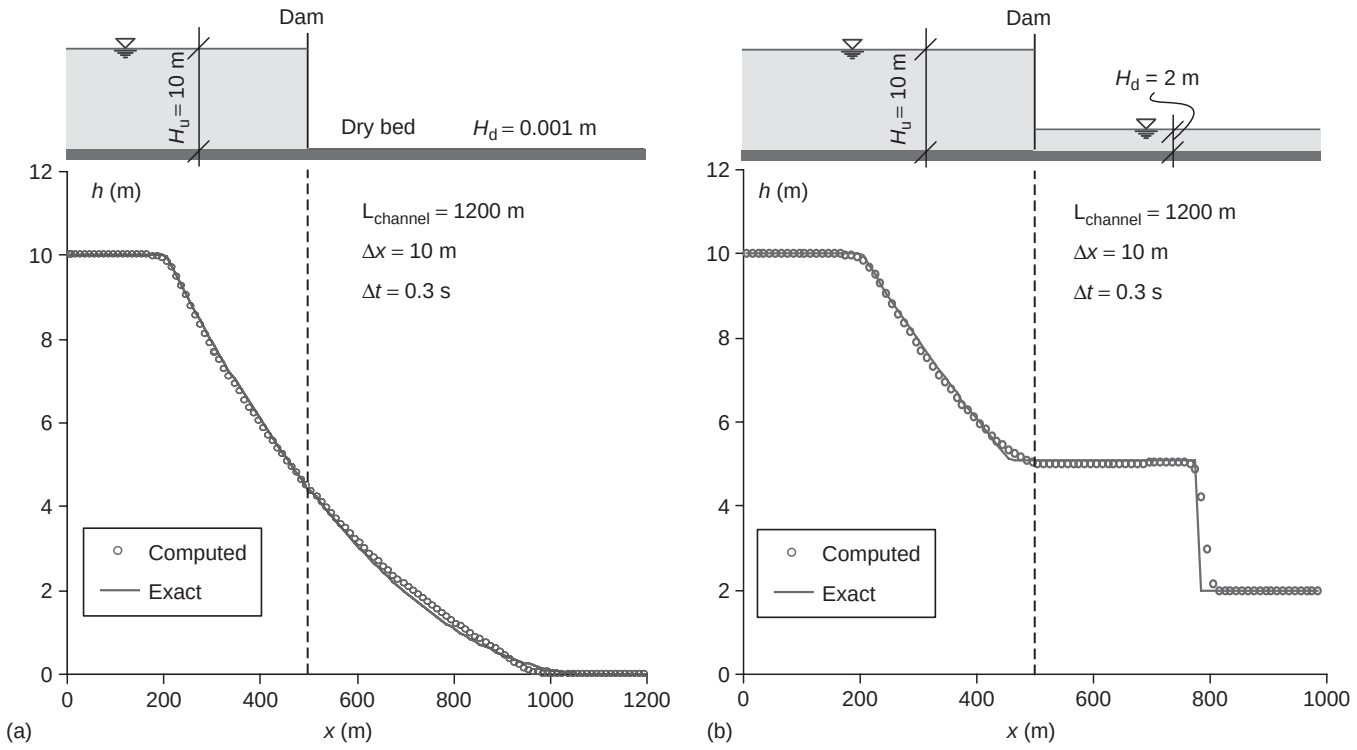

Figure 14 Dam break in a frictionless rectangular channel. (a) downstream is dry; (b) downstream has a water depth of 2 m. Equation (79b) is used to compute weighting factors. Initial conditions and other computational parameters are given in the figure. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

where ω_1 and ω_2, are the weighting factors used for calculating the gradient of the water-surface as a combination of forward and backward differences. Ying *et al.* (2003, 2004) propose two different choices for calculating these weighting factors:

$$\omega_1 = 1 - \frac{\Delta t}{x_{i+1-k} - x_{i-k}} \frac{U_{i+1-k} + U_{i-k}}{2} \quad \text{and}$$
$$\omega_2 = \frac{\Delta t}{x_{i+k} - x_{i-1+k}} \frac{U_{i+k} + U_{i-1+k}}{2} \tag{79}$$

or

$$\omega_1 = 1 - \sqrt{\frac{\Delta t}{x_{i+1-k} - x_{i-k}} \frac{U_{i+1-k} + U_{i-k}}{2}} \quad \text{and}$$
$$\omega_2 = \sqrt{\frac{\Delta t}{x_{i+k} - x_{i-1+k}} \frac{U_{i+k} + U_{i-1+k}}{2}} \tag{80}$$

The analysis shows that the conservative finite-volume scheme of Ying *et al.* (2003, 2004) is stable if the Courant number satisfies the following relationship: $C_{\mathrm{CFL}} = (U + \sqrt{gh})\Delta t/\Delta x$, where $U = |Q|/A$ is the magnitude of the average velocity at a cross section, and h the local water depth. The dry-bed condition is handled by maintaining a very small water depth even when the cross section is dry. Authors report that a general value of $h_{\min} = 0.001$ m can be used for all practical cases without introducing any noticeable error for the wave-propagation speed. The numerical tests show that the model is extremely robust and computationally very efficient. The results of several test cases are illustrated in Figures 14, 15 and 16.

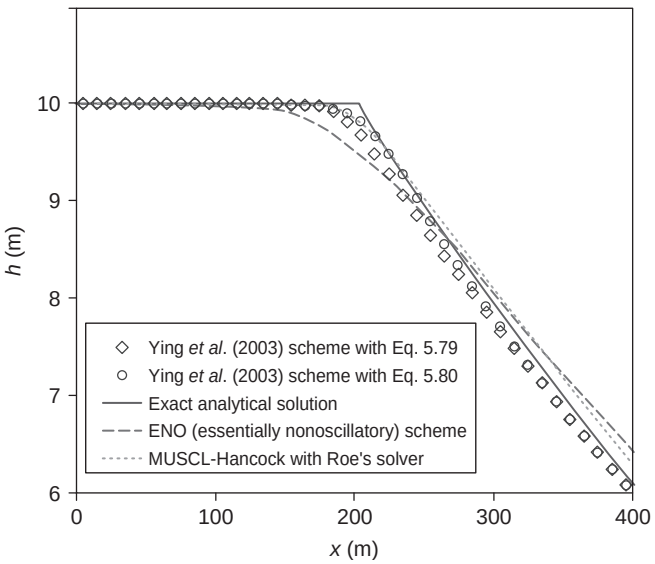

Figure 15 Comparison of Ying *et al.* (2003) scheme with ENO and MUSCLE-Hancock schemes for the case of dam break in a horizontal frictionless channel. The computational parameters are the same as in Figure 14(a). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

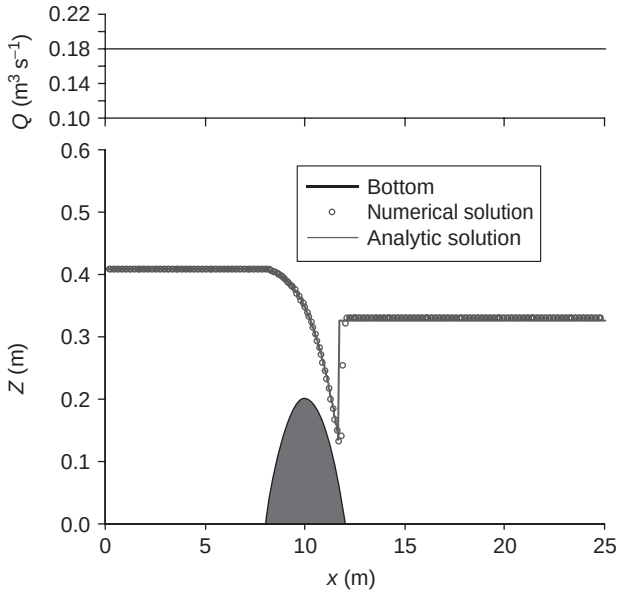

Figure 16 Numerical solution of flow over a bump using Ying *et al.* (2003) scheme. Note that the hydraulic jump downstream of the bump is finely resolved. The plot of discharge as a function of distance yields a constant line indicating an excellent mass conservation. CONCLUDING REMARKS FOR DISCONTINUOUS SOLUTIONS

The research on shock-capturing conservative finite-volume methods for solving hyperbolic conservation laws has made considerable progress in the recent years. The short introduction given here barely scratches the surface of this rapidly evolving research area. Zoppou and Roberts (2002) gives a short but complete overview of various methods as well as a comparison of the relative computational cost of various schemes. The readers interested on a more complete treatment of the topic are referred to excellent books by LeVeque (1999) and Toro (1999) and Toro (2001). Sample computer codes on exact Riemann solver and Godunov method can be found in the latter.

Conservation LAWs PACKage (CLAWPACK) is a package of Fortran subroutines for solving time-dependent hyperbolic systems of partial differential equations in 1, 2, and 3 space dimensions, including nonlinear systems of conservation laws. The software can also be used to solve nonconservative hyperbolic systems and systems with variable coefficients, as well as systems including source terms. The package includes an MPI version in which the domain

can be distributed among multiple processors, and adaptive mesh refinement versions (AMRCLAW) in two and three space dimensions. This package and the accompanying documentation can be downloaded from the website by LeVeque (2003).

Recently, Sobey (2001) reviewed the physical characteristics of the St. Venant equations expressed in the conservation form, and highlighted the challenges that a numerical model has to address in dealing with a hyperbolic system. He has also developed a series of benchmark test problems that will highlight the significant response patterns of a numerical model, and can be used to evaluate the performance of a numerical model of flood and tide propagation in channels. He stressed the importance of testing the models using such benchmark test problems as a routine and automatic part of any numerical model development exercise in this area.

Lai *et al.* (2002) gives various forms of conservation-form equations of unsteady open-channel flow. An analysis of the Riemann solvers available in the literature was carried out by Delis *et al.* (2000a), and they have compared the predictive ability of these solvers by applying them to the idealized and inhomogeneous dam-break problems. Delis *et al.* (2000b) had examined four implicit high-resolution TVD schemes for solving the St. Venant equations. Delis *et al.* (2000b) presented two new TVD schemes: one based on Harten's *et al.* (1983) modified flux and the second based on Van Leer (1979) MUSCL approach. Delis *et al.* (2000b) tested these two methods and a symmetric TVD proposed by Yee (1987) using the analytical solutions of the steady state benchmark test problems proposed by MacDonald *et al.* (1997). The idealized dam-break problem was also included in the test to check the accuracy of the schemes in an unsteady flow with shocks. From these tests, Delis *et al.* (2000b) concluded that the MUSCL method was the most efficient and robust.

140: Transport of Sediments

WALTER H GRAF AND MUSTAFA S ALTINAKAR

Laboratoire de Recherches Hydrauliques, Ecole Polytechnique Fédérale, Lausanne, Switzerland

A channel bed, made up of a granular material, is usually of a form which varies in space and time. The movement of the sediments, which make up the bed, represents a rather complex phenomenon. The hydrodynamic equations of the flow over a mobile bed are developed. The different modes of the transport of (noncohesive) sediments as bed load and as suspended load are presented. The formulae for the calculations of the transport of the total load are exposed, as well as their domain of application.

GENERALITIES

Notions

The flow of water over a mobile bed has the ability to entrain the sediments; a water–sediment mixture will consequently displace itself in the watercourse. The movement of the sediments – *erosion, transport, deposition* – will modify the flow, but also the channel bed. The interaction between the water and the sediments makes the problem a coupled one. When the bed is a *mobile* one, the fluvial hydraulics must concern itself with both the flow of the liquid phase, namely the mixture, and the movement of the solid phase, namely the sediments in the mixture.

The transport of these sediments plays an important role in all problems of fluvial hydraulics. The formulae, developed for the quantitative determination of the transport of sediments, are based on experimental results, and being often limited, they should be used with much caution, and they must be applied within hydraulic conditions under which they have been established.

Flow of a Mixture

For gravitational flow of a water–sediment mixture, one may distinguish three types of movement:

1. The mixture may be considered Newtonian if the volumic concentration of the particles is very small, $C_s \ll 1\%$. The difference between the density of the mixture and of the water, $\Delta\rho = (\rho_m - \rho) = (\rho_s - \rho)C_s$, remains also small, $\Delta\rho \ll 16\,\mathrm{kg\,m^{-3}}$.
   The *transport of sediments*, as bed load and suspended load, falls into this category. It is this type of transport of solid particles that is most often encountered in watercourses and treated in this article.
2. The mixture behaves like a quasi-Newtonian if the volumic concentration remains small, $C_s < 8\%$; the density difference becomes important, $\Delta\rho < 130\ \mathrm{kg\,m^{-3}}$.
   The transport of sediments as *concentrated suspension* (see Graf, 1971, 1984, pp. 182–186) notably close to the bed, as well as the *turbidity currents* fall into this category.
3. The mixture behaves non-Newtonian, if the volumic concentration becomes of importance, $C_s > 8\%$; the density difference is also very large, $\Delta\rho > 130\,\mathrm{kg\,m^{-3}}$.
   The flow of a non-Newtonian fluid modifies all concepts of Newtonian hydraulics.
   The transport of sediments as *hyperconcentrated suspension* (see Wan and Wang, 1994), the *debris flow* (see Takahashi, 1991), as well as *hyperconcentrated turbidity currents* (see Wan and Wang, 1994) fall into this category.

Modes of Transport (see Figure 1)

The transport of sediments by flow of water is the entire solid transport which passes through a cross section of a watercourse. Traditionally the transport of sediments is

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

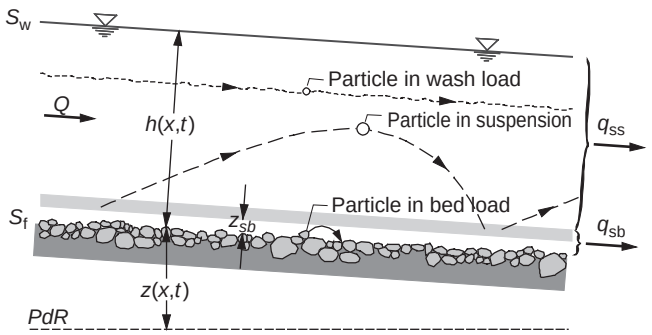

Figure 1 Scheme of the modes of transport. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

classified in different modes of transport that correspond to distinctly different physical mechanisms.

In a watercourse the sediments, namely the solid phase, are transported as:

1. *bed load*, q_{sb} – volumic solid discharge per unit width ($m^3\,s\,m^{-1}$) – when the particles stay in close contact with the bed;
2. *suspended load*, q_{ss}, when the particles stay occasionally in contact with the bed;
3. bed load + suspended load, being the (total) *bed-material load*, $q_s = q_{sb} + q_{ss}$, when the particles stay more or less in continuous contact with the bed.
4. *wash load*, q_{sw}, when the particles are almost never in contact with the bed; the particles are washed through the cross section by the flow.

The transport of sediments, namely the erosion of the bed (*see* **Chapter 137, Uniform Flow, Volume 4**), commences upon attainment of a certain critical value, which can be parameterized by the critical shear stress, τ_{ocr}.

It will be useful to give limiting values for the separation of the different modes of transport, using the ratio of the shear velocity of the flow, u_*, and the settling velocity of the particles, v_{ss} (see Graf, 1971, 1984):

- $u_*/v_{ss} > 0.10$ for beginning of bed-load transport,
- $u_*/v_{ss} > 0.40$ for beginning of suspended load transport.

To determine quantitatively the transport of sediments, there are three possibilities available, namely:

- using existing formulae (see Graf and Altinakar, 1998, Chap. 6),
- obtaining field measurements with adequate instruments (see Graf, 1971, 1984, Chap. 13),
- performing physical models (see Graf, 1971, 1984, Chap. 14).

The different modes of transport of sediments, quantified in form of solid discharge, q_{sb}, q_{ss}, and q_s, should be related to the liquid discharge, q. This will give the relation of the "sedimentological" rating curve for a given cross section of the channel. This curve, together with the "liquid" rating curve, gives a rather complete hydraulic description for a given cross section of a channel having a mobile bed.

The formulae, which are used to calculate the solid discharge, q_s, allow determination of the *capacity* of the transport of sediments for a given flow. Under such conditions, the transport of sediments is said to be in equilibrium.

HYDRODYNAMIC EQUATIONS

The hydrodynamic equations, and some solutions, for flow in an open channel over a mobile bed, when entrainment of sediments take place, will be presented next.

Equations of Saint-Venant–Exner

The equations of Saint-Venant (*see* Figure 2 and **Chapter 138, Unsteady Flow, Volume 4**) for unsteady and nonuniform flow over a *fixed bed* in a prismatic open channel of constant width, $B = Cte$, having a weak bed slope, S_f, were given before; for flow over a *mobile bed*, they can be written as:

$$\frac{\partial h}{\partial t} + h\frac{\partial U}{\partial x} + U\frac{\partial h}{\partial x} = 0 \qquad B = Cte \tag{1}$$

$$\frac{\partial U}{\partial t} + U\frac{\partial U}{\partial x} + g\frac{\partial h}{\partial x} + g\frac{\partial z}{\partial x} = -gS_e \tag{2}$$

The energy slope, S_e, shall be expressed with a relationship established for uniform flow, by using a friction coefficient, $\boldsymbol{f}$, for a mobile bed (*see* **Chapter 137, Uniform Flow, Volume 4**), or:

$$S_e = f(\boldsymbol{f}, U, h) \tag{3}$$

where h is the flow depth, U is the average velocity of the flow, and $z(x,t)$ gives the elevation of the channel bed.

For flow over a *mobile bed* (see Figure 2), the elevation (level) of the channel bed, $z(x,t)$, may vary. According to the relation of *Exner* (see Graf, 1971, 1984, p. 288), such a variation can be expressed in form of a continuity equation for the solid phase, namely:

$$\frac{\partial z}{\partial t} + \left(\frac{1}{1-p}\right)\frac{\partial q_s}{\partial x} = 0 \tag{4}$$

where p is the porosity of the sediments of the bed, being defined as the ratio of the volume of empty space (occupied by water) and of the total volume. $q_s = C_s U h$ is the volumic solid discharge per unit width and C_s is the volumic concentration of the solid phase, being defined

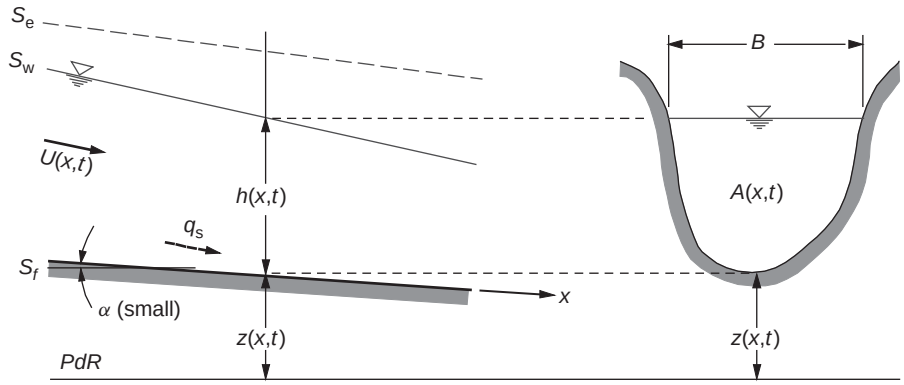

Figure 2 Scheme of unsteady and nonuniform flow over a mobile bed, $z(x, t)$. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

by the ratio of the volume of the sediments and of the volume of the mixture. In general one admits that the solid discharge, q_s, is a function – still to be determined – of the liquid discharge, $q = Uh$, or:

$$q_s = f(U, h;\ \text{sediment}) \tag{5}$$

The three equations, equations (1), (2), and (4), contain three unknowns, $U(x, t)$, $h(x, t)$, and $z(x, t)$, with their independent variables, x and t. The two other unknowns, S_e and q_s, have to be expressed with semiempirical relationships. The five relations, equations (1), (2), and (4) together with equations (3) and (5), are the *equations of Saint-Venant–Exner*.

The liquid and the solid phase are *implicitly* coupled by the semiempirical relations, equations (3) and (5). After the solution for the liquid phase, equations (1) and (2), a solution for the solid phase, equation (4), can be obtained, giving the variation of the bed elevation, $z(x, t)$.

To obtain solutions to the equations of Saint-Venant–Exner, analytical methods can be used for simple problems, and numerical methods for complex problems.

Propagation of Perturbations

The propagation of a perturbation, being a wave of small amplitude on the mobile bed, can now be investigated by using the equations of Saint-Venant–Exner. For a rectangular channel, these equations are written as six equations of partial derivatives:

$$\frac{\partial h}{\partial t} + h\frac{\partial U}{\partial x} + U\frac{\partial h}{\partial x} = 0 \tag{1}$$

$$\frac{1}{g}\frac{\partial U}{\partial t} + \frac{U}{g}\frac{\partial U}{\partial x} + \frac{\partial h}{\partial x} + \frac{\partial z}{\partial x} = -S_e \tag{2}$$

$$(1-p)\frac{\partial z}{\partial t} + \frac{\partial q_s}{\partial U}\frac{\partial U}{\partial x} = 0 \tag{4}$$

with:

$$\frac{\partial h}{\partial x}\,\mathrm{d}x + \frac{\partial h}{\partial t}\,\mathrm{d}t = \mathrm{d}h$$

$$\frac{\partial U}{\partial x}\,\mathrm{d}x + \frac{\partial U}{\partial t}\,\mathrm{d}t = \mathrm{d}U$$

$$\frac{\partial z}{\partial x}\,\mathrm{d}x + \frac{\partial z}{\partial t}\,\mathrm{d}t = \mathrm{d}z$$

In writing equation (4), it was assumed that the solid discharge is only a function of the flow velocity, $q_s = f(U)$.

Upon mathematical manipulations of these six equations the following cubic characteristic polynomial (see Vries, 1973, p. 2) is obtained:

$$-c_w^3 + 2Uc_w^2 + \left(gh - U^2 + \frac{g}{1-p}\frac{\partial q_s}{\partial U}\right)c_w - \frac{gU}{1-p}\frac{\partial q_s}{\partial U} = 0 \tag{6}$$

where the absolute celerity (the characteristic) is defined by $c_w = \mathrm{d}x/\mathrm{d}t$.

This equation, equation (6), has evidently three real roots, thus three characteristics. Two roots, c_{w_1} and c_{w_2}, are an expression of the celerity of the perturbation (wave) on the water surface; the third root, c_{w_3}, gives the celerity of a perturbation (undulation) on the mobile bed. The celerity, c_{w_3}, is positive for subcritical flow, $U < \sqrt{gh}$; the form (undulation) of the bed, usually called *dunes*, displaces itself in the same direction as the flow (see Vries, 1973, p. 3). If, c_{w_3}, is negative for supercritical flow, $U > \sqrt{gh}$; the form (undulation) of the bed, usually called *antidunes*, displaces itself in the opposite direction of the flow.

It seems reasonable (see Vries, 1973, p. 4) to assume that for $Fr = U/\sqrt{gh} \neq 1$ the celerities, c_{w_1} and c_{w_2}, of

the waves on the surface are much larger than the celerity, c_{w_3}, of the undulations on the bed.

When studying the perturbations on the bed having such a weak celerity, c_{w_3}, it is now possible to consider the flow of the liquid phase as quasi-steady; thus

$$\frac{\partial U}{\partial t} = 0 \quad \text{and} \quad \frac{\partial h}{\partial t} = 0$$

Consequently, combining equation (1) with equation (2), one can write a single differential equation, which is the equation of the free-surface flow, or

$$\frac{\partial U}{\partial x}\left(U - g\frac{h}{U}\right) + g\frac{\partial z}{\partial x} = -gS_e \tag{7}$$

By eliminating $\partial U/\partial x$ between equation (7) and equation (4), one obtains

$$\frac{\partial z}{\partial t} + c_{w_3}\frac{\partial z}{\partial x} = -c_{w_3}S_e = \mathbf{F}(U) \tag{8}$$

where $\mathbf{F}(U)$ is a friction (roughness) term – being responsible for the decay of the perturbation on the bed – and

$$c_{w_3} = \frac{g}{(1-p)}\frac{(\partial q_s/\partial U)}{(gh/U - U)} = \frac{1}{(1-p)}\frac{U(\partial q_s/\partial U)}{h(1-Fr^2)} \tag{9}$$

where $Fr^2 = U^2/gh$ is the Froude number. For subcritical flow, when $Fr^2 \ll 1$, and expressing the solid discharge by a power law of the form

$$q_s = a_s U^{b_s} \quad \text{and} \quad \frac{dq_s}{dU} = b_s\left(\frac{q_s}{U}\right) \tag{10}$$

one may write

$$c_{w_3} = \frac{1}{(1-p)}b_s\frac{q_s}{h} \tag{9a}$$

It is to be noted (see equation 9) that the celerity of propagation of the undulations, c_{w_3}, on the bed is usually rather small compared to the average velocity, U, of the flow itself.

Analytical Solutions

To obtain analytical solutions to the equations of Saint-Venant–Exner, which are nonlinear and hyperbolic, is a difficult and often impossible task. However, simplifications are possible, if one assumes that for flow at small Froude numbers, $Fr < 0.6$, a *quasi-steadiness* is maintained. This hypothesis of a steadiness of flow can be justified: in general a variation of liquid discharge, $\partial(Uh)/\partial t$, is a short-term phenomenon, while a variation of the bed elevation, $\partial z/\partial t$, is a long-term phenomenon, which produces itself when the variation of the discharge has already disappeared; thus the flow may be considered reasonably constant, $q = Uh = Cte$. Under such conditions, solutions are of great interest, notably if one studies the variation of the bed, $z(x, t)$, as a long-term phenomenon.

Using the hypothesis of quasi-steadiness of the flow, a system of two differential equations can be written as

$$\frac{\partial U}{\partial x}\left(U - g\frac{h}{U}\right) + g\frac{\partial z}{\partial x} = -gS_e \tag{7}$$

$$(1-p)\frac{\partial z}{\partial t} + \frac{\partial q_s}{\partial U}\frac{\partial U}{\partial x} = 0 \tag{4}$$

These two equations are nonlinear ones; only numerical solutions are possible. For certain special cases, analytical solutions (after linearization) can be of help to understand the problem, notably the relative importance of the different terms.

If one further assumes (see Vreugdenhil and de Vries, 1973, p. 8) that the quasi-steady flow is also quasi-uniform, $\partial U/\partial x = 0$, the above equation, equation (7), becomes

$$0 + g\frac{\partial z}{\partial x} = -gS_e = -g\frac{U^2}{C^2 h} = -g\frac{U^3}{C^2 q} \tag{11}$$

where C is the coefficient of Chézy and $q = Uh$ is the unit discharge.

By eliminating $\partial U/\partial x$ after differentiation of equation (11) with respect to x, one obtains for the above equation, equation (4):

$$\frac{\partial z}{\partial t} - K(t)\frac{\partial^2 z}{\partial x^2} = 0 \tag{12}$$

where the coefficient (of diffusion), $K(t)$, being a function of time, is given by

$$K = \frac{1}{3}\frac{\partial q_s}{\partial U}\frac{1}{(1-p)}\frac{C^2 h}{U} \tag{13}$$

This model, equation (12), is a *parabolic* one and is limited to large values of x and of t, namely, for $x > 3h/S_e$ (see Vries, 1973). The expression for the coefficient, equation (13), can also be written – upon linearization, possible for $U \cong U_o$, where the index, o, refers to the uniform (initial) condition and using the power-law expression for the solid discharge, equation (10) – in the following way:

$$K \equiv \frac{1}{3}b_s q_s \frac{1}{(1-p)}\frac{1}{S_{e_o}} \tag{13a}$$

This parabolic model – obtained by using important assumptions – is of considerable interest, since it allows the obtaining of analytical solutions for certain well-defined cases. Depending on the applied mathematical techniques

and on the hypothesis used, some solutions have been communicated in the literature (see Graf and Altinakar, 1998, Chap. 6).

A *hyperbolic* model for quasi-steady flow, but being nonuniform, has been proposed (see Vreugdenhil and de Vries, 1973, p. 5):

$$\frac{\partial z}{\partial t} - K\frac{\partial^2 z}{\partial x^2} - \frac{K}{c_{w_3}}\frac{\partial^2 z}{\partial x \partial t} = 0 \tag{14}$$

where K and c_{w_3} are respectively given by equation (13) and equation (9). Since an analytical solution to equation (14) is rarely possible (see Vries, 1973), this model turns out to be not all that useful.

A model of a *simple wave* (see Vreugdenhil and de Vries, 1973) is obtained by reduction of equation (8), or:

$$\frac{\partial z}{\partial t} + c_{w_3}\frac{\partial z}{\partial x} = 0 \tag{15}$$

where c_{w_3} is given by equation (9). Since the friction term, $\mathbf{F}(U)$, is now neglected, the application of this model remains limited to small values of x and of t, namely, for $x \ll 3h/S_{e_o}$.

Degradation and Aggradation

A *degradation* (or *aggradation*) in a reach of a watercourse is encountered if the entering solid discharge is smaller (or larger) than the capacity of the transport of sediments. The sediments of the bed will be eroded (or deposited) and as a consequence the elevation of the channel bed decreases (or increases). Degradation (erosion) and aggradation (deposition) are long-term processes of the evolution of the channel bed, $z(x, t)$.

The flow, being steady and uniform at the beginning, will also be steady and uniform at the end of the process; in between the flow becomes nonuniform and quasi-steady. If one assumes, that during this transition the flow can be considered as being quasi-uniform, $\partial U/\partial x = 0$, one may make use of the *parabolic model* (equation 12). Note that this model is limited to large values of x and of t, namely, for $x > 3h/S_e$, and for Froude numbers of $Fr < 0.6$. Analytical solutions to the parabolic model (equation 12) can be obtained for cases in which the initial and boundary conditions are well specified. Such solutions will not only clarify a physical problem, but can often be considered as a first tentative for an understanding of the problem. Caution is, however, necessary since this model was established using different assumptions.

The analytical solutions will certainly help to explain the long-term evolution of the bed of the channel, when the variation of the liquid discharge can be readily neglected. A detailed presentation of this model (equation 12), as applied to degradation and aggradation, is found in the literature (see Graf and Altinakar, 1998, Chap. 6).

Numerical Solutions

Analytical solutions of the equations of Saint-Venant–Exner are only possible when the hypothesis of quasi-steadiness of the flow is justified. Furthermore, it is often necessary to assume also quasi-uniformity of the flow. However, these assumptions are *no* more possible, if the temporal variation of the discharge, $\partial(Uh)/\partial t$, and the one of the elevation of the bed, $\partial z/\partial t$, are of the same order of magnitude, namely, relatively rapid.

If the flow is unsteady and nonuniform or steady and nonuniform, no analytical solutions, which are reasonably simple, are available. The system of the equations of Saint-Venant–Exner can be resolved – without making too severe assumptions – by numerical methods; this may be well achieved with the use of computers.

The numerical methods are essentially the same as the ones that are used to solve the equations of Saint-Venant, namely, for flow over a *fixed* bed (*see* **Chapter 137, Uniform Flow, Volume 4** and **Chapter 138, Unsteady Flow, Volume 4**). They become, however, rather complicated if they are applied for the modelization of flow over *mobile* bed.

BED-LOAD TRANSPORT

Notions

Transport as bed load is the mode of transport of sediments (see Figure 1) where the solid particles glide, roll, or (briefly) jump, but stay very close to the bed, $0 < z < z_{sb}$. The displacement of the particles is intermittent.

There exist a number of formulae that can be used for the prediction of the bed-load transport (see Graf, 1971, 1984, Chap. 7; Yalin, 1972 Chap. 5; and Raudkivi, 1976, 1990, Chap. 7). Many of these formulae are of empirical nature, but often have incorporated dimensionless numbers.

Theoretical Considerations

Consider that the bed of a channel (see Figure 1) is plane but mobile, composed of solid particles of uniform size which are being noncohesive. These particles displace themselves under the action of the flow, which is uniform and steady. For such simplified conditions, one tries to obtain functional relations. The form of such functions, being often rather complex, will be established by experiments, which more or less will take care of the reality of the problem.

A dimensionless analysis, using the Π-theorem (see Yalin, 1972, p. 61), shows that the arguments that quantify

the bed-load transport can be expressed by four dimensionless quantities:

$$\Phi = f\left(Re_*, \tau_*, \frac{R_h}{d}, \frac{\rho_s}{\rho}\right) \tag{16}$$

Thus an expression for a dimensionless *intensity of the solid discharge* as the bed load is obtained, or:

$$\Phi \equiv q_{sb*} = \frac{q_{sb}}{\sqrt{(s_s - 1)gd^3}} \tag{17}$$

where $q_{sb}\,\mathrm{m^2\,s^{-1}}$ is the volumic solid discharge per unit width, $Re_* = u_* d/\nu$ is a Reynolds number of the particle, $\tau_* = \tau_o/[(\gamma_s - \gamma)d]$ a dimensionless shear stress, R_h/d a relative depth, and $s_s = \rho_s/\rho$ a relative density. Since some terms, R_h/d and ρ_s/ρ, are included in the term of τ_*, and taking $\tau_* = f(Re_*)$, one can formulate now a rather simple relationship:

$$\Phi = f(\tau_*) \text{ or } \frac{q_{sb}}{\sqrt{(s_s - 1)gd^3}} = f\left(\frac{\tau_o}{(\gamma_s - \gamma)d}\right) \tag{18}$$

which is often written as:

$$\Phi = f(\Psi) \tag{18a}$$

where $\tau_* \equiv \Psi^{-1}$ and Ψ is called the *dimensionless intensity of shear stress*, applied upon the solid particles.

This expression (equation 18) links the solid transport, q_{sb}, to the shear stress, τ_*. Thus an increase in τ_* – passing by $\tau_{*_{cr}}$, where erosion begins – is responsible for an increase in q_{sb}. The form of this function (equation 18) must still be established; it is given by the formulae of bed-load transport, which are established by experiments performed in the laboratory and in the field.

One often assumes that this relation (equation 18) can be expressed in the form of a power law:

$$\Phi = \alpha(\tau_*)^\beta \tag{19}$$

Subsequently an approximate relation (see Vries, 1973) in the form of

$$q_{sb} = a_s U^{b_s} \tag{10}$$

is derived, where a_s, α and $b_s = 2\beta$, β are the coefficients that depend essentially on the granulometry. This simple, but often useful, relation shows that the average velocity, U, of the flow is the predominant parameter for the determination of the solid discharge, q_{sb}.

Bed-load Relations

At present, the formulae for a determination of the solid discharge as bed load give only reasonably satisfying results within a domain of the parameters for which the chosen formula has been established. Consequently, the application and use of such formulae have to be done with great care. A selection of two of the many available formulae (see Graf, 1971, 1984, p. 133) will be given, namely, the ones by Meyer-Peter *et al.* and by Einstein.

From the different empirical formulae which *Meyer-Peter et al.* have developed in 1934 and 1948 (see Graf, 1971, 1984, p. 136), their last one is presented, namely:

$$0.25\rho^{1/3}\frac{(g'_{sb})^{2/3}}{(\gamma_s - \gamma)d} = \frac{\gamma R_{hb}\xi_M S_e}{(\gamma_s - \gamma)d} - 0.047 \tag{20}$$

where $g'_{sb} = g_{sb}\,(\gamma_s - \gamma)/\gamma_s$ is the solid discharge in weight under water and $g_{sb}/\gamma_s = q_{sb}$; R_{hb} is the hydraulic radius of the bed. For a nonuniform granulometry, the mean diameter, $d = d_{50}$, is taken as the equivalent diameter. This relation can also be written in the dimensionless form such as:

$$\Phi = 8(\xi_M \tau_* - \tau_{*_{cr}})^{3/2} \tag{20a}$$

where $\tau_{*_{cr}}$ is the dimensionless critical shear stress. $\xi_M = (K_s/K'_s)^{3/2}$ is the roughness parameter, where K'_s is the roughness of the granulates, evaluated with the formula of Strickler, and K_s is the total roughness of the bed, evaluated with the formula of Manning-Strickler, or:

$$K_s = \frac{U}{R_{hb}^{2/3} S_e^{1/2}} \quad \text{and} \quad K'_s = \frac{26}{d_{90}^{1/6}}$$

In the absence of bed forms, it is recommended to take $\xi_M = 1$; but $1 > \xi_M > 0.35$ if bed forms are present.

This relation (equation 20) is applicable for rather large grain sizes, $d > 2\,\mathrm{mm}$, being uniform as well as nonuniform, and for bed slopes, being moderate to strong (see Table 1).

Using the concepts of hydrodynamics, *Einstein* developed in 1942 and 1950 (see Graf, 1971, 1984, pp. 139–150) a probabilistic model for the transport of sediments as bed load. To express the probability of motion, Einstein (1950, p. 37) postulated the following function:

$$p_e = 1 - \frac{1}{\sqrt{\pi}} \int_{-B_*\Psi_* - 1/\eta_o}^{+B_*\Psi_* - 1/\eta_o} e^{-\xi^2}\,\mathrm{d}\xi \tag{21}$$

where ξ is a variable of integration. B_* and η_o are constants to be determined experimentally. Ψ_* is Einstein's intensity of shear stress, which takes into account the nonuniformity of the granulometry of the bed and its roughness as well as the velocity distribution of flow. For a uniform granulometry, one takes (see Einstein, 1950, p. 36):

$$\Psi_* = \Psi', \text{ with } \Psi' = \frac{(\gamma_s - \gamma)d}{\rho u'^2_*} = \frac{(\gamma_s - \gamma)}{\gamma}\frac{d}{R'_{hb} S_f} = \frac{1}{\tau'_*}$$

Subsequently Einstein (1950) elaborated an equation of bed load by postulating that the rate of erosion is equal to the rate of deposition. This results in the following expression:

$$\left(\frac{p_e}{1-p_e}\right) = A_* \left(\frac{i_{sb}}{i_b}\right) \Phi = A_* \Phi_* \qquad (22)$$

where Φ is the intensity of transport after Einstein (1950) given by equation (17) and A_* is a constant to be determined experimentally. i_{sb} is a fraction (see Figure 4) of the granulometric curve of the unit solid discharge, g_{sb}, in weight and i_b is a fraction (see Figure 4) of the granulometric curve of the bed material. p_e is the probability of erosion of a particle. For a uniform granulometry, one takes (see Einstein, 1950, p. 36) simply:

$$\Phi_* = \Phi$$

The above relations (equations 21 and 22), put together, give now the final form of the *equation of bed load of* Einstein (1950), or:

$$p_e = 1 - \frac{1}{\sqrt{\pi}} \int_{-B_*\Psi_* - 1/\eta_o}^{+B_*\Psi_* - 1/\eta_o} e^{-\xi^2} \, d\xi = \frac{A_*\Phi_*}{1 + A_*\Phi_*} \qquad (23)$$

namely, a functional relation (see equation 18a), such as:

$$\Phi_* = f(\Psi_*) \qquad (23a)$$

The (universal) constants have now to be determined experimentally both for uniform and nonuniform granulometries (see Einstein, 1950, pp. 37 and 43); they are given (see Graf, 1971, 1984, p. 149) as:

$$A_* = 43.6; \quad B_* = 0.143; \quad \eta_o = 0.5 \qquad (23b)$$

The above relation (equation 23) is plotted in Figure 3 together with the data of Meyer-Peter *et al.* and Gilbert. The graphical representation facilitates the use of the relation (equation 23). Since a nonuniform granulometry can be broken down into its fractions, i_{sb}/i_b, this relation is rather flexible. For a quasi-uniform granulometry, an equivalent diameter of $d = d_{35}$ can be taken. The equation of Einstein (equation 23) is well suitable for uniform and nonuniform granulates over a large range of diameters, $d > 0.7$ mm, and of bed slopes (see Table 1). It is used worldwide with great success. It is interesting to remark that the relation of *Einstein* (equation 23) and the one of *Meyer-Peter et al.* (equation 20) give rather similar results (see Graf, 1971, 1984, p. 150), and this notably for $\Phi < 10$.

Granulometry, Armoring

The noncohesive sediments, which make up the bed of a watercourse, are in general of different sizes, being given by the granulometric curve of the bed material (see Figure 4a). This curve can be divided into fractions (percentages), i_{b_i}. For each fraction the average diameter, d_i, is determined

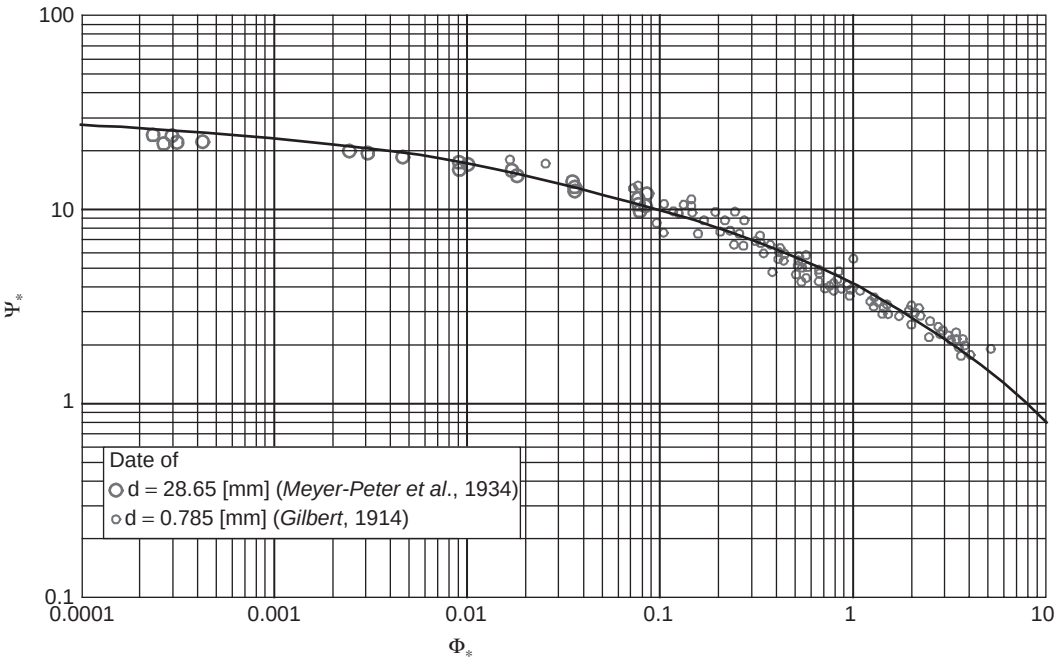

Figure 3 Equation of bed load, $\Phi_* = f(\Psi_*)$, of Einstein (see Graf, 1971, 1984, p. 148). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

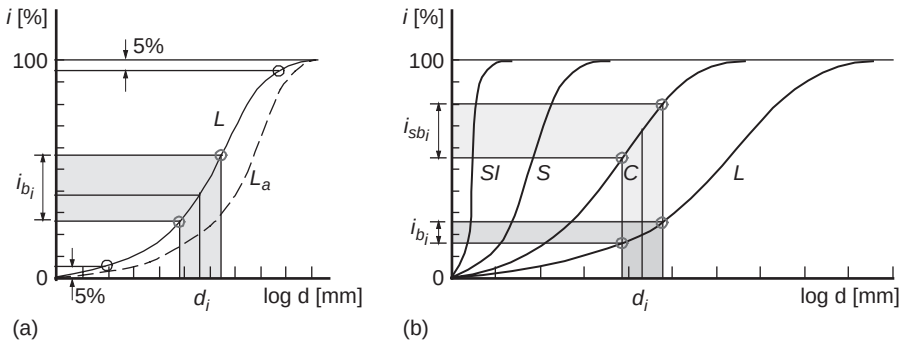

Figure 4 Scheme of granulometric curves for the bed material, L, and the armored bed material, L_a, the bed-load material, C, and the suspended (wash) load material, S (SI). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Table 1 Parameters used for establishing the different formulae

Formula	d [mm]	S_f [−]	d_x [mm], equivalent diameter for a nonuniform granulate
Meyer-Peter *et al.* (equation 20)	3.1–28.6	0.0004–0.020	d_m (d_{50})
Einstein (equation 23)	0.8–28.6	–	d_{35}
Graf and Acaroglu (equation 40)	0.3–1.7 (23.5)	–	d_{50}
Ackers and White (equation 43)	0.04–4.0	$Fr < 0.8$	d_{35}

and the corresponding solid discharge, $i_{sb_i} q_{sb_i}$, is calculated using one of the formulae for bed-load transport. For the entire granulometric mixture, the solid discharge is now obtained as: $q_{sb} = \sum i_{sb_i} q_{sb_i}$.

The granulometric curve of the bed material is in general different from the one of the material moving as bed load or as suspended load (see Figure 4b). Consequently, for an average diameter of the granulate, d_i, the given fraction of the granulometric curve of the bed material, i_{b_i}, will be different from the corresponding fraction of the granulometric curve of the solid discharge, i_{sb_i}. This subtlety was elaborated by Einstein (1950, p. 32) by introducing the ratio, i_{sb}/i_b, into the equation of bed-load transport (equation 23). For a very intensive sediment transport, all sizes (fractions) of particles will readily participate; consequently $i_{b_i} \equiv i_{sb_i}$, since the curves L and C become identical (see Figure 4b).

For cohesive material, the determination of the solid discharge represents a difficult task; the literature specialized on this topic should be consulted (see Graf, 1971, 1984, Chap. 12 and Raudkivi, 1976, 1990, Chap. 9).

On a channel bed of nonuniform granulometry, the smaller particles are more easily eroded than the larger ones and; a grain-size sorting takes place. An accumulation of the remaining larger particles results in an *armoring* of the bed, which subsequently protects the underlying "original" granulate (see Graf, 1971, 1984, p. 102). There exists only limited conclusive information about the ratio of the original granulometry, d, and the granulometry of the armor layer, d_a. For some Swiss rivers, having large bed slopes, $S_f > 0.03$ [−], and large grain sizes, $d_{50} > 6$ mm, an indicative relationship of:

$$\frac{d_{50_a}}{d_{50}} \approx 1.4; \quad \frac{d_{50_a}}{d_{90}} \leq 0.6$$

was developed by Correia and Graf (1988).

SUSPENDED-LOAD TRANSPORT

Notions

Transport of sediments in suspension is the mode of transport where the solid particles displace themselves by making large jumps, but remain in contact with the bed load and also with the bed. The zone of suspension is delimited by $z_{sb} < z < h$ (see Figure 1). The transport as suspended load could be considered as an advanced stage of transport as bed load; however, the analytical methods do not allow a description of these two modes of transport with the same (or single) relationship.

Theoretical Considerations

For steady uniform flow, the vertical distribution of the concentration of the suspended particles, $c_s(z)$, in the fluid can be obtained by using the equation of one-dimensional

diffusion-convection (see Graf, 1971, 1984, p. 166):

$$0 = v_{ss}\frac{\partial c_s}{\partial z} + \frac{\partial}{\partial z}\left(\varepsilon_s \frac{\partial c_s}{\partial z}\right) \tag{24}$$

where $c_s(z)$ is the local volumic concentration, ε_s is the diffusivity of the suspended particles, whose units are $[L^2\ T^{-1}]$, and v_{ss} is the settling velocity of the particles. Integration of the above equation (equation 24) yields:

$$v_{ss}c_s + \varepsilon_s \frac{dc_s}{dz} = Cte = 0 \tag{25}$$

where the constant of integration is taken to be $Cte = 0$, implying that $c_s = 0$ at the water surface for $\varepsilon_s = 0$. Equation (25) is valid only for weak concentrations, namely, for $(1 - c_s) \cong 1$ or $c_s < 0.1\%$. The above equation expresses that, at all levels, $z_{sb} < z < h$, the rate of sedimentation of particles per unit volume is equal to the rate of turbulent diffusion per unit volume.

In the open-channel flow, the turbulence and thus the diffusivity are vertically distributed, $\varepsilon_s(z)$. The distribution of the diffusivity – it was shown (see Graf and Altinakar, 1998, Chapt. 6) that the transport of matter and transport of momentum by turbulence are analogous and close to a solid boundary identical, $\varepsilon_s \approx \nu_t$ – is given (see Graf, 1971, 1984, p. 173) by:

$$\varepsilon_s = \kappa u'_* \frac{z}{h}(h - z) \tag{26}$$

This parabolic relation, established for unidirectional flow, has been experimentally verified (see Raudkivi, 1976, 1990, p. 170). Substitution of equation (26) into equation (25), and separation of the variables, yields:

$$\frac{dc_s}{c_s} = -\frac{v_{ss}}{\kappa u'_*}\left(\frac{h}{h - z}\right)\frac{dz}{z} \tag{27}$$

where one defines the *Rouse* exponent as:

$$\mathcal{Z} = \frac{v_{ss}}{\kappa u'_*} \tag{27a}$$

This expression (equation 27) can now be integrated by parts, within the limits of $a < z < h$ (see Graf, 1971, 1984, p. 173) and renders:

$$\frac{c_s}{c_{sa}} = \left(\frac{h - z}{z}\frac{a}{h - a}\right)^{\mathcal{Z}} \tag{28}$$

where c_{sa} is the concentration at a reference level, a. It gives the distribution of the relative concentration, c_s/c_{sa}, for one single particle size, v_{ss} and $\mathcal{Z}$. Note that in the definition of the Rouse exponent, $\mathcal{Z}$, the friction velocity, u'_*, due to the granulate must be used. In the Rouse exponent one should take the settling velocity, v_{ss}, of the particle in clear and quiescent water (see Graf, 1971, 1984, p. 45), thus being not influenced by turbulence or by concentration.

The equation for the distribution of the relative concentration (equation 28) for different values of the Rouse exponent, $\mathcal{Z}$, is shown in Figure 5. The following is to be observed:

– For small $\mathcal{Z}$-values, the relative concentration is large and tends to become uniform over the entire flow depth, h.

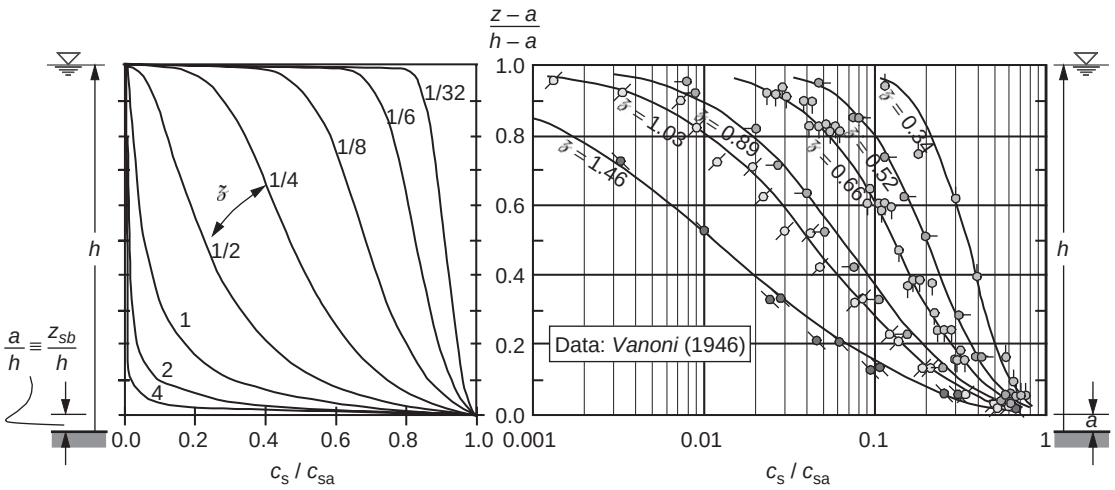

Figure 5 Vertical distribution of the relative concentration, c_s/c_{sa}, in a suspension. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

- For large $\mathcal{Z}$-values, the relative concentration is small at the water surface and is large close to the bed.
- The size of the particles, expressed with the settling velocity, v_{ss}, is directly responsible for these distributions.
- Close to the bed, $z \cong 0$,the concentration goes towards infinity, $c_s = \infty$, thus to an impossible value. Thus one delimits this level usually by $a \equiv z_{sb} \cong 0.05h$ or by $z_{sb} = 2d$, below which there exists the bed load (see Figure 1).
- The reference concentration, c_{sa}, is usually taken at a level of $a \equiv z_{sb}$; it can be calculated (see equation 34) with one of the bed-load formulae, q_{sb}.

Numerous investigations, both in laboratory and *in situ*, give evidence of the validity of the above equation (equation 28) (see Graf, 1971, 1984, p. 175).

Suspended-load Relation

The volumic solid discharge in suspension per unit width, in a region delimited by $z_{sb} < z < h$, is obtained by:

$$q_{ss} = \int_{z_{sb}}^{h} c_s u \, dz \tag{29}$$

where $c_s(z)$ is the local concentration (equation 28), and $u(z)$ is the local velocity. This relation is valid for a single particle size, d or v_{ss}. The distribution of the velocity shall be given by a logarithmic relation (see Einstein, 1950, p. 17), of the form:

$$u(z) = u'_* 5.75 \log\left(30.2 \frac{z}{\Delta}\right) \tag{30}$$

where $\Delta = k_s/\chi$ is a correction term, given in Figure 6, and u'_* is the friction velocity due to the granulate.

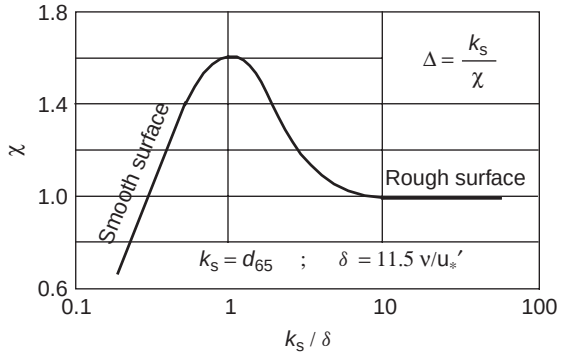

Figure 6 Correction coefficient of velocity distribution

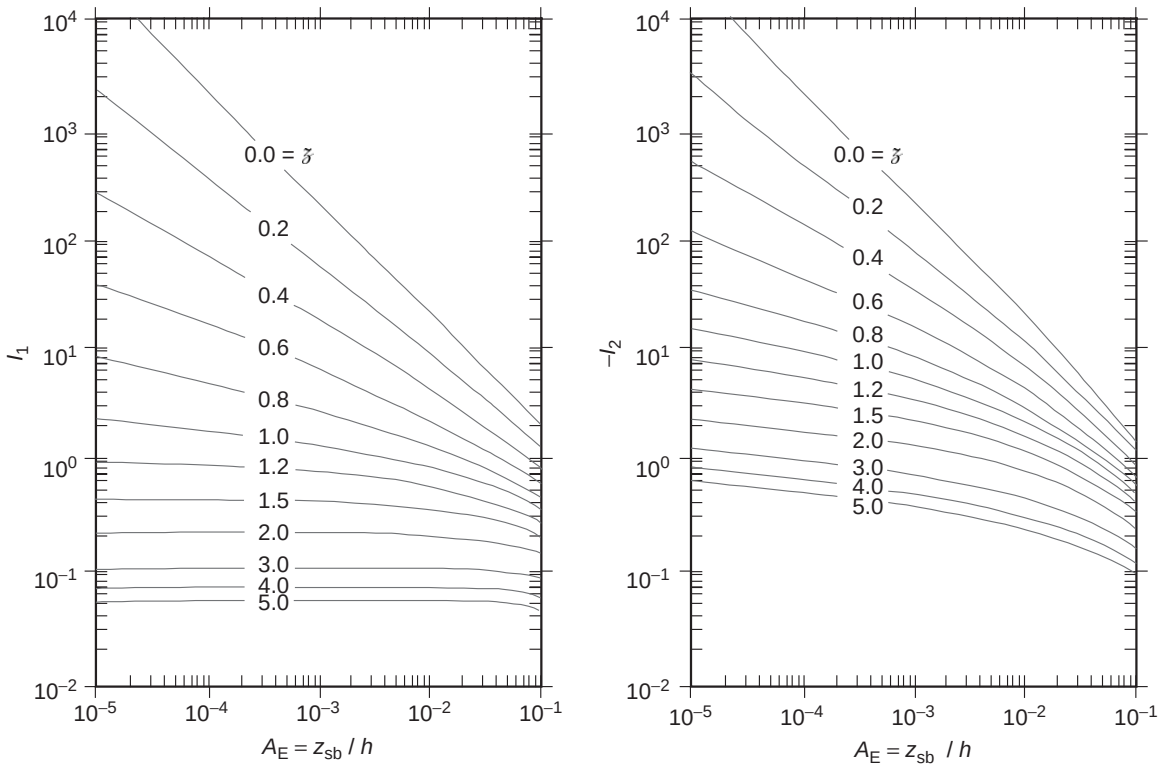

Figure 7 The integrals, $I_1(A_E, \mathcal{Z})$ and $I_2(A_E, \mathcal{Z})$, used in the method of Einstein (1950). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Upon substitution of equations (28 and 30) into the above equation, equation (29), one obtains:

$$q_{ss} = \int_{z_{sb}}^{h} c_{sa} \left(\frac{h-z}{z} \frac{a}{h-a} \right)^{\mathcal{Z}} u'_* 5.75 \log \left(30.2 \frac{z}{\Delta} \right) dz \tag{31}$$

Replacing $(a + z_{sb})$ by a dimensionless expression, $z_{sb}/h = A_E$, using h as the unity of z (see Einstein, 1950, p. 18), and after some mathematical manipulations, one gets:

$$q_{ss} = c_{sa} u'_* 5.75 h \left(\frac{A_E}{1-A_E} \right)^{\mathcal{Z}} \times \left\{ \log \left(30.2 \frac{h}{\Delta} \right) \int_{A_E}^{1} \left(\frac{1-z}{z} \right)^{\mathcal{Z}} dz + 0.434 \int_{A_E}^{1} \left(\frac{1-z}{z} \right)^{\mathcal{Z}} \ln z \, dz \right\} \tag{32}$$

The values of the following integrals

$$I_1 = 0.216 \frac{A_E^{\mathcal{Z}-1}}{(1-A_e)^{\mathcal{Z}}} \int_{A_E}^{1} \left(\frac{1-z}{z} \right)^{\mathcal{Z}} dz;$$

$$I_2 = 0.216 \frac{A_E^{\mathcal{Z}-1}}{(1-A_e)^{\mathcal{Z}}} \int_{A_E}^{1} \left(\frac{1-z}{z} \right)^{\mathcal{Z}} \ln z \, dz$$

are numerically evaluated (see Einstein, 1950, p. 19–24) and this for different values of A_E and $\mathcal{Z}$; they are given in Figure 7. Finally, the above equation, equation (32), can be put into the following form:

$$q_{ss} = 11.6 \, c_{sa} u'_* z_{sb} \left[2.303 \log \left(30.2 \frac{h}{\Delta} \right) I_1 + I_2 \right] \tag{33}$$

where q_{ss} is the volumic solid discharge per unit width of the suspended load.

The *reference concentration*, c_{sa}, shall be taken there, where the concentration distribution (equation 28) lacks any physical sense, particularly very close to the bed. It will thus be positioned within the layer where the bed load moves (see Figure 1). One usually assumes (see Graf, 1971, 1984, p. 191) that the thickness of this layer, called *bed layer*, is twice the grain diameter, $z_{sb} \approx 2d$; for a granulometric mixture, the bed layer takes different values for each granulometric fraction. It is now necessary to establish a relation between the bed-load and suspended-load transport; the reference concentration, c_{sa}, will make this link. Exploiting experiments, Einstein (1950, p. 40) proposed an expression for the reference concentration:

$$c_{sa} = \frac{q_{sb} i_{sb}}{11.6 \, u'_* z_{sb}} \tag{34}$$

Consequently, the solid discharge as suspended load per unit width (equation 33) is given by:

$$q_{ss} i_{ss} = q_{sb} i_{sb} \left[2.303 \log \left(30.2 \frac{h}{\Delta} \right) I_1 + I_2 \right] \tag{35}$$

$q_{ss} i_{ss}$ being the volumic solid discharge per unit width of the suspended load for one single granulometric fraction. This relation (equation 35) establishes the link between bed-load and suspended load transport for all particle sizes, which are found in the granulometric fraction of the bed load.

TOTAL-LOAD TRANSPORT

Notions

Total-load transport of sediments – or better called *total bed-material load transport* – is made up of transport as bed load (see Section "Bed-load transport") and of transport as suspended load (see Section "Suspended-load transport") or:

$$q_s = q_{sb} + q_{ss} (+ q_{sw}) \tag{36}$$

Added should (possibly) be the transport as wash load, q_{sw}.

Different formulae (see Graf, 1971, 1984, Chap. 9 or White *et al.*, 1973) exist, which can be used for the prediction of the bed-material load in a watercourse. The formulae for determination of the total load – just as the ones of the bed load – give only reasonable results in the domain of their established parameters (see Table 1). Thus an application of any formula must be done with great care. Here we will give a selection of some existing formulae.

Total-load Relations

Einstein (1950, p. 40) proposed a formula for bed-load transport (equation 23) and one for suspended-load transport (equation 35); combining these two relations, it is possible to get a formula for the bed-material load transport:

$$q_s i_s = q_{sb} i_{sb} + q_{ss} i_{ss} = q_{sb} i_{sb} \left[1 + 2.303 \log \left(30.2 \frac{h}{\Delta} \right) I_1 + I_2 \right] \tag{37}$$

This relation gives the sediment-transport capacity, but does not, of course, include the wash-load transport. This formula (equation 37) can be used if the hydraulic and sedimentological parameters are known in advance. If in addition a measurement of the suspended load is also available, there exists a modified version (see Graf, 1971, 1984, p. 207) of the above relation.

In many ways, the indirect method of Einstein (equation 37) is hydraulically rather complete, but its application might seem laborious.

Graf and Acaroglu (1968) developed a relation for the direct prediction of the bed-material transport, valid for open-channel flow (but also for flow in pipes).

A *parameter of shear intensity* was elaborated as a criteria of solid transport (see Graf, 1971, 1984, pp. 218 et 443):

$$\Psi_A = \frac{(s_s - 1)d}{S_e R_h} \tag{38}$$

which is the inverse of the dimensionless shear stress. Applying the concept of power (work) of a flow system, a *parameter of transport* was proposed (see Graf, 1971, 1984, pp. 219 and 446):

$$\Phi_A = \frac{C_s U R_h}{\sqrt{(s_s - 1)g d^3}} = \frac{(q_s/q) U R_h}{\sqrt{(s_s - 1)g d^3}} \tag{39}$$

which is similar to the dimensionless intensity of solid discharge, given by equation (17).

It could be shown that a functional relation between these parameters, Ψ_A and Φ_A (see equation 18a), whose form was experimentally determined, is possible. Using close to 800 experiments from the laboratory and close to 80 experiments in the field (see Table 1), all for free-surface flow (and close to 300 experiments for pipe-line flow), the following relationship (see Graf, 1971, 1984, pp. 220 and 448) was established:

$$\Phi_A = 10.39(\Psi_A)^{-2.52} \tag{40}$$

This relationship is found valid for $10^{-2} < \Phi_A < 10^3$ or for $\Psi_A \leq 14.6$; it is also valid when taking an equivalent diameter, $d \cong d_{50}$, if the granulometry is a nonuniform one.

Ackers and White (1973) proposed a direct determination of the total-load transport, q_s, using some sedimentological parameters.

A *parameter of mobility* of sediments was defined as:

$$F_{gr} = \frac{u_*^{n_w}}{\sqrt{(s_s - 1)gd}} \left[\frac{U}{\sqrt{32}\log(10h_m/d)} \right]^{(1-n_w)} \tag{41}$$

which becomes $F_{gr} = \sqrt{\tau_*}$ for very fine particles, where $n_w = 1$. A *parameter of transport* of sediments was postulated as:

$$G_{gr} = C_w \left(\frac{F_{gr}}{A_w} - 1 \right)^{m_w} \tag{42}$$

The total-load transport is now calculated according to:

$$C_s = \frac{q_s}{q} = G_{gr} \frac{d}{h_m} \left(\frac{U}{u_*} \right)^{n_w} \tag{43}$$

where C_s is the volumic average concentration in a section and $h_m = A/B$ is the average flow depth. The coefficients in the above relations were determined by regression analysis, using close to 1000 experiments in the laboratory and close to 250 experiments in the field, with sediments having a uniform and a nonuniform granulometry, $0.04 < d_{50}\,mm < 4.0$ and for flow at $Fr < 0.8$ (see Table 1). The resulting values of these coefficients are the following:

co-efficient	$d_* > 60$ $d > 2.5$[mm]	$1.0 < d_* \leq 60$	$d_* < 1$ $d < 0.04$[mm]
n_w	0.0	$(1 - 0.56 \log d_*)$	1.0
m_w	1.50	$(9.66/d_*) + 1.34$	
A_w	0.17	$0.23/\sqrt{d_*} + 0.14$	
C_w	0.025	$\log C_w = 2.86 \log d_* - (\log d_*)^2 - 3.53$	

Above, the dimensionless particle diameter, $d_* = d[(s_s - 1)(g/\nu^2)]^{1/3}$, is used. For a nonuniform granulometry, one takes $d = d_{35}$ as the equivalent diameter.

Application of Relations

Different formulae for the determination of the solid transport have been presented. However, none of these relations can pretend to translate the intrinsic complexity of the transport of sediments. Most of these formulae should not be used beyond the conditions within which they were established. Table 1 contains a summary of the range of the parameters, d and S_f, investigated for the establishment of each formula. Also listed are the recommendation by the authors for the choice of the equivalent diameter, d_x, if the granulometry is quasi or nonuniform.

The formulae for the transport of sediments are often established using laboratory data and less often using field data. A verification of these formulae in watercourses is a very delicate task, since it is difficult to measure correctly the solid discharge in the field. Furthermore, it is often a rather subjective evaluation, since the zones of the modes of transport cannot easily be separated.

Numerous studies have been reported comparing measurements in watercourses with the different existing formulae. Many (19) of the existing formulae for the calculation of the total transport have been studied by White *et al.* (1973) and compared with experimental results. They evaluated almost 1000 laboratory experiments with uniform and nonuniform sediments of $0.04 < d_{50}\,[mm] < 4.9$, at flow depth of $h < 0.4$ m, and almost 270 experiments in watercourses with sediments of $0.1 < d\,mm < 68.0$ and a width/depth ratio of $9 < B/h < 160$. Each formula was applied to all the data of the solid-discharge measurements. Subsequently a ratio of the values calculated, C_{calc}, and the values observed, C_{obs}, where $C \equiv C_s$ is the total-load transport, expressed in concentration, was established. Some

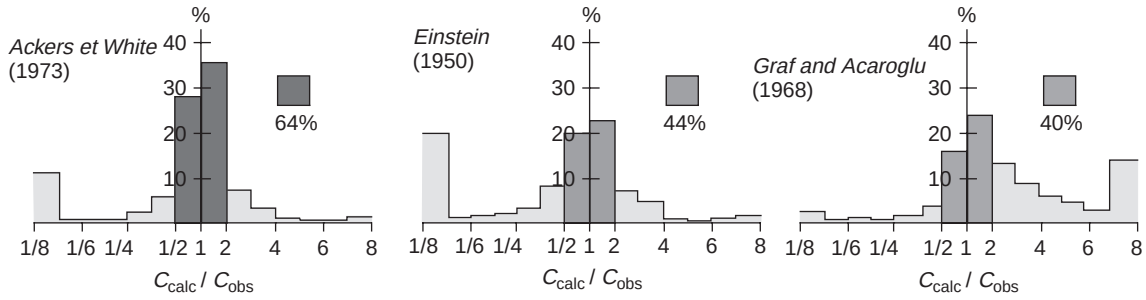

Figure 8 Comparison, with respect to C_{calc}/C_{obs}, of the success of prediction for the presented formulae

results of this investigation are given in Figure 8, where one may see the success of a prediction (in percentage) for different ranges of the ratio, C_{calc}/C_{obs}. For the formulae, which are presented in this article – considering only the range of $1/2 < C_{calc}/C_{obs} < 2$ – it can be seen that the percentage of success for the different formulae are as follows: is for the formula of:

Einstein (1950), equation 37:	44% of success
Graf and Acaroglu (1968), equation 40:	40% of success
Ackers and White (1973), equation 43:	64% of success

This implies that with the formula of Ackers and White, 64% of the experimental data can be predicted in the above-mentioned range. This is usually considered as a good (or a not-so-bad) result; more than half of the studied (19) formulae give results which are not as good, namely <40%.

The comparative study of White *et al.* (1973) is reasonably objective, but certainly not conclusive. Other studies exist (see Raudkivi, 1976, 1990, p. 227) that show clearly that an objective validation is nearly impossible.

Among the different existing formulae for the determination of the total-load transport, but equally for the ones of the bed-load and suspended-load transport, each one will give an answer, but none will be very precise nor very true. Thus the results obtained with these formulae give only valuable guidelines for the engineer. For practical purposes, it is advised to consult more than one formula; the obtained result may, however, render different values (see Graf, 1971, 1984, p. 156).

Wash Load

The wash load, q_{sw}, contains all these particles that are never in contact with the bed and displace themselves by being carried (washed) through the channel by the flow (see Figure 1). This mode of the transport of sediments is limited to the very finest particles, which are rare in the granulometry of the bed material. The distribution of these particles is rather uniform over the entire flow depth. Einstein (1950, p. 7) has proposed that the granulometry of the wash load is the fraction of granulometry of the bed that is smaller than 10%.

Since there exists no physical relationship to the flow, it has been difficult to advance an analytical method for the determination of the wash load. At present, no methods exist for the prediction of the wash load. The wash load depends more on the hydrological, geomorphological, and meteorological conditions within the drainage basin (see Graf, 1971, 1984, p. 232), namely on the overland surface erosion and less on the erosion in the stream bed. In order to obtain quantitative information on the wash load, measurements in the field must be performed. One measures thus the total suspended load, $q_{ss} + q_{sw}$. Subsequently the suspended load, q_{ss} (see Section Suspended-load transport), is calculated, and consequently the suspended wash load, q_{sw}, can be obtained.

[1]*Department of Civil Engineering, University of Glasgow, Glasgow, UK*
[2]*School of the Built Environment, Heriot–Watt University, Edinburgh, UK*

Computational river models are in widespread use for estimating flood extent and the effectiveness of proposed flood mitigation schemes. This paper investigates the application of commonly used computational models to river floods, highlighting the advantages and shortcomings and current research activity. 1D, quasi-2D, 2D, and 3D computational models are applied to simulate a large-scale physical model tested in the Flood Channel Facility (FCF), Wallingford, as well as field data from the River Severn near Shrewsbury. The results reveal that commonly used 1D models give a reasonable representation of flood levels and flood extent but do not include floodplain/main channel interaction losses associated with compound flows and can be in error in their predictions. This deficit can be overcome in a straightforward manner by using a modified conveyance at each cross section based on the depth-integrated turbulent form of the Navier–Stokes equation. This so-called Lateral Distribution Method (LDM) has been incorporated into a new Conveyance Estimation System (CES) funded by the EA/Defra Joint Research Programme in Flood and Coastal Defence and developed by HR Wallingford Ltd for use with 1D models. Alternatively, 2D models can be more useful when simulation of flood inundation extent is important. The use of 3D models is becoming more common due to their ability to simulate very complex flow patterns over short river reaches. Initial results indicate that the choice of mesh discretization in a 3D model has a significant influence on the ability of the model to reproduce secondary velocity fields correctly. Problems of data requirements, friction and free surface representation still persist in 3D models in general.

INTRODUCTION

The use of computer modeling in flood risk management is continuing to grow. This is related to the rapid increase in desktop computing facilities and the consequent decrease in the cost of computations. Indeed, decisions for many flood risk management strategies are now based exclusively on results from computer model predictions. Inherent in this observation is the assumption that computer simulations are accurate as well as cost-effective; otherwise, basing important strategic decisions on their output would be foolish. The results of computer simulations are only as good as the physical laws incorporated in the governing equations and the boundary conditions used to drive them. From the following, it is clear that these continue to improve.

ONE-DIMENSIONAL (1D) MODELS

These models are used widely for the simulation of flood wave propagation over relatively long lengths of rivers. They are well proven and work well for what they are designed for, that is, calculating flows and water levels during the propagation of floods through the river system. Their governing equations are based on the assumptions that water pressure is hydrostatic, water level is horizontal across the channel, and that the stream-wise component of velocity is dominant. This means that only two equations describing the conservation of mass and momentum along the river's longitudinal axis need be used. Yen (1973) provides a formal derivation of these equations, often referred to as the St. Venant equations. They can be written as,

$$B\frac{\partial \eta}{\partial t} + \frac{\partial Q}{\partial x} = q \tag{1}$$

Conservation of mass

$$\frac{\partial Q}{\partial t} + \frac{\partial}{\partial x}\left(\frac{\beta Q^2}{A}\right) + gA\frac{\partial \eta}{\partial x} + gAS_{\mathrm{f}} = 0 \tag{2}$$

Conservation of momentum

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

where Q is the river discharge, η is the water elevation, B is the flow top breadth, q is the lateral inflow per unit length, A is the flow area, R is the hydraulic radius, S_f is the friction slope, and β the momentum correction factor, which accounts for the fact that the velocity distribution over the cross section is nonuniform. The friction slope can be evaluated using any of the uniform flow friction laws.

$$Q = K(S_f)^{1/2} \tag{3}$$

where K is termed the channel conveyance.

Using Manning's equation

$$Q = \frac{AR^{2/3}}{n}(S_f)^{1/2} \tag{4}$$

$$K = \frac{AR^{2/3}}{n} \tag{5}$$

At certain river sections, such as bridges, weirs, local expansions or contractions, equations (1) and (2) do not apply and empirical laws must be used. These equations, when furnished with suitable initial conditions, may be solved by a numerical method to give flows and stages throughout the modeled river reach. Boundary conditions usually consist of specified flow hydrographs at upstream boundaries and specified water stages or rating curves at downstream boundaries, although alternative boundary conditions are possible. Cunge, *et al.* (1989) give a fuller description of the method and techniques involved.

In recent years, research in 1D modeling has focused on improving the physical representation of energy loss through the development of enhanced conveyance estimation techniques and better prediction of lateral floodplain inundation.

At present, cross-sectional conveyance for 1D river modeling is estimated using the divided channel method and a uniform flow law such as Manning's equation, Figure 1. In this approach, Manning's 'n' is a lumped parameter that attempts to account for all energy losses occurring between each model cross section. The advances in quasi-2D modeling described in the next section have provided the opportunity to improve upon this technique and explicitly include in 1D models the energy loss due to lateral shear stress and other second order effects such as flow expansion, contraction, and recirculation. The method underpins the calculation adopted in the newly developed Conveyance Estimation System (CES), HR Wallingford (2003). Here, equation (6) is solved to provide the depth-averaged velocity distribution across a channel cross section throughout the full range of flood stages. These are then integrated to provide a stage-discharge curve. This can be converted to a stage-conveyance curve using a representative slope (normally taken as the bed slope). Unlike the stage-conveyance curve obtained from the divided-channel method, this technique provides a stage-conveyance curve that includes the influence of secondary energy loss mechanisms. The CES software is currently being evaluated; however, examples of the application of the method can be found in Ervine and MacLeod (1999) and Forbes and Pender (2000).

The assumption that the water surface is horizontal at each channel cross section limits the ability of 1D models to simulate the exchange of water between the main channel and the floodplain. Traditionally, a storage cell approach has been adopted (Pender and Ellis, 1990; Pender, 1992), where the storage ponds are relatively large polygons hydraulically linked to the main channel and each other by weir or uniform flow laws. The increased availability of high-resolution, remotely sensed floodplain topography data has provided opportunities to develop enhanced techniques for the simulation of 2D flood inundation. These fall into two categories – raster flood routing and hydrodynamically linked 1D/2D modules. Considerable effort is currently going into the development and enhancement of raster models. Bates and De Roo (2000) describe the explicitly formulated raster flood routing model LISFLOOD-FP; whereas, Sen (2002) describes an alternative implicit formulation. The popularity of this technique arises from the

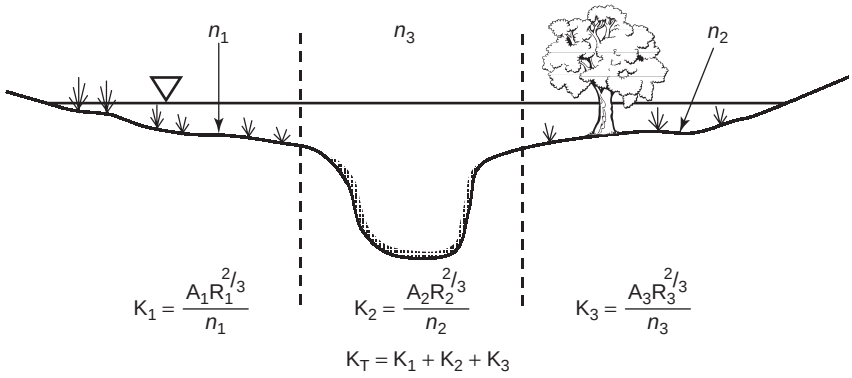

Figure 1 Divided Channel approach in flood modeling

fact that the data format means that results are easily integrated into commercial GIS software to provide a powerful tool for flood risk management decision makers, Wicks *et al.* (2003).

QUASI-2D MODELS

For over-bank flows, the depth-averaged velocity is clearly more complex, as sketched in Figure 2. A one-dimensional model is unable to predict the lateral distribution of velocity or shear stress, and hence the effects of shape and channel/floodplain interaction are not accounted for in 1D models. Improved methods for computing lateral distribution of velocity and shear stress are based on a quasi-2D approach (Wark *et al.*, 1990; Shiono and Knight, 1991; Ervine *et al.*, 2000). These methods are now being incorporated into a CES (HR Wallingford, 2003). Most lateral distribution methods (LDM) are based on the depth-integrated form of the Navier–Stokes equations:

$$\rho g H S_o - \frac{1}{8}\rho f U_d^2 \left(1 + \frac{1}{s^2}\right)^{1/2} + \frac{\partial}{\partial y}\left\{\rho \lambda H^2 \left(\frac{f}{8}\right)^{1/2} U_d \frac{\partial U_d}{\partial y}\right\} = \frac{\partial}{\partial y}\{H(\rho \overline{UV})_d\} \quad (6)$$

The first term in equation (6) represents the weight of fluid component in the longitudinal direction, the second term the bed friction, the third term the lateral shear (eddy viscosity), and the right-hand side term the secondary currents (3D mixing). Equation (6) was solved by Ervine *et al.* (2000) using the assumption that the temporal mean velocity components on the left-hand side of equation (6) are related to the depth-averaged velocity in a simplistic way by:

$$\overline{U} = K_1 U_d \quad (7)$$

$$\overline{V} = K_2 U_d \quad (8)$$

and by extension;

$$\overline{UV} = C_{uv} U_d^2 \quad (9)$$

The term $C_{uv}U_d{}^2$ is used to simulate a complex 3D mixing process that includes a horizontal shear layer, mass exchange in and out of the main channel, as well as expansion and contraction losses. C_{uv} is an empirical coefficient that varies with the geometry and roughness of the boundaries. Clearly, channel geometry has a large part to play in the magnitude of secondary cells. In each case, the transverse component V is closely associated with the depth-averaged velocity U_d, although the exact relationship is unknown. Ervine *et al.* (2000) showed that this simple approximation, when combined with good estimates of transverse turbulent shear stress, could produce much more satisfactory prediction of depth-averaged velocities.

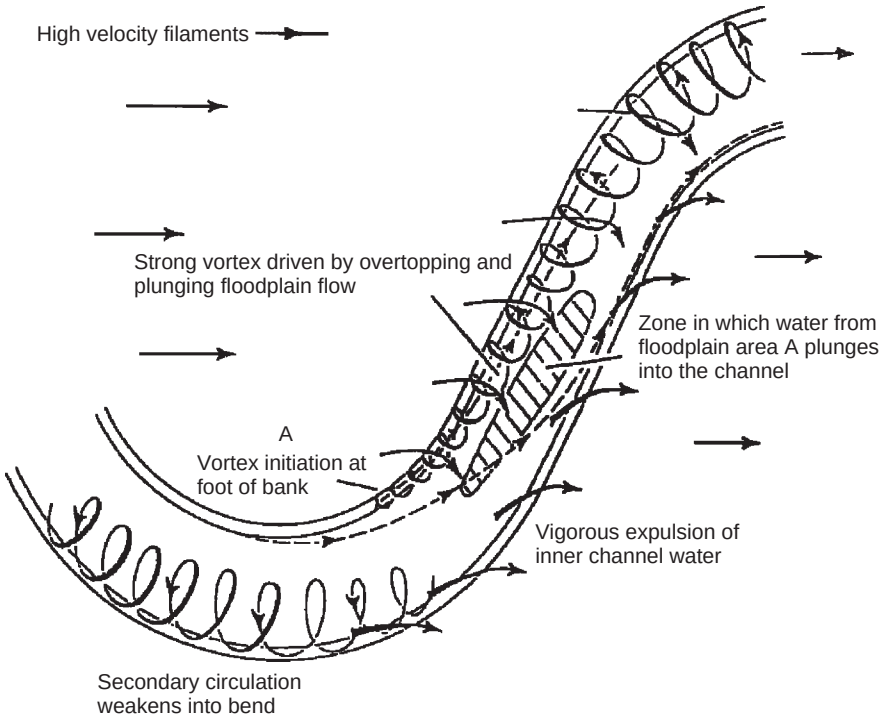

Figure 2 Complex flow patters in meandering overbank flows

To illustrate this, equations (6) and (9) are combined and applied to Flood Channel Facility FCF-Series B data with the comparison shown in Figure 3. This shows the depth-averaged velocity prediction for test B23 (60° cross-over angle meander, with trapezoidal main channel and smooth flood plains, depth = 0.2 m) at a bend apex. Clearly, a C_{uv} value of 5.5% greatly improves predictions at least in the main channel.

A more effective test of the validity of combining equations (6) and (9) is to compare the output with measurements of boundary shear stress. The present analytical solution is used to predict the boundary shear stress distribution

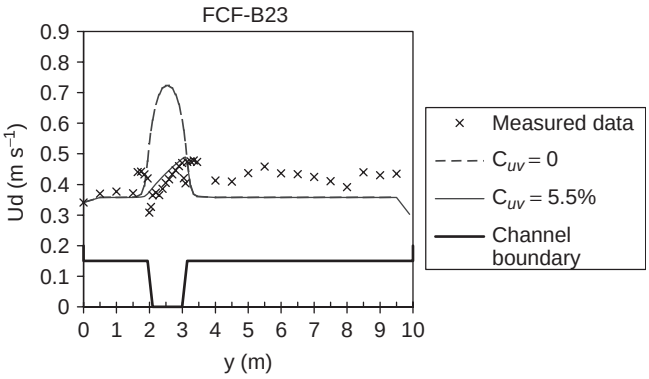

Figure 3 Comparison between analytical and experimental lateral distribution of depth-averaged velocity for meandering overbank flow. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

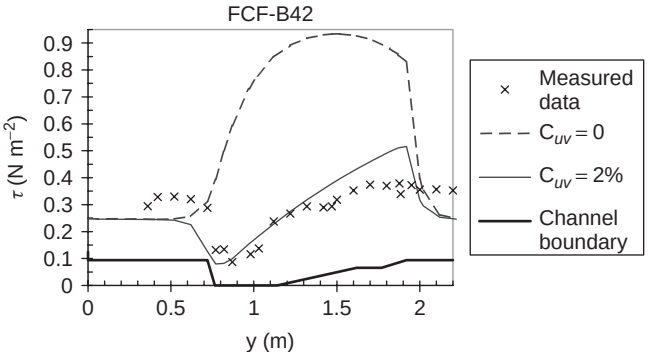

Figure 4 Comparison between analytical and experimental lateral distribution of boundary shear stress distribution for meandering overbank flow. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

for other FCF data. Figure 4 shows the boundary shear stress distribution for experiment FCF-B42, the quasi-natural cross section, focusing in the region of the main channel and both excluding and including the secondary cell term in the main channel. The predictions in Figure 4 focus in the region of the quasi-natural main channel area and only prove satisfactory when the secondary flow term is included.

This method has been applied to predict depth-averaged velocity values in River Severn at Lower Farm near Shrewsbury during a flood of approximately 103 m^3 s^{-1}. The reach modeled is shown in Figure 5. Figure 6 plots the

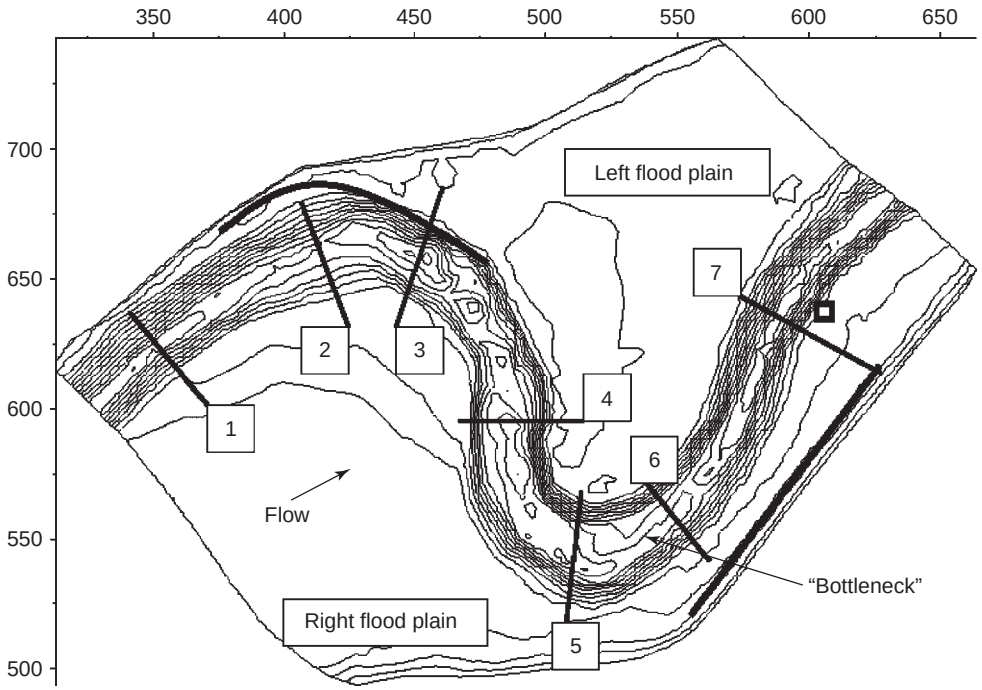

Figure 5 Site of three-dimensional flood measurements on River Severn

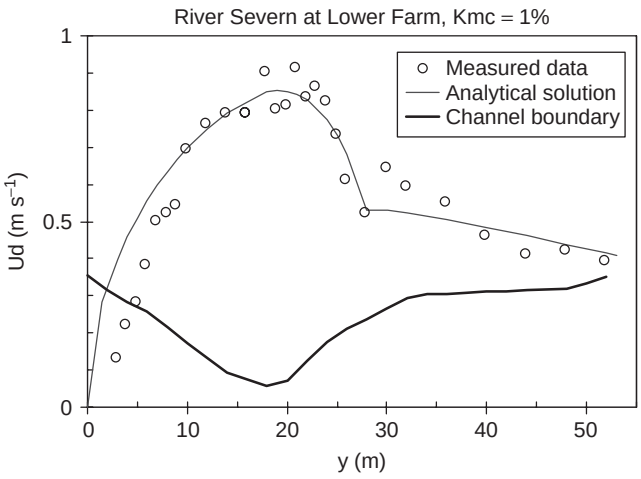

Figure 6 Comparison of measured and computed depth-averaged velocity at the River Severn for C_{uv} of 1%. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

predicted-against-measured depth-averaged velocity using the secondary current term $C_{uv} = 1\%$ for measurements at cross section 7. A reasonable correlation is revealed emphasizing the importance of secondary current term in predicting depth-averaged velocity values. The reduced value of $C_{uv} = 1\%$ reflects the distance downstream of cross section 7 from the previous bend. One would expect that the parameter C_{uv} would reflect the intensity of secondary cells in different channels and, therefore, the C_{uv} value for a meandering compound channel would be much greater than the one for a straight compound channel. The findings obtained so far indicate that $0.2\% < C_{uv} < 0.5\%$ for straight compound flows, and $2\% < C_{uv} < 5\%$ for meandering compound flows at least at a bend apex cross section.

TWO-DIMENSIONAL (2D) MODELS

When the river geometry results in both horizontal velocity components being important and strong vertical mixing promoted by bed roughness, then a depth-averaged form of the Reynolds' Averaged Navier–Stokes equations is appropriate. The depth-averaged equations may be written in a natural coordinate system as

$$\frac{\partial \eta}{\partial t} + \frac{\partial \overline{U}h}{\partial x} + \frac{\partial \overline{V}h}{\partial y} = 0 \tag{10}$$

Conservation of mass

$$\frac{\partial \overline{U}h}{\partial t} + \beta\left[\frac{\partial}{\partial x}(\overline{UU}h) + \frac{\partial}{\partial y}(\overline{UV}h)\right] + gh\frac{\partial \eta}{\partial x} + \frac{\tau_{\mathrm{bx}}}{\rho} + F_x - \frac{1}{\rho}\left[\frac{\partial}{\partial x}\mathrm{T}_{xx} + \frac{\partial}{\partial y}\mathrm{T}_{xy}\right] = 0 \tag{11}$$

Conservation of momentum in x direction

$$\frac{\partial \overline{V}h}{\partial t} + \beta\left[\frac{\partial}{\partial x}(\overline{VU}h) + \frac{\partial}{\partial y}(\overline{VV}h)\right] + gh\frac{\partial \eta}{\partial y} + \frac{\tau_{\mathrm{by}}}{\rho} + F_y - \frac{1}{\rho}\left[\frac{\partial}{\partial x}\mathrm{T}_{yx} + \frac{\partial}{\partial y}\mathrm{T}_{yy}\right] = 0 \tag{12}$$

Conservation of momentum in y direction

where η is the water elevation, $\overline{U}$ and $\overline{V}$ are depth-averaged velocities in the horizontal directions, β is the momentum correction factor, h is the water depth, τ_{bx} and τ_{by} are the bed shear stresses in the horizontal directions, $F_{x,y}$ represents some external body force, and T_{xx} and T_{xy} and so on are the horizontal stresses.

Appropriate boundary conditions for the solution of the above equations are the specification of flow or water elevation or some combination of the two at the open boundaries, and at closed boundaries some relationship describing the flow at water/land interfaces (zero flow normal to the land and a relationship between flow and stress tangential to the land).

The computational effort required to carry out 2D modeling is significantly higher than for 1D modeling, but resulting simulations are better able to represent flow events; such as, the extent of flood inundation following a dam break and flow separation (recirculation and dead zones). The first models used finite difference techniques (Leendertse, 1967; Vreugdenhil and Wijbenga, 1982) and the method characteristics (Townson, 1974). With the development of the finite element method (Brebbia *et al.*, 1978) and associated numerical techniques (Brooks and Hughes, 1982; Hervouet, 1991), enhanced hydraulics codes were produced, such as RMA-2 (King and Norton, 1978) in the early 1970s and TELEMAC-2D in the late 1980s (Hervouet, 1991). The finite element method proved useful in representing complex geometries; however, it is a demanding method to implement numerically and possess limitations in its ability to conserve mass. Recently, the finite volume method has emerged as the preferred numerical technique for 2D flood modeling because of its conservative properties, numerical accuracy, and simplicity in application (Sleigh *et al.*, 1998).

Recent research has focused on the treatment of wetting-and-drying and adaptive meshing to capture flood spreading and inundation (Lynch and Gray, 1980; Akanbi and Katopodes, 1988; Tchamen and Kahawita, 1998). In particular, the work by Bates *et al.* (1993, 1996) has illustrated the capability of the finite element code TELEMAC-2D to reproduce the transit of a flood wave and the corresponding flood map dynamically. Such codes can now support river models of up to 60 km (Bates *et al.*, 1996).

As mentioned earlier, the need to improve predictions of flood inundation extent to support flood risk management decisions has resulted in research into the development of hybrid 1D/2D models, Dhondia and Stelling (2002). These models utilize 1D modeling techniques to simulate flows through the river network with dynamic linking to 2D hydrodynamic models for the simulation of floodplain flows. Dhondia and Stelling (2002) provide a case study of such a technique applied to the Sistan–Baluchistan River Basin in the Islamic Republic of Iran and Wicks *et al.* (2004) discuss the performance of various modeling methods applied to urban inundation in London, UK.

THREE-DIMENSIONAL (3D) MODELS

The complex topography of natural channels and their flood plains results in a velocity field that is highly three-dimensional. This has implications for the mechanics of sediment entrainment and deposition as well as pollutant mixing and dispersion. Models that represent three-dimensional flow are referred to as 3D models. TELEMAC-3D, FLOW 3D, and CFX computational software are typical of this group.

Some three-dimensional flow mechanisms for simple meandering compound channels are shown in Figure 2. The primary flow direction within the main channel (below the bank full level) tends to follow the channel sidewalls (the stream-wise direction), whereas on the floodplain, above bank full level, the flow tends to follow the general valley direction. As a result, a horizontal shear layer develops at around the bank full level in the main channel, especially at the cross-over region. A bulk exchange of fluid between the floodplain and the main channel takes place; this is particularly pronounced in the cross-over region. The fluid near the outside of the main channel emerges onto the adjacent floodplain shortly after each bend apex. On the other hand, the flow from the upstream floodplain is partially entrained by secondary flows in the main channel as it passes over the cross-over region and, consequently, a local plunging zone is found in this locality.

Morvan *et al.* (2000) have used CFX 4 to model the FCF–B23 experiment as discussed in the section on quasi-2D models. The total flow depth is 200 mm, giving a 50-mm depth on the floodplain. The discharge is set at $0.25\,m^3\,s^{-1}$. The roughness height of the mortar surfaces has been calculated from Manning's "*n*" values to be between 0.2 mm and 0.8 mm. A first CFX model was built using a mesh with 49 200 cells to model the downstream half of the FCF flume. During preliminary calculations, it became apparent that the discretization close to the walls was insufficient, and affected the solution. To achieve a better level of mesh independence a second mesh was constructed using 218 120 elements for half the flume length.

At the inlet, a velocity profile was set so that the overall mass flow is equal to $250\,kg\,s^{-1}$. The turbulent kinetic energy was set to 9.0×10^{-4} ($m^2\ s^{-2}$) and the dissipation length scale to 0.1 m. The outlet mass flow matches that of the inlet. The wall boundary is modeled using a simplified rough wall boundary equation as:

$$\frac{u_\tau}{u_*} = \frac{1}{\kappa}\ln(E' y^+) \tag{13}$$

with,

$$E' = \frac{E}{(1 + 0.3k_s^+)} \tag{14}$$

where κ is the von Karman constant, y^+ is the nondimensional distance from the wall, E is the law of the wall constant, and k_s^+ is the nondimensional roughness height. This is in agreement with other correction terms given in the literature for open-channel flows at high Reynolds number, but less satisfactory at the lower end of the turbulent transition region. The free surface is modeled as a rigid lid. This assumption is acceptable at low Froude numbers, provided there are no large oscillations of the free surface. The pressure field is monitored to ensure the correctness of this assumption.

The results for the velocity at the bend apex and cross-over sections obtained using a k-ε turbulence model are shown on Figure 7 (looking downstream). They should be compared with the actual laboratory data in Figure 7. At the bend apex cross section, flow separation from the inner bank of the main channel is reasonably well represented, although the floodplain flow on the left bank seems to have too much impact on the main channel flow in the model. The cross-over region is adequately modeled, and the rotational impact of the floodplain flow is clearly visible. Along the left bank, a very strong vertical velocity field can be seen. The vertical distribution of secondary velocities of the principal secondary cell in the main channel at the cross-over section is shown in Figure 8(a), and can be compared with the measured FCF data in Figure 8(b). The intensity of the rotation at this location is reproduced well.

A similar exercise has been conducted for velocity data at the River Severn, near Shrewsbury. A plan view of the river reach is shown in Figure 5. Figure 9 and 10 show the comparison between the predicted and measured velocity profiles with depth at cross-sections 4 and 5 in the vicinity of the second bend in the reach. These data were recorded during a flood in October 2000 with flood discharge of the order of $100\,m^3\ s^{-1}$. Comparisons exhibit considerable discrepancy between measured and computed, calling into question both measurement accuracy and accuracy of frictional representation and discretization in the model. Clearly, this science is still in its infancy.

CONCLUSIONS

It is apparent that river flooding is on the increase, and also that there needs to be continued research and development of computational models for predicting flood flows. The choice of model is dictated by the information required to support decision making. 1D models are appropriate for decision support at reach and catchment scales, 2D models are useful where inundation extent and plan velocity fields are important issues, and 3D models are finding greater application in river engineering where detailed 3D velocity fields are required.

Commonly used 1D models are usually adequate to simulate flood levels and, to some degree, lateral extent of flooding. They can provide more useful information when combined with GIS, and future trends indicate an integration of 1D models with 2D flood-spreading algorithms that utilize remotely sensed data. Until now, 1D models have not included floodplain/main channel interaction losses associated with out-of-bank flows. The effect of these interactions has recently been incorporated into ISIS using modified conveyance at each cross section.

The analytical solution to the quasi-2D depth-integrated turbulent form of the Navier–Stokes equation that takes into account the secondary flow term in the formulation, has been shown to predict the distribution of depth-averaged velocity with some accuracy. The value of C_{uv} required to represent secondary cells varies from 0.2% to 0.5% for straight channels and 2% to 5% for meandering channels.

The use of three-dimensional models in natural channels with flood plains is in its infancy. A number of problems arise, including the mode and degree of discretization, handling of roughness and flow resistance, handling of the free surface, and other effects. The FCF flume and the River Severn have been simulated three-dimensionally using the CFX code. The results demonstrate the ability of the CFX model to reproduce complex flow hydrodynamics adequately by using a simple turbulence model, particularly in the FCF. The River Severn comparison is more problematic, emphasizing the need for careful, detailed field data. The results indicate that the choice of mesh discretization has a significant impact on the ability of the numerical scheme to reproduce secondary velocity fields correctly; however, increasing computer power and improved numerical techniques, such as unstructured grids and coupled solvers, suggest that this could be a short-lived concern.

142: Debris Flow

ARONNE ARMANINI, LUIGI FRACCAROLLO AND MICHELE LARCHER

CUDAM and Department of Civil and Environmental Engineering, University of Trento, Trento, Italy

The principal features of debris flow are described. One section is devoted to debris-flow triggering, accounting for the geomechanical criteria by Takahashi (1978) and for most recent hydrological distributed models. In a second section, the rheology of debris flows is described: the theory of dispersive stresses by Bagnold, the kinetic theories of dense gases, and some recent experimental observations about debris flows in equilibrium. A section is devoted to mathematical models and the final section discusses debris flows countermeasures.

INTRODUCTION

Debris flow is a motion of widely sorted debris (from a few millimeters to some meters) inside a watery matrix or also in the presence of clayish mud. One of the most evident facts is the floatation of huge boulders on the surface of the debris flow. Taking up the original definition proposed by Takahashi (1981), debris flows are *massive sediment transport* phenomena that manifest themselves in mountain streams characterized by a steep slope, where the motion of the granular phase is induced directly by gravity. Here, the ratio between the liquid and the solid transport rates is relatively low, and can be zero in case of dry granular mixtures (e.g. dry landslides). On the contrary, in the case of ordinary sediment transport (bed load and suspended load), sediments are not driven directly by gravity, but by the hydrodynamic actions induced by the fluid, and liquid–solid transport ratio is relatively high. There is a wide range of two-phase sediment-laden motions for which this distinction is not so sharp. Other situations outside simple schemes concern cases where, although the solid transport rate is in the debris-flow range, the finest fractions of the grain distribution change the rheology of the interstitial fluid. In fact, the role of fine sediments, because of their size, and in some cases, of their electrochemical properties, is completely different from the coarser ones: they can mix with water, forming a homogeneous interstitial fluid (slurry), typically characterized by high viscosity and in some cases by cohesive behavior. Its composition is strongly connected to the flow dynamics, making it very difficult to define and distinguish the role of the two phases. Further, complications take place when a third phase, constituted by air and other gases, is present inside and affects the flowing mixture, such as in the stout front of advancing debris-flow waves.

The picture presented above is mirrored by manifold classifications found in literature, where massive phenomena involving the liquid and solid phase are reported with different terminology: for example, *debris flows, mud flows, hyperconcentrated flows*, and so on, any of them possibly being preceded by adjectives such as *turbulent, laminar*, and so on. Recently, the knowledge about granular flows has progressed a lot, and nowadays (2003) there is a wide literature regarding both the rheological features of these kinds of flows and the applicative aspects concerning design criteria for defence and protection works.

As a rule, there are at least two fundamental elements that must be present for the triggering of a debris flow: an opportune succession of rain events and the availability of solid material. As better explained afterwards, the weather event has to present absolutely particular characteristics: generally it must be very intense, but in order to be able to move the bulk it must also be preceded by an event long enough to take the sediments to saturation. The concomitance of these happenings gives little predictability to debris-flow events that are relatively rare, but present a remarkable destructive power; they concern above all small basins and in particular alluvial fans that have often undergone a recent urbanization. Basically, they are nonstationary phenomena developing in particularly

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

short times. Because of their unexpected character, their destructive power is often undervalued: small creeks that are affected by very modest solid or liquid events for decades, are sometimes affected by debris flows of huge intensity. The recurrence of such events, in fact, is very difficult to determine; systematic observations show that the debris flows have return times of the order of 50–100 years, a period of time during which the phenomenon is likely not to manifest at all. Unlike floods in water streams, in which some extreme events happen almost regularly every year, even though with a different intensity, for debris flows it is exactly the sudden and often unexpected triggering that makes the phenomenon insidious.

DEBRIS-FLOW TRIGGERING

The assessment of debris-flow risk is very difficult as three main factors participate in the triggering of debris flows: the rainfall intensity, the initial state of the basin soil moisture, and the presence of enough sediment. The analysis of many different events has shown that generally the debris flows manifest themselves after an extreme rainfall event following a rainfall of long duration. In a certain area, in fact, debris flows usually occur when the antecedent rainfall intensity exceeds a certain critical value. Yet, it is necessary that in a suitable previous period (of the order of 7 to 10 days) a congruous volume of rain has fallen, making at least part of the valley saturated.

A more physically based approach consists in using a steady-state shallow subsurface flow model (e.g. *TOPMODEL* by Beven and Kirkby, 1979) to evaluate the saturated areas and their expansion during the storm. However, unlike landslides generated in hillslopes by subsurface flow, debris-flow initiation is mainly due to surface runoff and a complete rainfall-runoff model is required. If design of defence works is implied, a special kind of rainfall representation could be useful in the form of intensity-duration-frequency (IDF) curves that relate the rainfall intensity and duration to a prescribed return time. If just the peak discharge is required, some simplified models are available and are sufficient for this goal (Rigon *et al.*, 2005). According to the theory presented below, once the runoff creates a flow depth greater than a suitable threshold, the slope collapses and the debris-flow run-out starts. This critical value depends obviously on the geometric, geologic, and morphologic characteristics of the debris deposit and of the sublayer on which it lies.

This approach alone is, however, not sufficient to get the total of sediment mass moved. Besides the weather events, there must also be a deep-enough debris storage so that the frequency of debris flows does not coincide with that of intense rainfall events. Hampel (1968) distinguishes between watercourses with a rocky channel bed and those which flow on erodible alluvial deposits. The former require a gradual debris accumulation between an event and the following ones and are temporarily stable after the event; the latter can be destabilized by an event and this can bring about a period of activity with rather high frequencies, followed by the return to a state of rest. The use of stochastic models to assess the contemporary presence of all the conditions required is presently (2003) being studied, but it is still not sufficiently tested to be utilized in field applications (Iida, 1999).

A further possibility of debris-flow generation is obviously due to the dynamic action of landslide in their run-out from hillslopes into channels or the collapse of retention structures existing along the mainstream. The total quantity of debris that rests after the event is usually due both to the size of the source of material (especially if it derives from a landslide) and to the dynamics of the debris flow, which erodes the bed on which it is moving.

Takahashi (1978) first introduced the stability theory regarding loose materials for the study of debris-flow triggering. This theory refers to a noncohesive and uniform granular body and is based on the balance of forces acting in different imbibition conditions. The Takahashi instability condition is written as follows:

$$\tan\alpha \leq \tan\varphi \frac{C_0\Delta}{1 + C_0\Delta + \dfrac{1}{n}\dfrac{h_0}{D}} \tag{1}$$

where α is the inclination angle of the deposit, φ is the friction angle of the material, C_0 is the volume concentration of the particles in a state of rest, h_0 is the flow depth of the water flowing over the deposit (in uniform-flow condition), $\Delta = (\rho_s - \rho)/\rho$ is the relative density of the immersed material, D the mean diameter of the material, and n is a nondimensional coefficient of the order of the unit depending on the shape and distribution of the grains. Note that if $h_0 = 0$, corresponding to a *completely saturated* body with no surface runoff, the stability condition becomes:

$$\tan\alpha \leq \tan\varphi \frac{C_0\Delta}{1 + C_0\Delta} \tag{2}$$

Once in movement, the body is soon transformed into a debris flow. In this situation, the dynamic friction can also move the material lying underneath the layer initially made unstable; this phenomenon is known as *mass entrainment*. Moreover, according to Takahashi (1978) the values of the ratio (h_0/nD) able to generate a real debris-flow range between 0 and 1.33. For values below 0, there is a partially dry deposit which, when it becomes unstable owing to big enough slopes, gives rise to a landslide. For values over 1.33, there is a movement more similar to bed load rather than to debris flow. In short, according to Takahashi, the

slopes for which there is debris-flow range between the two following extremes:

$$\tan\varphi\frac{C_0\Delta}{1+C_0\Delta+1.33}\le\tan\alpha\le\tan\varphi\frac{C_0\Delta}{1+C_0\Delta} \qquad (3)$$

If, for example, for the above-cited parameters we assume the following values that are characteristic of stony, noncohesive material, $C_0 = 0.7$, $\Delta = 1.65$, $\tan\varphi = 0.8$, we obtain:

$$15°9' \le \alpha \le 23°5' \qquad (4)$$

Once the movement is triggered, the debris flows can flow even with slopes smaller than the limit on the right of relation (4). Anyway, with slopes lesser than 3° the debris flows do stop. Consequently, the basins that are more frequently affected by debris flows are those in which the presence of hillslopes or torrents with slopes comprised between the limits listed above are statistically more important.

The analysis of the historical events in the different regions suggests that the debris-flow phenomena regard essentially small catchments, generally from 2 to 10 km^2. Other elements that are important for the debris-flow formation are the geology and the vegetative cover. It is evident that the presence of vegetation inhibits strongly the debris-flow formation; therefore, debris flows are more likely to form above the vegetation limit. After all, it is at higher elevations that there are hillslopes with a slope ranging between the limits cited.

Other mechanisms generating debris flows are given by landslides depositing in the channel bed, or by the collapse of a natural dam which was formed temporarily in the channel bed because of the stop of vegetation transported by the current, or else by the collapse of some retention structures (in particular check dams) built along the mainstream of the river affected by an initial debris flow.

DEBRIS-FLOW RHEOLOGY AND DYNAMICS

Once started, debris flows tend to assume a typical layout, formed by a round-shaped *front* in which the biggest boulders tend to accumulate, followed by a *body* in which the free surface is nearly parallel to the undisturbed debris bed. In this part, the motion can be assumed to be close to the uniform motion. The central part with uniform motion is followed by a *tail*, in which the flow depth becomes thinner and where the zone of erosion is exposed (see Figure 1).

It is possible to study the behavior of the motion in the different parts of the debris flow separately. It is, above all, the part with quasi-uniform motion that becomes significant, since the hypothesis of uniform flow makes it possible to give a detailed determination of kinematic and dynamic

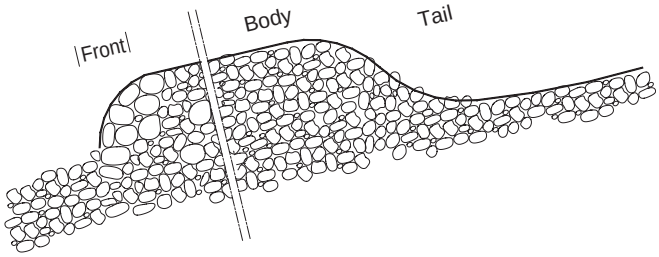

Figure 1 Scheme of the longitudinal section of a debris flow: in the central part (body) the motion is quasi-uniform

conditions. The study of debris-flow dynamics requires the knowledge of the interaction between particles and interstitial fluid, between the contour, the particles, and the interstitial fluid, and among the particles themselves. Therefore, the quantitative description of debris-flow dynamics is very complex. It is often convenient to consider the debris flow as a continuous medium, to which is assigned a suitable rheological law able to simulate the different interactions between particles, fluid, and wall. In fact, a granular material subjected to deformation can determine different types of interactions among grains and, therefore, it can generate stresses by different mechanisms. Individual particles may interact with one another in rigid particle clusters, generating a network of contact forces through sustained rolling or sliding contacts, or by nearly instantaneous collisions, during which momentum is exchanged and energy is dissipated because of inelasticity and friction. The relative importance of these mechanisms may be used as the characteristic defining the various flow regimes (Savage, 1984). Basically, the main interactions can be listed as follows:

- deformation of the mean fluid field by the particles;
- collisions among the particles;
- friction among the particles during long contact periods;
- deformation of the turbulence structure generated by the wall.

Depending on particle concentration and hydrodynamic conditions, some of the mechanisms described above can prevail with respect to the others.

Theory of Dispersive Stresses

Theoretical and experimental findings by Bagnold (1954), regarding the rheology of a gravity-free dispersion of large solid spheres in a Newtonian fluid under shear, probably represent the most extensively cited research over the last 50 years among scientists involved in the study of debris flows, snow avalanches, and of the flow of granular materials in general. Bagnold's theory presents some conceptual limits that have been analyzed in detail in the recent literature, among others by Hunt *et al.* (2002). Yet, it has the merit of being simple and of being the first

one that indicated the physics of the phenomenon clearly; moreover, it has been successfully applied to debris flows, above all by Takahashi (1978).

The theory is based on the observation that when particles collide among themselves or on the containment wall, collisions manifest themselves as an increase in pressure called *dispersive pressure*. According to Bagnold (1954), two extreme situations can occur. The first one occurs in the presence of particles of small size being well dispersed within the interstitial fluid: the debris flow assumes then a *macroviscous* behavior and the viscous stresses prevail with respect to the dispersive ones because of the intergranular collisions.

On the contrary, an opposed situation occurs when the particles have high concentrations and the debris-flow speed is high, and then the collisions are much more frequent. In this regime, called *grain-inertia*, the collisions among grains are the determining factors as to the debris-flow resistance and the effect due to the viscosity of the interstitial fluid is negligible.

Bagnold distinguished *grain-inertia* and *macroviscous* flow regimes on the basis of the nondimensional parameter B_a presented in equation (5), subsequently termed *Bagnold number*, representing the ratio between stresses due to inertia and those due to viscosity.

$$B_a = \rho \frac{D^2(du/dz)}{\mu}\lambda^{1/2} \text{ with } \lambda = \frac{1}{(C_0/C)^{1/3} - 1} \qquad (5)$$

where D is the grain diameter, λ is Bagnold *linear concentration*, C is the volume concentration of the solid fraction, C_0 is the maximum concentration possible (*concentration at rest*), du/dz is the shear rate, μ and ρ are the dynamic viscosity and the mass density of the interstitial fluid. Bagnold called *macroviscous* the regime characterized by small Bagnold numbers ($B_a < 40$), where the shear stresses behave like a Newtonian fluid with a viscosity corrected by the presence of the particles, and *grain-inertia* the other regime, is characterized by $B_a > 450$, where the stresses were independent of the fluid viscosity and proportional to the square of the shear rate and to the square of the linear concentration λ. The intermediate range of Bagnold number ($40 < B_a < 450$) occupies a transitional region.

Bagnold derived simple analyses to explain the rheological behavior in the two limiting regimes. In the viscosity-dominated *macroviscous regime*, shear and normal stresses are linear functions of the shear rate du/dz. Bagnold identified the presence of a normal stress in radial direction, termed *dispersive pressure*, and attributed it to a statistically preferred anisotropy in the spatial particle distributions. He proposed the following relations for the shear stress τ and the normal stress σ:

$$\text{in the macroviscous region}: \tau = 2.25\lambda^{3/2}\mu\frac{du}{dz}$$

$$\sigma = \frac{\tau}{\tan\varphi} \qquad (6)$$

$$\text{and in the grain-inertia region}: \sigma = 0.042\rho\left(\lambda\frac{du}{dz}D\right)^2\cos\varphi$$

$$\tau = \sigma\tan\varphi \qquad (7)$$

It should be noted that both in the macroviscous and in the grain-inertia regime, the normal stress is proportional to the shear stress in the form $\tau = \sigma \tan\varphi$, where φ represents a dynamic friction angle, depending on collision conditions. Such behavior is reminiscent of the Coulomb criterion used to describe the stresses in cohesionless soils under conditions of limited equilibrium. According to Brown and Richards (1970), typical values for φ obtained during quasi-static yielding at low stress levels are close to the angle of repose, that is, about 24° for spherical glass beads and 38° for angular sand grains. Bagnold proposed a dynamic friction angle $\varphi \cong 37°$ for the macroviscous regime and $\varphi \cong 18°$ for the grain-inertia regime.

As a completion of Bagnold's theory, nowadays the macroviscous regime is considered to be practically absent in debris flows, while where the shear rate and the velocity of the fluid are small, a regime called *frictional* or *quasi-static* takes place, in which the contact among particles is quasi-permanent and the ratio between normal and shear stress can be considered roughly constant.

Kinetic Theories

Within a granular flow, the velocity of each particle may be decomposed into the sum of a mean velocity and a random component, taking into account the relative motion of the particle compared to the time-averaged value. Ogawa (1978) introduced first the concept of *granular temperature* T_s, where $3T_s$ is the mean square of particle velocity fluctuations as expressed by equation (8), and Savage and Jeffrey (1981) made the first attempt to make more substantial use of the ideas contained in the previous theoretical work that had dealt with dense gases, for example, Chapman and Cowling (1970).

$$T_s = \frac{1}{3}\langle u'^2 + v'^2 + w'^2\rangle \qquad (8)$$

In analogy with thermodynamic temperature, granular temperature plays similar roles in generating pressures and in governing the internal transport rates of mass, momentum, and energy.

Granular temperature can be generated with two distinct mechanisms (Campbell, 1990). The first, the so-called *collisional temperature generation*, is a by-product of inter-particle collisions, in the sense that two colliding particles

will have resultant velocities depending not only on their initial velocities but also on the type of collision they experienced; therefore, they will contain apparently random velocity components. The second mode of temperature generation, the so-called *streaming temperature generation*, is itself a by-product of the random particle velocities. Following its random path, a particle moving parallel to the local velocity gradient will acquire an apparently random velocity that is proportional to the difference in mean velocity between its present location and the point of its last collision. It should be noted that in both mechanisms of granular temperature generation, the magnitude of the generated random velocities is proportional to the local velocity gradient. However, unlike the collisional temperature generation, the streaming mechanism can generate only the component of random velocity lying in the direction perpendicular to the mean velocity gradient, therefore the generated granular temperature will be anisotropic.

Campbell (1990) describes how the physical similarity between rapid granular flows and kinetic-theory view of gases has led to a great deal of work on creating similar models for granular materials on the basis of the idea of deriving a set of continuum equations (typically mass, momentum, and energy conservation) entirely from microscopic models of individual particle interactions. All the models are based on the assumption that particles interact by instantaneous collisions, implying that only binary or two-particle collisions need to be considered. Particles are usually modeled in a simple way, ignoring surface friction or any other particle interactions tangential to the contact-point, and considering a constant coefficient of restitution to represent the energy dissipated by the impact normal to the point of contact between the particles, even though Lun and Savage (1986) and other researchers showed a strong dependence of the coefficient of restitution on the relative impact velocity. Furthermore, molecular chaos is generally assumed, this implying that the random velocities of particles are independently distributed.

Jenkins and Hanes (1998) apply kinetic theories to a sheet flow in which particles are driven by turbulent fluid and supported by their collisional interactions rather than by the velocity fluctuations of the interstitial fluid. Azanza *et al.* (1999) adapted kinetic theories to a channel flow in which the particles are driven by gravity. Armanini *et al.* (2005) accounted for the interstitial fluid interaction by means of an added mass coefficient.

The constitutive relation for the particle pressures is therefore:

$$\sigma = C\rho_s\left(1+\frac{r\rho}{\rho_s}\right)(1+4Cg_0)T_s \text{ where } r=\frac{1+2C}{2(1-C)} \tag{9}$$

The function $g_0(C)$ describes the variation of the particle collision rate with concentration, and was derived by Carnahan and Starling (1969) from considerations about the nearly geometric form of the virial series for nonattracting rigid spheres.

$$g_0(C)=\frac{(2-C)}{2(1-C)^3} \tag{10}$$

Again, the constitutive relation for the particle shear stress is taken to be the one for a dense molecular gas, in the form:

$$\tau = -\frac{8D(1+r\rho/\rho_s)\rho_s C^2 g_0 {T_s}^{1/2}}{5\pi^{1/2}}\left[1+\frac{\pi}{12}\left(1+\frac{5}{8Cg_0}\right)^2\right]\frac{du}{dz} \tag{11}$$

The balance of particle fluctuation energy is equal to that for the energy of the velocity fluctuations of the molecules of a dense gas. For inelastic particles, the gradient of the vertical component Q of the fluctuation energy flux, expressed by equation (13), is required to balance first the net rate of fluctuation energy production per unit of volume of the mixture, and secondly the rate of collisional dissipation γ_d:

$$\frac{dQ}{dz}=\tau\frac{du}{dz}-\gamma_d \tag{12}$$

where the first term (on the left-hand side) represents the energy diffusion, the second one the net rate of production (the rate of working of the particle shear stress through the mean shear rate) and the last one, γ_d, is the rate of collisional dissipation. Particles are driven into collisions by the mean motion, creating fluctuation energy, while the inelasticity of the collisions dissipates fluctuation energy into real thermal energy.

The constitutive relation for the flux of particle fluctuation energy is taken to be the one for a dense molecular gas, in the form given by Chapman and Cowling (1970), while the rate of collisional dissipation per unit of volume may be calculated using the Maxwellian velocity distribution function, in the form given by Jenkins and Savage (1983):

$$Q=-4\left[1+\frac{9\pi}{32}\left(1+\frac{5\pi}{12Cg_0}\right)^2\right]\frac{C^2 g_0}{\pi^{0.5}}\rho_s\left(1+\frac{r\rho}{\rho_s}\right)D{T_s}^{1/2}\frac{dT_s}{dz} \tag{13}$$

$$\gamma_d = 24(1-e)\frac{C^2 g_0}{\pi^{0.5}}\frac{\rho_s(1+r\rho/\rho_s)T_s^{3/2}}{D} \tag{14}$$

Savage (1998) developed a theory for slow, dense flows of cohesionless granular materials for the case of planar deformations, employing the notion of granular temperature. The conservation equations for mass, momentum, and particle fluctuation energy are employed. At

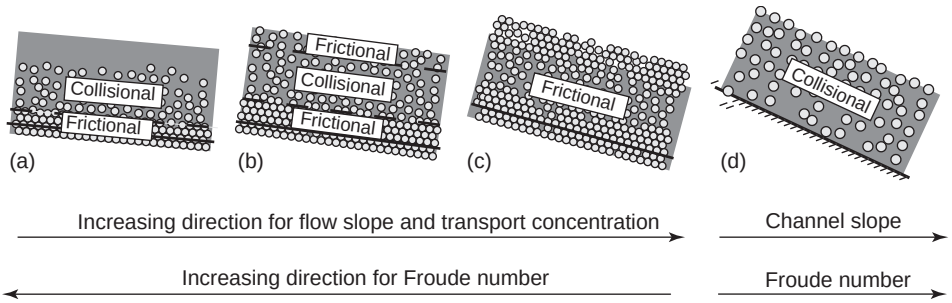

Figure 2 Typology of the flows examined: (a) loose bed, immature (or oversaturated) debris flow; (b) loose bed, mature debris flow; (c) loose bed, plug (or undersaturated) debris flow; (d) rigid bed debris flow

low deformation rates, the apparent form of the constitutive behavior is similar to that of a liquid, in the sense that the actual viscosity *decreases* as the granular temperature augments, contrary to rapid granular flows, in which viscosity *increases* as granular temperature augments.

Stresses are constituted by two parts: a rate-independent, dry friction contribution, and a rate-dependent viscous part, having a quadratic dependence on the shear rate, obtained from the high shear rate granular flow kinetic theories in the form of equations (9) and (11). The magnitude of the rate-independent contribution was chosen so that the sum of the two parts satisfied the overall momentum balance perpendicular to the flow direction.

Savage and Jeffrey (1981) introduced a parameter R, involving the particle diameter D, the square root of the granular temperature and the shear rate, written in the form:

$$R = \frac{D}{T_s^{1/2}} \frac{du}{dz} \tag{15}$$

As discussed in Savage (1998), in both analyses and computer simulations, typically the parameter R is found to be of the order of the unit for granular flows, ranging from purely collisional to slow, predominantly frictional flows.

Experimental Analysis

In contrast with previous experimental studies dealing with solid–liquid flows in annular shear cells, closed ducts, or nonrecirculatory chutes, the experimental analysis carried out in a steady uniform channel flow has shown that the dynamics of a free-surface debris flow constituted of sedimentable material is more articulated than what was predicted by Bagnold for gravity-less granular flows. Contrary to what was presupposed by Takahashi (1978) in adapting Bagnold's theory to debris flows, in the experiments it has been observed that a debris flow can present a series of layers one on top of the other, each governed by a different rheology. The experiments by Armanini *et al.* (2005) permit to distinguish four main regimes of interest (Figure 2): (a) loose bed, immature debris flow; (b) loose bed, mature debris flow; (c) loose bed, plug debris flow; and (d) rigid bed flow.

The first three regimes (a)–(c) exhibit loose-bed equilibrium conditions. The immature debris-flow regime (a) is characterized by the flow of a clear water layer over a fluid-driven sheet of granular material supported by contacts with the stagnant bed. For mature debris flow (b), the entire moving layer is composed of a mixture of liquid and grains. In the "plug" debris flow (c), a partially emerged, quasi-static assembly of grains translates over a liquid-granular shear layer.

The possibility for the flowing mixture to have an underlying bed formed by the same constituents (*movable bed*) leads to the formation of an *equilibrium condition*, since the slope of the bed is a dependent variable dynamically coupled with the flow. For nonequilibrium conditions, the mixture has to flow over a nonerodible bed, and in uniform-flow conditions, the free surface is parallel to the rigid bed of the flume; therefore the presence of the solid phase results somehow in a variable independent of the bed slope. In fact, in this case the solid discharge is smaller than the effective transport capacity of the current. The distinction between *equilibrium* and *nonequilibrium conditions* has of course a strong influence on the rheological processes throughout the cross section of the uniform flow. In fact, considering the profiles of the variables of interest in the stress formation (mean velocity, velocity fluctuations, and solid concentration), one can observe that they change enormously from cases with or without equilibrium. The experimental results made it possible to create a picture of the flow rheology that is rather simple: throughout the flow depth there are layers dominated by collisions among grains, whereas the complementary domains are essentially frictional. When the two rheological mechanisms coexist, the separation between collisional and frictional layers is represented as a rather sharp interface, correspondent to Stokes numbers, defined by equation (16), being equal to $5 \div 10$. Large Stokes numbers characterize collisional regions, while small ones

characterize frictional layers.

$$St = \frac{1}{18}\frac{\rho_s}{\rho}\frac{D^2 \mathrm{d}u/\mathrm{d}z}{\nu} \tag{16}$$

In equation (16), ν is the kinematic viscosity of the interstitial fluid and $D(\mathrm{d}u/\mathrm{d}z)$ represents the relative velocity between adjacent sheared rows of particles.

Moreover, the experimental vertical profiles of energy production, diffusion, and dissipation (Armanini *et al.*, 2003) lead to the conclusion that in the collisional layers energy production balances roughly energy dissipation, so that in equation (12) the diffusive term can be neglected. Exploiting this assumption, normal and shear stress described by equations (9) and (11) depend on the square of the shear rate, exactly like in Bagnold's grain-inertia theory, even if the ratio between shear and normal stresses is perfectly constant only in Bagnold's conjectures.

Global Relations for Debris Flows in Equilibrium

According to the descriptions above, a succession of frictional and collisional layers, one on top of the other, constitutes debris flows. However, considering the debris flow throughout its depth, if the frictional layers, characterized by small mean velocities, give a negligible contribution to the total discharge of the flow, uniform-flow formulas can be obtained referring only to the collisional/grain-inertia layers. For this purpose, it can be assumed (Takahashi, 1978) that the flow is steady and uniform and that the tangential projection of the entire burden of the flow (water + grains) is charged over the solid phase only, therefore assuming that the shear stress in the liquid phase is negligibly small. Moreover, the vertical component of momentum balance for the particle phase requires that the gradient in the particle pressure σ balances the buoyant weight of a unit volume of particles.

$$\frac{\mathrm{d}\sigma(z)}{\mathrm{d}z} = C\rho\Delta g\cos\alpha\frac{\mathrm{d}\tau}{\mathrm{d}z} = (C\Delta + 1)\rho g\sin\alpha \tag{17}$$

Under these hypotheses and considering the concentration C to be constant (which corresponds to assume the dynamic friction angle φ to be constant), it is possible to integrate Bagnold's grain-inertia rheological equation (7) combined with equation (17) throughout the flow depth, thus obtaining a relation between the mean velocity and the slope of the current in uniform motion in the same form of Gaukler–Strickler or Chezy formula. In this case, Chezy friction coefficient χ_{DF} is a function of the solid fraction, of the sediment size, of the ratio between fluid and solid density, of the friction angle φ of the material, and of the flow depth h.

$$U = \chi_{DF}\sqrt{h\sin\alpha} \quad \text{with } \chi_{DF} = \frac{2}{5}\frac{h}{\lambda D}\sqrt{g\frac{\rho}{\rho_s}\frac{(C\Delta+1)}{a\sin\varphi}} \tag{18}$$

Bagnold suggests to assume $a = 0.042$, while, on the basis of debris-flow laboratory data, Takahashi (1978) proposed a greater coefficient $a = 0.35$. This value corresponds in case of real debris flows (e.g. for $D = 5\,\mathrm{cm}$, $C = 0.56$, $\varphi = 36°$, $\Delta = 1.65$, $h = 3\,\mathrm{m}$, $C_0 = 0.70$, $\lambda = 13$) to a Chezy coefficient $\chi_{DF} = 11\,\mathrm{m}^{1/2}\,\mathrm{s}^{-1}$. The debris-flow concentration, if assumed to be equal to that of incipient movement in saturated conditions, can be expressed by the following relation as a function of the channel slope and of the relative density of the material:

$$C = \frac{\tan\alpha}{\Delta(\tan\varphi - \tan\alpha)} \tag{19}$$

Takahashi (1991) proposed empirical formulas similar to equation (18) when the regime is clearly not dominated by collisional particle interactions.

In case of viscous debris flow or mudflows, the problem fluid is often treated as a single-phase visco-plastic fluid, characterized by a Herschel–Bulkley rheology (Coussot, 1997). This kind of approach is particularly suitable when the presence of silt and clay is relevant. For low solid concentrations, the flows behave like a Newtonian fluid, while by increasing the concentration the mixture presents a yield stress τ_c and a nonlinear relation between the shear stress and the shear rate, as expressed by equation (20):

$$\tau = \tau_c + k\left(\frac{\mathrm{d}u}{\mathrm{d}z}\right)^n \text{ if } \tau > \tau_c$$
$$\left(\frac{\mathrm{d}u}{\mathrm{d}z}\right)^n = 0 \text{ if } \tau < \tau_c \tag{20}$$

where k and n are parameters depending on the type of fluid and on its concentration, to be determined by means of laboratory tests and by the utilization of a rheometer. Like equation (7), equation (20) expresses a rheological link between shear stress and shear rate, and therefore it can be integrated throughout the flow depth in order to obtain the mean velocity value in uniform-flow conditions.

$$U = \frac{n}{(n+1)h}\left(\frac{\rho_m g\sin\alpha}{k}\right)^{1/n}\left(h - \frac{\tau_c}{\rho_m g\sin\alpha}\right)^{1+(1/n)} \times\left[h - \frac{n}{2n+1}\left(h - \frac{\tau_c}{\rho_m g\sin\alpha}\right)\right] \tag{21}$$

where ρ_m represents the density of the homogeneous mixture. If we assume $n = 1$ and $k = \mu$, relations (20) and (21) are referred to the case of a Bingham fluid.

Debris-flow Peak Discharge

Takahashi (1978) proposed a scheme for the estimation of debris-flow peak discharge based on the hypothesis that, after a short time, the debris-flow front assumes a self-similar profile. In this way, it is possible to make some assessments regarding the ratio between liquid and solid discharge.

The debris-flow front is supposed to move with velocity U_f and also the tail goes downhill with uniform speed U_t, smaller than U_f; in order that debris-flow profile becomes longer without becoming thicker.

With reference to Figure 3, the balances of liquid and solid phase masses give:

$$U_0 h_0 = U_f(1-C)h - U_t(1-C)h - U_t(1-C_0)sa + U_t h_0 \tag{22}$$

$$U_f C h = U_t C h - U_t C_0 a \tag{23}$$

where h is the front depth, a is the depth of the excavation produced by the passing of the tail, s is the degree of saturation of the pores under the debris flow. The liquid feeding from upriver gives rise to a speed U_0 and to a flow depth h_0 and then to a discharge per length unit $q_0 = U_0 h_0$.

From equation (23), we infer that the front speed must be lesser than the tail speed ($U_t < U_f$), and then that the debris flow itself tends to become longer while going downhill.

From equations (22) and (23), which admit that, as the debris flow passes by, the material in the channel bed is completely saturated ($s = 1$), we derive the following relation between the debris-flow discharge and the incoming liquid discharge:

$$U_f h = U_0 h \frac{C_0}{C_0 - C + \dfrac{h_0}{a} C\left(1 - \dfrac{U_0}{U_f}\right)} \tag{24}$$

Equation (24), relative to the propagation of a quasi-stationary debris-flow front, can be utilized to derive the relation between debris-flow discharge and incoming liquid discharge. Supposing that the front speed U_f coincides with the speed of the incoming water, then relation (24) becomes the following:

$$Q_{DF} = Q_0 \frac{C_0}{C_0 - C} \tag{25}$$

where Q_{DF} is the debris-flow peak discharge and Q_0 is the liquid peak discharge. As previously observed, in general, we can assume $C_0 \cong 0.65$ for natural debris.

According to Takahashi (1978), for sufficiently high slopes ($i > 20°$), debris-flow concentration can be assumed to be equal to 90% of the maximum concentration. By doing so, equation (25) becomes $Q_{DF} = 10 Q_0$.

In the case of milder slopes ($i < 20°$), debris-flow concentration is assumed to be equal to that of incipient movement in saturated conditions expressed by equation (19).

In practice, debris-flow concentration ranges between the following limits:

$$0.3 < \frac{C}{C_0} < 0.9 \quad 1.43 Q_0 < Q_{DF} < 10 Q_0 \tag{26}$$

Liquid peak discharge Q_0 can be calculated with common hydrologic methods.

An alternative method used to determine debris-flow peak discharge consists in assimilating the debris-flow front to that which forms after the collapse of a natural dam. The expression obtained is a function of the torrent depth h_m, to be evaluated upstream of the dam, and of the torrent width B.

$$Q_{DF} = \frac{8}{27} B h_m \sqrt{g h_m} \tag{27}$$

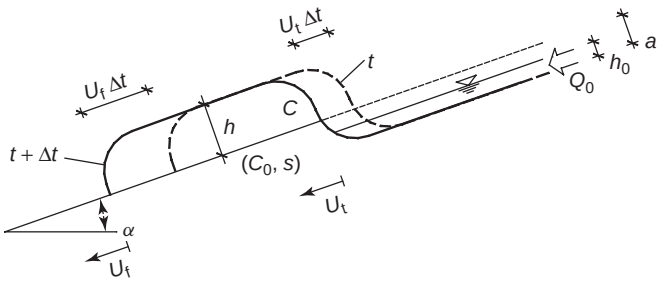

Figure 3 Scheme of quasi-uniform propagation of debris-flow front

MATHEMATICAL MODELING

Mathematical models are tools suitable to describe the general features of initiation, motion, and deposition of a gravity-driven mixture of debris and water and, lastly, the zoning of areas where damage is likely to occur. Owing to the high complexity that characterizes a real event, simplified assumptions in the mathematical modeling have to be introduced. At present in the applications the grain-size composition in the mixture is generally not accounted for, and only the solid concentration, which may change in time and space, remains to characterize the flowing sediments. Therefore, the possibility to represent the variations of the sediment size throughout the debris flow (from its steep front, mainly constituted of boulders, to the tail) is generally very limited.

General three-dimensional models require an extremely high computing time and level of hardware to determine the relevant solutions by means of numerical techniques, and are applicable, at present, to local situations only.

The representations in a reduced two- or one-dimensional frame correspond to depth- or section-integrated models.

This averaging process requires hypotheses about the profiles of the field variables (velocities, pressure, concentration) through the flow depth. These assumptions make it possible to derive models where the flow domain is the basal topography.

The characterization of the fluid mixture takes into account the fact that the fluid is not strictly homogeneous, but made up of different phases. The liquid phase refers to the interstitial slurry that is made up of water and of the finest grain fractions. The solid phase represents the coarser grain fractions. Some models admit that the two phases have different velocity distributions. The coupling between the two phases is present both in the mass conservations and in the momentum equations (due to the solid–liquid stress interaction). When we apply the hypothesis that there is no relative velocity between the two phases, the resulting integrated models present only one momentum equation, referring to a fluid having the bulk mass density.

Since attention is focused on averaged equation models, the rheological properties of the flowing mixture is lumped in the definition of algebraic expressions for the tangential stresses acting on the boundaries of the flow domain, especially on the bottom. Therefore, the boundary stresses are a function of the field variables of the model (such as flow depth, velocity, slope, sediment size) and show up as source terms in the momentum equations.

Mathematical and numerical models are thought of with proper boundary and initial conditions. Debris flows run-out and depositions over fans clearly depend on the incoming hydrograph. Initial conditions may also play a significant role, as in cases where the flow is triggered by an abrupt collapse of barrages (dam break–induced debris flows; Fraccarollo and Capart, 2002).

Motion equations are based on conservation laws. Their number, along with the number of variables, depends on the refinement of the model. The options mainly concern the number of phases and the number of momentum equations, one for each direction and phase-velocity field. In case of a nonhomogeneous fluid, the bed-level changes in time and the morphological evolutions are part of the solution. For sake of simplicity, one-dimensional models are referred to a flow section of unit width and rectangular shape, assuming no frictional influences from the sidewalls.

Modeling of a one-phase system in the one-dimensional framework is herein reported:

$$\begin{cases} \frac{\partial}{\partial t}(h) + \frac{\partial}{\partial x}(Uh) = 0 \\ \frac{\partial}{\partial t}(Uh) + \frac{\partial}{\partial x}\left(\beta U^2 h + g\frac{h^2}{2}\right) + gh\frac{\partial z_b}{\partial x} = -\frac{\tau}{\rho_m} \end{cases} \tag{28}$$

where h is the flow depth, U is the flow-depth-averaged velocity, $\rho_m = \rho(C\Delta + 1)$ is the density of the homogeneous mixture, z_b is bed elevation, τ/ρ_m represents the only source term, providing the shear stress at the bottom, β is the momentum-flux coefficient that takes into account the nonuniform velocity distribution through the flow depth.

In this context, the main point characterizing the fluid is the formulation of the wall friction force, to be deduced from rheological assumptions. Many rheological models have been tested in the past by different authors. Most of them can be classified in the following categories: (i) models for muddy fluid (e.g. Bingham models); (ii) models for mixtures in the inertial regime (e.g. equation 11); (iii) a combination of different dissipation models, including strain-rate independent contributions, to simulate grain-to-grain static prolonged contact, and various strain-rate dependent ones, such as Newtonian, turbulent, or collisional behaviors.

Under the same hypotheses, and moreover assuming $\beta = 1$, the two-dimensional extent of the mass and momentum balances are:

$$\begin{cases} \frac{\partial}{\partial t}(h) + \frac{\partial}{\partial x}(hU) + \frac{\partial}{\partial y}(hV) = 0 \\ \frac{\partial}{\partial t}(hU) + \frac{\partial}{\partial x}\left(\frac{1}{2}gh^2 + hU^2\right) + \frac{\partial}{\partial y}(hUV) + gh\frac{\partial z_b}{\partial x} = -\frac{\tau_x}{\rho_m} \\ \frac{\partial}{\partial t}(hV) + \frac{\partial}{\partial x}(hUV) + \frac{\partial}{\partial y}\left(\frac{1}{2}gh^2 + hV^2\right) + gh\frac{\partial z_b}{\partial y} = -\frac{\tau_y}{\rho_m} \end{cases} \tag{29}$$

where the inner shear stresses have been also neglected, as in most models of this kind, and where τ_x and τ_y are the components of the bottom shear stress and U and V are the components of the velocity.

One of the answers expected from model applications for mapping the risk concerns the description of debris deposition phenomena at the alluvial fans. In case of a homogeneous fluid, the stopping of the flow can be induced by a visco-plastic constitutive law (i.e. Bingham, Herschel–Bulkley models): when the yield stress balances or exceeds the local acting forces, the fluid comes to a local stop throughout the flow depth.

On the contrary, in situations where the debris deposition comes together with a reduction of the water content because of a velocity reduction of the flow over the alluvial fan, it is necessary to exploit models dealing with a nonhomogeneous two-phase fluid. The presence of solid and liquid phases is accounted for by considering the volumetric solid concentration (depth averaged) in both mass and momentum conservations. With a full two-phase model, two mass and two momentum equations should be considered. However, assuming that the velocities of the two phases are correlated, it comes out that a single momentum equation (and a single velocity field), associated to the bulk fluid-density, remains.

Here, it is chosen to represent the formally simpler case, assuming that there is no velocity-phase difference. The

following model is obtained in the one-dimensional case:

$$\begin{cases} \frac{\partial}{\partial t}(h + z_b) + \frac{\partial}{\partial x}(Uh) = 0 \\ \frac{\partial}{\partial t}(Ch + C_b z_b) + \frac{\partial}{\partial x}(CUh) = 0 \\ \frac{\partial}{\partial t}[(C\Delta + 1)Uh] + \frac{\partial}{\partial x}\left[(C\Delta + 1)\left(\beta U^2 h + kg\frac{h^2}{2}\right)\right] \\ \qquad +(C\Delta + 1)gh\frac{\partial z_b}{\partial x} = -\frac{\tau}{\rho} \end{cases} \tag{30}$$

where C is the depth-averaged solid concentration, ρ is the water density, k is the active/passive coefficient employed in soil mechanics, determined by the depth-averaged ratio between the vertical and the longitudinal normal stresses (Savage and Hutter, 1991; Iverson, 1997); k is often assumed equal to one, as for pure fluids.

In two-phase models (equation 30) one more closure-assumption, relevant to the volumetric solid concentration C, is needed with respect to the homogeneous fluid model (equation 28). This relation can be derived from assuming a transport-capacity formulation, under the hypothesis that the processes of debris transport rapidly fit the dynamic changes (hypothesis referred to as *equilibrium*). Regarding the transport-capacity formulation to be used, equation (19) is an example concerning granular debris flows. Many other empirical laws can be considered, spanning from refinements of bed-load formulations often employed in torrential floods (Armanini, 2005), to more specific laws devoted to the massive sediment transport under consideration.

Under the same hypotheses, assuming, moreover, that the β and k coefficients are equal to unity, the two-dimensional extension of the mass and momentum balances can be derived, in which, as in the case of homogeneous fluid, the inner shear stresses can be neglected.

MITIGATION AND RISK REDUCTION MEASURES

The mitigation remedial and defence techniques against debris flows are in their present form relatively recent tools: in the past, in fact, people simply tried not to build in the areas where there had been previous debris-flow events.

Only recently, as a consequence of the frantic development of the tourism settlements, risk areas, frequently located along the alluvial fans, have started to be urbanized. In general, the defence works against the debris flows can be classified in two categories: the active countermeasures and the passive countermeasures.

The former consist basically of interventions aiming at reducing the risk of debris-flow triggering. Then they are meant to give stability to the debris deposits in the torrents beds or in the hillslopes. The latter instead are works built to defend directly the settlements or the zones subject to

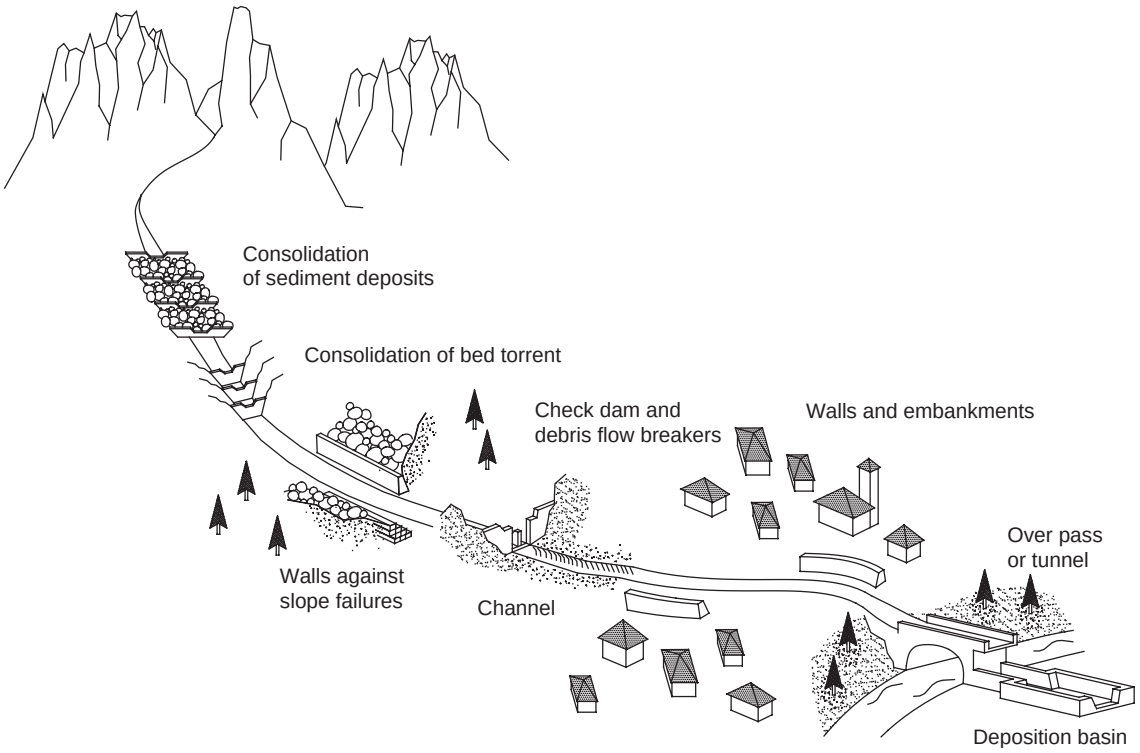

Figure 4 Scheme of the different types of active defence works against debris flows

debris-flow risk or the single structures (Figure 4). There are of course works responding to both criteria.

Consolidation of the Debris Deposits

The stabilization of the debris deposits is obtained either by reducing the slope or by hindering or reducing the possibility of saturation. This objective can be reached by consolidation works transversal to the deposits (endowed, where possible, with effective draining systems), by piling and anchors and, where possible, by vegetation. However, the bulkiest sources of the material mobilized by the debris-flow events are often located in places hardly reachable by the mechanical means; moreover, it is often counterproductive to move the deposits themselves in order to build drainages, as the movement of the material may increase its instability. As a result, the cases of applicability of these devices are often limited.

Consolidation of Riverbed and Lateral Slopes

In case the debris deposit affects directly the channel bed, the more limited the extent of the works is, the easier is the consolidation. The works constructed in these cases are sills or traditional closed check dams designed to reduce and to stabilize the riverbed slope and therefore to reduce the flow velocity. Often, in fact, the channel bed instability initially gives rise to an intense bed load that can degenerate into a debris flow owing to the erosion of the riverbanks or to the accumulations caused by the geometric variations of the sections (natural dam break). A system that augments the channel bed stability is represented by the chains of consolidation dams. The check dams built for this purpose are absolutely similar to the check dams used in case of solid ordinary transport. A phenomenon that characterizes the passing of the debris flow and that must be considered in the dimensioning of the check dam foundations is the amplification of flow depth from bed fluidification that accompanies the passing of the debris flow (Jäggi and Pellandini, 1997).

Debris-flow Breakers

More often, open check dams are built to intercept the solid material. However, debris flows usually occur in streams with a steep slope, where there is often lack of space where the material can be stored. In this case, the objective of the check dam is to diminish the flow velocity in order to reduce its destructive power in case of a dynamic impact. Therefore, these structures must resist above all the dynamic impact and they should also intercept the huge boulders.

Various devices have been proposed for this purpose. The most common structures are slit check dams with quite a large opening often protected by one or more stout buttresses that are dimensioned so that they can resist the dynamic impact (Figure 5).

Figure 5 Slit check dam with a series of debris-flow breaker on Torrent Chieppena – Trentino Italy (Provincia Autonoma di Trento, 2002). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

The hydrodynamic working of such structures is not clear and practical criteria suggested by experience are used for their design. The most effective results are obtained by water separation because the reduction of water concentration increases considerably the energy dissipation inside the flow and consequently its velocity.

Yet it is important that the volume upstream of the check dam remains free after each event, therefore the opening must allow the removal of the material accumulated. Accordingly, it can be useful to dimension the opening, so that the excavators meant to remove the material accumulated can pass through it.

The upstream side of the buttresses is inclined with respect to the vertical so as to reduce the dynamic impact of the debris flow that depends on the normal component of velocity. The inclination adopted varies between 45% and 60%.

The overpressure Δp generated in the dynamic impact of the debris-flow front colliding against a vertical wall is obtained by applying the mass balance and the motion quantity balance, thus obtaining (Armanini and Scotton, 1993) the following expression:

$$\Delta p = \rho_{\mathrm{m}} U (U - a_{\mathrm{w}}) \tag{31}$$

where ρ_m is the debris-flow density, U is the mean velocity of the front and a_w is the velocity of propagation of the gravitational wave reflected by the wall.

Very often relation (31) is corrected with an opportune coefficient α_p in order to consider possible secondary effects. The impact coefficient α_p often includes the effect of the reflected wave:

$$\Delta p = \alpha_p \rho_s U^2 \tag{32}$$

The coefficient α_p varies from 2 for quite slow and dense debris flows to 0.7 for faster and more liquid debris flows.

Debris Flows Artificial Channels and Retention Basins

It has been already pointed out that often there is not sufficient space to intercept all the debris-flow volume upstream urbanized areas. Provided that debris-flow breakers and check dams have reduced the flow velocity and intercepted part of the largest boulders, it is necessary to canalize the torrent downstream the retaining works, often by building artificial channels able to deviate the debris flow. These channels usually cross the villages and the alluvial fans where the space available is limited. Yet, it is useful to distinguish between a channel designed for the water discharge only and one affected by remarkable solid discharges or by debris flows. Often, it is the second necessity that is more urgent. Then the channel is supposed to resist to high velocities and strong tangential stresses, and must offer a very stable bed. Therefore, it is often necessary to resort to channels covered and strengthened with concrete. In this case, the covering surface is often smoothed to reduce the wall roughness. This is not the case of the channel for debris flow (Figure 6) where the resistance does not depend on surface roughness, but on particle collisions.

Figure 6 Artificial channel on Torrent Gola – Trentino Italy (Provincia Autonoma di Trento, 1991). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Bends with strong curvatures must be avoided in order to prevent depositions induced by secondary effects due to the supercritical nature of the flow, and in any case free-surface elevation must be properly accounted for, in order to avoid lateral debris-flow flooding.

In other cases, it can be useful to deviate the debris flow on the side to safeguard some sites. This deflection is obtained by the same techniques used for the snow avalanches, that is, by diverting walls or dikes.

The topography of the torrent often does not offer spaces granting a sufficient volume for the deposition of the solid material. In this case, it is necessary to create such storages. The debris retention basins are created through lateral training dikes, protected downstream by a check dam, which, if necessary, is inserted into the body of an artificial banking.

To optimize the volume available, it is necessary to remember that the widening cone of an overcritical current depends on the Froude number of the incoming current.

Acknowledgment

The authors thank Prof. Riccardo Rigon for his help in preparing the section about the triggering of debris flow.

143: Mountain Streams

ARONNE ARMANINI

Department of Civil and Environmental Engineering, University of Trento, Trento, Italy

This paper illustrates the main features of the hydraulics of mountain streams. The effects of small submergence and riverbed steepness on sediment motion initiation and transport are discussed together with the effect of big roughness elements and pool-riffle and step-pool sequences on velocity distribution and flow resistance. Finally, the most used torrent defense techniques are described.

INTRODUCTION

A definite distinction between mountain and valley rivers is practically impossible, except for the obvious observation that mountain water courses are those that are located in mountain areas. However, skipping a rigorous definition, there are many features that characterize mountain rivers. First of all, mountain streams are characterized by high slopes: for example, gradients greater than 0.02 along the majority of the length. Other strong differences concern the morphological, geological, and hydrological characteristics. Natural mountain streams present strong boundary variations both in the geometry and in the roughness elements that compose their bed. Generally speaking, these variations are due to geological constraints prevailing over the sedimentological influences that determine the features of valley rivers. Moreover, the hydrological regimes of mountain streams are very unsteady, characterized by intense floods and sediment transport peaks.

According to Wohl (2000) the most relevant characteristics of the mountain rivers are:

- *steep average gradients;*
- *high channel-boundary resistance and high boundary roughness from bedrock and coarse clasts that are more likely to be present along these channels than along low-gradient channels;*
- *highly turbulent flow and stochastic sediment movement resulting from the steep gradient and rough channel boundaries;*
- *strongly seasonal regime with high spatial and temporal discharge variability resulting from the effect of changes in precipitation with elevation and basin orientation;*
- *channel morphology that has high spatial variability because of the external control of geology, but low temporal variability because only infrequent flood or debris flows are able to exceed channel-boundary resistance*.

In particular, the sediments transport is dominated by the bed load and is very unsteady, ranging from long periods of limited sediment supply to intense events able to determine major morphological changes.

However, the concept of mountain river covers a great variety of different situations both from a hydrological point of view, because of different regional conditions, and from a morphological point of view because of different altitudes. Nonetheless, the hydraulic tools used in the analysis of mountain streams are not very different from those employed in valley rivers, apart from the fact that certain parameters play a more important role in these conditions. An evident difference between mountain streams and lower-gradient rivers is due to the fact that the geometry of a valley stream is largely determined by its water and sediment regimes: they are the "*authors of their own geometry*" (Leopold and Langbeim, 1962). In mountain streams, watershed morphology and geology are mainly responsible for the characteristics of their streams, maybe with the exception of their parts flowing into the alluvial fans.

VELOCITY DISTRIBUTION

The analysis of river hydraulics is generally based on the ideal concept of (temporary) steady and (locally) uniform conditions. While the low-gradient rivers for most of the

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

time and far away from the control sections are not far from satisfying this condition, at least locally, in mountain rivers it is very rare to find reaches that can be considered uniform, mainly because of the great variability of the geometry of the cross sections. However, the reference to uniform and steady conditions is often necessary in order to apply a very large amount of mathematical and physical findings and technical tools developed in low-gradient hydraulics.

Accordingly, it is possible to affirm that the hydraulics of mountain rivers is based on the same principles as the hydrodynamics of rivers. Generally speaking, one important difference lies in the relative roughness, that in mountain rivers is generally one or more orders of magnitude higher that in low-land rivers. The wall in this situation can be considered hydraulically rough and the flow is determined by the turbulence generated by the roughness wall elements. The velocity distribution in the *inner region* ($y/h <\sim 0.15$) is often expressed by a logarithmic law:

$$\frac{u}{u_*} = \frac{1}{\kappa} \ln \frac{y + y_o}{d_s} + B_r \tag{1}$$

where $u_* = \sqrt{\tau_o/\rho}$ is the friction velocity, y the direction normal to the bed and y_o a reference height, $\kappa \simeq 0.4$ the von Kármán constant and d_s a suitable characteristic grain size. B_r is an integration constant, depending mostly by the wall roughness elements. In the sand-grain bed this constant assumes the value 8.5. In large relative roughness B_r assumes values ranging from 3.25 to 6.26 (Graf, 1989).

In very small relative submergence, the existence of a layer near the top of roughness elements (*roughness layer*) dominated by the wakes generated by the individual grains has been recognized. Within this layer the local velocity distribution along the depth tends to be more uniform, and Reynolds stresses ($\overline{u'_x u'_y}$) tend to be suppressed (Nakagawa *et al.*, 1989). This situation seems to lead to an imbalance of the longitudinal momentum because the longitudinal component of the water weight would not be balanced by a proper shear stress. The roughness layer, however, is characterized by strong space heterogeneity. In order to write the momentum balance correctly, it is useful (Nikora *et al.*, 2001) to perform a double integration (in time and in space along planes parallel to the channel bed). As a consequence of the double integration process in the momentum balance, some extra terms, called *dispersive stresses* (or *form-induced stresses*), appear. Four layers may be identified: (a) interfacial sublayer, (b) form-induced sublayer (c) logarithmic layer and (d) outer layer (Figure 1).

According to the these authors, in the form-induced layer and in the interfacial sublayer the velocity distribution, double-averaged on space and time, $\langle \overline{u}(y) \rangle$, presents a linear

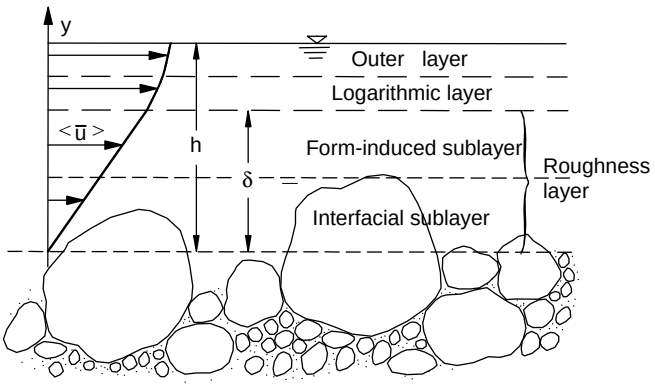

Figure 1 Sketch of layers distribution in small submergence conditions in gravel-bed rivers (Reproduced from Nikora *et al.*, 2001)

distribution

$$\frac{\langle \overline{u} \rangle}{u_*} = C \frac{y}{\delta} \tag{2}$$

while the logarithmic layer is characterized by a velocity profile similar to equation (1).

$$\frac{\langle \overline{u} \rangle}{u_*} = \frac{1}{\kappa} \ln \frac{y}{\delta} + C \tag{3}$$

C is a coefficient depending on roughness that in case of small relative submergence ranges from 3 to 7; δ is the boundary between the linear and the logarithmic regions. The outer layer is similar to the homologous layer for a hydraulically smooth bed.

According to Nikora *et al.*, (2001), in a very small relative submergence flow ($2 \div 5 > h/k_e \geq 1$), where h is the water depth and k_e is the roughness height, it is possible to postulate that the linear relation (2) is valid over the whole depth, and to assume for the height of the linear layer, $\delta = d_{84}$.

HYDRAULIC RESISTANCE

As a rule, the resistance law of a mountain stream can be obtained by cross-section (or depth) integration of velocity distribution (e.g. equation (1) or equations (2) and (3)). In addition to the grain resistance, in very steep channels, a form resistance also should be taken into account.

In the literature, many empirical formulas on hydraulic resistance of mountain rivers (gravel-bed and boulder-bed rivers) can be found. It is advantageous to divide them into two groups: the logarithmic and the power law. The logarithmic resistance formulas have the form of Nikuradse formula for flat channel flow, with different coefficients, and mostly with different expression for the roughness

parameter:

$$\frac{U}{u_*} = A \ln Y + B \tag{4}$$

U is the depth-averaged velocity, Y is a dimensionless parameter representative of relative roughness, A and B are empirical constants. As equivalent roughness, many authors suggest to take $k_e = (3 \div 3.5)d_{84}$. Table 1 reports the parameters of formula (4).

Often, instead of the log formula (4), a power law formula is preferred:

$$\frac{U}{u_*} = A_1 Y^{\beta} \tag{5}$$

The coefficient A_1 and the exponent β depend on the definition of relative submergence adopted and vary from author to author (Table 2).

The first two formulas have been derived for relatively low-gradient rivers, but are widely employed in engineering works in mountain rivers.

Expressions linking directly the discharge to the channel, or basin characteristics are sometimes employed: however, these formulas are calibrated for a specific stream and do not have a universal validity.

THE INITIATION OF SEDIMENT MOVEMENT

The mechanics of the initiation of sediment motion in mountain streams does not differ substantially from that in small-gradient streams, except for the influence of some parameters being usually negligible in the latter: in particular, the effect of slope, small submergence, and grain-size heterogeneity.

The dimensionless groups affecting incipient motion condition may be pointed out by means of dimensional analysis. The motion initiation condition of a particle lying on the stream bed is expressed by a relation between the following nine parameters:

$$\text{funct}(U, h, \tau_o, \rho, \rho_s, g, d_s, \mu, \sigma_s) = 0 \tag{6}$$

Where, ρ and ρ_s are the density of the fluid and of the sediments respectively, g is the gravity acceleration, d_s is

the size of a diameter representative of bed material and σ_s is a suitable parameter representative of the grain-size distribution (e.g. standard deviation of grain-size distribution). By means of the Π theorem relation, (6) reduces to a relationship between six dimensionless groups:

$$\text{funct}\left(\frac{u_*^2}{g\Delta d_s}, \frac{\rho u_* d_s}{\mu}, \frac{h}{d_s}, \frac{U}{u_*}, \frac{U}{\sqrt{gh}}, \sigma_s\right) = 0 \qquad (7)$$

where $\Delta = (\rho_S - \rho)/\rho$ represents the relative submerged density of the bed particles. The first group is the Shields' mobility parameter, $\tau_{*c} = u_{*c}^2/g\Delta d_s$. The second group is the grain Reynolds number, $R_* = u_{*c}/g\Delta d_s$. The third ratio is the relative submergence, h/d_s. The fourth group is the relative resistance, $\sqrt{8/f} = U/u_*$. The fifth group is the Froude number, $F_r = U/\sqrt{gh}$. The last parameter σ_s is related also to grain size, roughness distribution, and spacing, but, as for flow resistance, the dependence on this parameter can be included in the definition of the representative diameter. The grain-size distribution, however, is very important in all the cases where a selective removal or deposition of material occurs.

The direct dependence on relative resistance U/u_* can be omitted because it depends on relative submergence h/d_s and on Froude number F_r. According to Shields (1936), the motion initiation of the particles laying on a bed of a small-gradient river depends on the mobility parameter and on the grain Reynolds number: $\tau_{*c} = f_{\text{Sh}}(R_*)$ (Figure 2).

Compared with Shields' analysis, then, the critical shear stress (incipient motion) in mountain streams shows a further dependence on relative submergence h/d_s and Froude number F_r (Graf, 1989).

Different combinations of dimensionless groups have been used by different authors. In the mountain restoration technique, the critical slope, the critical discharge (Schoklitsch, 1962; Graf, 1984), and the critical Froude number are often used. It is possible to account for the new parameters by multiplying the original Shields' function f_{Sh} by a special function that becomes a unit function when the influence of these new parameters disappears. The effect of the longitudinal slope is accounted for just by introducing in the force balance the effect of the longitudinal component of the particle submerged weight (Christensen, 1996):

$$\tau_{*c} = f_{\text{Sh}}\left(\cos\alpha - \frac{\rho_s}{\rho_s - \rho}\frac{\sin\alpha}{\tan\varphi}\right) \qquad (8)$$

where φ is the angle of repose of the bed material and α is angle of channel bed.

Experimental evidence shows that the critical mobility decreases when submergence decreases, owing to the effect of small submergence. An empirical relation matching the experimental data is the following (Armanini, 1999):

$$\tau_{*c} = f_{\text{Sh}}\left(1 + 0.67\sqrt{\frac{d_s}{h}}\right) \qquad (9)$$

According to some authors, instead of the mobility parameter, which depends on bed shear stress, it is more advantageous to refer directly to the critical liquid discharge (Schoklitsch, 1962):

$$q_{\text{cr}}^* = \frac{q_{\text{cr}}}{d_s\sqrt{gd_s}} \qquad (10)$$

Bathurst *et al.*, (1987) suggest that, in nearly uniform conditions, the critical discharge depends substantially on the local bed slope:

$$q_{\text{cr}}^* = 0.21 i_f^{-1.12} \qquad (11)$$

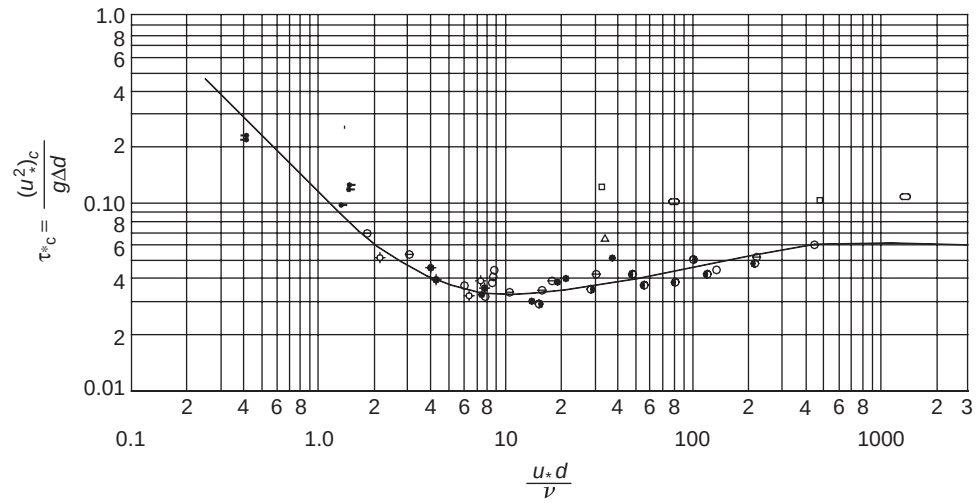

Figure 2 Shields' diagram

where $d_s = d_{50}$ has to be assumed as particle diameter in equation (10); the relation (11) has been calibrated for $0.25\% < i_f < 10\%$. By contrast, according to Whittaker and Jäggi (1986), it is

$$q^*_{\mathrm{cr}} = 0.257 \left(\frac{\rho_s - \rho}{\rho} \right)^{0.5} i_f^{-1.12} \qquad (12)$$

Hiding and Armoring

Mountain rivers are characterized by a wide grain-size distribution. This peculiarity has important consequences both on sediment movement initiation and on sediment transport. In a mixture of large and small particles, the larger ones tend to move more easily than if they were in a bed of uniform size because of their greater exposure, while smaller particles are protected by the larger ones from the movements (Figure 3). This phenomenon is termed *hiding*.

Since according also to Shields' criterion the mobility of a particle is inversely proportional to its size, the exposure effect makes the mixture movement more equalized.

The hiding effect is usually accounted for by means of a suitable *hiding* (or *exposure*) *coefficient* that multiplies the mobility of each individual fraction, calculated as if the bed was uniformly composed of material of this fraction. The hiding coefficient is therefore a function of the size of the individual fraction and of the average grain size (Table 3).

A second effect due to the nonuniformity of the grain size is the bed *armoring*.

It has been frequently observed that in certain conditions the surface of a gravel river is composed of a layer of material coarser than that composing the layers immediately below the bed surface. This effect is due to the fact that when the sediment supply vanishes or nearly vanishes, the finer fractions tend to be removed from the bed surface while the value of the bed shear stress is not high enough to move the coarser fraction. Then the size composition of the surface tends to become coarser. The difference between the surface and the subsurface material in the armored layer is often very strong, and the rupture of the armored layer is an instantaneous event that can move large quantities of material and it can be accompanied by evident erosion and deposition phenomena, which can damage the structures along the water course. The mechanism creating and destroying the armor layer is enhanced during the rising and falling limb of the hydrograph.

The grain-size distribution of the armored layer has been analyzed both theoretically and experimentally giving the

		$n = 0.87$	Andrews (1983)
		$n = 0.88$	Ferguson *et al.*, (1989)
		$n = 0.94$	Diplas (1987)
		$n = 0.98$	Parker *et al.*, (1982)

following expression:

$$F_j = f_j \frac{d_j^n}{\sum f_j d_j^n} \tag{16}$$

F_j is the percentage of the jth fraction in the armored layer and f_j is the percentage of the same fraction in the subsurface layer, which is assumed to be identical to the grain-size distribution of transported material. The exponent n in equation (16) is not far from unity ($n = 1.12 \div 1.35$) (Parker and Sutherland, 1990).

Because of the hiding effect in an armored bed, the critical shear stress corresponding to each grain-size fraction $(\tau_{*c})_j$ is considerably affected by the presence of surrounding particles of different size. Monomial expressions are often used to express the fractional mobility

$$(\tau_{*c})_j = (\tau_{*c})_u \left(\frac{d_j}{d_{us}}\right)^{-n} \tag{17}$$

Andrews (1983) proposed n = 0.872 and $d_u = d_{50s}$ (the median diameter of the subsurface bed material), and $(\tau_{*c})_u = 0.0834$ (the relative dimensionless critical shear stress).

From equation (16), it is possible to obtain the critical shear stress of an armored bed. For example, Günter (1979) introduced the following empirical relation between the critical dimensionless shear stress $(\tau_{*c})_{dmo}$ of an armored bed and the dimensionless shear $(\tau_{*c})_e$ for uniform bed material, the mean grain size of bed surface material, d_{ms}, and the mean grain size of bed subsurface material, d_{mo}:

$$(\tau_{*c})_{dmo} = (\tau_{*c})_e \left(\frac{d_{ms}}{d_{mo}}\right)^{0.67} \tag{18}$$

The theoretical analysis of heterogeneous-sized material (Parker and Sutherland, 1990) has highlighted that a surface coarsening occurs also in normal upstream sediment feeding conditions. In this situation, termed *dynamic armoring*, the mean size of the material transported is generally finer than that comprising the channel bed surface, but is slightly coarser than that composing the subsurface layer. The dynamic armoring is due to the nonlinearity of the relation between solid discharge and grain-size distribution of the material.

SEDIMENT TRANSPORT

The small relative submergence and the direct effect of gravity forces on the particles modify also the sediment transport formulas. With respect to the quantities considered in the dimensional analysis of the previous section, one more parameter relevant to sediment transport rate should be introduced. The corresponding dimensionless group is usually given by the Einstein (1950) transport parameter:

$$\Phi = \frac{q_S}{d_s \sqrt{g \Delta d_s}} \tag{19}$$

In the most common formulas used in the small-gradient streams, Φ depends on the mobility parameter τ_*, in some cases on a suitable grain Reynolds number and on the same parameter under critical conditions τ_{*c}. In the case of mountain streams, the transport parameter Φ should depend also on relative submergence and on Froude number. However, it should be noted that the critical mobility parameter τ_{*c} does not appear in the dimensional analysis and that this parameter implicitly accounts for slope and relative submergence. Nonetheless, in some formulas recommended for mountain streams, the bed slope or Froude number explicitly appears (Table 4).

Schoklitsch (Schoklitsch, 1962) type formulas are also recommended for mountain streams with slope $i >\sim 0.01$ (Bathurst *et al.*, 1987) and for steeper channels ($i >\sim$

Table 4 Different sediment transport formulas used in mountain streams

Formula		Remarks	Authors
$\Phi = 8(\tau_*' - \tau_{*c})^{1.5}$	(20)	Proposed for $d_{50} \leq 7$ mm, but widely used also for coarser material	Meyer-Peter and Müller (1948)
$\Phi = 4\left(\frac{d_{90}}{d_{30}}\right)^{0.2} i_f^{0.6} \tau_*^{0.5}(\tau_* - \tau_{*c})\frac{U}{u_*}$	(21)	$0.03 \leq i_f \leq 0.20$	Smart and Jäggi (1983)
$\Phi = \frac{3.1}{\Delta^{0.5}}\left(\frac{d_{90}}{d_{30}}\right)^{0.2} \tau_*^{0.5}(\tau_* - \tau_{*c})F_r^{1.1}$	(22)	$0.004 \leq i_f \leq 0.20$	Rickenmann (1991)
$\Phi = 17\tau_*'^{1.5}\left(1 - \frac{\tau_*}{\tau_{*c}}\right)\left(1 - \sqrt{\frac{\tau_{*c}}{\tau_*}}\right)$	(23)	Used also for debris flows	Ashida and Michiue (1971)
$\Phi = 11.933\tau_*^{1.5}\left(1 - \frac{0.0329}{\tau_*}\right)$	(24)	$\tau_* > 0.06$	Parker (1989)
$\Phi = 10.4\tau_*^{1.5}\left(1 - \frac{0.045}{\tau_*}\right)^{2.5}$	(25)	$d = d_{50}$; $\tau_* > 0.0659$ (the Authors give $\Phi \leq 10^{-2}$)	Graf and Suszka (1987)

$0.05 \div 0.17$) (Rickenmann, 2001). This type of formulas are based on critical liquid discharge of equation (10).

$$q_s = 2.5\frac{\rho}{\rho_s} i^{1.5}(q - q_{cr}) \tag{26}$$

Schoklitsch type equations are preferred in mountain streams because they do not contain explicitly the water depth or the bed shear stress, quantities often difficult to be determined because of the geometric heterogeneity that characterizes mountain water courses.

In some cases, the sediment transport in mountain streams presents a two-phased feature: up to a certain value of the discharge, the transport load is composed of relatively fine material, while, when the discharge exceeds a threshold value, the grain-size composition of the transported material changes rather abruptly and becomes coarser. (Ryan *et al.*, 2002). This phenomenon is associable with the rupture of the armored layer especially in the pool-riffle sequences. The pools feed the finer material that characterizes phase 1; during phase 2, coarser particles are supplied by break-up of armored layer of riffle units.

Many of the anomalies that characterize mountain streams are probably due also to the wide grain-size distribution of the bed material. Often the representative diameter of the bed material is coarser than the mean diameter of the sediment supply causing static and dynamic armoring, two phases sediment transport, apparent non equilibrium between sediment transport and transport capacity, and so on. It is possible in some cases to account separately for the contribution of each single fraction. In order to estimate the global transport rate, one must first calculate the transport rates q^*_{sj} for each single fraction – as if the bed was uniform in size and composed of the material of the individual class – and multiply these values by the percentage f_j of the material of the jth class present on the bed surface, accounting for the hiding factor, and summing this product up to all the classes considered:

$$q_s = \sum_j^M f_j q^*_{s\xi j} \tag{27}$$

where $q^*_{s\xi j}$ is the transport capacity of each single class modified by the hiding factor ξ_j.

MOUNTAIN CHANNEL MORPHOLOGY

The morphology of mountain rivers is extremely variable, ranging from bed rock–dominated systems to braiding or meandering reaches in the alluvial low gradient parts.

In the literature, different channel classification systems for mountain rivers are present. Montgomery and Buffington (1997) indicate step pool, plane bed, and pool riffle as possible categories at reach scale to classify the mountain streams.

In step-pool sequences, steps are usually composed of groups of boulders organized along straight or curved lines. Woody debris steps often occur. Unlike the dunes in low-slope rivers, step and pool geometry is scarcely regular. Typical step length ranges from tens of centimeters to tens of meters.

According to Wohl (2000), step and pool sequences occur at bed gradients ranging from 3 to 10%; Whittaker and Jäggi (1986) suggest a minimum bed slope of 7.5%. Step and pool configurations do not have to be considered as a permanent feature of a mountain reach as they can be suppressed or substantially modified during major flood events, while the most evident sequences form during floods with a return period ranging from 20 to 50 years. Step-pool sequences affect also the local and the average flow resistance: form resistance prevails over grain resistance. The flow regimes change from supercritical just after the steps to subcritical just upstream the chutes, with a hydraulic jump and strong energy dissipation in the transitions.

The morphological conditions in which step-pool sequences form and their formation mechanism are not clear. Two major theories have been suggested (Abrahams *et al.*, 1995). A first hypothesis states that step-pool sequences derive from antidunes disturbed by a large heterogeneity in the grain size and, in particular, by the presence of larger boulders that have fixed some of the antidunes thereby hindering their migration. A second approach is based on the hypothesis that the bed forms must maximize the flow resistance. Flume results and findings on natural step-pool streams suggested the following relations between average step length $\overline{L}$ and height $\overline{H}$ and average channel slope angle α (Figure 4):

$$\frac{\overline{H}}{\overline{L}} = 0.67(\sin\alpha)^{0.682} \tag{28}$$

A similar relation has been suggested also by Wohl and Grodek (1994). These relations are based on the assumption that the step height $\overline{H}$ is independent of the average bed slope. Average pool spacing is about four times the water depth.

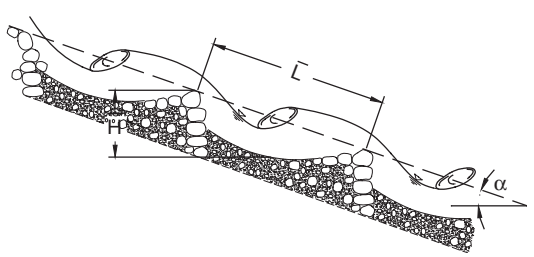

Figure 4 Sketch of step-pool sequence

Plane bed without regular bed forms characterizes mountain reaches with slopes between 0.01 and 0.05. Plane bed reaches have a relatively homogeneous grain-size bed composed of gravel and cobbles and a relatively uniform hydrological regime. The bed, often armored and with the absence of standing bars, probably indicates a limited sediment supply.

Pool-riffle reaches are nearly periodic planimetric structures characterized by sequences of relatively deep depressions (pools) followed by high-gradient shallows (riffles). Pool-riffle sequences occur at moderate slopes (0.05–1%) and are generally unconfined. Typical periodic distance between consecutive pools is about 5–7 channel width (Leopold and Wolman, 1957). Pools, often related to local scouring process due to flow convergence, are composed of relatively finer sediments and characterized by relatively low velocity at low stage discharges. Riffle units are often armored. Different theories on stability of pool-riffle sequences have been proposed in the literature: minimal potential energy loss or minimum power expenditure, energy reversal, and also hydrodynamic instability by deformation of alluvial bars similar to that in low-gradient rivers (Whittaker and Jäggi, 1982).

Montgomery and Buffington (1997) has given an account of forced riffles induced by large wood debris especially in forested channels.

TORRENT CONTROL CRITERIA

Sediment transport, bed and side erosion, and deposition processes in mountain rivers are phenomena that may be several orders of magnitude stronger than in valley rivers. For this reason, the defense or protection criteria in mountain environment concern mostly the control of sediment transport, while in low-gradient rivers, protection devices are designed mostly with respect to liquid discharges and volumes.

The control of sediment transport during floods is essentially a problem of controlling a large quantity of sediments released during short, intense events. In mountain streams, the sediment can be transported as an ordinary sediment transport (*bed load* and *suspended load*), mainly owing to the hydrodynamic forces of the water, or as a sediment gravity flow (*debris-flow* or *mud flow*) depending on the morphology, the concentration and quality of sediments (grain-size distribution), and the modes of mobilization. The gravity sediment transport is typical of very steep torrents, and its treatment requires a particular approach and appropriate techniques, which will be considered in a specific **Chapter 142, Debris Flow, Volume 4** (Armanini *et al.*, 2005).

The following strategies are often proposed in order to reduce the sediment transport movement along the river and to control the erosion/deposition processes:

- Prevention of bed and banks erosion through the so-called *consolidation check dams* as nonerodible sills in a river.
- Prevention of downstream overdeposition by structures capable of capturing the sediments in the upper part of the stream. The usual technique consists in the construction of one or more *retention dams*. The shape of this second kind of dam is often the same as the previous one, but its size and the purpose are different.

In the past, the strategy for preventing the further transport of sediment along rivers, and above all along torrents, was based on the building of high and large dams to trap more sediments and to resist high impact pressure.

The designed discharge of these structures depends on the importance of the work and the settlements to be protected. Often, a discharge corresponding to a return period of 50–100 years is assumed. The central weir of the dam is calculated as a trapezoidal broad-crested weir (Figure 5):

$$Q = \sqrt{\frac{4}{27}}\left(B_g + \frac{4}{5}nh_{\mathrm{m}}\right)\sqrt{2g}h_{\mathrm{m}}^{1.5} \tag{29}$$

It was soon observed that the space available for retaining the sediments is usually filled in a relatively short time, after which the dam practically loses its main purpose. With a traditional check dam, the whole sediment transport is stopped, causing a strong sediment imbalance in the downstream reach of the river. The reappearance of erosion, in sections previously subject to deposition, has been observed many times.

The next step was the development of *open dams* (Figure 6) with different purposes and different shapes. Meanwhile, it was gradually established that the purpose of sediment control was not to stop all the sediment transport but to reduce the sediment peak discharge by means of a temporary retention process. Minor floods should flow undisturbed through the structure.

The first type of open dam was designed with the purpose of retaining the larger stones through a sieving effect. A great variety of shapes and structures have been designed and tested to pursue and optimize this objective.

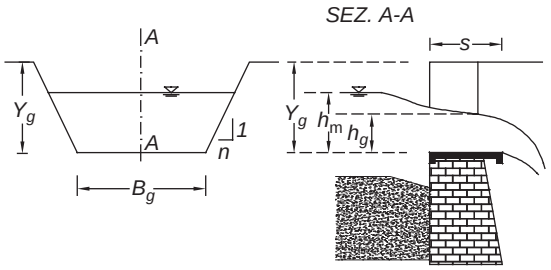

Figure 5 Sketch of the flow over the weir of the check dam

Figure 6 Retention check dam (Provincia Autonoma di Bolzano Alto Adige, 1977) (a) and sequence of consolidation check dams Rio Val de Casa (b) (Provincia Autonoma di Trento, 1991). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Figure 7 Beam dam in Tyrol, Austria. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Basically, this kind of open check dam is composed of wide horizontal openings, which possibly do not narrow the torrent width, guarded by a grid of beams, whose purpose is sieving (*filtering*) sediments and logs: the space among the beams is proportional to the size of the biggest boulders; this check dam was called *grid dam* or *beam dam* (Figure 7).

Although there are no generally accepted rules as to the distance between the beams, as a guiding framework the beam spacing varies between 1.2 and 3 times the maximum grain size being allowed to pass through. In practice, however, the retention effect is strongly reduced by the presence of woody debris: it has been generally observed that beam dams tend to be clogged with logs and other vegetation carried by the current, thus causing complete stoppage even of the finest sediment. For this reason, the distance between the beams in the lower part of the opening is sometimes larger (in order to allow smaller floods to flow undisturbed) than in the upper part (where the filtering effect has to be enhanced).

Once a beam dam is obstructed, it is necessary to remove artificially the logs and large boulders behind the grid by removing the beams or by mechanical excavation of deposited material.

At first, the *slit-dams* were based on similar criteria (Figure 8). This kind of open check dam is provided with only one central opening whose size is proportional to the size of the material to be retained. Also in this case, if the

Figure 8 Slit dam on Rio Inguela, Trentino Italy (Provincia Autonoma di Trento, 2002). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

opening is not large enough, a progressive obstruction tends rapidly to transform the open check dam into a closed one.

It has been recently realized that the retention effect is induced by a hydrodynamic effect rather than through a sieving effect. The cross-section contraction created by the opening inside the dam induced a backwater effect and a hydraulic jump during floods; along this reach the flow velocity is reduced, thus allowing most of the sediments to deposit. The deposited material should be subsequently eroded during minor floods. It is important that the slit allows minor floods to flow undisturbed, with a velocity sufficient to carry the material and possibly to erode the deposit.

A calculation of the optimum opening can be done by imposing the conservation of liquid and solid mass and on the momentum conservation; thus it is possible to find a relation between dam height H_{cd} and opening width b_{cd} (Armanini and Larcher, 2001) (Figure 9).

$$\begin{cases} Q = U_o h_o B_o = U_{cd} h_{cd} b_{cd} \\ Q_s = 8 B_o ((\tau_*)_o - \tau_{*_c})^{1.5} = 8 B_{cd} ((\tau_*)_{cd} - \tau_{*_c})^{1.5} \\ z_o + h_o + \dfrac{Q^2}{2g B_o^2 h_o^2} = h_{cd} + \dfrac{Q^2}{2g B_{cd}^2 h_{cd}^2} \end{cases} \tag{30}$$

Where $(\tau_*)_o$ and $(\tau_*)_{cd}$ are the mobility parameters calculated upstream the dam (section $O - O$ in Figure 9) and inside the slit (Section $Cd - Cd$ in the same figure) respectively. Here, the Meyer-Peter and Müller (1948) equation (20) has been used to calculate the sediment transport rates, but other formulas can be employed. A simplified but working version of this relation is the following:

$$H_{cd} = \frac{Q}{\chi B_o} \left(\tau_{*c} \Delta d_s + \left(\frac{1}{8} \frac{Q_s \Delta}{B_o \sqrt{g}} \right) \right)^{-1/2} \left(\frac{B_o}{B_{cd}} - 1 \right) \tag{31}$$

where χ is Chézy friction coefficient; Q and Q_s are respectively the liquid and the solid design discharges; τ_{*c} is Shields' mobility parameter (see Section "THE INITIATION OF SEDIMENT MOVEMENT"); B_o and b_{cd} are the width of the undisturbed torrent and that of the opening; d_s is the representative size of the bed material.

In comparison with the traditional closed retention dams, the open structures have the undisputed advantages of maintaining the filling space over many years and allowing the flowing through of minor floods. In any case, if necessary, there is the possibility of recreating the deposition space after a filling, if there is access for excavators and trucks. The impact on downstream morphological equilibrium and

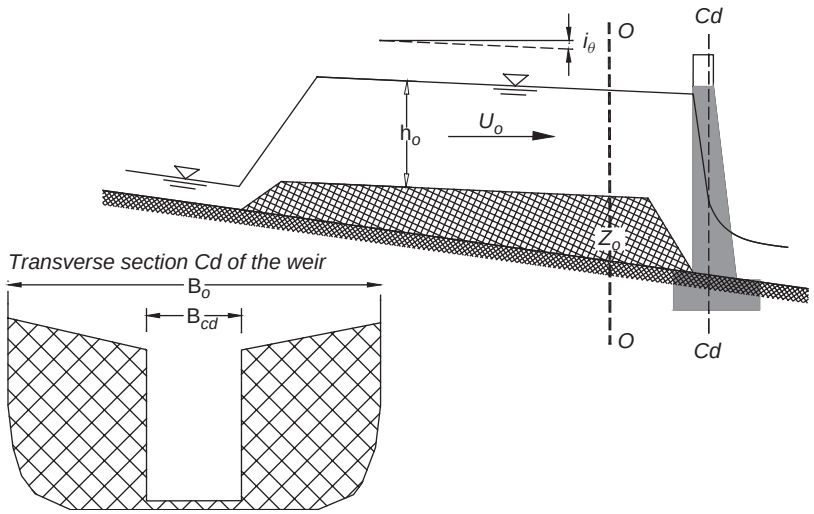

Figure 9 Sketch of the calculation of deposition upstream the silt weir

ecosystems is highly reduced, because a nearly continuous sediment discharge is allowed.

An important problem, that often compromises the efficiency of any device in controlling sediment transport, is the presence of vegetable material such as logs and plants. Special devices, formed by rows of steel ropes taut across the river and inclined toward the bank, have been experimented. In this case the trees are pushed toward the bank, where they can be removed by machines.

144: Regulated Lowland Rivers

HUIB J DE VRIEND

WL Delft Hydraulics, Delft, The Netherlands

The article describes flow, sediment transport, and morphological processes in regulated lowland rivers and the impact of human activities thereon. It gives some elementary examples of the morphological response to deviations from a prismatic straight channel, in an attempt to bridge part of the gap between textbook knowledge and reality. Moreover, it shows that even a regulated river is still to some extent natural, thus variable and unpredictable.

INTRODUCTION

Ever since man has started using rivers for his purposes, he has attempted bringing these rivers under his control. River regulation has now become a common practice all over the world (for example, see Figure 1). A wide variety of enabling structures, ranging from large regulation works to simple groynes and bank protections, has been invented and put into place. Each of these structures has its own specific impact on the river's behavior, an impact we would better know on beforehand, if we prefer to avoid unpleasant and often costly surprises. Therefore, a separate article is dedicated to the phenomena that are typical of regulated lowland rivers.

Figure 1 The Lower Rhine, an example of a regulated lowland river (flow from bottom right to top left). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

UPPER, MIDDLE, AND LOWER REACH

The profile of a river can roughly be divided into: a relatively steep upper reach, often in mountainous terrain and with high flow velocities, a more gently sloping middle reach with gradually finer sediments and inflow from tributaries, and a mildly sloping lower reach with relatively low flow velocities and fine sediments. River regulation in the upper reach concerns either discharge regulation by high dams or sediment retention by check dams. In the middle reach, which often lies in a wide valley, water levels may be regulated by weirs and navigation locks, and the banks protected by riprap or other material. In the lower reach, the river is surrounded by land that is mostly built up from river sediment left behind after migration of the river channel or deposited during inundation events. This part is often aligned by dikes or levees, in order to prevent inundation of riparian zones. As a consequence, there is no more sediment deposition in the riparian zones, whereas the river keeps on building out its delta thus shifting its own downstream boundary. Since the slope remains the same, the bed at a fixed point along the river tends to build up. This may continue until the river bed lies well above the surrounding land. In this situation, the river gets hydrologically disconnected from the surrounding land.

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

Figure 2 Drainage basin of the Yellow River. Note that the lower reach (about 700 km long) is hydrologically almost disconnected from the surrounding land. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Parts of the Lower Yellow River, for instance, lie more than 15 m above the surrounding land (also see Figure 2). It is not surprising, therefore, that the Chinese call this reach the *suspended river*.

FUNCTIONS AND HUMAN INTERVENTIONS

Lowland rivers in densely populated areas usually have four main functions: (i) safe conveyance of floods, sediment, and ice; (ii) fresh water supply; (iii) navigation; and (iv) discharge of (treated) wastewater. Apart from these four, there can be various other functions such as agriculture, recreation, or cooling water supply. Pressure on space and the demand for safety against flooding have led people to embanking rivers and fixing their course. Navigability requirements led them to reducing the width, so as to have sufficient depth under a wide range of conditions. Width-reduction also helps to increase the flow velocity, thus reducing any probability of ice jamming. Dams are not only used for power generation, or storage for irrigation, but also for discharge regulation (e.g. the Three Gorges Dam in the Yangtze River, China) and sometimes even for sediment-transport regulation further downstream (e.g. the Xiaolangdi Dam on the Yellow River, China; see Figure 3). Barrages and weirs can be used to set up the water level in times of low discharge so as to improve navigability, but also to regulate the discharge distribution between river branches.

Figure 3 Combined release of clean (white) and heavily sediment-laden (dark) water through the Xiaolangdi Dam, Yellow River, China. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

IMPACTS AND RESPONSES

These human interferences with nature have their consequences for the river's behavior. Dams and barrages are barriers to the sediment that tends to pile up in the reservoir upstream, whereas the flow downstream of the structure is undersaturated with sediment and tends to erode the bed. Bend cutoffs, which reduce the river length, can easily be shown to lead to (limited) river bed erosion in the entire upstream reach. According to Lane's balance (Lane, 1955), a reduction of the main channel width produces not only a larger depth, but also a smaller longitudinal slope. Since the normalization of the Rhine branches in the first half of the twentieth century, the bed of the Lower Rhine near the Dutch–German border has come down by more than a meter and the erosion process still continues (Visser *et al.*, 1999). Floodplain encroachments for housing, industry, or other activities that reduce the space for flood water storage, leads to changes in the flood conveyance properties of the river. Urban bottlenecks hamper the passage of flood waves and set up the water level over some distance upstream. Nature development in originally open floodplains (e.g. pasture land) will lead to vegetation growth, which may reduce the flood conveyance capacity. As a consequence, compensating measures are needed, or the vegetation has to be removed from time to time (floodplain rejuvenation; e.g. van der Lee *et al.*, 2001).

River regulation generally tends to evoke further regulation, as it increases safety and facilitates the use of the riparian zones for economic activities, thus attracting more people and more economic activities, which tend to demand more from the river. Although heavily influenced by man, regulated rivers are still to a certain extent natural in that they often experience strong discharge variations and have a mobile bed consisting of natural sediments. At the basin scale, the overall channel pattern is often natural at large, with artifacts here and there (e.g. the Pannerdensch Kanaal in the Rhine branches, or the Atchafalaya diversion in the Mississippi; see Figure 4). Water and sediment inputs into the river are not constant in time, not even in a statistical sense. They depend on the climate and on the land use in the river basin. The downstream boundary is often a shelf sea, or the ocean, with all its inherent water level variations (tides, storm surges, sea level rise). Clearly, real-life rivers seldom resemble the highly schematic situations that are usually considered in simplified models. There are always complications requiring special attention.

Figure 4 About one-quarter of the Mississippi River discharge (at the top) is diverted to the Atchafalaya River via three man-made channels with regulation works. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

PROCESSES AT THE BASIN SCALE

The river basin is the area that is drained by the river. On almost every point on land one can say by which river it is drained. This explains how in the north of France there can be roadmarks indicating the exact location of the drainage divide between the Atlantic and the Mediterranean basins.

The rainfall–runoff relationship is a typical property of a river (sub)basin, indicating how rainfall patterns in the basin translate into discharge hydrographs in the streams and rivers forming the drainage network of that basin. Land use (agriculture, forestry, etc.) and land cover (forests, pasture land, cities) determine the specific properties of this relationship, but are also subject to continuous changes due to changing human activities and climate change. Rainfall-runoff relationships are therefore not necessarily time-invariant (*see* **Part 10: Rainfall-runoff Processes** of this encyclopedia).

On the other hand, it is very difficult, if not impossible, to evaluate such a relationship on the basis of elementary data, such as soil composition, vegetation type, or topographic maps. Empirical methods are therefore inevitable, but they require homogeneous data over a long period of time, that is, data of which the statistical properties do not change through that period. In areas with much human activity, such as densely populated regions, such homogeneous data do not exist, as things keep on changing all the time. In such situations, rainfall–runoff relationships have to be estimated (*see* **Part 11: Rainfall-runoff Modeling** of this encyclopedia).

Another important (sub)basin process is the sediment yield. Sediment is produced by the weathering of rock, by

Figure 5 The Loess Plateau, the vast erosion area where the Yellow River picks up its huge sediment load (flow from top to bottom). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

the erosion of loose deposits, or as a residue of organic processes (cf. Figure 5). The production rate depends on geological structure, terrain properties, climate, land cover, land use, and so on. Well-known examples of human influence are landslides, mudflows and erosion due to deforestation, sediment retention by check dams, and sediment blocking by large river dams. Since the sediment yield of the basin determines the sediment input into the river, it also has its impact on river morphology (*see* **Part 7: Erosion and Sedimentation** of this encyclopedia).

FLOOD WAVES

Human interventions in the river bed and the floodplains change the flood conveyance properties of a river. In general, the propagation speed of a flood wave increases if the flow velocity in the main channel increases and if the storage capacity of the floodplain decreases. At the same time, the peak height of the flood wave increases if this capacity decreases. Floodplain encroachment occurs at the expense of storage capacity and is therefore detrimental to a river's flood conveyance capacity. In the Middle Rhine, for instance, many decades of ever further confinement of the river have made flood waves propagate much faster (i.e. less warning time), with much higher peak discharges (i.e. higher maximum water levels). Figure 6 shows the results of a numerical model exercise for the same flood wave in the Middle Rhine with the geometry of 1882/1883 and that of 1995. The changes in geometry reduce the lead time

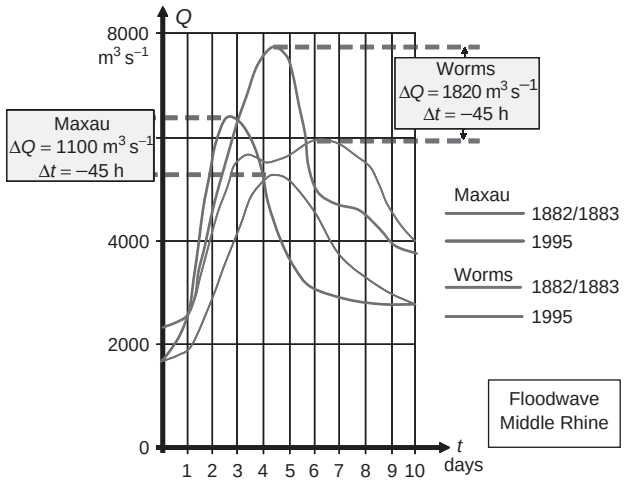

Figure 6 The same floodwave in the Middle Rhine at Maxau and Worms, computed with the geometry of 1882/1883 and that of 1995 (after: KHR, 1993). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

to peak passage by about two days and increase the peak discharge by some 30%.

People have begun to realize that this process may have gone too far. Many present-day river improvement projects, therefore, focus on creating more space for the river in flood situations. Examples of space-creating measures are channel widening, floodplain lowering, digging side channels, building flood bypasses, removing summer obstacles, setting back dikes, and so on (for instance, see Silva *et al.*, 2001).

ROUGHNESS AND FLOW RESISTANCE

An insufficiently known aspect of discharge variations is the so-called *dynamic roughness*, that is the variable bed-form roughness associated with varying discharge. The bed-form dimensions (e.g. Figure 7) exhibit a retarded response to the flow velocity, whence they cannot be related to the instantaneous discharge. Instead, a relaxation-type bed roughness submodel should be included in models predicting flood levels (Wilbers and ten Brinke, 2003). The relationship between bed-form dimensions, bed roughness, and flow conditions is subject to further research at various places around the world.

We do not know to what extent the bed-form changes observed under extreme conditions can be extrapolated to design conditions, which are sometimes far beyond the highest flood on record. In the case of the Dutch Rhine branches, for instance, the design discharge is $16\,000\,\mathrm{m^3\ s^{-1}}$, whereas the highest discharge on record is $12\,600\,\mathrm{m^3\ s^{-1}}$, observed in 1926. Clearly, this introduces

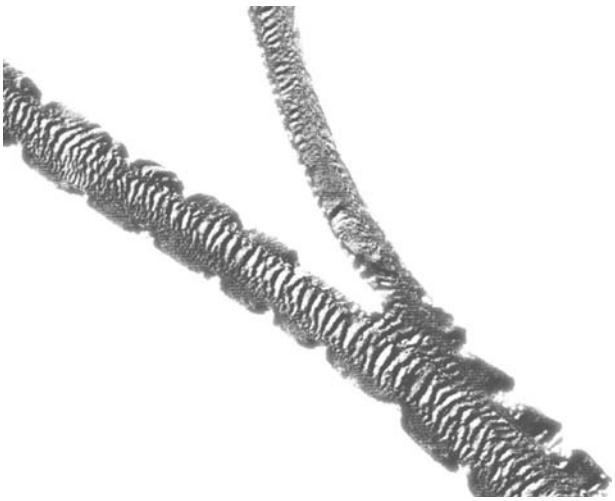

Figure 7 Bed-form pattern around the Pannerdensche Kop bifurcation in the Rhine, as observed under flood conditions with multibeam sonar. Typical wave length: 50 m (Reproduced from Ten Brinke, W., (2004) by permission of Veen Magazines)

significant uncertainties in the prediction of the design water levels.

TRANSPORT OF SUSPENDED AND DISSOLVED MATTER

Rivers transport not only sediment but also many other types of particulate and dissolved matter, often originating from human activities in riparian zones. This includes industrial waste, which used to be discharged untreated into the river until the last few decades since when water quality regulations became stricter. As a consequence, much of the fine sediment deposited in the floodplains is polluted with heavy metals, phosphates, nitrates, and so on. Handling this heavily polluted material sometimes constitutes a major problem to large-scale river restoration schemes (*see* **Part 8: Water Quality and Biogeochemistry** of this encyclopedia).

A particular problem of groyne-regulated rivers is the complexity of the pollutant pathways. This plays a special role in the case of calamitous pollution events, when an amount of pollutant is discharged into the river at a certain location and at a certain point in time. This pollutant is transported down the river and will at a certain moment reach water intakes and other sensitive points. The accurate prediction of that moment and the duration of the dangerous situation can be of major societal importance, especially when health risks are involved. Modeling this type of phenomenon in groyne-regulated rivers is particularly difficult, because part of the material lingers behind in the groyne fields and reenters the main channel at a later stage (van Mazijk, 1996). In 1-D model terms, this means a strong dispersion effect, which does not affect the maximum speed of the pollutant cloud, but has a major effect on the length of its tail, and hence on the duration of the dangerous period at any point along the river (*see* **Chapter 100, Water Quality Modeling, Volume 3**).

SEDIMENT TRANSPORT

The general mechanisms of sediment transport in regulated rivers are not different from those in natural rivers or mobile-bed irrigation channels. The shear stress exerted by the flow on the bed brings the sediment into motion if a certain threshold value is exceeded. Clearly, this threshold depends on the grain size and the sediment density. Once this threshold is exceeded, transport may take place in different regimes: in a thin sheet along the bed, via migrating bedforms (ripples, dunes), rolling downhill while being transported downstream, avalanching down steep slopes, or suspended in the water column. In the latter case, the turbulent water motion delivers the power needed to keep the sediment grains in suspension. Irrespective of the regime, the transport rate is a nonlinear function of the shear stress (for further details see Graf, 1998; *see* **Chapter 140, Transport of Sediments, Volume 4**).

This means that the sediment transport rate increases along with the flow velocity and the bed roughness. In flood conditions, both are large, so large amounts of sediment are set into motion. The probability of branches getting choked with sediment during an extreme flood event is therefore not hypothetical, although we are still not able to quantify it. We do know, however, that in heavily sediment-laden rivers, such as the Lower Yellow River, flood levels cannot be computed without taking due account of the morphological changes during the event (e.g. Kemink *et al.*, 2003).

Another reference is that the total amount of sand deposited in the floodplains of the Rhine branches during the 1995 flood event is estimated at 300 000 m^3 (ten Brinke, 2004), which is of the same order of magnitude as the river's yearly sediment load (*see* **Chapter 84, Floodplain Sedimentation – Methods, Patterns, and Processes: A Review with Examples from the Lower Rhine, the Netherlands, Volume 2**).

If floodplains are lowered as part of a scheme to increase the flood conveyance capacity of a river without dike strengthening, their sediment-trapping capacity is likely to increase. If, in addition, the summer levees bordering the main channel are removed, the inundation frequency of the floodplains will increase, and therewith the amount of sediment deposited there. At some distance from the main channel, this sediment will mainly be fine fractions, such as clay, but closer by, there will also be deposition of sand (cf. Figure 8). In the dry season, this sediment is available for aeolian processes such as dune formation. Given the above quantities of sand deposited in the floodplains during a large

Figure 8 Sand deposited in a floodplain of the Waal River during a flood event. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

flood, this must influence the overall sediment balance of the river.

A specific aspect of groyne-regulated rivers is the sediment balance of the groyne fields. Altogether they store a large amount of sediment and if they all trap or release part of that sediment at the same time, this must influence the main channel. Investigations so far (e.g. Yossef and de Vriend, 2004) indicate that groyne fields tend to import sediment under low-flow conditions via the recirculation zones between the groynes, as well as under high-flow conditions via secondary currents induced by the groynes. This suggests that they would accrete consistently until they have reached some equilibrium state where the net import is zero. In reality, however, it turns out that navigation-induced water motion plays a key role in the sediment balance. Especially, ship-induced water level set-down turns out to be effective in drawing sediment out of the groyne field (ten Brinke, 2004). Consequently, the sediment content of the groyne fields tends towards a nontrivial dynamic equilibrium state, which also depends on the type and the intensity of the navigation (see Figure 9).

GRADED SEDIMENT

Sediment in real-life rivers is hardly ever uniform in grain size. As sediments of different grain sizes respond differently to hydrodynamic and gravitational forcing, a variety of mechanisms tends to segregate coarse and fine sediment.

The dynamic interaction between hydrodynamics, sediment transport, bedforms, and bed roughness is further complicated if the bed sediment is nonuniform in grain size. Bedforms migrate by erosion at the upstream side and

Figure 9 The morphological state of groyne fields is influenced by navigation (flow from top to bottom). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

deposition of the eroded sediment at the downstream side. The latter is usually so steep that deposited grains tend to slide down the slope. This so-called *slip-face* is a very good grain-size selector, as every building contractor knows. The coarsest grains tend to roll further down the slope than the finer ones, so that the sediment composition in the troughs becomes relatively coarse. Thus, the bedforms tend to form a coarse layer at their trough level while migrating down the river (Blom *et al.*, 2003; also see Figure 10). When during an extreme flood the bedforms are high, the troughs are deep, and the coarse layer is formed at a level that is usually not reached under less extreme conditions. The coarse layer formed in the Lower Rhine during the 1995 flood, for instance, is still visible in boxcores taken today.

Once this coarse sublayer has formed, it keeps the troughs from digging deeper into the bed and thus limits the bedform height. This constitutes a self-regulatory feedback system.

Another mechanism is selective transport. Under moderate flow conditions, the coarsest sediment fractions do not move, whereas the finer ones do. Thus, it is possible that in an erosion area the coarser sediment lags behind and forms a so-called *armor layer* on top of finer sediment, thus protecting the latter from being eroded. This phenomenon is often found downstream of sediment-blocking structures, such as dams, barriers, or weirs, or in the scour holes near bridge piers, groyne heads, and so on. The flow there is undersaturated with sediment and therefore tends to pick

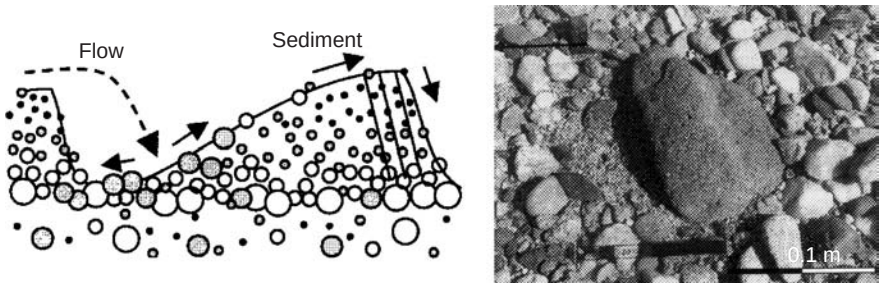

Figure 10 Interaction of water and sediment motion causes sorting of graded sediment. (a) vertical sorting by bedforms (Blom *et al.,* 2003). (b) a coarse armor layer on top of a finer substrate

up sediment from the bed. After some time, the formation of the armor layer keeps the bed from further eroding, thus constituting yet another self-regulatory feedback.

At a larger scale, the bed composition may vary in space and time, under the influence of variations in sediment supply, discharge variations, nonuniformities in the river geometry, bifurcations, confluences, and so on. This means that the bed composition waves migrate more or less continuously through the river (e.g. Ribberink, 1987). This, in its turn, influences the sediment transport, the bed roughness, and the flow. Thus, the bed composition is in continuous interaction with the other elements of the morphodynamic system.

Because of gravitation, sediment is transported more easily downhill than uphill. This downhill gravitational transport component works out differently for grains of different size. This means that in situations with a cross-stream bed slope, like in a bend, or near a bifurcation or a confluence, there is a cross-stream segregation by grain size. Coarser sediment generally stays near the foot of the slope, whereas, the fines are carried uphill. Since sediment transport is quite dispersive, this segregation usually gets undone after a bend or a confluence, but at bifurcations it may strongly influence the grain size of the sediment entering the branches. This so-called *Bulle-effect* (Bulle, 1926; also see Jansen, 1979) depends on the curvature-induced secondary flow, hence, on the shape of the bifurcation.

LARGE-SCALE MORPHOLOGICAL EQUILIBRIUM STATE

A regulated lowland river of which the alignment and the width are fixed has two degrees of freedom left to accommodate the supply of water and sediment from upstream; that is, its water depth, h, and its slope, S. If the discharge, Q, and the sediment input, Q_s, as well as the downstream water level are constant in time, a static equilibrium state would develop. If we assume a rectangular cross section of constant width B, and a power-law relationship between the transport rate per unit channel width and the mean flow velocity, this state can be derived from first physical principles and is given by

$$h_{eq} = \left(\frac{Q_s}{a_s B}\right)^{-1/b_s} \frac{Q}{B}; S_{eq} = \left(\frac{Q_s}{a_s B}\right)^{3/b_s} \frac{Bf}{8gQ} \qquad (1)$$

in which a_s is the coefficient of proportionality in the transport formula, b_s is the exponent of the velocity in that formula, f is the Darcy Weisbach friction factor, and g is the acceleration due to gravity.

Typical values of b_s are between 3 and 5, and a_s can be shown to be inversely proportional to some representative grain size. If the sediment supply is assumed independent of the discharge, the above formulae show that the product of equilibrium, depth, and slope is independent of the discharge. So if the depth increases, the slope decreases. This is exactly what has happened in the Rhine branches after the normalization in the late nineteenth and early twentieth centuries (Visser *et al.*, 1999).

The formulae also show the equilibrium slope to decrease with the discharge and increase with the grain size. This corresponds qualitatively with the general observation that the slope of a river tends to decrease from upstream (low discharge, coarse sediment) to downstream (high discharge, fine sediment). In reality, sediment supply and discharge are coupled to some extent, if only because the inflow from the tributaries also brings in sediment. In general, the transport rate will be an increasing function of the discharge. This explains why the slope in river channels is found to be less than inversely proportional to the bankfull discharge (gravel-bed channels: $S \propto Q^{-0.4}$, sand bed channels: $S \propto Q^{-0.3}$; e.g. Knighton, 1998).

The static equilibrium relationships (1) can be used to construct the equilibrium bed topography in a river. Starting from the given downstream water level, one can construct the water surface, which is a continuous broken line consisting of piecewise straight lines under slope S_{eq}.

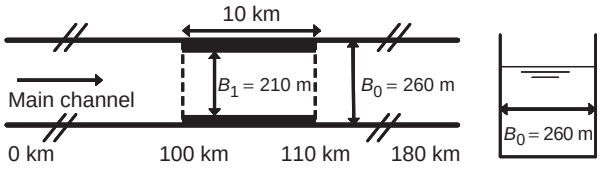

Figure 11 Hypothetical case of a prismatic channel with a long constriction

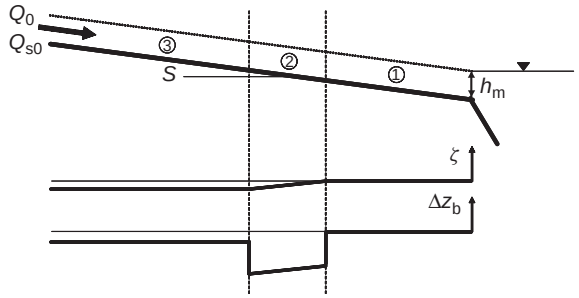

Figure 12 Static equilibrium state for this case. Section 2 is the constricted reach. The top panel shows the initial state, the lower panels show the changes of the water level, $\Delta\zeta$, and the bed level, Δz_b

Subsequently, one can draw the equilibrium bed level at a distance h_{eq} below and parallel to this water surface.

Figures (11) and (12) show how this works out for a large-scale human intervention, in this hypothetical case a 10-km long constriction assumed to be created suddenly in an otherwise prismatic channel with a constant supply of water and sediment and a mobile bed in equilibrium. According to equation (1), the equilibrium water depth will be larger in the constricted reach, and the water surface slope, as well as the bed slope, will be smaller. Consequently, the bed level and the water level in the whole reach upstream of the constriction will come down slightly.

MORPHODYNAMICS

Static equilibrium is a useful theoretical concept that helps understanding river morphology, but it has little to do with reality in most rivers in which such an equilibrium state is never reached. How close the bed topography gets to the equilibrium state depends on the ratio between the rate at which the system tends towards this equilibrium (the morphological time scale) and the characteristic time scale of the natural (e.g. seasonal) variation of conditions. In most rivers, this ratio is such that time-dependent morphological processes are predominant.

Time-dependent morphological processes are rather complicated, because of the dynamic interaction of water motion, sediment transport, and bed level changes. Yet, some of this morphodynamic behavior can be understood by considering two limit cases, one for length scales that are small compared to the length scale involved in the backwater curve (typically $h/3S$) and one for length scales that are large compared to this backwater scale. In the former case, bed perturbations behave like nonlinear kinematic waves in that they propagate downstream at a speed $c_b = b_s Q_s/(Bh)$ and in the meantime undergo a deformation due to the faster propagation of the higher parts. Thus, upstream-facing slopes tend to flatten out and downstream facing ones tend to develop into a shock front (see Jansen, 1979).

The large-scale limit behavior is essentially different and can be shown to have a diffusive character (e.g. Ribberink and van der Sande, 1987). This means that a perturbation at this scale tends to spread out in both directions (upstream and downstream) and to decrease in amplitude at an ever slower rate during the process. This provides a mechanism for morphological effects at large distances upstream of an intervention.

These two effects are clearly visible in the animation of Figure 13. It concerns a numerical model simulation for the above hypothetical case. The animation shows the time evolution of the bed profile starting from the equilibrium situation before the constriction was applied. In the beginning, it shows how the bed erodes very rapidly in the constricted reach, while the erosion products are deposited just downstream of that reach. The hump of sand formed in this way starts expanding in the downstream direction, and when the supply from the eroding constricted

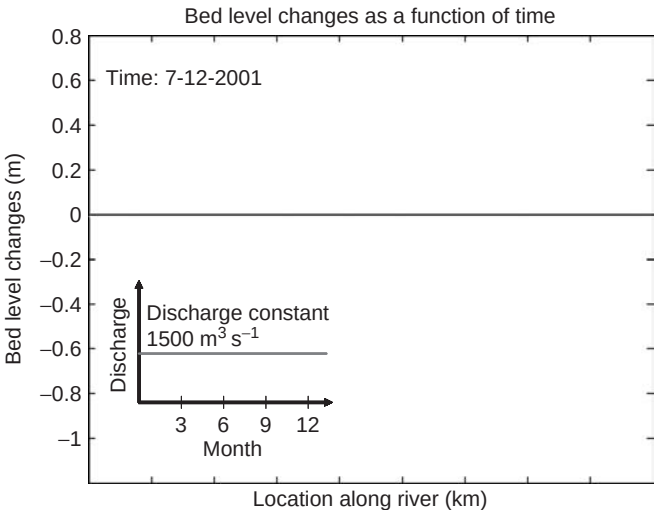

Figure 13 Animation of a morphodynamic simulation for the case shown in Figure 11, with constant discharge and sediment supply (animation goes with this article; courtesy Saskia van Vuren; also see **http://www.sobek.nl** for a free trial copy of the software). A color version of the animation is available at http://www.mrw.interscience.wiley.com/ehs

zone drops off, it migrates further downstream until it has moved out of the model area. Subsequently, there is a much slower large-scale adjustment to the boundary conditions, with the theoretical equilibrium state as a final result.

MORPHOLOGY AND TIME-VARYING INPUTS

Discharge variations inevitably influence the morphological behavior of a river. For example, in Figure 11, the rate of erosion in the constricted reach will be a function of the discharge. Hence, the sediment supply to the downstream reach will depend on the discharge. Discharge variations will therefore cause the formation of bed waves, which will from thereon propagate downstream and ultimately leave the model domain, as shown in the animation of Figure14. The bed waves are of practical importance, as they may hamper navigation, or jeopardize the stability of structures.

Bedwave formation due to discharge variation will generally be induced by geometrical nonuniformities in the river geometry. This may also concern the floodplain geometry, as is shown in the example in Figure 15 for a hypothetical case of floodplain lowering. At every nonuniformity, every discharge variation will yield a morphological response in the form of erosion or accretion. This causes a surplus or a deficit in the sediment supply to the reach downstream of the nonuniformity, forming a hump on, or a hole in, the bed there. These bed disturbances start traveling downstream through the river and may give rise to problems with navigability or structure stability. Recent investigations for the Waal River have shown that their effect on the flood

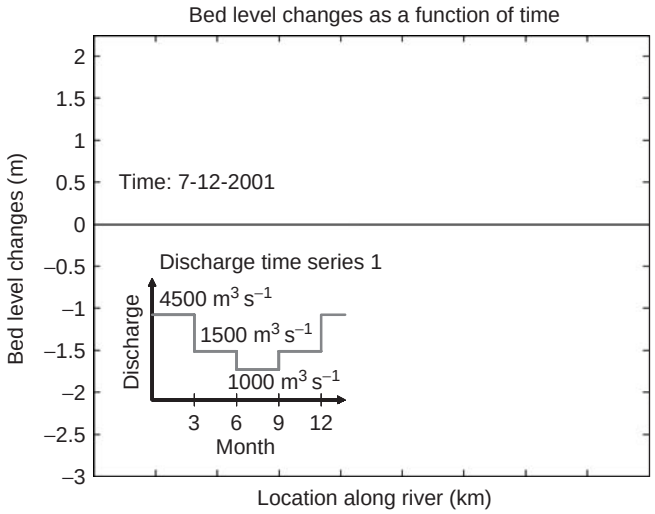

Figure 14 Morphodynamic simulation for the case shown in Figure 11, with a stepwise varying discharge and sediment supply (animation goes with this article; courtesy Saskia van Vuren; also see **http://www.sobek.nl** for a free trail copy of the software). Figure 15 Morphological effect of a geometrical nonuniformity (hypothetical floodplain lowering) in combination with discharge variations. (a) situation. (b) bed-level changes in the main channel for two different hydrographs, and the mean and the 90% confidence interval for a large number of such hydrographs (courtesy Hanneke van der Klis). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

conveyance capacity of this river is minor (van Vuren *et al.*, 2003), except near bifurcations.

Figure 15 also shows that the response is different for every discharge hydrograph. Monte Carlo Simulation with a large number of statistically equivalent hydrographs provides information on the statistical properties of the bed-level variations (see van der Klis, 2003). In the figure, the mean and the 90% bandwidth are indicated. These are useful indicators for the design of structures, or making decisions whether or not to dredge the navigation channel.

Clearly, the bed waves will not be reproduced by any model with a constant discharge. The mean bed-level change due to the floodplain lowering, however, looks rather similar to what would be found in the case of a constant discharge (see Figure 12). Hence one might think that it must be possible to find a constant discharge that yields a good estimate of this mean response. This

will not be the mean discharge, since the water and sediment mechanics underlying the morphological changes are strongly nonlinear. Hence, substituting the average discharge into a transport–discharge relationship will not yield the average transport rate. The discharge that does produce the right average transport rate, called the *dominant discharge*, is generally well above average. Since the sediment balance equation is linear, the right transport field must give the right short-term bed-level changes. Yet, the dominant discharge approach generally does not produce the right equilibrium state, because the nonlinear feedback between the bed-level changes and the water and sediment motion will exert its influence in the longer run. It can be shown from the basic equations for uniform one-dimensional straight channel flow with a mobile bed in equilibrium that the key morphological properties, that is, the bed slope and the water depth in the river mouth, are determined by different statistical properties of the discharge, and that each of these properties is different from the mean discharge and the dominant discharge. In other words, even a simple property as the equilibrium state in a straight channel of uniform width cannot be described with a single representative discharge. For further details, see the discussion on the dominant discharge concept in Jansen (1979).

THREE-DIMENSIONAL MORPHODYNAMICS

Although rivers are sometimes considered as lines in the landscape and their behavior is often described with one-dimensional models, the flow and sediment-transport phenomena are essentially three-dimensional. In fact, the one-dimensional description is cross-sectionally averaged, instead of genuinely 1-D. This cross-sectionally averaged description is useful in many situations, especially when considering large-scale effects. At intermediate and local scales, however, it is not always applicable.

A well-known example of an essentially 3-D phenomenon is bend morphology. Although the alignment of regulated rivers is fixed, it usually contains windings, sometimes referring to the ancient channel pattern, sometimes the result of consecutive realignment measures. The flow pattern in these curved reaches is three-dimensional, due to curvature-induced secondary flows. As a consequence, the flow-induced bed shear stress has a component towards the center of curvature, which tends to force sediment towards the inner bank. There it piles up and forms a so-called *point bar* (cf. Figure 16), until the transverse slope becomes steep enough for the downhill gravitational transport component to balance the secondary-flow induced component.

This model applies only to bends with a constant radius of curvature and an infinite angle of rotation. Such bends do not exist in reality, rather the curvature varies continuously along the river. This means that spatial lag effects come into play: neither the velocity distribution nor the bed topography can adjust immediately to a change in curvature. The adaptation length scale for the flow, λ_w, is determined by the interplay between inertia and bed friction, the one for the transverse bed slope, λ_s, by the channel aspect ratio, the amount of sediment to be moved per unit channel length and the efficiency factor of the downhill gravitational transport component. The ratio of these two scales, called the *interaction parameter IP*, determines the transition behavior of the bed topography (Struiksma *et al.*, 1985).

Figure 16 View of the freely meandering Usumacinta River in Guatemala (flow from top to bottom). Note that the location level of the point bar does not coincide with the maximum curvature. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

$$\lambda_{\mathrm{w}} = \frac{4}{f}h;\ \lambda_{\mathrm{s}} = \frac{\beta}{8}\left(\frac{B}{h}\right)^2 h;\ IP \hat{=} \frac{\lambda_{\mathrm{s}}}{\lambda_{\mathrm{w}}} = \frac{\beta f}{32}\left(\frac{B}{h}\right)^2 \quad (2)$$

in which β is the coefficient of proportionality between the bed slope and the downhill gravitational transport rate.

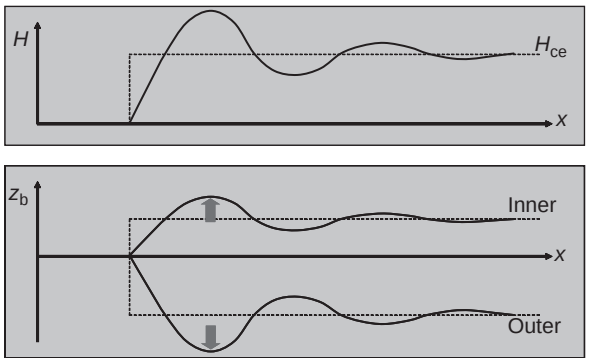

Figure 17 Damped oscillatory transition phenomenon at the entrance to a bend of constant curvature. H indicates the bed-level difference between the inner and the outer bend, H_{ce} the value it would take if the bend would continue infinitely. The lower panel gives the bed along the inner and outer bend. x is the position along the channel axis. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

For a certain range of values of *IP*, the transverse bed slope exhibits a damped oscillatory adaptation to a change in curvature (Figure 17). In system terms, this behavior is called *forced,* referring to the forcing by the channel curvature. It comes with an overshoot of the transverse bed slope in the beginning and just beyond the end of the bend, which may have implications for navigability and bank stability. For curvature variations of a certain wave length, this forced behavior may even be in resonant interaction with the curvature. Some researchers claim this to be the onset of meandering.

The forced behavior described earlier refers to the static equilibrium state, with constant discharge and sediment supply. The interaction of the retarded adjustment of the velocity field and that of the transverse bed slope also gives rise to a form of free (as opposed to forced) behavior, that is, the formation of a downstream migrating system of bars alternately at the left and the right bank of the river (Figure 18). Like the point bar formation in bends described previously, this formation of so-called *alternate bars* is governed by the channel aspect ratio. When this exceeds a certain threshold value, the bars begin to develop spontaneously, insofar as there is no spatio-temporal variation in the system's forcing that imposes this type of behavior. The extent to which the equilibrium amplitude is reached depends on the duration of the state of threshold exceedance, which is usually limited due to stage variations.

Blondeaux and Seminara (1985) came up with a unified theory for free and forced bars based on a weakly nonlinear stability analysis of the coupled water–sediment bed system. Later on, their group at the University of Genoa has done pioneering work on other types of morphodynamic instabilities (e.g. Blondeaux, 2001).

Figure 18 Jaeggi's famous shot of alternate bars in the Rhine in Switzerland (Jaeggi, 1984; flow from bottom to top) © American Society of Civil Engineers (ASCE)

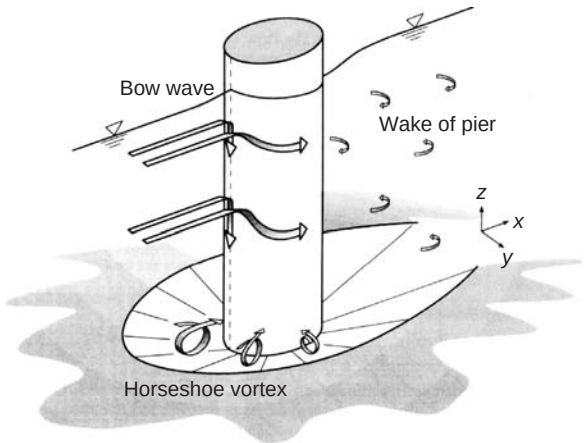

Figure 19 Scour around bridge piers cannot be modeled without taking due account of the 3-D horseshoe vortex (Graf, 1998)

This theoretical work starts from idealized situations that are seldom found in reality. Yet, the insight it gives

means an important support to numerical modeling of more realistic situations. One of the software systems enabling 3-D morphodynamic modeling is Delft3D (see **http://wldelft.nl/soft/d3d** for further reference).

At a local scale, essentially 3-D phenomena occur near structures and obstacles, such as bridge piers (Figure 19) and groyne heads. Here we need to distinguish two modes of scour called *clear water scour* and *live bed scour*, respectively. Clear water scour occurs if the shear stress at the undisturbed bed is below the threshold of motion. Near the structure, this threshold is exceeded and the bed keeps on eroding until the shear stress has been reduced to the threshold level. Strictly speaking, the erosion downstream of a sediment-blocking barrier or weir is also a case of clear water scour, because the critical shear stress is reached via coarsening of the bed sediment, rather than by a decrease of the bed shear stress.

An example of live bed scour is the development of scour holes and deposition areas (so-called *groyne flames*; see Figure 20) in groyne-regulated rivers (e.g. Yossef and Klaassen, 2002). Especially the scour holes near the tips of the groynes cannot be described without considering the 3-D water motion in the eddies shedding from the tip, which are very efficient in picking up sediment from the bed. The practical relevance of these phenomena lies primarily in the potential limitation of navigability due to the groyne flames.

Navigability is an important aspect of many regulated rivers. Bends are critical in this respect, especially because the point bar formation in the inner bend tends to reduce the navigable width exactly in a reach where extra width would be welcome, because the pathway of ship is larger in a bend, and because loaded ships tend to cross over towards the deep outer bend. Various measures have been taken to artificially increase the navigable width in bends, such as maintenance dredging, filling up the outer bend with riprap (Figure 21), increasing the flow resistance in the outer bend by bottom groynes, suppressing the secondary flow by bottom vanes, and so on (also see Klaassen *et al.*, 2002). All these measures, except for the dredging and the vanes, have in common the tendency to shift the maximum transport rate towards the inner bend, and also that they end somewhere near the bend exit. This combination leads to an unnatural transverse distribution of the sediment transport at the end of the structure, and hence to an increased pickup of sediment where the transport coming out of the bend is too low and an increased deposition where the transport is too high. This leads to an anomaly in the transverse bed slope, which decays further downstream (see Figure 21). Depending on the value of the interaction parameter, this can be an exponential or a damping oscillatory process. In any case, it has the effect of shifting the critical point for navigability from the bend to the reach just downstream of the bend.

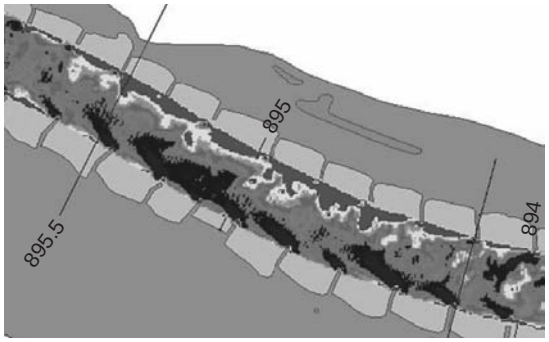

Figure 20 Groyne flames as observed in the Waal west of Nijmegen (flow from right to left). The asymmetry between the left and the right part of the channel is due to point bar formation in this slightly curved reach (courtesy Rijkswaterstaat). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Note the strong scour at the left bank just downstream of the filled area, and the deposition at the opposite side (courtesy Rijkswaterstaat). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

CONCLUSION

Many of the above examples illustrate that effective river regulation is possible only on the basis of a thorough understanding of the dynamics involved in the river's response to the regulation measures. The same goes for the management of regulated rivers. Despite the control measures put in place, the river keeps part of its natural character, including the variability and the limited predictability involved. This has to be borne in mind whenever we are tempted to think that we are in full control of these systems.

PART 13

Groundwater

145: Groundwater as an Element in the Hydrological Cycle

WILLIAM M ALLEY[1], JAMES W LA BAUGH[2] AND THOMAS E REILLY[2]

[1] United States Geological Survey, Office of Ground Water, San Diego, CA, US
[2] United States Geological Survey, Office of Ground Water, Reston, VA, US

Groundwater commonly is portrayed in diagrams of the hydrological cycle as a single pool of water with simple transfers of water to and from the land surface, oceans, and atmosphere. In reality, groundwater is an integral part of a complex hydrological cycle that involves the continuous movement of water on Earth. We begin with a global perspective on the importance of groundwater in the hydrological cycle and then address the importance of understanding the dynamics of groundwater-flow systems. We next turn our attention to groundwater budgets and the effects of humans and climate on these budgets. The final section is devoted to a discussion of interactions between groundwater and surface water, and we highlight the importance of these interactions in the hydrological cycle.

INTRODUCTION

Groundwater occurs almost everywhere beneath the land surface. The widespread occurrence of potable groundwater is a major reason it is used as a source of water supply worldwide. Groundwater also plays a crucial role in sustaining streamflow during dry periods and is vital to many lakes and wetlands. Moreover, many plants and aquatic animals depend greatly upon the groundwater that discharges to streams, lakes, and wetlands.

Groundwater commonly is portrayed in diagrams of the hydrological cycle as a single pool of water with simple transfers of water to and from the land surface, oceans, and atmosphere. In reality, groundwater is an integral part of a complex hydrological cycle that involves the continuous movement of water on Earth. In this article, we begin with a global perspective on the importance of groundwater in the hydrological cycle. The importance of understanding the dynamics of groundwater-flow systems is then addressed. We next turn our attention to groundwater budgets and the effects of humans and climate on these budgets. The final section is devoted to a discussion of interactions between groundwater and surface water, and we highlight the importance of these interactions in the hydrological cycle.

GROUNDWATER IN THE HYDROLOGICAL CYCLE OF THE EARTH

The volume of water contained in groundwater storage often is compared to other major global pools of water within the Earth's hydrological cycle. Published estimates of the volumes of water in major global pools are shown in Table 1. While the estimates of the volume of water in the Earth's oceans and atmosphere shown in Table 1 are relatively similar, the estimates for groundwater storage vary greatly. In part, this variability is due to different considerations of depth and salinity in defining the global groundwater pool, and, in part, the variability reflects less knowledge about groundwater than other global pools of water. The estimates of water contained as soil moisture also illustrate considerable uncertainty.

Note that early estimates by Kalle (1945) of the global groundwater pool greatly underestimated its volume. Kalle's estimates are shown for historical purposes, but are not considered further in the discussion below.

The two major pools of freshwater are groundwater and water contained in glaciers and polar ice. As shown in Table 1, and depending on its definition, the groundwater pool may constitute from less than one-third to more

than twice the volume of water contained in glaciers and polar ice.

Table 2 focuses on the global freshwater resource and shows the relative amounts of groundwater and other sources of freshwater (ignoring water frozen in glaciers and polar ice). Despite uncertainty in the values, it is clear that groundwater is the major pool of nonfrozen freshwater on Earth, likely composing more than 95% of this resource. Lakes and reservoirs contain much of the remaining nonfrozen (available) freshwater with considerable uncertainty about the volume contained as soil moisture. Rivers contain only a tiny fraction of the available freshwater.

Comparisons also can be made in the annual global fluxes of water as indicated in Table 3. The values for groundwater discharge to oceans shown in Table 3 include only estimates for direct discharge to bays, estuaries, and oceans. Groundwater also reaches coastal waters indirectly by discharge to streams and rivers that drain to coastal waters. The values for runoff to oceans shown in Table 3 include this indirect groundwater discharge to streams and rivers. For example, L'vovich (1979) estimates that 12 of the 41 thousand km^3 per year of runoff to oceans consists of groundwater discharge to streams and rivers.

The residence time of groundwater can vary from a few days to more than 10 000 years. It is difficult, however, to estimate an average global residence time for groundwater, because of the previously noted complexities in defining the global groundwater pool. In comparison, the average residence time for continental runoff in free-flowing rivers likely varies between 16 and 26 days, and regulation by reservoirs has increased the mean age of continental runoff to slightly longer than a month (Vörösmarty and Sahagian, 2000).

Some discussions of the global groundwater pool distinguish between groundwater in "active" exchange with the Earth's surface (commonly referred to as renewable groundwater) and "fossil" water accumulated over tens of thousands of years under different climatic conditions, which, once used, cannot be replenished readily (sometimes referred to as nonrenewable groundwater). Commonly, it is difficult to describe the two categories of groundwater reserves quantitatively and to draw boundaries between them.

Water withdrawals by humans are superimposed upon the natural pools and fluxes of groundwater. Groundwater withdrawals are large and have increased greatly during the past 50 years. Perhaps as many as two billion people depend directly upon groundwater for drinking water, and 40% of the world's food is produced by irrigated agriculture that relies largely on groundwater (United Nations Environment

Programme, 2003). Unfortunately, despite the importance of groundwater, estimates of its use in many countries are either unavailable or of poor quality.

Finally, it is worth noting that groundwater depletion may have affected global water balances enough to contribute to sea-level rise during the past century as a result of water pumped from wells that returns to the sea by runoff or evaporation/precipitation (Sahagian *et al.*, 1994). Extensive drainage of wetlands during the past century also may have contributed to sea-level rise.

GROUNDWATER-FLOW SYSTEMS

The three-dimensional body of Earth material saturated with moving groundwater that extends from areas of recharge to areas of discharge is referred to as a groundwater-flow system (Figure 1). Perhaps the most obvious source of water to groundwater-flow systems (or more simply referred to as groundwater systems) is areal recharge from precipitation. Water from areal recharge flows from the water table where the recharge enters the saturated groundwater system through the flow system to the discharge area (which is a stream in Figure 1). Surface water features such as streams, wetlands, and lakes can either be the location of water entering the groundwater system (recharge area) or the location of water leaving the groundwater system (discharge area).

The areal extent of groundwater-flow systems varies from a few square kilometers or less to tens of thousands of square kilometers. The lengths of groundwater-flow paths range from a few meters to tens, and sometimes hundreds, of kilometers. A deep groundwater-flow system with long flow paths between areas of recharge and discharge may be overlain by, and in hydraulic connection with, several shallow, more local, flow systems.

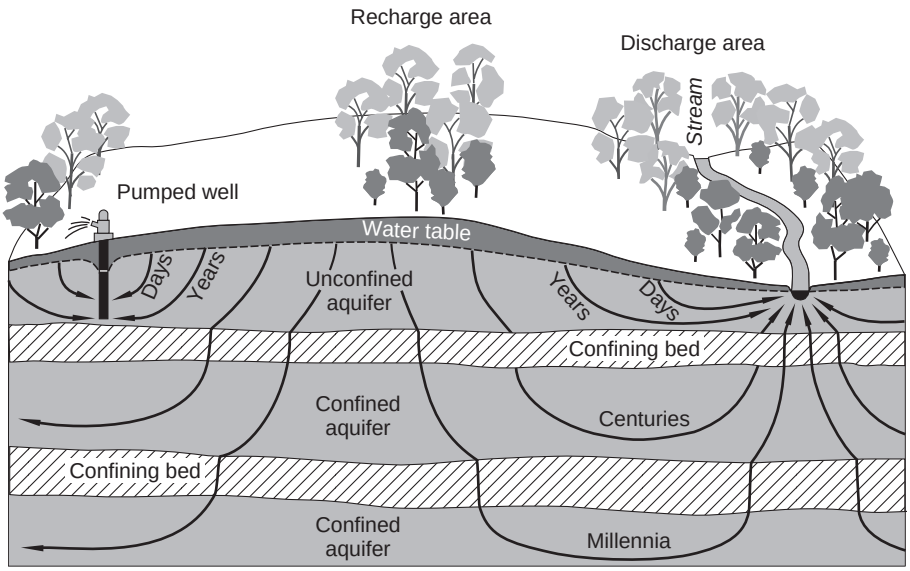

Figure 1 Groundwater system showing generalized flow paths of groundwater movement and the relative age of the water since the time of recharge. (Modified from Heath, 1983 and Winter *et al.*, 1998)

Factors that control Groundwater Movement

Two types of factors control groundwater movement: factors within the porous media and factors along the boundaries of the porous media where the water enters and leaves the groundwater system.

The equation that describes the movement of groundwater within a porous media is known as *Darcy's law*. In simplified terms, the average linear velocity (Freeze and Cherry, 1979) of the water is calculated from Darcy's law as:

$$v = -\left(\frac{K}{n}\right) i \qquad (1)$$

where v is the average linear velocity (referred to as velocity for the remainder of the text) of the groundwater (LT^{-1}), K is the hydraulic conductivity (LT^{-1}), n is the effective porosity (dimensionless), and i is the hydraulic gradient (the change in head per unit of distance; dimensionless), which is a negative number in the direction of flow. As a result, the hydraulic conductivity, effective porosity, and hydraulic gradient are all important in the determination of the movement of groundwater. The hydraulic conductivity, which represents the ability of the geologic framework to transmit water, is a property of the porous media and the fluid contained therein. The hydraulic conductivity of a groundwater system can vary over many orders of magnitude (Figure 2). The larger the hydraulic conductivity of a porous media, the easier it is for water to flow through it. The porosity is the ratio of the volume of the voids divided by the total volume. The effective porosity is the volume of the voids that are interconnected and available for fluid transmission divided by the total volume. The hydraulic gradient is the change in static head per unit of distance in a given direction (Lohman *et al.*, 1972). The static head generally is measured as the water level in a well. The water-level distribution or potentiometric surface describes the hydraulic gradient within an aquifer, which, in turn, determines the direction and rate of groundwater flow. For groundwater systems in cavernous karst terrain or in fractured-rock systems, the validity of Darcy's law, which was developed for porous media, may not be strictly applicable (White, 1993), and other methods for determining the velocity distribution may be required.

Darcy's law describes the rates and directions that water will flow in a groundwater system. The other important factors that are necessary to adequately understand the movement of water in a groundwater system are the sources of water to the system and the stresses (including water use) on the system. The external boundaries of the groundwater system, such as streams and areal recharge, affect the paths of water movement and the hydraulic head distribution (Reilly, 2001). The location of wells and water use (for example, irrigation) also impact where water moves within the groundwater system.

Time of Travel in a Groundwater Flow System

The age (time since recharge) of groundwater varies in different parts of groundwater-flow systems. The age of groundwater increases along a particular flow path through the groundwater-flow system from an area of recharge to

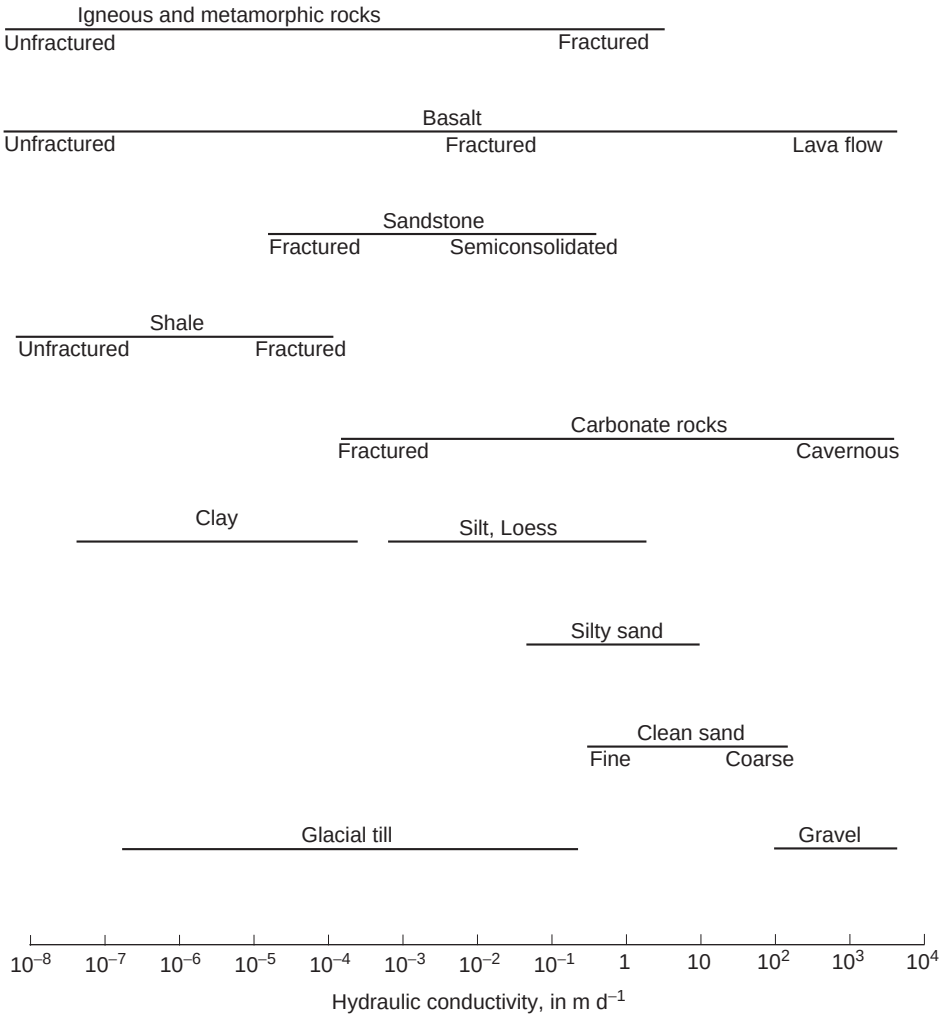

Figure 2 Range of hydraulic conductivity for selected rock types (Modified from Heath, 1983)

an area of discharge. In general, Darcy's law determines the flow velocity, and, therefore, the time of travel. Travel times within groundwater systems can vary considerably (Figure 1). In shallow flow systems, ages of groundwater at areas of discharge can vary from less than a day to a few hundred years. In deep, regional flow systems with long flow paths (tens of kilometers), ages of groundwater may reach thousands or tens of thousands of years or more. The shallower and younger groundwater tends to be more vulnerable to contamination from human activities at the land surface (Focazio *et al.*, 2002).

Fractured-rock systems in bedrock usually have smaller effective porosities than unconsolidated porous media such as sands and gravels, and flow velocities through fractured rock can be relatively fast. For example, travel times of water over distances of several kilometers have been estimated at less than a year for municipal wells completed in fractured dolomite in Wisconsin (Rayne *et al.*, 2001). In such cases, seasonal variations in recharge and pumping affect the variability in travel times. In more sluggish groundwater systems, such as the Bangkok Basin in Thailand (Sanford and Buapeng, 1996), long-term climate and geologic change need to be considered in understanding the movement of groundwater over tens of thousands of years.

Tracer techniques have been applied widely to estimate the residence time of subsurface waters, as well as the amounts and timing of recharge and discharge (Cook and Böhlke, 1999). Most tracer techniques require knowledge (or assumption) of the time history of tracer input at the land surface or the water table. This temporal pattern then is correlated to a concentration-depth pattern in the subsurface at a point in time. Other approaches use information on decay products to determine age. Tracers can occur naturally (chloride, heat, the stable isotopes ^{2}H and ^{18}O), occur in the atmosphere as a result of human activities (tritium, ^{36}Cl, CFCs), or be applied intentionally on the land surface (fertilizers, pesticides). Isotopes of elements,

such as radon, dissolved from host rocks also can be used to estimate residence times and interactions with surface water. Over the past decade, research in age dating and tracking young groundwater (<50 years old) using multiple tracers has resulted in major breakthroughs in understanding the dynamics of groundwater systems.

The time required for water to move through a groundwater system also can be estimated for some systems on the basis of aquifer storage volumes. A three-dimensional groundwater system contains a specific volume of water in the pores and cracks of the media. This volume has been referred to here as the volume in storage or the "pool" of water in storage (V in units of L^3). The rate at which this volume is replaced is related to the rate of recharge entering the system that displaces the water in storage; this is the flux of water entering the system (Q in units of L^3T^{-1}). In an average (or simplified) sense that does not take into account differences in flow paths and the nature of the framework, the time required for water to move through the entire system is simply VQ^{-1}. This approach may yield a poor approximation in complex flow systems, such as karst or fractured rock.

GROUNDWATER BUDGETS

Water budgets are used widely to account for flow and storage changes in various hydrological systems, including rivers, lakes, drainage basins, the land surface, and groundwater systems. In its most basic form, a water budget is expressed simply as:

$$\text{Inflow} - \text{Outflow} = \text{Change in Water Storage} \quad (2)$$

Each of the three main terms in the water-budget equation can include both natural (e.g. precipitation) and human-induced (e.g. imported water) components. Quantities in the budget apply to a predefined volume and can either be flow rates [L^3T^{-1}] or volumes [L^3] for a specified time period.

Understanding water budgets for groundwater systems is both critically important and challenging. Groundwater is hidden from view, and groundwater divides do not necessarily coincide with surface-water divides (Winter *et al.*, 2003). Several aquifers may underlie the land surface at any given location with varying hydraulic properties and locations of recharge.

Under natural (predevelopment) conditions, a groundwater system is in long-term equilibrium. That is, averaged over some period of time (and in the absence of climate change), the amount of water entering or recharging the system is approximately equal to the amount of water leaving or discharging from the system. Inflows (recharge) to a groundwater system under natural conditions include areal recharge from precipitation on the land surface and recharge from losing streams, lakes, and wetlands. Outflows (discharge) from a groundwater system under natural conditions include discharge to surface-water bodies and groundwater evapotranspiration. Because the system is in equilibrium, the quantity of water stored is constant or varies about some average condition in response to annual or longer-term climatic variations. This predevelopment water budget is shown schematically in Figure 3(a).

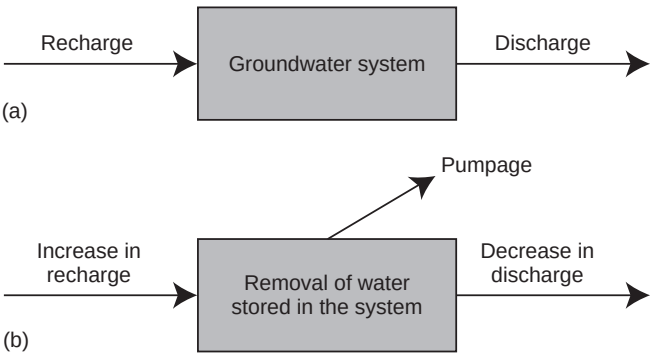

Figure 3 (a) Predevelopment water-budget diagram illustrating that inflow equals outflow. (b) Water-budget diagram showing changes in flow for a groundwater system being pumped. The sources of water for the pumpage are changes in recharge, discharge, and the amount of water stored. (Alley *et al.,* 1999)

Effects of Human Activities on Groundwater Budgets

Withdrawals of groundwater by pumping change the natural (or predevelopment) flow system. Water that is withdrawn must be supplied by some combination of (i) more water entering the groundwater system (increased recharge), (ii) less water leaving the system (decreased discharge), and (iii) removal of water that was stored in the system. This statement, illustrated in Figure 3(b), can be written in terms of rates (or volumes over a specified period of time) as:

$$\text{Pumpage} = \text{Increased recharge} + \text{Water removed from storage} + \text{Decreased discharge} \quad (3)$$

That is, the water pumped from the system must come from some change of flows and from removal of water stored in the predevelopment system (Theis, 1940; Lohman, 1972). Note that the initial predevelopment water-budget values do not enter directly into the budget calculation.

Regardless of the amount of water withdrawn, the system will undergo some drawdown in water levels in pumping wells to induce the flow of water to these wells, which means that some water initially is removed from storage. For most groundwater systems, the change in storage in response to pumping is a transient phenomenon that occurs as the system readjusts to the pumping stress. The relative

contributions of changes in storage, changes in recharge, and changes in discharge evolve with time. If the system can come to a new equilibrium, the changes in storage will diminish to zero and inflows will again balance outflows:

$$\text{Pumpage} = \text{Increased recharge} + \text{Decreased discharge} \quad (4)$$

Thus, the long-term source of water to discharging wells is typically a change in the amount of water entering or leaving the system.

The time that is required to bring a hydrologic system into equilibrium depends on the rate at which the discharge can be captured, which is a function of the characteristics of the aquifer system and the placement of pumping wells (Lohman, 1972). In many circumstances, the dynamics of the groundwater system are such that an approximate equilibrium condition would not be reached for decades or even centuries.

A prevalent view among many hydrologists and nonhydrologists alike is that the development of a groundwater system is considered to be "safe" if the rate of groundwater withdrawal does not exceed the rate of natural recharge. Bredehoeft *et al.* (1982) referred to this concept as the "Water-Budget Myth". It is an oversimplification of the information that is needed to understand the effects of developing a groundwater system. Natural recharge is a critical element for understanding water budgets, is an essential parameter in the modeling of aquifer systems, and its estimation is fundamental to understanding contaminant transport from the land surface. Nonetheless, an estimate of natural recharge, by itself, is of limited value in determining the amount of groundwater that can be withdrawn on a sustained basis. How much groundwater is available for use depends much more upon how changes in inflow and outflow, which result from pumping, affect the surrounding environment and the acceptable trade-off between groundwater use and these changes. Achieving this trade-off in the long term is a central theme in the evolving concept of sustainability (Alley *et al.*, 1999; Sophocleous, 2000; Alley and Leake, 2004).

In determining the effects of pumping and the amount of water available for use, it is critical to recognize that not all the water pumped is necessarily consumed (Kendy, 2003). For example, some of the water pumped for irrigation is consumed by evapotranspiration and some of the water returns to the groundwater system by infiltration, canal leakage, and other means of irrigation return flow. Most other uses of groundwater are similar, in that some of the water pumped is not consumed, but is returned to the system.

Although withdrawal of groundwater is the most direct way in which humans affect groundwater budgets, many other human activities commonly must be considered, particularly those that affect recharge rates. Changes in the patterns and rates of recharge can be caused by irrigation and urban development, removal or changes in the type of vegetation, changes in surface-water flows and storage, and land drainage. Identifying human practices that influence recharge is straightforward, but quantifying the effects of these practices is very difficult. For example, built-up and paved areas promote runoff and inhibit infiltration. The enhanced runoff, however, may be channeled to a retention basin or infiltration gallery, resulting in the relocation of recharge areas and the transition from slow, diffuse recharge to rapid, localized recharge (Lerner, 2002). Wastewater infiltration also is often a major component of overall recharge to aquifers around urban areas, especially in more arid climates (Foster and Chilton, 2004).

Artificial recharge with excess surface water or reclaimed wastewater is increasing in many areas, thus becoming an increasingly important component of the hydrological cycle. In fact, with long-term intensive use, much of the local groundwater may be derived from artificial recharge (Shelton *et al.*, 2001)

Examples of large-scale changes that can occur in the water budgets of regional groundwater systems are illustrated by examining the simulated sources of water (increased recharge, decreased discharge, and changes in storage) that supplied withdrawals from nine major groundwater systems in the United States. These results, shown in Figure 4, are from numerical simulations of major regional aquifer systems for the period of development up through the mid to latter 1980s. The results illustrate large variability in the relative proportions of different sources of water to pumping wells. The Floridan and Edwards–Trinity aquifer systems, which equilibrate rapidly after pumping, were simulated as steady state with no long-term change in storage for the simulation period. In contrast, the Southern High Plains, where most natural discharge occurs far from pumping wells, and the deeply buried Great Plains aquifer system had substantial changes in groundwater storage. In some areas, such as the California Central Valley and Eastern Snake River Plain, return flow of excess irrigation water was the major change in the water budget during the simulation period. Note that the distinction between changes in recharge and changes in discharge commonly is a function of how the system was defined (i.e. a gain to one system may result in a loss from an adjoining system). For example, groundwater withdrawals from confined aquifers (Northern Atlantic Coastal Plain and Gulf Coastal Plain) can cause flow to be diverted (recharged) into the deeper regional flow regime that would otherwise discharge to streams in the outcrop areas.

Effects of Climate on Groundwater Budgets

Climate affects groundwater budgets in several ways. Most directly, climate influences the rates and distribution of

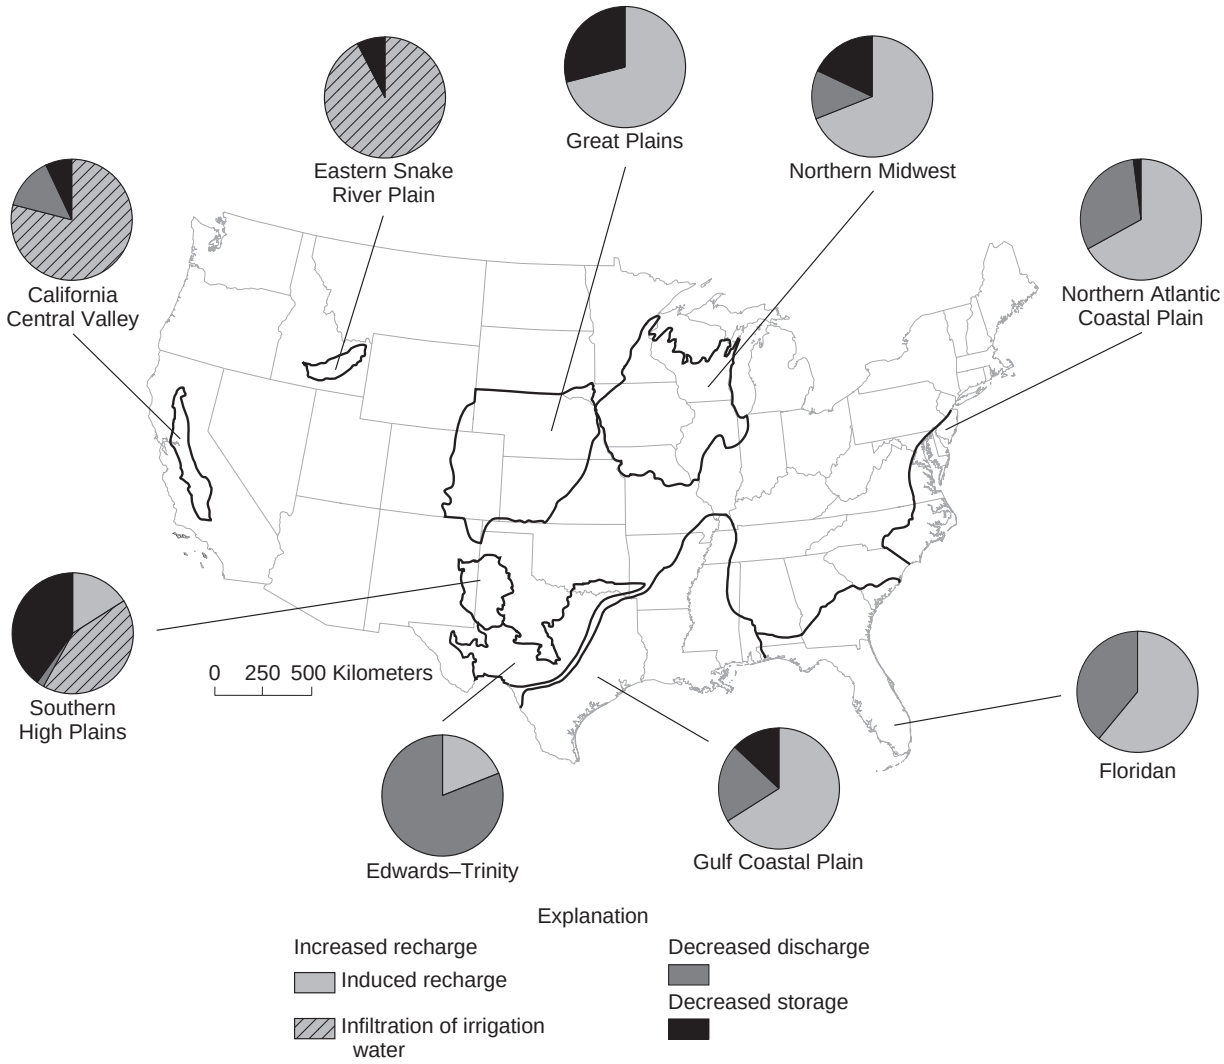

Figure 4 Sources of water that supply withdrawals from major aquifer systems in the United States based on model simulations for various periods through the 1970s and 1980s. The results illustrate the variety of ways in which overall groundwater budgets can change in response to large-scale pumping. The simulations of the aquifer systems were done at different stages in their development, and, in many cases, are not representative of today's conditions given the dynamic nature of groundwater systems. (Data from Johnston, 1999; Modified from Alley *et al.,* 2002)

recharge. Climate also affects human demands for groundwater and affects plant transpiration from shallow groundwater in response to changing inputs of solar energy and changing depths to the water table. Some groundwater responses to climate variability and change may show considerable temporal lag, given the relatively long response times of groundwater systems. For example, long-term trends in the balance between precipitation and evapotranspiration – caused by either long-term variability or by anthropogenic global change – may affect groundwater discharge, but their effects may be attenuated and spread out over time. As an indication of the effects of long-term climate changes on groundwater systems, much of the water pumped today in arid regions comes from aquifers that were recharged at higher rates during wetter or cooler conditions in the past (e.g. Zhu *et al.*, 1998).

Long-term droughts may be viewed as a natural stress on groundwater systems that in many ways have effects similar to groundwater withdrawals; namely, reductions in groundwater storage and accompanying reductions in groundwater discharge to streams and other surface-water bodies. Because climate stress on the hydrologic system is added to the existing or projected human-derived stress, droughts represent extreme hydrologic conditions that may be important in long-term groundwater management.

Human-induced climate change in the coming decades may affect groundwater resources in several ways, including (i) long-term changes in groundwater recharge resulting

from changes in the annual and seasonal distribution of precipitation and temperature, (ii) more severe and longer lasting droughts, (iii) changes in evapotranspiration resulting from changes in vegetation, and (iv) possible increased demands for groundwater as a backup source of water supply. Surficial aquifers that supply much of the water in streams, lakes, and wetlands are likely to be the part of the groundwater system most sensitive to climate change. Climate not only affects groundwater budgets, but to the extent that groundwater systems influence evapotranspiration and runoff, changes in groundwater fluxes also may affect climate (National Research Council, 2004).

Several studies have used atmospheric circulation models and future scenarios of precipitation and temperature to simulate the effects of climate change on groundwater recharge, storage, and discharge. For example, York *et al.* (2002) illustrate the potential importance of links among climate, shallow groundwater levels, and groundwater evapotranspiration using a coupled aquifer-land surface-atmosphere model.

INTERACTIONS BETWEEN GROUNDWATER AND SURFACE WATER

Interactions between groundwater and surface water are an integral part of the hydrological cycle. The interactions need to be viewed at a range of scales and as having large variability in space and time. Many of the early studies of these interactions focused on streams. Once thought to be of little consequence and thus ignored, interactions of groundwater with lakes, wetlands, estuaries, and oceans are now recognized as important processes. The interactions of surface-water bodies with groundwater systems are governed by the positions of the water bodies relative to the groundwater-flow system, the characteristics of surface-water beds and underlying geologic materials, and the climatic setting (Winter *et al.*, 1998).

Streams

Streams interact with groundwater in various ways. Depending upon the relation between groundwater head at the stream–channel interface and the stream stage, a stream may gain water from inflow of groundwater through the streambed (gaining stream; stream stage < groundwater head), lose water to groundwater by outflow through the streambed (losing stream; stream stage > groundwater head), gain water from groundwater on one side of the stream and lose water to groundwater on the other side (flow-through), or possibly have zero exchange (parallel-flow) when the channel stage and groundwater head are equal throughout a cross section (Woessner, 2000). The position of a channel within a floodplain can control the type of exchange. For example, flow-through reaches are most often found when a channel cuts perpendicular to the fluvial plain groundwater-flow field (Wroblicky *et al.,* 1998; Woessner, 2000). Larkin and Sharp (1992) classify stream-aquifer systems based on the predominant regional groundwater-flow component as (i) underflow component–dominated (groundwater flow is largely parallel to and in the same direction as the stream), (ii) baseflow component–dominated (groundwater flow is largely perpendicular to and from the stream), and (iii) mixed. They conclude that the dominant groundwater component (baseflow or underflow) can be inferred from geomorphic data such as channel slope, river sinuosity, degree of river incision through the alluvium, width-to-depth ratio of the bankfull river channel, and the character of the fluvial depositional system.

In some environments, streamflow gain or loss can persist; that is, a stream might always gain water from groundwater, or it might always lose water to groundwater. In many environments, the flow direction can vary along a stream; some reaches receive groundwater and other reaches lose groundwater. Flow directions between groundwater and surface water also can change on daily or shorter timeframes as a result of individual storms causing focused recharge near the streambank, flood peaks moving down the channel, or transpiration of groundwater by streamside vegetation.

Losing streams can be connected to the groundwater system by a continuous saturated zone or can be disconnected from the groundwater system by an unsaturated zone. An important feature of streams that are disconnected from groundwater is that pumping shallow groundwater near the stream does not affect the flow of the stream near the pumped wells.

Even in settings where streams are primarily losing water to groundwater, certain reaches may receive groundwater inflow during some seasons. The amount of water that groundwater contributes to streams can be estimated by analyzing streamflow hydrographs to determine the groundwater (baseflow) component (Rutledge, 1993; Halford and Mayer, 2000). The proportion of stream water derived from groundwater inflow varies considerably among different physiographic and climatic settings, as illustrated in Figure 5 for streams in 10 different regions in the United States.

Water exchange across the interface between groundwater and surface water has been explored in some detail in the past decade (Jones and Mulholland, 2000). Many studies have demonstrated that local geomorphic features such as streambed topography, streambed roughness, meandering, and heterogeneities in sediment hydraulic conductivities can give rise to localized flow systems within streambeds and banks (Harvey and Bencala, 1993; Winter *et al.,* 1998). The near-stream subsurface environment in which there is active

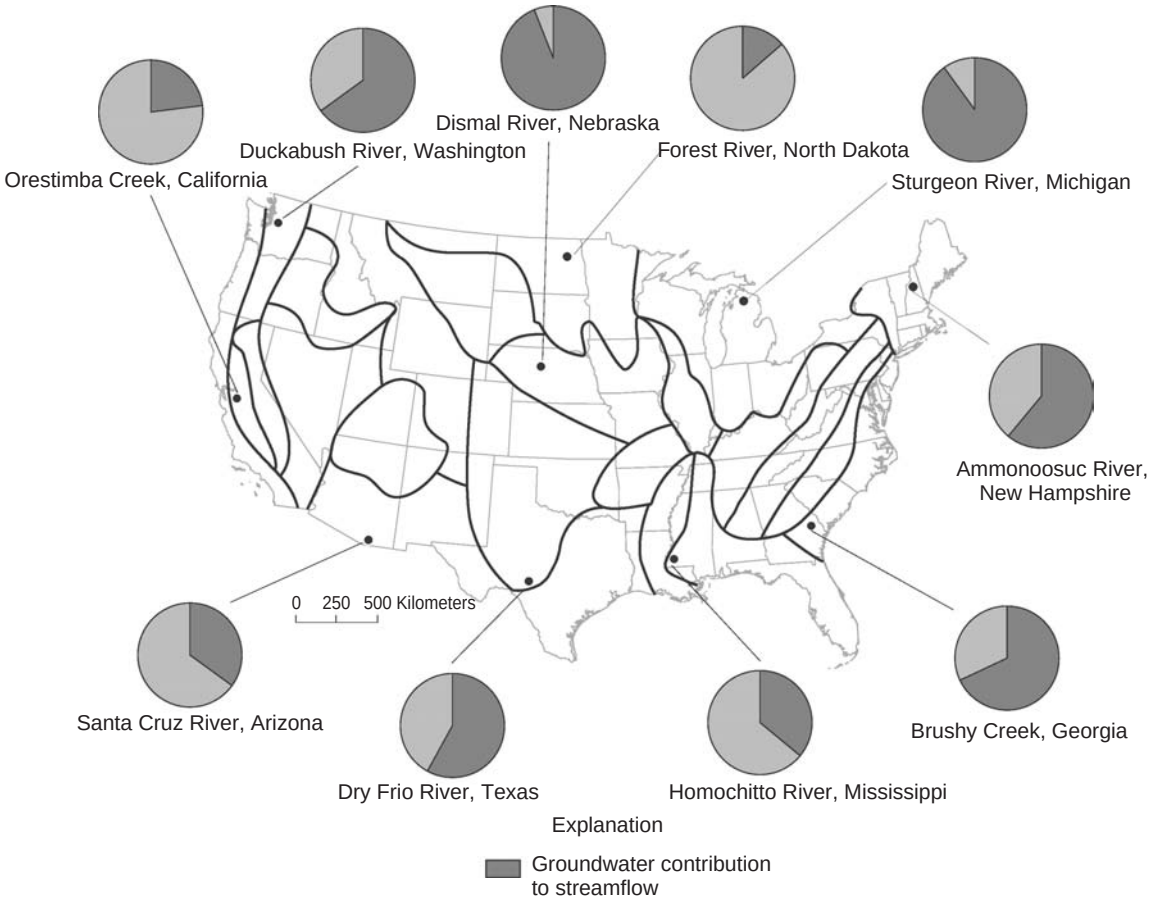

Figure 5 Twenty-four regions were delineated in the conterminous United States where the interactions of groundwater and surface water are considered to have similar characteristics. The estimated groundwater contribution to streamflow is shown for specific streams in 10 of these regions. (Modified from Winter *et al.,*1998)

exchange between surface water and groundwater commonly is referred to as the hyporheic zone. The hyporheic zone can be viewed as a zone in which finer-scale interactions between the stream-channel water and groundwater occur within the context of larger-scale patterns of loss and gain of channel water in drainage basins. Understanding these very localized subsystems within the hydrological cycle is increasingly viewed as important to understanding the chemical composition of surface and subsurface water and stream and riparian ecology (Brunke and Gonser, 1997; Boulton, 2000). For example, an important feature of water exchange between streams and hyporheic zones is that surface water is kept in close contact with chemically reactive mineral coatings and microbial colonies in the subsurface, having resultant effects on biogeochemical processes such as nitrification (Dahm *et al.,* 1998; Hinkle *et al.*, 2001). Localized exchange of surface water and groundwater also can result in thermal effects that influence the distribution of biota and biogeochemical processes. For example, thermal effects of groundwater discharge have been directly related to fish habitat, both in terms of spawning areas and refuge for adults when ice forms in colder environments (Power *et al.,* 1999)

Lakes and Wetlands

The relation of lakes and wetlands to groundwater can be viewed as occurring in three different ways: (i) lakes and wetlands may recharge groundwater without receiving groundwater input, (ii) they may both recharge groundwater and receive discharge water from groundwater, or (iii) they may receive groundwater discharge, but not discharge water to groundwater (Sloan, 1972; Winter, 1976; Boyle, 1994). These relations are influenced by the positions of the lakes or wetlands within regional flow systems (Smith and Townley, 2002). Groundwater-flow patterns in the vicinity of these water bodies can vary in response to shifts in subsurface-water divides that occur during wetter or drier conditions (Holzbecher, 2001).

The amount of groundwater moving into or through lakes and wetlands varies considerably. Negligible to relatively small amounts of groundwater move into or

through lakes and wetlands in poor hydraulically conductive materials, such as some crystalline rocks (Schindler *et al.*, 1976), clayey till (Shaw and Prepas, 1990), lacustrine clays (Zektzer and Kudelin, 1966), or dense organic peats. More considerable amounts of groundwater move into or through lakes and wetlands in more conductive materials such as sandy tills, sands, or sands, and gravels (Shaw and Prepas, 1990), as well as in karst (Lee, 2002).

Groundwater movement into and out of lakes and wetlands can be diffused, focused, or some combination thereof. Focused groundwater discharge into lakes and wetlands is in the form of springs. The direction of flow at the periphery of lakes and wetlands can be affected by transpiration. Flow reversals in response to transpiration have been documented in a variety of geologic materials, such as glacial till (Meyboom, 1967), organic peat (Fraser *et al.*, 2001), and sandy till (Doss, 1993).

Springs

Springs typically are present where the water table intersects the land surface. They may form at topographic depressions; along lithologic contacts where permeable rocks overlie rocks of much lower permeability; along joints, fractures, or faults; or in karst areas (Fetter, 1988). Springs serve as important sources of water to streams and other surface-water features, as well as being important cultural and esthetic features in themselves. The important role of springs in human settlement is evident from the many localities named after the local springs. The constant source of water typical at many springs leads to abundant growth of plants and, in many cases, to unique habitats. Groundwater development can lead to reductions in spring flow, alterations of springs from perennial to ephemeral, or elimination of springs altogether. Springs typically represent points on the landscape where groundwater-flow paths from different sources converge. Groundwater development may affect the amount of flow from these different sources to varying extents, thus affecting the chemical composition of the spring water. Where springs discharge at land surface, they may offer a relatively easy place to measure natural groundwater discharge. However, because springs integrate the signal of hydrologic and geologic processes, sometimes over large spatial areas and long periods of time, they typically provide only an indirect source of information about groundwater systems (Manga, 2001).

Bays, Estuaries, and Oceans

The interface between saltwater and freshwater in groundwater systems is important in determining the amount of freshwater available in the aquifer system. This boundary generally occurs as fresh groundwater discharges into salty bays, estuaries, and oceans; however, the boundary also occurs inland where deeper brines bound an active freshwater flow system. In relatively homogeneous porous media, the denser saltwater tends to remain separated from the overlying freshwater. A transition zone, however, known as the *zone of diffusion* or the *zone of dispersion*, forms between the two fluids. In coastal areas where the porous media is heterogeneous in nature, a system of layered mixing zones can form. Substantial groundwater withdrawals can cause surrounding saltwater to move into areas of groundwater use in coastal (Bear *et al.*, 1999; Barlow, 2003) and inland (Lahm and Bair, 2000) areas, decrease the volume of freshwater available for use, and reduce the amount of freshwater discharged into coastal ecosystems.

Most research to date has been on the landward movement of saltwater in response to pumping in coastal areas. More recently, the seaward flow of fresh groundwater to coastal ecosystems and the role of groundwater in delivering nutrients and other dissolved constituents to these systems have received increased attention (Burnett *et al.*, 2002). As with all the components of the hydrological cycle, this circulation of water from one part of the cycle to another part is important to many issues.

The time required for the saltwater–freshwater interface and freshwater discharge to respond to human and natural changes can range from almost instantaneous to thousands of years. In some coastal areas, such as New Jersey, United States, and Suriname, South America (Kooi and Groen, 2001), relatively fresh groundwater found far off the coast is hypothesized to be water that was recharged during the Pleistocene when sea levels were much lower and has not yet been discharged to the surface.

CONCLUDING REMARKS

During the past 50 years, groundwater depletion has spread from isolated pockets to large areas in many countries throughout the world. Although sometimes viewed as a separate resource, groundwater is in fact an integral part of the hydrological cycle. Groundwater systems are dynamic and continually changing in response to human and climatic stresses. Linkages with surface water and the land surface are numerous and extend over many different timescales.

Future success in understanding the dynamic nature of groundwater systems will rely on continued and expanded data collection at various scales. Despite their importance, groundwater data have received little attention in concerns expressed about the continuity of global water data, primarily because such concerns have focused more on visible atmospheric and surface-water monitoring networks.

Water-level measurements from wells remain the principal source of information on the effects of hydrologic stresses on groundwater systems. Advances in instrumentation now enable the collection of real-time water-level data allowing scientists to observe diurnal and seasonal

trends from well networks across large areas (Cunningham, 2001). To understand the true nature of change in a groundwater system and to differentiate between natural and human-induced changes, records of water-level measurements over substantial periods are required (Taylor and Alley, 2001).

Surface-water depletion is viewed increasingly as the limiting factor to the long-term utilization of groundwater resources, yet the distinctly different temporal and spatial scales at which groundwater and surface-water systems operate present major challenges to their integrated analysis. The locations, quantity, and timing of reductions in surface-water flow resulting from groundwater development are fundamental questions at the scales of years to decades, whereas ecological issues require attention to seasonal and even diurnal changes in groundwater recharge and discharge. There is a continuing need to develop modeling tools that better represent groundwater as an integral part of the hydrological cycle; for example, coupled watershed and groundwater models are needed to better simulate the hydrological continuum from the atmosphere, to the land surface, to the unsaturated and saturated subsurface zones, and then back to surface waters or land surface.

Finally, groundwater systems have value not only as perennial sources of water supply, but also as reservoirs for cyclical injection and withdrawal to modulate the variability inherent in surface-water supplies. Management approaches increasingly involve the use of artificial recharge of excess surface water or recycled water by direct well injection, surface spreading, or induced recharge from streams. Many scientific challenges remain, however, to understand more fully the long-term responses of aquifer systems to alternate management approaches (Galloway *et al.*, 2003).

146: Aquifer Recharge

JOHN R NIMMO[1], RICHARD W HEALY[2] AND DAVID A STONESTROM[1]

[1] United States Geological Survey, Menlo Park, CA, US
[2] United States Geological Survey, Denver, CO, US

Aquifer recharge is important both for hydrologic understanding and for effective water resource management. Temporal and spatial patterns of unsaturated-zone processes such as infiltration largely determine its magnitude. Many techniques of recharge estimation exist. Water budget methods estimate all terms in the continuity equation except recharge, which is calculated as the residual. Detailed hydrologic models based on water-budget principles can produce recharge estimates at various scales. Empirical methods relate recharge to meteorologic and geographic parameters for a specific location. Surface-water methods include stream-hydrograph analyses to estimate baseflow (groundwater discharge) at lower elevations in a watershed, which is taken to equal the recharge that has occurred at higher elevations. Subsurface methods include analysis of water-table fluctuations following transient recharge events, as well as diverse unsaturated-zone methods. The zero-flux plane method determines the recharge rate from the change in water storage beneath the zero-flux depth, a boundary between water moving upwards due to evapotranspiration and water moving downward due to gravity. Lysimeter methods use buried containers filled with vegetated soil to mimic natural conditions. Water exiting the bottom is considered to be recharge. Darcian methods for estimating flux densities use unsaturated hydraulic conductivities and potential gradients, indicating recharge rates under appropriate conditions. Chemical mass-balance methods use conservative tracers that move with recharging water. Tracer concentrations in deep unsaturated-zone water, together with tracer input rates, indicate recharge rates. Distinct chemical "markers" can indicate travel times, hence, recharge rates. Thermal methods use heat as a tracer. Moving water perturbs temperature profiles, allowing recharge estimation. Geophysical methods estimate recharge based on water-content dependence of gravitational, seismic, and electromagnetic properties of earth materials.

INTRODUCTION

Defined as water that moves from the land surface or unsaturated zone into the saturated zone, aquifer recharge is vitally important for understanding the hydrologic cycle as well as for applications to water-resource management. The definition used here excludes saturated flow between aquifers so it might be more precisely termed "aquifer-system" or "saturated-zone" recharge. This definition avoids double-accounting in large-scale studies. Recharge is commonly expressed as a volume [L^3], typical units being m^3 or acre-ft. Recharge rate expresses either a flux [L^3T^{-1}] into a specified portion of aquifer, or a flux density [LT^{-1}] (volume per unit surface area) into an aquifer at a point. Over the long term, recharge naturally balances the total losses of water from the saturated zone. In some systems that are characterized by low permeabilities and sensitivity to climatic change, this long-term balance can be discerned only on millennial timescales.

Because it represents replenishment of aquifers critical to maintaining water supplies and ecosystems, recharge has obvious practical importance, especially where ground water is extracted for human use. It is a vital component for evaluating sustainability, as streamflow is for surface water. In the hydrologic balance of an aquifer, recharge processes act in opposition to discharge processes, so the relative magnitudes of recharge and discharge rate give a basic indication of the health of the aquifer and related systems.

Quantitative estimation of recharge rate contributes to the understanding of large-scale hydrologic processes. It

Encyclopedia of Hydrological Sciences. Edited by M G Anderson, 2005.

is important for evaluating the sustainability of groundwater supplies, though it does not equate with a sustainable rate of extraction (Bredehoeft *et al.*, 1982). Where contamination of an aquifer is a concern, the flux of water into the aquifer is essential information; estimating the recharge rate is a first step toward predicting the rate of solute transport to the aquifer. In cases where advection dominates the transport of contaminants (*see* **Chapter 152, Modeling Solute Transport Phenomena, Volume 4**), little additional hydraulic information may be needed to estimate travel times and solute fluxes. Moreover, recharging fluxes and their distribution need to be known for assessment of aquifer vulnerability to contamination, prediction of zones of significant contamination, and evaluation of remedial measures.

Our aim in this article is to provide an understanding of recharge in terms of its processes, its role as a component of the hydrologic cycle, and means for its local or regional estimation. We approach it mainly from the perspective of natural science, emphasizing recharge from natural processes, but also with attention to anthropogenic sources such as irrigation, wastewater disposal, and deliberate augmentation of groundwater. The discussion of estimation techniques makes up the largest part of this article, and we have included much description and explanation of basic recharge processes within this discussion.

RECHARGE IN NATURE AND APPLICATIONS

Sources and Basic Processes

The nature of the water source to a large extent determines which subsurface processes are relevant or dominant in the transport of water to the aquifer. In addition to precipitation, which is commonly the dominant source, other possible sources include surface-water bodies, irrigation, and artificial recharge.

In some cases, perennial or ephemeral surface water in the form of rivers, canals, and lakes may enter the aquifer directly (Winter *et al.*, 1998). Surface-water bodies, however, are not always recharge sources; they can instead be associated with aquifer discharge. A reach of a stream is considered "gaining" or "losing" depending on whether aquifer discharge or recharge dominates over that reach. If there is no unsaturated zone, recharge and discharge may proceed by analogous processes, in each case dictated by the net driving force (usually a combination of gravity and the pressure gradient) at the bottom of the surface-water body. Surface water in direct contact with the saturated zone can be treated in terms of surface water-groundwater interaction, for example, with stream-gauging. This is described further below and in **Chapter 145, Groundwater as an Element in the Hydrological Cycle, Volume 4**. In some cases, especially in drier climates, water from a body of surface water first travels through the unsaturated zone before reaching the aquifer.

Where recharge occurs from precipitation or other sources through an unsaturated zone, general expectations are (i) that gravity is the dominant driving force for recharge (as matric-pressure gradients would typically act to oppose recharge or would balance out over time) and (ii) that the hydraulic conductivity is markedly less in the unsaturated than in the saturated zone. It is not always possible to make a direct analogy between the recharge and discharge processes as with gaining and losing streams. Capillary forces may draw aquifer water upward into the unsaturated zone, but its future transport and ultimate discharge from the aquifer occur to a large extent through saturated-zone processes. Thus unsaturated-zone processes are critical to the evaluation of recharge in practical circumstances.

Deliberate or artificial-recharge operations frequently employ surface-water ponds or streams to put water into the subsurface, though in some applications the water for recharge is injected at significant depth. Natural and artificial recharge mostly involve the same types of processes, though artificial recharge may easily create situations that would be unusual in nature, for example, a thick unsaturated zone under a pond. Irrigation and other water-use practices can contribute to recharge, typically in ways analogous to precipitation or surface water, depending on the mode of application.

Variation

Recharge rates vary considerably in time and space. Recharge often occurs episodically in response to storms and other short-term, high-intensity inputs. Some, perhaps most, of the water that becomes recharge may be spatially concentrated in narrow channels as it passes through the unsaturated zone. Time- and space-concentration are important because for available water at the land surface, there is competition among alternative possible fates such as recharge, runoff, and evapotranspiration. For a given amount of infiltration, temporal concentration favors recharge because it entails shorter residence times for water in the portions of the soil from which evapotranspiration takes place. Similarly, a larger fraction will become recharge if it is concentrated in narrow channels such as fingers or macropores, not only because this tends to hasten its passage through the unsaturated zone, but also because the water then occupies less of the volume of soil from which evapotranspiration takes place.

Temporal Distribution of Recharge

Temporal variation occurs in general with seasonal or short-term variations in precipitation, runoff, or evapotranspiration. Evapotranspiration, in particular, is important because

it may extract most or all of the water that infiltrates. The time of greatest recharge is normally when much water is present, so that the processes other than recharge, especially evapotranspiration, are overwhelmed. Because flow rates are much greater in soil at high than at low water content (*see* **Chapter 150, Unsaturated Zone Flow Processes, Volume 4**), the downward flow important for recharge is much greater at high water contents. The slower vertical flow occurring with moderate or low water contents allows more water to remain for extraction from the soil without recharge.

Temporal concentration commonly occurs during storms, floods, and snowmelt. Variability is especially evident in thin unsaturated zones, where recharge may occur within a short time, often much less than one year (e.g. Delin *et al.*, 2000), and sometimes much less than one day (e.g. Gburek and Folmar, 1999). In deep unsaturated zones, recharge may be homogenized over many years such that it occurs with constant flux even though fluxes at shallow depths are erratic. Figure 1 illustrates temporal effects with an example from Dreiss and Anderson (1985).

Variation over time can also be significant over a longer term. Climatic change, for example, can systematically alter recharge patterns over hundreds or thousands of years. Sometimes, especially in arid regions with thick unsaturated zones, evidence for such change may be present in the observable distributions of water and other substances within the unsaturated zone (Tyler *et al.*, 1996).

Spatial Distribution of Recharge

Spatial variation occurs with climate, topography, soil, geology, and vegetation. For example, a decrease of slope or increase of soil permeability may lead to greater infiltration and greater recharge.

Topography influences recharge in several ways. It controls the generation of runoff. Steep slopes, especially if they are convex, may decrease infiltration and recharge. Swales and other concavities that tend to collect surface water may increase infiltration and recharge. Spatial concentration and increased recharge typically occur in depressions and channels, where higher water contents promote rapid movement by increasing the hydraulic conductivity (K), the amount of preferential flow, and the downward driving force at a wetting front.

Vegetation influences recharge mainly through its water-distributing activity. Where water is a significant limiting factor of vegetation growth, roots usually extract most of the water that infiltrates. This may be the case in all but the most humid climates. The result is that evapotranspiration may nearly equal infiltration, leaving recharge as a small fraction of infiltration. Artificial control of vegetation may counter natural influences. Agricultural practices, for example, may leave land fallow part of the time, decreasing total annual evapotranspiration from what it would be naturally. The depth range over which roots can extract water is frequently an important issue. Depending on the plant species, soil, and climate, roots may be present and active at depths of 10 m or more.

Another effect of evapotranspiration is that by drying the root zone, it enhances gradients that may be drawing water upward from the water table, in effect causing discharge through the unsaturated zone. The depth of the water table is a major influence in this process. Such discharge is likely to be greater if the water table is within or near the root

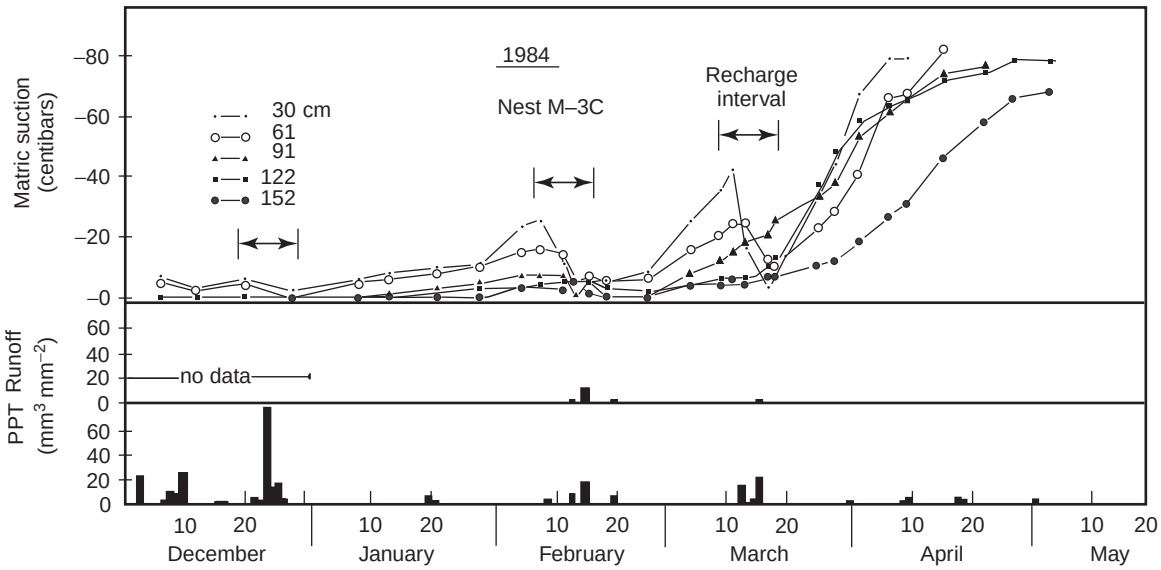

Figure 1 Measured precipitation (PPT), runoff, and matric pressure at several depths for a five-month period on a marine terrace (Reprinted from Ground Water, the National Ground Water Association. Copyright 1985)

zone. The process is thus affected by water-table variation, whether caused by natural processes or artificial recharge or withdrawal.

The character of the subsurface is also a major influence on recharge. Fractures, preferential flow, karst features, and so on, can lead to enhanced recharge by increasing spatial concentration. Features that act to hold water near the surface tend to increase evapotranspiration, and decrease recharge. For example, stratification of the unsaturated zone retards downward flow. Soil water hysteresis also acts during redistribution of water in the unsaturated zone to hold water high in the profile; therefore soils with more pronounced hysteresis of soil water retention may have greater evapotranspiration and less recharge (*see* **Chapter 150, Unsaturated Zone Flow Processes, Volume 4**). The medium also affects the thickness of the zone most affected by evapotranspiration; the presence of bedrock at shallow depth, for example, may confine roots to a thin zone and allow more water to escape their influence by flowing into the bedrock.

Recharge Distribution and Applications

The importance of the variability of recharge in time and space depends on the nature of the application as well as the processes. Water supply issues related to depletion of an aquifer as a whole usually make use of averages over a large area, generally an entire watershed or aquifer. Usually this type of application also requires a time average suitable for predicting long-term sustainability. Thus the period of averaging may include centuries since the last major climatic change. Issues of contaminant transport from a point source usually need a point or highly localized estimate of recharge rate, for a time period about as long as the contaminant would remain present in significant quantities. Aquifer vulnerability assessments and diffuse-source contamination (e.g. from agricultural pesticides) often require knowledge of the distribution of recharge rates over a specified area with high spatial resolution.

Certain time and space scales are inherent in the relevant conceptual models to be chosen or developed. For example, with a deep unsaturated zone in a granular medium, virtually all temporal fluctuations may be averaged out before water enters the saturated zone, making a decadal or longer scale appropriate. If there is a predominance of fracture flow or a shallow unsaturated zone, however, the conceptual model might need to allow for variations on a daily basis.

Methods of estimating recharge produce estimates pertaining to different time and space scales. Many methods fundamentally assess recharge in a way that is highly localized or specific in time and space while others produce recharge estimates that are temporally or areally averaged. For point applications, areal estimates will generally not be suitable unless spatial variability is slight, or unless it is possible to delineate features on the ground that might permit evaluation of likely deviations from the areal average. Additional data relating to the finer scale would be needed to estimate recharge at a given point. For areal applications when the available recharge estimates are point estimates, the area of interest can be divided into subareas within which recharge is more likely to be uniform, and an integrated estimate may be produced using point data in each subarea. Thus, for a given application, a good conceptual model of the hydrologic system and its recharge processes is essential for selecting recharge estimation methods, and for integrating point measurements to represent an area.

ESTIMATION OF RECHARGE

Because of the extreme variability of recharge rates and the fact that many relevant processes cannot be directly observed, recharge is usually difficult to estimate, especially when it involves unsaturated flow. There is no single instrument with the simplicity of a thermometer or pressure gauge that measures unsaturated-zone flux, so estimates are normally based on a combination of various types of data. Particular difficulties in the unsaturated zone are the extreme nonlinearity of basic unsaturated hydraulic properties, the typically extreme heterogeneity of these properties and other relevant features of the unsaturated zone, and the frequent occurrence of preferential flow (*see* **Chapter 150, Unsaturated Zone Flow Processes, Volume 4**). In addition, important processes that compete for water in the unsaturated zone, such as evapotranspiration, often are also difficult to evaluate. A quantitative estimate of recharge may depend on a combination of data that themselves have substantial uncertainty. For these reasons it is wise to apply multiple methods and compare their results.

Much software for simulating surface water, groundwater, and unsaturated-zone transport has been developed that is useful in investigations of aquifer recharge. Public-domain software related to various methods described in this article is available at **`http://water.usgs.gov/software/index.html.`**

Water-budget Methods

Water-budget methods comprise the largest class of techniques for estimating recharge. The water budget is an integral component of any conceptual model of the system under study. Hence, analysis of the water budget is of great value in any recharge study. Simple water budgets can be readily constructed and refined as needed. As noted by Lerner *et al.* [1990], a good method for estimating recharge should explicitly account for all water that does not become recharge.

The water balance for a control volume, such as an aquifer or a watershed, can be stated as (Scanlon *et al.*,

2002)

$$P + Q_{on}^{sw} + Q_{on}^{gw} = ET^{sw} + ET^{uz} + ET^{gw} + Q_{off}^{sw} + Q_{off}^{gw} + Q_{bf} + \Delta S^{snow} + \Delta S^{sw} + \Delta S^{uz} + \Delta S^{gw} \quad (1)$$

where superscripts refer to surface water, groundwater, unsaturated zone, or snow, P is precipitation and irrigation; Q_{on} and Q_{off} are water flow into and out of the basin; Q_{off}^{sw} is surface-water runoff; Q_{bf} is baseflow (groundwater discharge to streams or springs); ET is evapotranspiration; and ΔS is change in water storage. Units may be any of those presented earlier for recharge. Following our definition, as water that enters the saturated zone, recharge can be written as (Schicht and Walton, 1961):

$$R = \Delta Q^{gw} + Q_{bf} + ET^{gw} + \Delta S^{gw} \quad (2)$$

where R is recharge and ΔQ^{gw} is the difference between groundwater flow out of and into the basin. This equation simply states that water arriving at the water table (i) flows out of the basin as groundwater flow, (ii) discharges to the surface, (iii) is lost to evapotranspiration, or (iv) remains in the subsurface, augmenting storage. Substitution into (1) results in another useful form of the water balance:

$$R = P + Q_{on}^{sw} - Q_{off}^{sw} - ET^{sw} - ET^{uz} - \Delta S^{snow} - \Delta S^{sw} - \Delta S^{uz} \quad (3)$$

Water-budget methods include all techniques based, in one form or another, on one of these water balance equations.

Applications of various forms of equations 1 to 3 abound in the literature. An attractive feature of these methods is their flexibility; applications are often simplistic, but can be quite complex. Derivation of equations 1 to 3 requires few assumptions on the mechanisms that control individual components. Hence, through careful adaptation the equations can be applied over a wide range of space and timescales. For example, the water budget equation can be applied to study water movement in a soil lysimeter at scales of centimeters and seconds. At the same time, the water-budget equation is an integral part of Global Climate Models (GCMs) that predict global climate changes over periods of centuries.

The most common way of obtaining an estimate of recharge by these methods is the indirect or "residual" approach whereby all of the variables in the water budget equation, except R, are either measured or estimated and R is set equal to the residual. The accuracy of the recharge estimate is then dependent on the accuracy with which the other water-budget components can be measured or estimated. Consider a simple example where the only significant components of equation 3 are recharge, precipitation, and unsaturated zone ET and ΔS. Using the residual approach, we can write:

$$(R + \varepsilon_R) = (P + \varepsilon_P) - (ET^{uz} + \varepsilon_{ET}) - (\Delta S^{uz} + \varepsilon_S) \quad (3a)$$

Where the ε terms represent measurement errors. The magnitude of the error in the recharge estimate, ε_R, could be as large as $|\varepsilon_P + \varepsilon_{ET} + \varepsilon_S|$. In arid settings where R is generally a small fraction of P or ET, $|\varepsilon_R|$ can exceed the true value of R, even if the other error terms are relatively small. This can be a serious limitation on application of the residual approach. Timescales for application of water-budget methods are important; more frequent tabulations are likely to improve accuracy. Averaging over longer time periods tends to dampen out extreme precipitation events and hence underestimate recharge. For example, in an arid region, potential ET averaged over a week or a month will usually greatly exceed average P over the same period. But on a daily basis, P can exceed potential ET – a necessity for recharge to occur. Narayanpethkar *et al.* (1994) used a water-budget method to derive an estimate of 23 mm yr^{-1} of recharge in a region of India; Steenhuis *et al.* (1985) estimated recharge to be 400 mm at a site in the eastern US.

Direct water-budget approaches are based on measurements of changes in water storage within some compartment (such as a soil column) and partitioning of those changes to recharge and possibly to other components such as evapotranspiration. Included in this class are the zero-flux plane method and the use of lysimeters, both discussed in a subsequent section.

Modeling Methods

Hydrologic models constitute an important class of water-budget methods. The commonly used groundwater and surface-water flow equations are, in fact, variations of equations 1 to 3. Several modeling approaches have been used to estimate recharge.

Watershed models have been applied at a variety of spatial scales. Some of these models provide a single, lumped value of recharge for the watershed. Others allow disaggregation of the watershed into distinct hydrologic zones that may receive varying amounts of recharge. Watershed models generally require daily climatic data and information on land-surface features and land use. Streamflow data, and less frequently groundwater data, are used to calibrate the models. Bauer and Mastin (1997) used a watershed model to estimate recharge in three small watersheds (average drainage area 0.4 km^2) in western Washington. On the other end of the spatial scale, Arnold *et al.* (2000) applied the SWAT model to the entire upper Mississippi River Basin (492 000 km^2). Recharge estimates in different parts of that basin were between 10 and 400 mm yr^{-1}. Figure 2

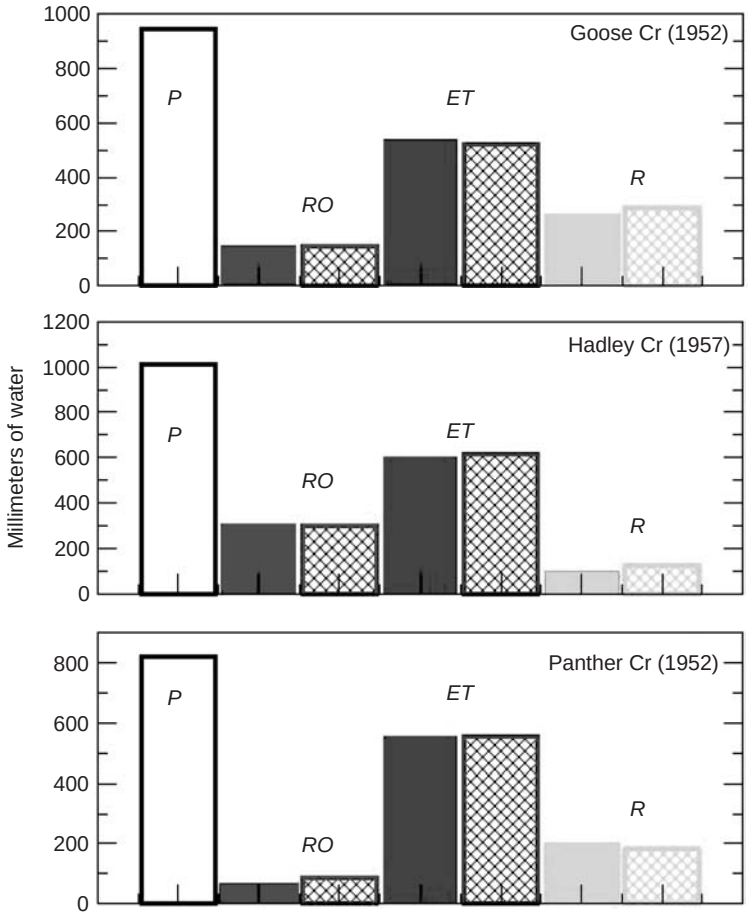

Figure 2 Water-budget components for three watersheds in Illinois: actual (Schicht and Walton, 1961), shown as solid bars; and predicted with the SWAT model (Arnold and Allen, 1996), shown as hatched bars. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

shows one-year water budgets, including recharge, for 3 small streams in Illinois as measured by Schicht and Walton (1961) and as predicted by Arnold and Allen (1996) using the SWAT model.

Recharge is an integral component of groundwater flow models, and estimates of recharge can be generated through model calibration. Recent incorporation of automatic inverse modeling techniques (Hill *et al.*, 2000) to these models has facilitated this process. A concern with these inverse techniques, however, is the possibility that they could generate nonunique solutions (i.e. different parameter values could produce identical results). This situation can be avoided by calibrating with data on both groundwater head and flux, or by independent determination of hydraulic conductivity. Tiedeman *et al.* (1998) developed estimates of recharge for the Albuquerque Basin in New Mexico using this approach.

One-dimensional models of vertical flow through the unsaturated zone have also been used to estimate recharge rates. As with watershed models, daily climate data are usually used. Information on hydraulic properties of sediments within the unsaturated zone is also required. The complexity of these models varies widely, from a simple reservoir (bucket) model to analytical or numerical solutions to Richards' equation. Example applications include those of Scanlon and Milly (1994), Kearns and Hendrickx (1998), and Flint *et al.* (2002).

A powerful feature of all models is their predictive capability. They can be used to gauge the effects of future climate or land-use changes on recharge rates. Sensitivity analyses can also be used to identify model parameters that most affect computed recharge rates (*see* **Chapter 155, Numerical Models of Groundwater Flow and Transport, Volume 4** and **Chapter 156, Inverse Methods for Parameter Estimations, Volume 4**).

Empirical equations, such as the Maxey-Eakin equation (Maxey and Eakin, 1949), are often used to obtain quick and inexpensive estimates of recharge. These equations, usually developed for specific regions, relate recharge to more easily measured phenomena such as precipitation,

temperature, elevation, vegetation, and soil type. While the accuracy of these equations may not be sufficient for some studies, the simplicity of the approach facilitates application over large areas using a Geographic Information System (GIS) and remotely sensed data.

Methods Based on Surface-water Data

Several methods are available for estimating recharge from data collected in surface-water bodies. Most of these methods require data on stream discharge at multiple points or times. Stream loss or seepage to the subsurface can be determined indirectly as the difference in discharge between a downstream and an upstream measurement point. This method is referred to as the Channel Water Balance Method and is appropriate for application only on losing streams. Stream or transmission loss does not necessarily equate with recharge. Water lost from a stream could remain as bank storage, be consumed by evapotranspiration, or become recharge. Stream loss falls into the category termed "potential" recharge by Lerner *et al.* (1990). Seepage estimates obtained by this method represent a value that is integrated over the length of stream channel between the two measurement points. Surface/groundwater exchange at specific points in a surface-water body can be directly measured with seepage meters (Kraatz, 1977; Lee and Cherry, 1978).

Stream flow hydrographs for gaining streams can be analyzed to estimate what portion of that discharge can be attributed to baseflow (also known as *groundwater discharge*). The rate of groundwater discharge is closely related to the rate of recharge; however, the two are not necessarily equal (equation 2). It is unlikely that all recharge in a basin would eventually be discharged to streams. Recharge may be lost to evapotranspiration, pumpage, or groundwater flow out of the basin. Care should be taken in understanding runoff processes in any given watershed. Some basins are unsuitable for hydrograph analysis. In particular, basins with upstream regulation, significant groundwater withdrawals, topographically flat terrain, karstification, or losing stream reaches should be avoided. Hydrograph analysis is usually performed for relatively humid regions where streams are perennial, with well-sustained base flow. Analytical techniques include hydrograph separation (Sloto and Crouse, 1996), chemical hydrograph separation (Hooper *et al.*, 1990), recession-curve displacement (Rorabaugh, 1964; Rutledge, 1998), and analysis of flow-duration curves (Kuniansky, 1989). Using an automated hydrograph recession-curve analysis computer program, Rutledge and Mesko (1996) analyzed discharge records from 89 basins in the eastern US and obtained recharge estimates between 152 and 1270 mm per year. Daniel and Harned (1998) analyzed 161 water years of record from 16 surface-water stations with the local minimum method (Pettyjohn and Henning, 1979) and recession-curve displacement and found that the former method provided estimates that were on average 21% less than those of the recession-curve displacement method.

Methods Based on Groundwater Data

Information on groundwater levels and how those levels vary in time and space can be used to estimate recharge. The most widely used of these methods is the water-table fluctuation (WTF) method (Healy and Cook, 2002). Other methods in this group include variations of the Darcy Methods (as discussed below), flow net analysis (Cedergren, 1977), and various semiempirical modeling approaches (e.g. Su, 1994; Wu *et al.*, 1997).

The WTF method uses the following equation to estimate recharge to unconfined aquifers:

$$R = S_y \frac{\mathrm{d}h}{\mathrm{d}t} \approx S_y \frac{\Delta h}{\Delta t} \tag{4}$$

where S_y is specific yield, h is water-table height, $\mathrm{d}h/\mathrm{d}t$ is the derivative of water-table height with respect to time, which is approximated as the difference in h (Δh) over the elapsed time between measurements (Δt). Equation 4 is applied only over periods of water-level rise (i.e. Δh is positive). The method works best over short periods for shallow water tables that display sharp water-level rises and declines. The method inherently assumes that recharge occurs only as a result of transient events; recharge occurring under steady flow conditions cannot be estimated.

Despite its simplicity and an abundance of available data, there are difficulties in application of the WTF method (Healy and Cook, 2002). Phenomena other than recharge can induce fluctuations in the water table. These include evapotranspiration, changes in atmospheric pressure, the presence of entrapped air ahead of a wetting front, extraction or injection of water by pumping, temperature effects, and tidal effects (Todd, 1989). Careful examination of water level records in conjunction with climatic data is necessary in order to correctly identify water level rises that can be attributed to recharge events. Determining values for S_y can be problematic. There are many methods for measuring or estimating values of S_y (e.g. laboratory methods, field methods, water-budget methods, and empirical methods), but all of these have a degree of associated uncertainty. Rasmussen and Andreasen (1959) applied this method to a small basin in the eastern US and determined that over a 2-year period annual recharge averaged 541 mm. Figure 3 shows average weekly water levels and precipitation for that study. The dashed lines in Figure 3 are the extrapolated recession curves (traces that the well hydrograph would have followed in the absence of the rise-producing precipitation). Δh is measured as the difference between a hydrograph peak and the recession curve at the time of that peak.

The zero-flux plane (ZFP) is the plane within the subsurface where the vertical hydraulic gradient is zero;

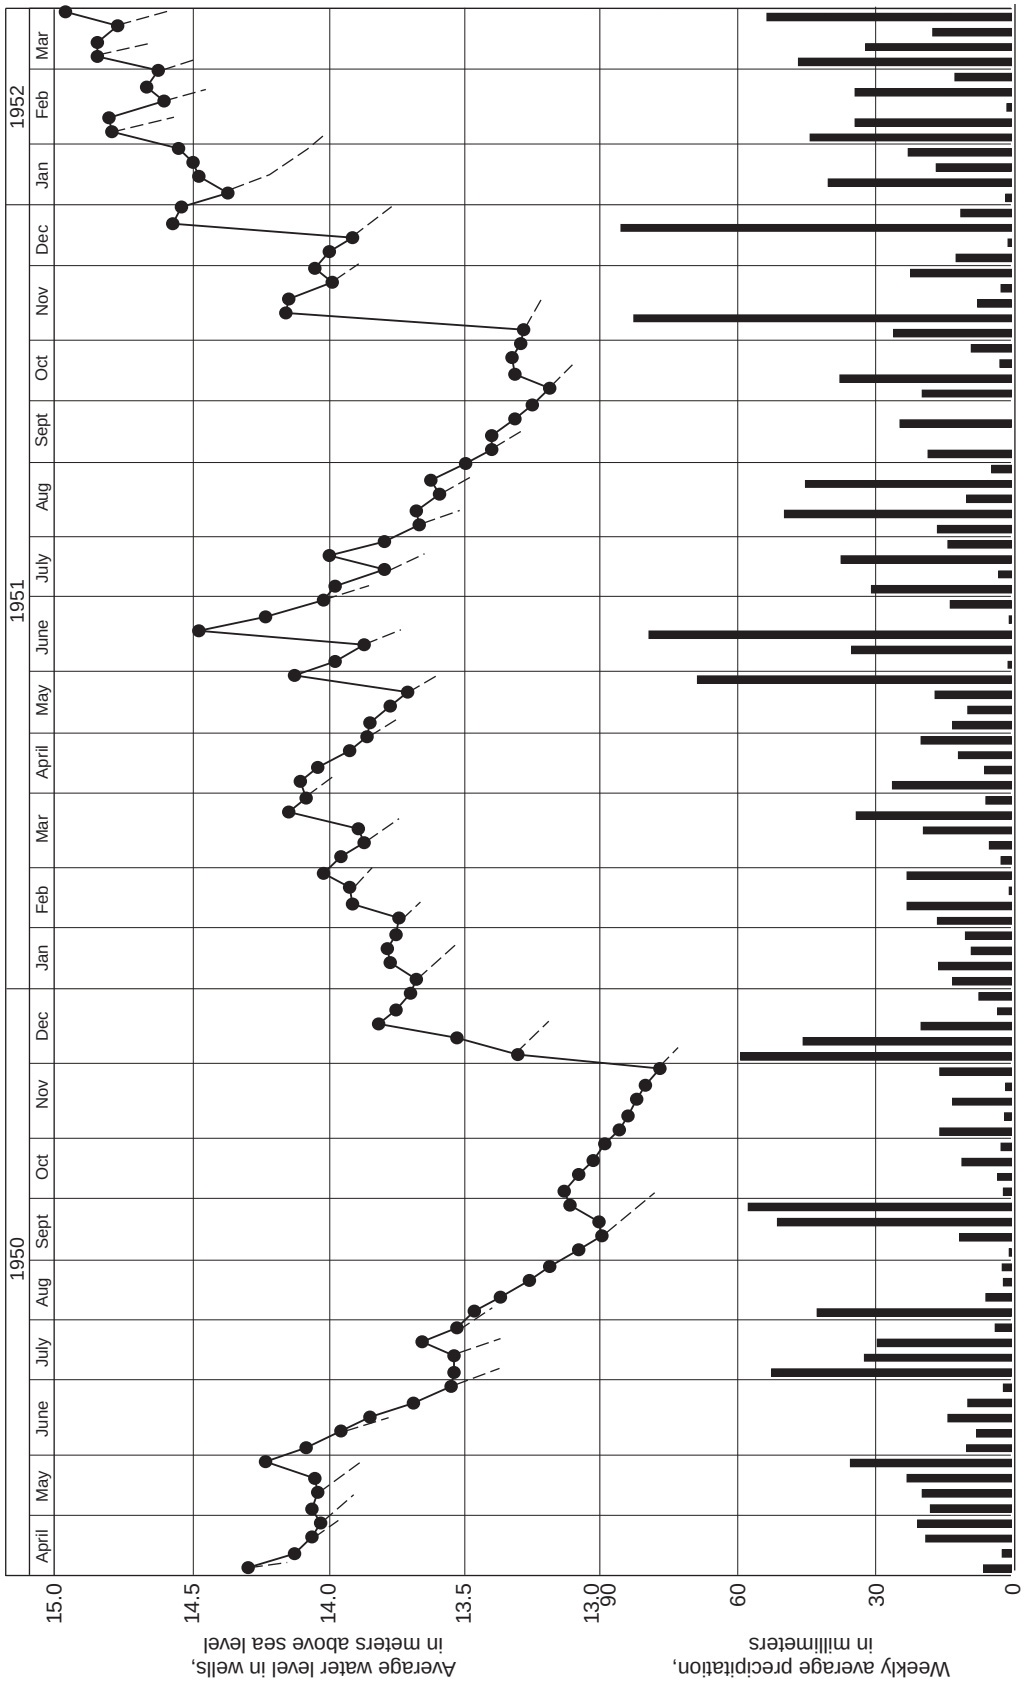

Figure 3 Average water levels in wells and weekly precipitation for Beaverdam Creek basin study of Rasmussen and Andreasen (1959), cited by Healy and Cook (2002)

that is, the plane marks the boundary between water that is moving upwards in response to evapotranspiration and water that is draining downward to become recharge. In applying this method, recharge rate is equated with the rate of change in water storage (drainage) beneath the ZFP (Richards *et al.*, 1956; Roman *et al.*, 1996). Data requirements for this method may be too onerous for some studies. Frequent measurements of soil matric pressure are needed at several depths to accurately locate the ZFP. Soil moisture content must also be measured over the entire thickness of the unsaturated zone. The method cannot be used when water is moving downward throughout the entire profile (i.e. when the ZFP is at land surface). Sharma *et al.* (1991) applied the ZFP method at eight sites in a semiarid region of Western Australia; estimated recharges rates ranged from 34 to 149 mm yr^{-1}.

Lysimeters are containers filled with soil and possibly vegetation and are placed in an environment that mimics natural conditions (Brutsaert, 1982; Young *et al.*, 1996). Fluxes to and from lysimeters are monitored with drains and water-collection vessels or balances that measure changes in weight. The instruments are usually used to measure *ET*. However, if the base of a lysimeter is below the ZFP, drainage from it can be assumed equal to recharge. Kitching *et al.* (1977) used a lysimeter with a surface area of 100 m^2 to measure recharge rates of 342 to 478 mm yr^{-1} for Bunter Sandstone in England.

Darcian Methods

Applied in the unsaturated zone, Darcy's law gives a flux density (q) equal to hydraulic conductivity (K) times the driving force, which equals the recharge rate if certain conditions apply. The basic requirements of the method are to determine K and the driving force, and then to calculate the downward flux density from Darcy's law in a form such as

$$q = -K(\theta)\left(\frac{d\psi}{dz} + \rho g\right) \qquad (5)$$

where θ is the water content, ψ is the matric pressure, z is the vertical coordinate, ρ is the density of water, and g is the gravitational acceleration. K would have SI units of $m^2\,Pa^{-1}\,s^{-1}$. Another common form of equation (5), with ψ in head units, has the gravitational term equal to unity. **Chapter 150, Unsaturated Zone Flow Processes, Volume 4** gives additional information about equation (5) and its variables. To use (5) in estimating recharge, accurate measurements are necessary to know $K(\theta)$ adequately under field conditions at the point of interest. For the total driving force, gravity being known, it is essential to determine the matric-pressure gradient or to demonstrate that it is negligible. For purposes requiring areal rather than point estimates, additional interpretation and calculation are necessary. Even when properly applied, Darcian methods do not necessarily indicate total recharge; some types of preferential flow are inherently non-Darcian and if significant would need to be determined separately.

In the simplest cases, in a region of constant downward flow in a deep unsaturated zone as illustrated in Figure 4(a), gravity alone drives the flow. With a sample from the zone of uniform ψ, K measurements at the original field water content directly indicate the long-term average recharge rate. The depth required for flow to be steady depends on the climate, medium, and vegetation. Fluxes

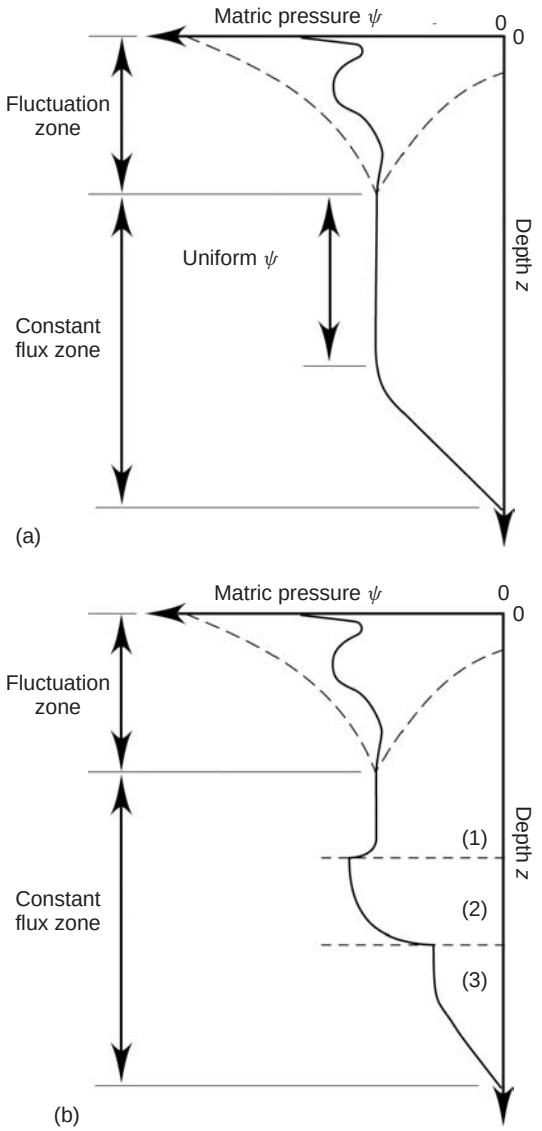

Figure 4 Hypothetical profiles of matric pressure as a function of depth in an unsaturated zone deep enough that its lower portion has a constant downward flux of water in (a) a uniform and (b) a layered profile. Dashed curves indicate possible extremes in the upper portion. The lower horizontal line in each diagram indicates the position of the water table

and water contents fluctuate within the root zone, and possibly to considerably greater depths. Evidence from field experiments (e.g. Nixon and Lawless, 1960) and theoretical assessment of the damping of moisture fluctuations as they move downward (Gardner, 1964) suggest that depths of a few meters are often adequate. In some cases, however, moisture fluctuations have been detected at depths of tens of meters (e.g. Jones, 1978). An obvious way to evaluate steadiness is to measure water content or matric pressure in the zone of interest for a period of a year or more. Where that is not possible, the evaluation of such factors as the homogeneity of the unsaturated zone and the distribution of water within it may help to indicate the degree of steadiness with depth.

In early applications of this technique (Enfield *et al.*, 1973; Stephens and Knowlton, 1986), limited accuracy of K estimates was a significant problem. Accurate laboratory K measurements on core samples, as by the steady-state centrifuge method, are of great value (Nimmo *et al.*, 1994). Figure 5 shows an example of measured hydraulic conductivities with the field water content and its associated K value identified. It happens for sample M30 that two measured $K(\theta)$ points have θ nearly equal to its field value, but even where this is not the case, having measurements at values both higher and lower than the field θ permits the appropriate K to be ascertained by interpolation.

In the examples of Figure 5, as is common, the $K(\theta)$ relation is very steep in the relevant range, meaning that uncertainty in the field θ leads to a greatly magnified uncertainty in the inferred recharge rate. To have reasonable confidence in the recharge estimate, accurate knowledge of the *in situ* water content of the sampled material is essential. In the cases illustrated, it was necessary to work with the water content of the identical soil mass just after sampling, corrected for evaporation between sampling and the first weighing. The oven-dry weight of that same soil must be known, here obtained by drying after K measurements were completed and corrected for losses of dry matter during experimental operations.

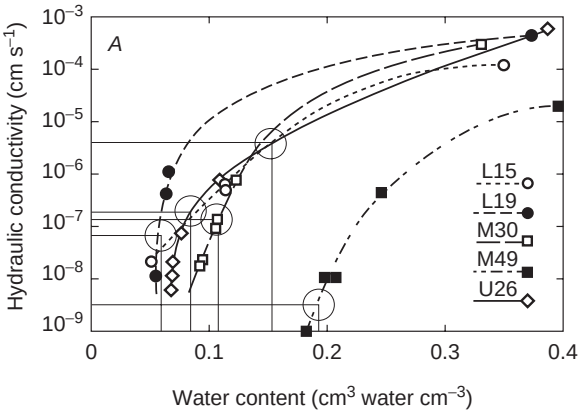

Figure 5 Steady-state centrifuge measurements of hydraulic conductivity versus water content, for five core samples from the unsaturated zone below a desert wash. To indicate recharge flux, the original field water content of each sample is indicated with its corresponding hydraulic conductivity (Reproduced from (Nimmo *et al.*, 2002) by permission of American Geophysical Union)

Variations of the steady-state method are possible for some cases that fall short of the ideal of constant and uniform flow and moisture conditions within a finite portion of the unsaturated zone. One important case is steady flow in a layered medium, in which θ and matric pressure vary spatially as necessary to give K the value needed at each point to maintain a constant Darcian flux density (Figure 4b). Nimmo *et al.* (2002) demonstrated a method for handling this problem using spatially detailed estimates of unsaturated hydraulic properties to compute the uncertainty ascribable to inadequate knowledge of the actual matric-pressure gradient. In such a case one can use geologic data, to the extent possible, to indicate the spatial variability of hydraulic properties.

A more challenging problem is the case where downward fluxes are not steady in time. Some situations may be treated as sometimes-steady, especially if there is evidence that conditions are nearly constant for an extended period such as a growing season. In others, the deviations may be small enough in magnitude that the error from assuming true steadiness is tolerable. It must be acknowledged however, that these approximations compromise not just the magnitude of uncertainty but also the possibility of claiming the inferred recharge rate as a long-term average.

For the general case in which flow is not steady, the appropriate Darcian methods are more complex. Transient water contents and matric pressures must be measured in addition to K (Freeze and Banner, 1970; Healy, 1989). The field site needs to be instrumented with devices for these measurements (*see* **Chapter 150, Unsaturated Zone Flow Processes, Volume 4**). With knowledge of K and the gradient of matric pressure, Darcy's law (equation 5) straightforwardly indicates the flux density at a given time and position, and its downward component is interpretable as recharge if the setting and conditions are such that fates other than recharge can be ruled out. Transient recharge computed with Darcy's law can relate to storms or other short-term events, or provide data for integration into temporal averages. Considerable equipment and labor is required for this, however. It would not usually indicate the long-term average recharge rate accurately, but it can have a valuable payoff in giving a detailed picture of the behavior of water in the unsaturated zone.

Chemical Tracer Methods

Geochemical tracers that have been used for recharge estimation include tritium (^{3}H), oxygen-18 (^{18}O), and deuterium (^{2}H), which are constituents of the water molecule

(H_2O); naturally occurring anions such as chloride (Cl^-) and bromide (Br^-); agriculturally introduced chemicals including nitrate (NO_3^-); applied organic dyes such as fluorescein ($C_{20}H_{12}O_5$); and dissolved gases including chlorofluorocarbons (CFCs), sulfur hexafluoride (SF_6), and noble gases such as helium (He) and argon (Ar). Concentrations of these constituents in pore water are related to recharge by applying chemical mass-balance equations, by taking advantage of distinctive temporal patterns in the composition of infiltrating water, or by determining the "age" of the water (i.e. the time since the water was in contact with the atmosphere). Geochemical tracers provide point and areal estimates of recharge. Of the many geochemical tracers that have been used for research purposes, only a few have found widespread use at scales relevant to aquifer recharge. They are the main subjects of this section.

The chemical mass-balance approach assumes that the tracer is conservative and moves with pore water, without significant retardation or acceleration due to electrochemical interactions with solids. Chemical mass-balance methods can be applied at basin scales using only groundwater and atmospheric-deposition data, (e.g. Dettinger, 1989; Anderholm, 2000). When applied to the unsaturated zone, chemical mass-balance estimates are obtained by equating the time-averaged flux of tracer across the land surface with the tracer flux at a depth sufficient to be unaffected by evapotranspiration and other temporally varying influences:

$$q_{m,z_0} = C_z q_z \tag{6}$$

Here q_{m,z_0} is the average flux of tracer across the land surface (mass of tracer per unit land surface per unit time), C_z is the tracer concentration in pore water at the evaluation depth z (mass of tracer per unit volume of pore water), and q_z is the water-flux density at z (volume of water per unit bulk area normal to the flux direction per unit time). As with the Darcian method (equation 5), q_z equals the recharge rate if certain conditions apply.

Soluble tracers reach the land surface in atmospheric deposition of dust (dry fall) and in precipitation. Infiltration of runoff (streamflow and sheetwash) supplies additional tracer where overland flow occurs. Irrigation water, agricultural chemicals, and engineered structures provide additional tracer to cultivated areas and areas of artificial recharge. The total flux of tracer across the land surface is the sum of the fluxes from constituent sources, that is

$$q_{m,z_0} = C_p P + C_r R + C_i I + C_f F + C_a A \tag{7}$$

where C_p is the effective tracer concentration in precipitation (i.e. including tracer in dry deposition), C_r is the concentration of tracer in infiltrating runoff, C_i is the concentration of tracer in irrigation water, C_f is the concentration in fertilizer and other agricultural applications, C_a is the concentration in artificial-recharge water, and P, R, I, F, and A are the volumes of precipitation, runoff, irrigation, agricultural applications, and artificial-recharge water that infiltrate per unit time per unit land surface. The first term on the right-hand side represents atmospheric sources, the second term overland-flow sources, and the last three terms anthropogenic sources. One or two terms usually dominate in a given environment.

Substituting equation (7) into equation (6) and rearranging yields the water-flux density at depth z (q_z) in terms of measured quantities, that is.

$$q_z = \frac{(C_p P + C_r R + C_i I + C_f F + C_a A)}{C_z} \tag{8}$$

If z is in a zone of steady flux, that is, if climatic and other inputs are approximately stationary over relevant timescales (dictated by travel times between the land surface and the aquifer), then q_z is equal to the recharge rate at the sampled location. Application of equation (8) also assumes negligible preferential flow (or sufficient sampling to provide adequate averaging of preferential pathways), in addition to conservative transport (Wood, 1999; Scanlon, 2000). Collectively, these assumptions imply that tracer fluxes at depth are in approximate steady-state equilibrium with the time-averaged tracer fluxes across the land surface.

Recharge rates can also be determined from apparent travel velocities of a tracer (solute) "marker" through the unsaturated zone, using (Saxena and Dressie, 1984; Gvirtzman and Magaritz, 1986; Williams and Rodoni, 1997)

$$q_z = \bar{\theta}\frac{(z_2 - z_1)}{(t_2 - t_1)} \tag{9}$$

where $\bar{\theta}$ is the average volume fraction of water between z_1 and z_2. Here z_1 and z_2 are the depths of a solute marker at times t_1 and t_2. Like the mass-balance method (equation 8), the tracer-velocity method requires that the marker move conservatively with the water and that water contents at depth remain constant through time.

The most widely used geochemical tracer for recharge estimation is chloride. Chloride is abundant in nature, conservative in hydrologic settings, and readily analyzed. Chloride mass-balance methods have proven especially useful in arid and semiarid regions (Stone, 1984; Edmunds *et al.*, 1988; Allison *et al.*, 1994; Phillips, 1994; Prudic, 1994; Tyler *et al.*, 1996; Roark and Healy, 1998; Maurer and Thodal, 2000; Izbicki *et al.*, 2002; Stonestrom *et al.*, 2003b). Figure 6 (adapted from Stonestrom *et al.*, 2003b) shows an example of a conservative tracer (chloride) applied in three distinct hydrologic settings in an arid environment: beneath native xeric vegetation, beneath an ephemeral stream, and beneath an irrigated crop. Results in Figure 6 are plotted in integral form (as cumulative chloride versus cumulative water, starting at the land surface).

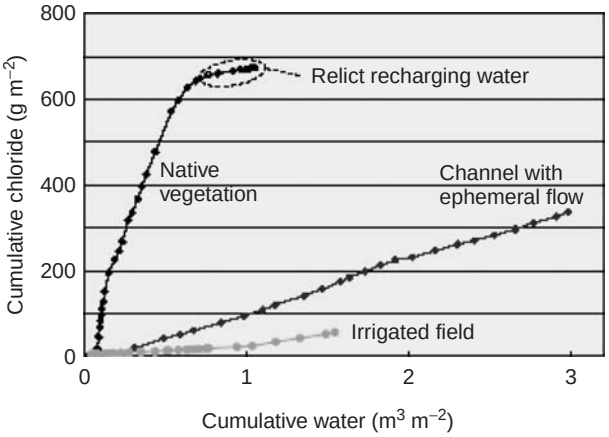

Figure 6 Concentrations of chloride in pore water, given by the slopes of the curves, indicate aquifer recharge for quasi-steady conditions. Recharge beneath irrigated field is higher than beneath ephemeral channel. Profile beneath native vegetation has multiple slopes reflecting climate-induced changes in recharge. Example from the Amargosa Desert, Nevada (Stonestrom *et al.*, 2003b). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

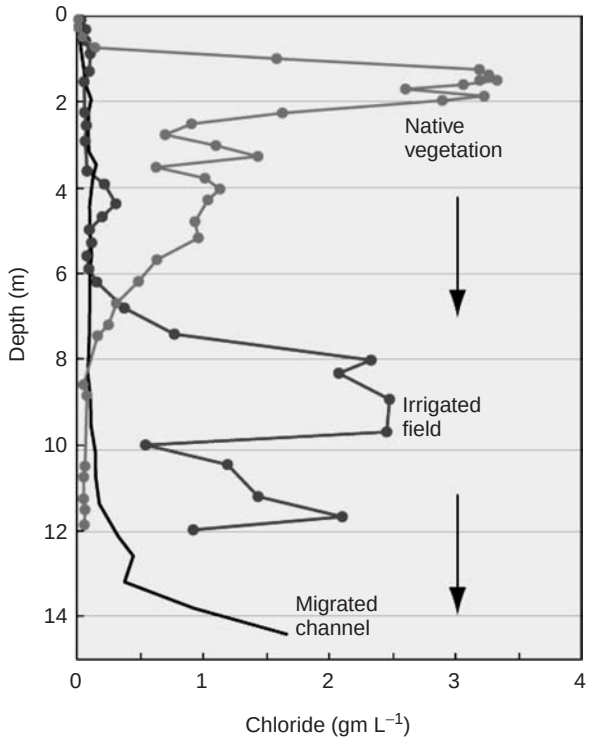

Figure 7 Travel-time of a solute marker indicates aquifer recharge under certain conditions. Here accumulations of chloride, common beneath native vegetation in arid and semiarid environments, served as the marker. Recharge following conversion to agriculture mobilized the marker in one case. Recharge following flood-induced channel migration mobilized the marker in another. Example from the Amargosa Desert, Nevada (Stonestrom *et al.*, 2003b). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Plotted this way, linear relations that extrapolate through the origin are consistent with the assumption that transport of water and solute at depth are in approximate equilibrium with average net inputs across the land surface. Slopes of the relations (equal to pore-water concentrations) are inversely proportional to recharge rates. Profiles beneath the channel and irrigated field meet the criteria for application of the method; the profile beneath native xeric vegetation does not. Water in the deep unsaturated zone here is relict infiltration from a prior climatic period. Figure 7 (adapted from Stonestrom *et al.*, 2004) shows displaced chloride "markers" used in the tracer-velocity method (equation 9).

Distinct isotopic "species" of water also serve as tracers for determining recharge. The isotopic composition of precipitation varies with altitude, season, storm track, and other factors. Recharge estimates using distinct isotopic species of water employ temporal or geographic trends in infiltrating water (Saxena and Dressie, 1984; Gvirtzman and Magaritz, 1986; Williams and Rodoni, 1997). Isotopically distinct water can be used in mass-balance or tracer-velocity methods (equations 8 and 9). Deuterium and oxygen-18 labeled species are conservative tracers. Mass-balance methods can be applied to tritium-labeled species taking radioactive decay into account.

Tritium and other nonconservative tracers can indicate the length of time that water has been isolated from the atmosphere, that is, its "age". In principle equivalent to tracer-velocity methods, age-dating methods are usually applied to the saturated zone. Recharge rates can be inferred from groundwater ages if mixing is small. If ages are known along a flow line, the recharge rate is given by

$$q = \bar{\theta} L (A_2 - A_1)^{-1} \tag{10}$$

where $\bar{\theta}$ is the average volumetric water content along the flow line, A_1 and A_2 are the ages at two points, and L is the separation length. One point is often located at the water table. Preindustrial water can be dated by decay of naturally occurring radioisotopes, including carbon-14 and chlorine-36 (Leaney and Allison, 1986; Phillips *et al.*, 1986). The abundance of tritium, chlorine-36, and other radioisotopes increased greatly during atmospheric weapons testing, labeling precipitation starting in the 1950s (Knott and Olimpio, 1986). Additional anthropogenic tracers for dating postindustrial recharge include chlorofluorocarbons, krypton-85, SF_6 and agricultural chemicals (Ekwurzel *et al.*, 1994; Davisson and Criss, 1996; Busenberg and Plummer, 2000).

Heat-based Methods

Heat is a useful tracer for estimating aquifer recharge. Perturbations of purely conductive propagation of temperature fluctuations from the land surface into the subsurface indicate recharge rates in shallow profiles beneath streams and other sources of water (Rorabaugh, 1954; Lapham, 1989; Stonestrom and Constantz, 2003). Water that moves below the reach of seasonal temperature oscillations perturbs the geothermal temperature distribution at depth. The degree of perturbation thus indicates recharge rates in deep unsaturated zones (Rousseau *et al.*, 1999). Measured temperature profiles are used in analytical or numerical inversions of the equation(s) governing the coupled transport of heat and water, solving for water flux at the water table. Numerical inversions can treat sediment heterogeneities as well as arbitrary initial and boundary conditions.

Daily or annual temperature fluctuations can often be approximated by sinusoidal functions (Figure 8). If recharging fluxes are steady and materials homogeneous, the

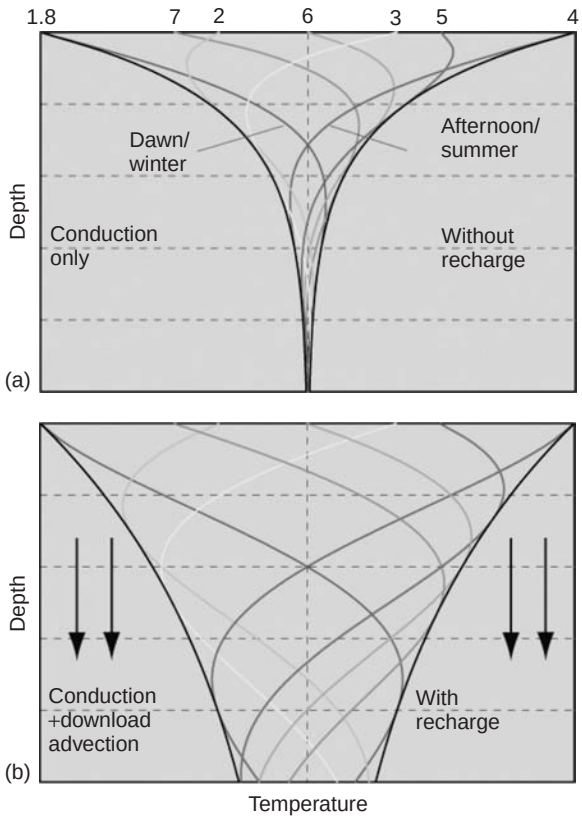

Figure 8 Recharging water advects diurnal and seasonal temperature fluctuations deeper into the profile than conduction alone. Numbered lines show successive temperature profiles over one daily or annual cycle (profiles 1 and 8 are identical, but separated by one cycle). The amount of downward shift in the bounding envelope depends on the rate of aquifer recharge. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

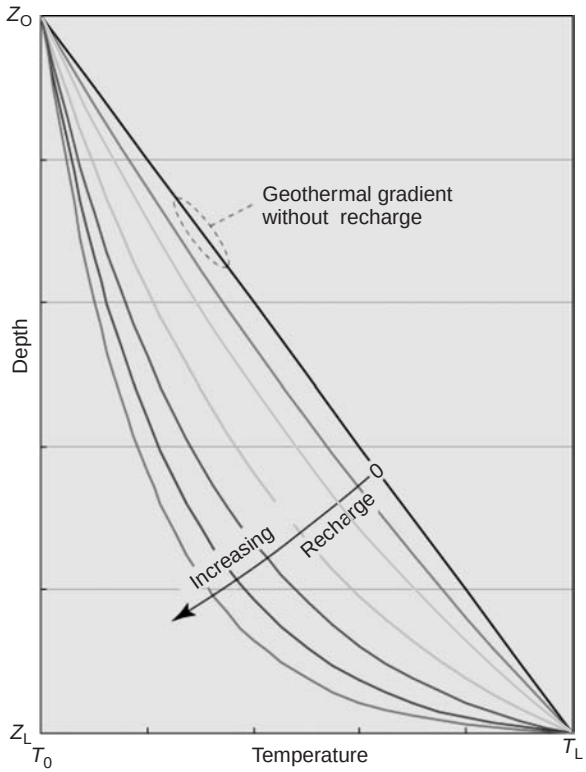

Figure 9 Recharging water in the deep unsaturated zone perturbs the steady geothermal profile produced by conduction alone. The degree of departure from the purely conductive profile indicates the amount of recharge. T_0 and T_L are temperatures at depths, Z_0 and Z_L, beneath the maximum penetration of seasonal fluctuations. A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

recharge rate q can be obtained by inversion from the phase shift (b) and attenuation (a) of the temperature waves as they propagate downward from the land surface (Stallman, 1965)

$$T(z) = T_0 + \Delta T \exp(-az) \sin\left(\frac{2\pi}{\tau - bz}\right) \qquad (11)$$

where a and b are related to thermal-conduction and advection constants K' and V' by

$$a = \left[\left(\frac{K' + V'^4}{4}\right)^{\frac{1}{2}} + \frac{V'^2}{2}\right]^{1/2} - V'$$

and

$$b = \left[\left(\frac{K' + V'^4}{4}\right)^{\frac{1}{2}} - \frac{V'^2}{2}\right]^{1/2}$$

Here T_0 and ΔT are the mean and amplitude of the temperature signal at the land surface, V' and K' are defined as

$$K' = \frac{\pi C_b}{\kappa_b \tau}$$

and

$$V' = \frac{qC_w}{2\kappa_b}$$

C_b and C_w are the volumetric heat capacities of the bulk medium and water, κ_b is the thermal conductivity of the bulk medium, and τ is the period of forcing. Any self-consistent system of units (such as SI units) can be used to compute the recharge flux q, which is directly proportional to V'.

Below the depth of seasonal fluctuations, temperature profiles will be bowed away from linear profiles by recharging water, with the degree of curvature related to the magnitude of recharge (Figure 9). In dimensionless form (Bredehoeft and Papadopoulos, 1965)

$$\frac{[T(z) - T_0]}{[T_0 - T_L]} = \frac{[\exp(q/\lambda) - 1)]}{[\exp(Lq/\lambda) - 1)]} \tag{12}$$

where T_L is the temperature at the water table, at depth L, and $\lambda(= \kappa_b/C_b)$ is the thermal diffusivity of the bulk medium. As with equation (11), any self-consistent units can be used to compute the recharge flux q by inversion of the measured temperature profile, in this case the steady profile at depth.

Other Geophysical Methods

Many geophysical techniques provide data relevant to recharge based on the water-content dependence of gravitational, seismic, or electromagnetic properties of earth materials. For quantitative estimates of recharge rate, repeated high-precision gravity (microgravity) surveys indicate changes in mass due to recharge events (Pool and

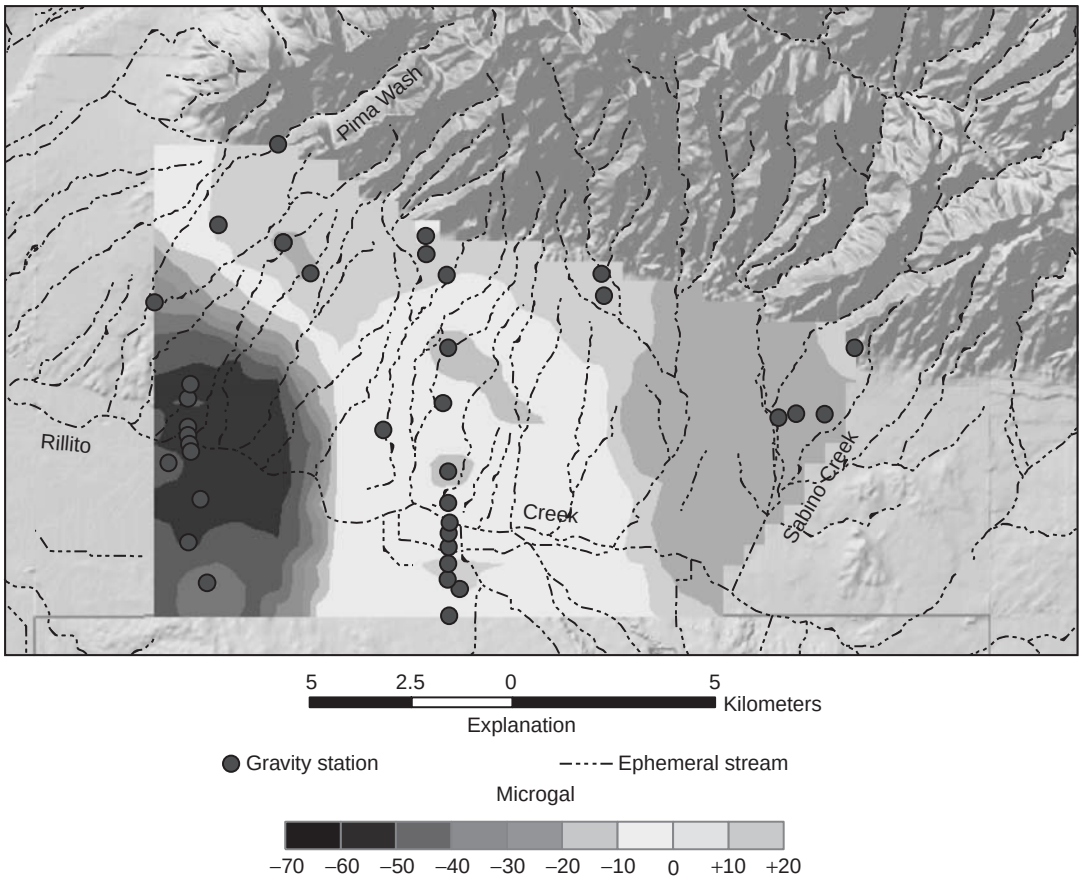

Figure 10 Changes in mass from aquifer recharge can be measured by repeated microgravity surveys. The example shows positive increases in gravity due to rising groundwater levels along the mountain front beneath tributaries to the ephemeral Rillito river, Arizona between June 1999 and March 2002. Pumping-related decreases in groundwater mass are evident downstream, beneath the main stem (unpublished data of Donald R. Pool, USGS, Tucson, AZ). A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

Schmidt, 1997; Figure 10). Similarly, repeated surveys using seismic or ground-penetrating-radar equipment show recharge-induced changes in water-table elevation (Haeni, 1986; Bohling *et al.*, 1989). Electrical resistance tomography can image zones of high-water content. Resistance tomographs have been used to map recharge areas in three dimensions based on land-surface measurements (Stonestrom *et al.*, 2003a). In addition to surface-based techniques, cross-bore tomographic imaging produces detailed three-dimensional reconstructions of water distribution and movement during periods of transient recharge (Daily *et al.*, 1992).

The next wave of advances in recharge estimation may involve remote sensing (RS) (see Part 05). Although still in the developmental stage, the broad spatial coverage afforded by satellite and aerial-borne instruments makes RS methods particularly attractive. Some of these methods attempt to directly determine changes in the amount of water stored in the subsurface, such as Synthetic Aperture Radar Interferometry (InSAR) (Hoffmann *et al.*, 2001; Lu and Danskin, 2001) and remotely sensed changes in gravity. Other RS methods contribute more indirectly to recharge estimation, for example, where RS data indicate certain components of the water budget equation, such as precipitation and evapotranspiration, or parameter values required in simulation models, such as soil properties, vegetation type and density, and land-use practices.

[3]*University of California, Lawrence Livermore National Laboratory, Livermore CA, US*

The characterization of porous or fractured media is a site, scale, and project-specific process aiming at a quantitative description of the geometry and properties of the geological structures controlling groundwater flow and solute transport. The characterization process involves four main steps (i) the definition of the domain and the goals of the characterization; (ii) the collection and analysis of field observations allowing the construction of a geometrical model; (iii) the collection and analysis of field measurements allowing to construct a property model; and (iv) the collection and analysis of field data relative to the state of the system and their integration within the geometrical and property models (inverse problem). When data are sufficient and structures are relatively well known, deterministic techniques of interpolation can be successfully applied to construct the geometric or the parameter models. However, because of the lack of sufficient data, stochastic models are often employed to characterize the heterogeneity that usually exists; such models also facilitate the quantification of the uncertainty in model predictions. Without describing the details of every technique, this article provides an overview of the tools most often used for the characterization of porous or fractured aquifers.

INTRODUCTION

Aquifer characterization can be defined as the process of data acquisition, analysis, and integration leading to a description of aquifer geometry and properties. This process may be relatively straightforward and limited to mapping the extent of an aquifer, its thickness, and estimating average properties such as transmissivity and storativity. It may as well be a much more complex task, integrating data obtained from various field investigations and involving intensive numerical modeling. The level of complexity of the characterization process is related to the goals of the study, the geological conditions, and the level of confidence required by the stakeholders. For example, evaluating the safety of a deep underground nuclear waste repository requires higher characterization efforts than estimating the amount of groundwater exploitable in a small shallow aquifer. Furthermore, the characterization efforts are oriented toward specific aquifer properties and objectives depending on the project. In the nuclear waste repository project, it may be important to have an accurate description of the diffusion properties of the geological materials, while this aspect may be irrelevant for the water resource project. Similarly, the thermal properties of the underground will have to be characterized in the framework of a geothermal project, but are not relevant in the case of groundwater protection.

The above examples demonstrate that characterization is a site, scale, and project-specific activity, the aim of which is not to describe all the properties of the system, but to focus on the major structures and properties relevant to the processes of interest. This requires the collection of specific field observations, their analysis, and their quantitative integration into a synthetic descriptive model of the reality.

Most of the difficulties associated with subsurface characterization stem from the high spatial variability of the

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

subsurface environment. This heterogeneity is an intrinsic property of geological formations and results from the complexity of the geological processes (sedimentation, diagenesis, rock deformation, etc.). Additionally, only sparse information is available from outcrops, boreholes, or geophysics. The lack of information combined with the intrinsic heterogeneity is the source of uncertainty that makes the characterization of subsurface hydrogeological systems challenging.

The aim of this article is to present an overview of the usual steps and techniques used for the characterization of porous and fractured media. Subsequent articles within the encyclopedia cover technical aspects of data acquisition and modeling techniques used for data integration. Some specific technical points such as interpolation methods are covered in more detail, as they are not treated elsewhere within the encyclopedia.

The article encompasses six sections. The first section introduces the main steps involved in the characterization and highlights some key features and difficulties. Subsequent sections discuss deterministic, stochastic, and genetic techniques. The final section is devoted to inverse modeling.

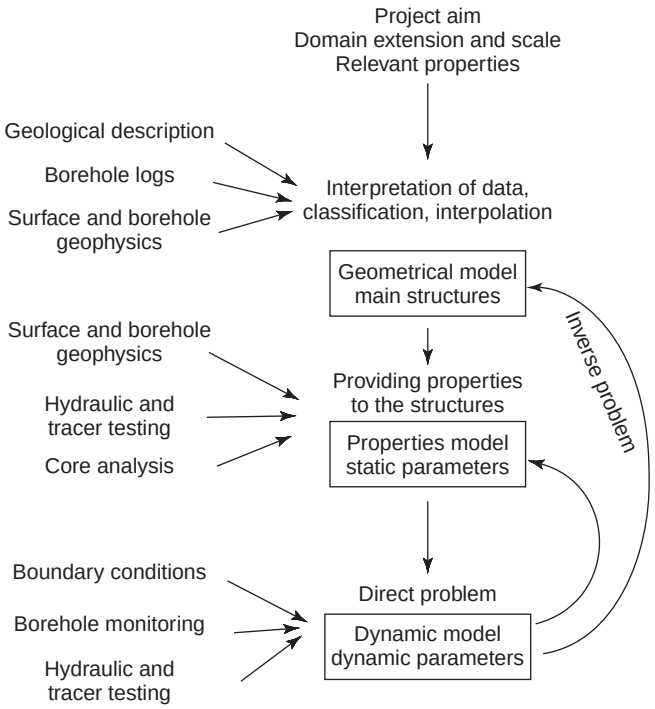

Figure 1 A schematic diagram of the characterization process

CHARACTERIZATION PROCEDURE

The Typical Steps of Characterization

The goal of characterization is to build a model in which the parameters involved in the processes under consideration are specified everywhere within the domain of interest. The four major steps of the characterization procedure are illustrated in Figure 1.

The first step is the definition of the project goals, domain of investigation, and the selection of the relevant processes and variables. Then, characterization consists of collection, interpretation, and analysis of measurements from various data sources. It is useful to distinguish between static (time invariant) and dynamic (time dependent) properties. This definition is not strict: some static properties in a given context (e.g. the aquifer geometry) may be considered as dynamic in another context (e.g. aquifer geometry during land subsidence; *see* **Chapter 158, Anthropogenic Land Subsidence, Volume 4**). Another useful distinction is the separation between measurable quantities (state variables) and physical parameters that cannot be directly measured but that parameterize physical laws (e.g. hydraulic conductivity).

The second step is the definition of the geometry of the structures controlling groundwater flow and transport. It relies on local geological observations, general geological knowledge related to the type of environment encountered, and geophysical investigations (*see* **Chapter 148, Aquifer Characterization by Geophysical Methods, Volume 4**). The end product is a geometric model that encompasses all relevant features: including aquifer, aquitard, channels, faults, lenses, and so on.

In the third step, field experiments such as hydraulic testing (*see* **Chapter 151, Hydraulics of Wells and Well Testing, Volume 4**) laboratory experiments, geochemical sampling, and tracer testing allow determination of the physical properties (static and dynamic) of the main structures. Of course, the separation between geometric modeling and defining properties is not straightforward in practice, as the knowledge of the properties is often required to decide whether a geological object is a relevant structure, and whether it is necessary to define its geometry.

The final step is the integration of the dynamic observations (state variables such as hydraulic head) with the static properties. The ultimate goal is that the geometric model and the property model must be in agreement with the dynamic observations. The main objective is therefore to link the geometry, the physical parameters, and the state variables through a system of partial differential equations that can be solved analytically or numerically (*see* **Chapter 152, Modeling Solute Transport Phenomena, Volume 4**; **Chapter 155, Numerical Models of Groundwater Flow and Transport, Volume 4**; **Chapter 150, Unsaturated Zone Flow Processes, Volume 4**; and **Chapter 157, Sea Water Intrusion Into Coastal Aquifers, Volume 4**). The model is then used in an

inverse procedure (*see* **Chapter 156, Inverse Methods for Parameter Estimations, Volume 4**) in order to improve the property model and/or the geometric model so that the calculated state variables match the observed ones under certain criteria.

Typical Goals of the Characterization

Depending on the type of aquifer, and on the project goals, different properties may be relevant, but in most cases the basic goal is to characterize the water conductive features. This means that for a porous media the most relevant property is the hydraulic conductivity. For fractured media, the relevant properties are the intensity of fractures, their extension, their connectivity, their apertures, and the hydraulic conductivity of the matrix. Table 1 provides a summary of the typical goals for subsurface characterization.

Deterministic versus Stochastic Methods

The geometric model, the property model, and the dynamic model can be defined within a deterministic or stochastic framework. In the deterministic framework, a unique geometry and property map are considered. On the other hand, in the stochastic framework (*see* **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**), the unique estimate is replaced by an ensemble of equally probable realizations, generally characterized by a statistical model. The main advantage of the stochastic approach is that it provides a formal means to quantify uncertainty. In practice, however, stochastic and deterministic approaches are often complementary: some parts of the characterization process are described deterministically while others are described statistically.

The Scale Issue

One important difficulty that arises during the characterization process is the integration of observations and measurements that have been collected at different scales. It is important to distinguish four main scales of interest (Haldorsen and Lake, 1982; Dagan, 1989): the microscale, the macro or laboratory scale, the mega or local scale, and the giga or regional scale (Figure 2).

Scale issues arise because a physical law that describes a process at one scale may differ when it is averaged or upscaled over a large volume. Furthermore, when the form of the equation remains identical between different scales, values of the physical parameters have to be averaged in a way that is physically consistent. Most often the relevant parameters are not additive and cannot be simply averaged by a standard mean.

Table 1 Typical goals for the characterization of fractured or porous media

All cases	Porous media	Fractured media	Project-specific
Geological and hydrogeological boundaries	Hydraulic conductivity	Frequency of fracture occurrence / density	Thermal properties
Head/ pressures	Specific storage	Orientation – extension	Diffusion properties
Fluxes	Porosity	Aperture	Geochemistry
	Dispersivity	Transmissivity	Stress/deformation
		Connectivity	Salinity
		Matrix properties	

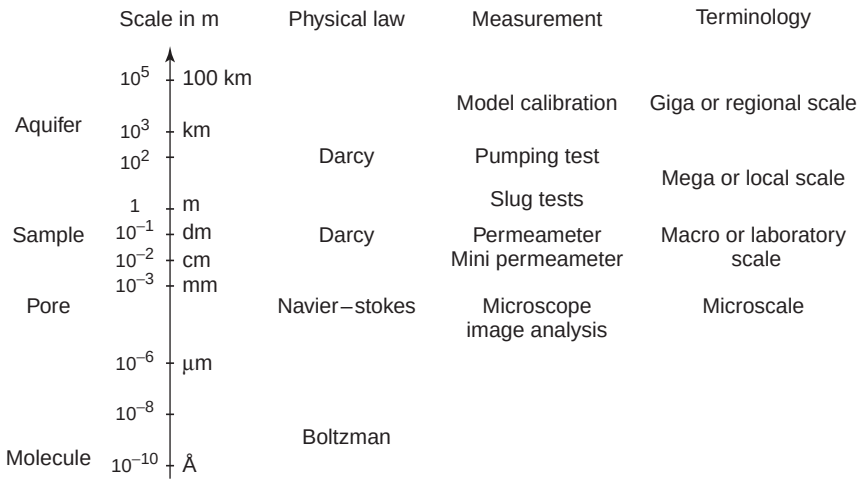

Figure 2 Definition of the characterization scales

To further illustrate these principles, at the microscopic scale the governing equations for groundwater flow are the Navier–Stokes equations (Figure 2). These are parameterized using the fluid viscosity and density, which are the relevant properties at the pore scale. Characterization techniques at this scale include microscopy, X-ray tomography, 3D pore space reconstruction, and so on. Moving to the macroscopic scale, it is possible to demonstrate theoretically that under low Reynolds number, the flux of groundwater through a porous medium obeys Darcy's law (Matheron, 1967; Mei and Auriault, 1989). The relevant physical parameters that remain are the fluid viscosity and density, but the geometry of the microscopic pore network is now characterized by two macroscopic properties, namely, the permeability and the porosity. Again, moving to a larger scale (mega or gigascopic) it is still possible to prove that the new governing equation is identical in form to Darcy's law (Matheron, 1967; Sáez *et al.*, 1989), but the permeability represents now an average of the small-scale permeabilities that account for their spatial distribution in the aquifer, and becomes a tensorial quantity in most cases, even when it is a scalar at the smaller scale. Many upscaling tools exist depending on the type of permeability distribution, but the most accurate techniques require a detailed knowledge of the spatial distribution of the permeability (Renard and de Marsily, 1997).

One of the best examples of a detailed study of scale dependence of the permeability is provided by Tidwell and Wilson (1999). They used an automated mini air permeameter in order to map the permeability of the face of a tuff sample. They measured the permeability with different injection devices (seals) having different radii. In this way, they characterized the permeability field of a sample face at different scales. Figure 3(b) and 3(c) present two permeability maps obtained using different seal sizes. It is apparent from the figures that when the seal size increases, heterogeneities are smoothed out. The statistical description of the permeability field is a function of the scale of observation. The mean slightly decreases with increasing scale (Figure 3e), the variance significantly

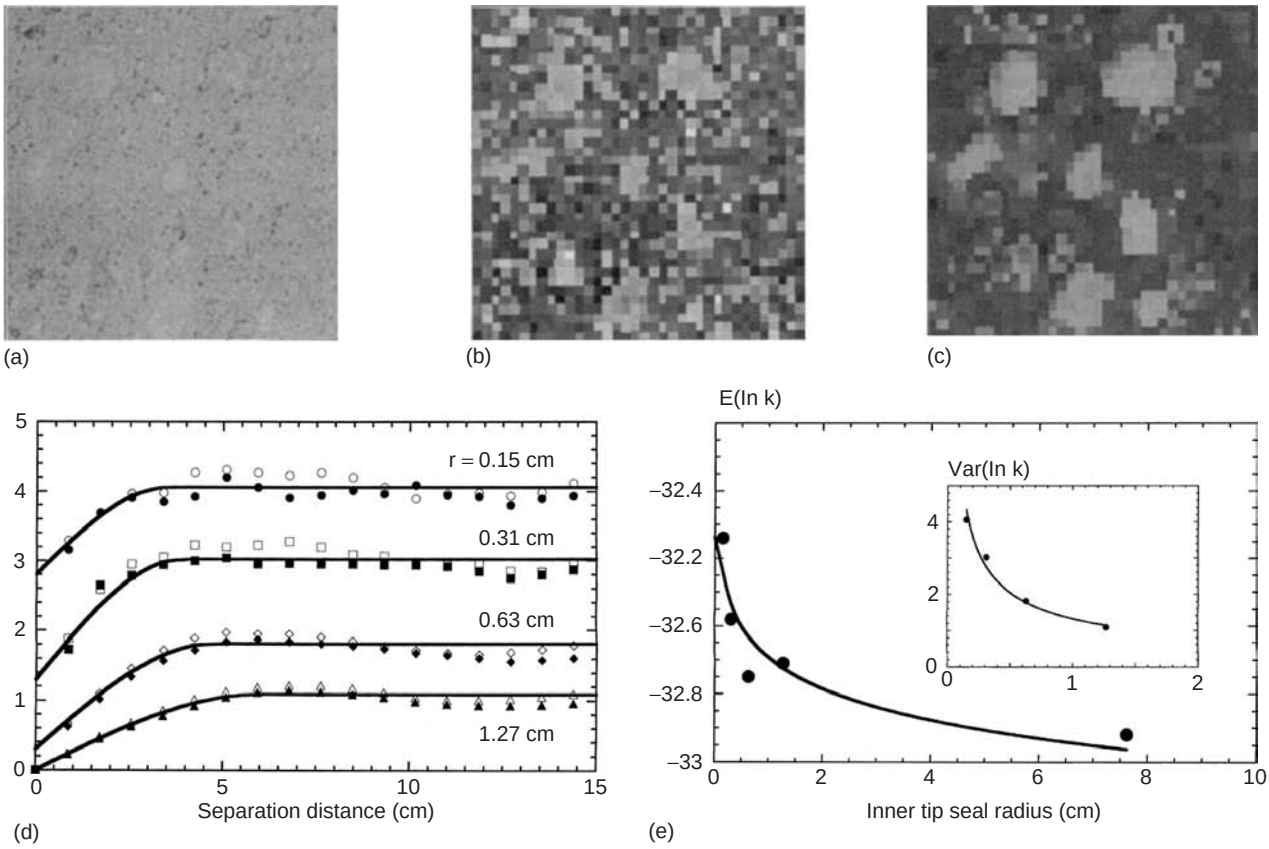

Figure 3 Characterization of the permeability field of a tuff sample at several successive scales. (a) Photograph of the sample face (30 cm times 30 cm); (b) and (c) permeability maps, measured with an injection device having an inner tip seal radius of 0.15 cm and 0.63 cm respectively, showing the smoothing of the permeability contrast with increasing size of measurement device; (d) semi-variograms of the permeability fields as a function of the tip seal radius, r; (f) expectation and variance of the permeability as a function of the tip seal radius (Reproduced from Tidwell and Wilson, 1999 by permission of American Geophysical Union)

decreases (Figure 3e), and the correlation length increases (Figure 3d).

On a much broader range of scales, several authors (Clauser, 1992; Sánchez-Vila *et al.*, 1996; Schulze-Makuch and Cherkauer, 1998) indicate that the average hydraulic conductivity of a formation increases with scale (Figure 4). These observations contradict the results of Tidwell and Wilson (1999). However, the apparent increase must be analyzed with caution because many experimental data at the laboratory scale are biased towards low values (Zlotnik *et al.*, 2000).

The dependence of hydraulic conductivity with scale is not the exception; the characterization of most parameters strongly depends on the scale of observation. Last but not the least, the elements on which the static and dynamic models have been discretized will, in general, be larger than the support on which measurements have been taken. Therefore, the values assigned to the model elements will always represent some type of averaged, or upscaled value of the underlying hydraulic conductivity distribution. This implies that larger the elements, the smoother their spatial distribution. Large elements should be sampled from probability distributions with smaller variance and larger continuity than small elements. When all elements in the model are of the same size and shape, the only decision to make is the choice of a random function model; however, when the model has been discretized with elements of different sizes, care should be taken to ensure the proper spatial variability for each element size. The rigorous method of defining the parameter values is to establish an upscaling rule to allow the transfer of the statistical characterization that can be inferred from the measurements, at the measurement support, up to the simulation support. Unfortunately, in most cases this extrapolation is never made, and the statistical characterization of the measurement values is transferred into the simulation support without any correction, incurring in what some authors have termed "not accounting for the missing scale" (Durlofsky, 1992).

DETERMINISTIC CHARACTERIZATION

In this section, we review a few deterministic tools used to define the geometry of a hydrogeological system and to describe the distribution of properties within the geological formations.

Zonation

The whole domain is splitted volume into subvolumes corresponding to different geological objects that can represent hydrostratigraphic units or subunits.

Recently, automatic algorithms have been developed to construct the zonation in three dimensions using geological observations along outcrops, borehole logs, and interpretative vertical sections (Courrioux *et al.*, 2001). Every point that identifies an interface between two zones is represented in three dimensions by a pair of points located on each side of the interface and labeled with a number corresponding to the identifier of the zone. An initial partition of the three-dimensional space is constructed with the help of a Voronoï diagram and interfaces are subsequently smoothed. An example of the application of this method is provided in Figure 5.

Interpolation

Often data are available at points. The data must be interpolated in order to reconstruct either a geometric surface or the spatial distribution of a parameter. The interpolation problem is widely encountered in many fields of

The dots represent the data points; the grey zone represents the volume where the interpolated concentrations exceed a threshold (Jones N.L. *et al.*, 2003; reprinted from Ground Water with permission of the National Ground Water Association. © 2003)

sciences. Consequently, a wide variety of techniques are available. Among the techniques most often used are linear piecewise interpolation, inverse distance weighting, polynomial interpolation, splines, natural neighbor, kriging, and radial basis functions. These techniques are implemented in numerous software packages such as Surfer (**http://www.goldensoftware.com**), ArcGis (**http://www.esri.com**), Idrisi (**http://www.clarklabs.org**), GMS (**http://chl.erdc.usace.army.mil**), Earth Vision (**http://www.dgi.com**), and FeFlow (**http://www.wasy.de**)

The relative efficiency of interpolation techniques has been investigated in many articles, one of the most recent is the article by Jones *et al.* (2003) who compared the application of inverse distance weighting, natural neighbor, and kriging for the characterization of four different contaminant plumes in three dimensions (Figure 6). This study illustrated that at three sites the kriging technique gave the lowest error; the inverse distance weighting gave the lowest error at one site and performed well otherwise. The natural neighbor method was the least accurate. Note that kriging is considered here as a deterministic method, since only the interpolated values are used but not the estimated uncertainty. The conclusions of Jones *et al.* are not really surprising since kriging (as will be discussed more in detail in the Section "Geostatistics") is a method whose principle is to minimize estimation errors. What should be assessed is the validity of the variogram analysis of Jones *et al.* when the inverse distance method performed better than kriging. Nonetheless, the main point of interest of their study is that it showed that inverse distance methods, which are very fast and do not require a variogram analysis, perform rather well and can provide an acceptable interpolated map at least in the preliminary stage of a study.

Discrete Smooth Interpolation

A particularly interesting interpolation technique in the framework of geological objects is the so-called Discrete Smooth Interpolation or DSI (Mallet, 2002). The principle of DSI is to construct a discrete representation of an object, a triangulated surface for example, and to impose some constraints on the object. For example, certain nodes are given some fixed positions while others exist, but their location is not known *a priori*. On a node, the orientation of the surface can be defined as a constraint, while its position is unknown. Some constraints such as a minimum distance can be imposed between objects as well. The basis of the DSI algorithm is to minimize the roughness of the discrete object subject to predefined constraints. Generally speaking, the roughness itself is defined as the sum of the squared distance between any point of the graph and the center of gravity of its immediate neighbors.

DSI is an extremely versatile technique. It can be used to interactively model the geometry of complex geological structures including layers and faults. As an example, Figure 7 shows the three-dimensional geometry of the Soûltz horst (Alsace, France). Site characterization is carried out in the framework of a hot dry rock geothermal energy project. In this case, the reservoir geometry was constrained by borehole observations and five seismic profiles. After having identified the different faults and horizons on the seismic profiles, DSI was used to interpolate the triangulated surfaces corresponding to faults and geological boundaries between layers (Renard and Courrioux, 1994).

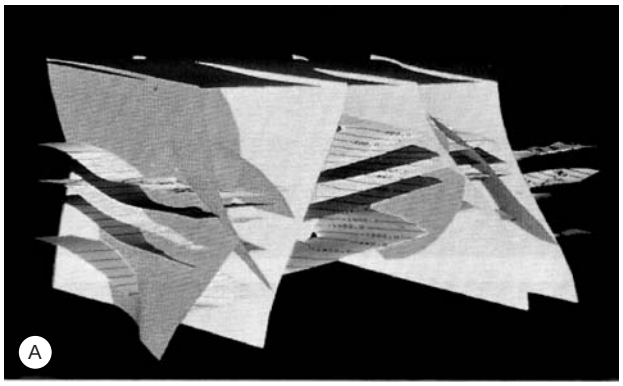

Figure 7 Three-dimensional geometry a network of 18 faults and five stratigraphic layers. The top surface represents the topography, the geometric model extends to a depth of 2 km and has an extension of 6 km by 2 km (Reprinted from Renard and Courrioux 1994. © 1994, with permission from Elsevier) A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

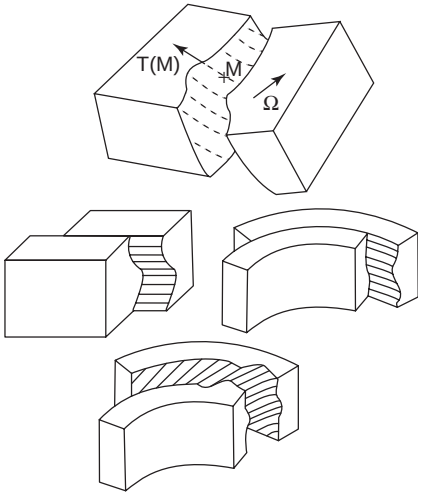

Figure 8 Examples of admissible surfaces for a fault (Reprinted from Thibaut *et al.*, 1996. © 1996, with permission from Elsevier)

Plausibility Constraints

When interpolating, a common problem is to respect not only the raw data but also some knowledge related to the type of variable that is interpolated. For example, the hydraulic conductivity or the concentration cannot be negative. Another example is the interpolation of the geometry of a three-dimensional surface describing a fault from a series of points in space. In order to be acceptable, it must belong to a certain type of surface such as planes, spheres, cylinders, and surfaces of revolution (Figure 8) as the fault surface has been created by the relative movement of two rigid blocks (Thibaut *et al.*, 1996). Mallet (2002) discusses how to implement such constraints within DSI. As a last example, the interpolation of hydraulic head data must honor boundary conditions. Delhomme (1979) demonstrates how the kriging technique can be modified to account for such constraints (Figure 9).

STOCHASTIC CHARACTERIZATION

Stochastic modeling allows assessing uncertainty. In this section, we present an overview of the statistical models

most currently used for the characterization of porous and fractured media. We start the review with standard statistics, and follow with object-based models, geostatistics, and finally a short overview of the emerging field of multiple points geostatistics.

Statistics

The first kind of stochastic analysis, which is conducted when characterizing a hydrogeological system, is to investigate the univariate and nonspatial statistics. The most simple and complete statistical tool during this first step is to analyze the experimental probability density functions (pdf). The pdf allows the analyst to infer the degree of variability of the property, the type of probability law that would best represent the data, the possible multimodality, and so on. When conducting such analyses, special tools must be used when dealing with data that fall into a finite mathematical space (i.e. compositional data, fracture orientations). In the case of fracture orientation, the field data are a series of orientation angles (strike and dip). The usual way to represent these statistics is a contoured stereographic projection that allows the main families of fractures, their mean orientation, and variability around the mean to be defined (*see* **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**).

When the experimental statistics have been analysed, simple statistical models can be used to represent the data. For example, Figure 10 shows an example of porosity pdf taken from a number of sandstone samples. The resulting plot indicates that, in this case, a Gaussian distribution, defined by its mean and variance, can be used to model the porosity distribution.

The statistical analysis of fracture observations along boreholes, tunnel faces, or maps requires some specific tools. For example, the statistics are calculated from data that are usually gathered on 1D or 2D space, but they need to be corrected by stereological techniques in order to estimate the 3D statistics. Chilès and de Marsily (1993) provide an excellent overview of specific statistical (and geostatistical) techniques used to analyze fractures and fracture networks. One of the particular aspects of fracture network statistics is that they often exhibit a very wide range of scales and therefore their statistics can be described by power laws (Figure 11) relating over certain domains (Bonnet *et al.*, 2001; Bour *et al.*, 2002).

A second step of the statistical characterization is to investigate the multivariate statistics to define correlations between them. The variables can be numerical properties and also categorical properties such as lithofacies or hydrofacies indicators. When a large number of numerical variables are available (e.g. geophysical logging), a systematic statistical analysis complemented with the application of a classification algorithm may allow the various relevant litho or hydrofacies identifications in a semiautomatic way. The same statistical techniques are applied to characterize water types within an aquifer (Güler *et al.*, 2002).

Object-based Models

Object-based models attempt to reproduce the geological architecture of the aquifer by locating objects with shapes that resemble geological bodies using rules about their position, size, and shape, and also rules of attraction, repulsion, and spatial proportions. These objects are assimilated to specific geologic facies, which are later assigned porosity and hydraulic conductivity values.

The most common algorithms used in object-based models are Boolean models. These models work with deterministic shapes defined by stochastic parameters. For instance, the early models by Haldorsen and Lake (1984) reproduce sand/shale reservoirs in which shales are included as parallelepipeds with random locations and sizes. Generating such a model starts by randomly drawing a point in space and then drawing at random the three sizes of the parallelepiped (representing a shale inclusion) that is located at the drawn point. This procedure is repeated until a predetermined sand/shale proportion is reached. These models have evolved substantially to include (i) more elaborate shapes, which may better resemble the geological bodies (Figure 12) and (ii) complex rules regarding allowed relative positions of the objects, that is, following a stratigraphic sequence, erosion rules, and so on (Jussel *et al.*, 1994; Scheibe and Freyberg, 1995).

Realizations generated with object-based models are appealing to geologists; however, their main drawback is the difficulty to condition these realizations to large amount of data: it is very difficult to randomly draw objects obeying all rules and honoring borehole information. Other drawbacks are that lithofacies do not conform to the simple geometries used, lithofacies are not randomly distributed in space, and that these algorithms are difficult to generalize and must be custom designed for each depositional pattern. Some of these drawbacks have been addressed by Tyler *et al.* (1994) with different degrees of success.

Geostatistics

The word geostatistics, or geographical statistics, was defined by Matheron in 1962 to designate a set of statistical techniques used for ore reserve evaluation. The key concept is to quantify, in statistical terms, how the information provided by a sample located in space and/or time influences the statistics of possible values of the same variable at any distance from this data point. This information is quantified with a variogram or a covariance function. The same tools can also be applied to a set of different variables accounting for spatial cross-correlation between variables. These techniques and formulations are described in various references

(Matheron, 1962; Journel, 1989; Goovaerts, 1997; Kitanidis 1997; Chilès and Delfiner, 1999; *see* **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**).

In practice, dedicated software is available either as interactive packages such as Isatis (**http://www.geovariances.com**), WinGslib (**http://www.gslib.com**), Gocad (**http://www.gocad.com**), Fsstools (**http://www.fssintl.com**), Earth Vision (**http://www.dgi.com**), or as source libraries such as gslib (**http://www.gslib.com**) and the geostatistical template library GsTL (**http://pangea.stanford.edu/~nremy/GTL/GsTL_home.html**).

Applying geostatistics first involves an exploratory data analysis. If we greatly simplify the procedure, the data exploration consists of analyzing the experimental variogram of the data in order to identify the most appropriate variogram model. The exploratory data analysis can be applied either to a continuous variable or to an indicator variable that represents the presence or absence of a geological object (lithofacies).

When the variogram model is inferred, kriging is used to interpolate at any location conditioned to data within the neighborhood and the variogram. Kriging provides an estimation of the expected value of the variable and its variance that represents the possible error of estimation at the same location. Maps obtained by kriging have already been shown in Figure 6 and Figure 9.

When the characterization process requires an estimation of a property P_1 that does not linearly depend on the property P_2 for which data is available, it is necessary to use nonlinear geostatistical techniques. For example, the statistical expectation E() being a linear operator (i.e. an arithmetic average), and if P_2 is a nonlinear function of P_1, that is,

$$P_2 = f(P_1) \tag{1}$$

then the expectation of P_2 is not equal to the transform of the expectation of P_1:

$$E[P_2] = E[f(P_1)] \neq f(E[P_1]) \tag{2}$$

It means that it is erroneous to apply a nonlinear function to a kriged map in order to estimate the expected value of the transform.

To circumvent this problem, the most general nonlinear geostatistical technique is the use of stochastic simulations. Instead of estimating the expected value, the principle is to generate a series of equiprobable realizations that are constructed in order to honor the data points, the variogram, and the pdf of the data. One can then apply the nonlinear transformation to each of these maps and calculate the statistics of the results. Another important aspect is that the kriged field is smoother than the data (Figure 13). The simulated field, instead, has the same spatial structure (variogram) as observed in the data (Figure 13), as well as the same pdf, but it is only one possible reality, one equiprobable realization. Estimation (kriging) and simulation are therefore not applicable for the same purposes. Kriging is useful to map the expected value and to identify the main trends in a field. Simulations are useful when predictions, such as flow and transport simulations, must be applied on the field.

When applied to generate equiprobable realizations of a continuous variable, some geostatistical models rely heavily on the use of a multi-Gaussian distribution. This multi-Gaussian character has some unwanted side effects that should be carefully considered before use, namely, the lack of connection of the extreme values at the tails of the probability distributions, that is, it is very difficult for multi-Gaussian-based realizations to display flow channels or flow barriers (Gómez-Hernández and Wen, 1998; Wen and Gómez-Hernández 1998).

As an alternative to multi-Gaussian models, indicator-based geostatistical models were developed. In indicator-based geostatistics, the different classes (or categories) in which the range of variability of the parameter under study could be divided, are independently characterized, thus controlling the spatial correlation of all classes, particularly those at the extreme ends of the distribution. Each indicator class is characterized by its own variogram function. One of the earliest applications of indicator-based geostatistics was discussed by Gómez-Hernández and Srivastava (1990) in the context of the simulation of a sand-shale sequence.

The main advantage of all geostatistical methods is their ability to be conditional to parameter measurements. Thus, the realizations not only have the spatial patterns characterized by the variogram function but also honor the parameter data. As a consequence, the larger the number of conditioning data, the more alike are the generated realizations and less the uncertainty on the predictions based on these conditional realizations.

Multiple-point Geostatistics

A recent development of geostatistics that goes beyond the variogram-based geostatistics (whether Gaussian or indicator) deserves a section of its own. The major criticism to geostatistical methods has come from the proponents of object-based simulations criticizing the difficulty in reproducing intricate geological patterns when the only controlling tool is the variogram (a two-point statistics measure). For instance, it is very difficult to generate meandering-like depositional patterns, or realizations respecting certain stratigraphical ordering of the facies generated. A solution to this problem was proposed by Strebelle (2002) that departs from traditional geostatistics. Conditional probability values are computed directly from conditioning data using the exact geometrical pattern of the surrounding data with respect to the point being estimated. (In traditional geostatistics, these conditional probabilities are computed

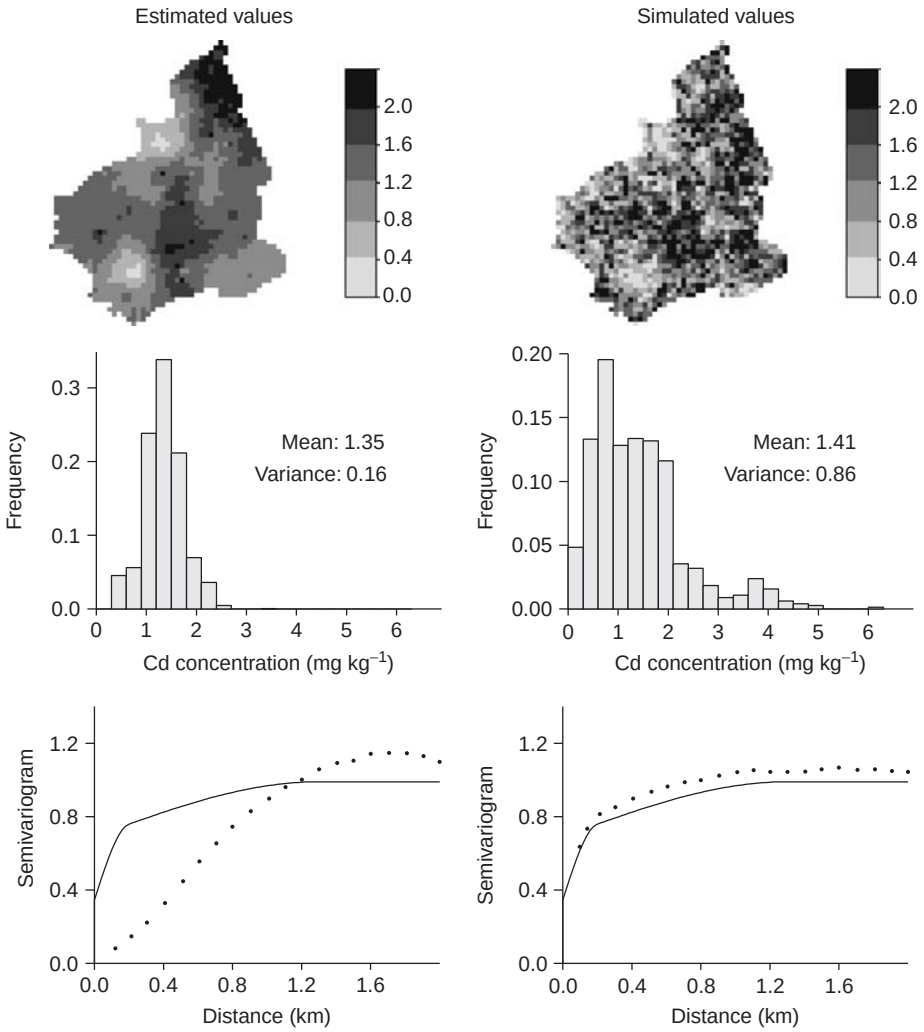

Figure 13 A typical example showing the differences between a map of Cadmium (Cd) interpolated with ordinary kriging (a) and simulation (b). The figure shows the differences in pdfs and variograms calculated *a posteriori* for the two maps. The solid line represents the variogram model and the dotted line represents the experimental variogram calculated *a posteriori* on the interpolated fields (Reproduced from Goovaerts, 1997 by permission of Oxford University Press)

by considering only the separation vectors between each pair of data, and between each datum and the point being estimated.) Evaluating the conditional probability in the way proposed by Strebelle requires establishing the probability distributions for any possible data configuration. Since this is impossible to perform from sample data, Strebelle suggests the use of training images derived from outcrops, expert knowledge, or even a geologist's drawing. He also suggests to only use the nearby data; therefore, reducing the number of conditioning data configurations for which the probability distribution has to be derived.

Multiple-point geostatistics is capable of generating realizations that are very similar to those obtained with object-based algorithms, with the advantage that it can be made conditional by construction, therefore surpassing the main problem of object simulation.

The main criticism to multiple-point geostatistics is the selection of a training image from which to infer the multiple-point statistical model, especially in three dimensions. Outcrops are good for 2D realizations, but there are no three-dimensional outcrops, and it is not trivial to combine multiple 2D training images into a single 3D one. A possible solution to the problem of 3D training images would be to use a genetic model or an object-based model to generate a realization from which to infer the multipoint statistical model. Multiple-point realizations based on such a model will look like the ones obtained from the genetic or object-based models, but will be conditional to well data. Another caveat is that its implementation for practical applications is full of difficulties and computational tricks if CPU-times are to be kept reasonable.

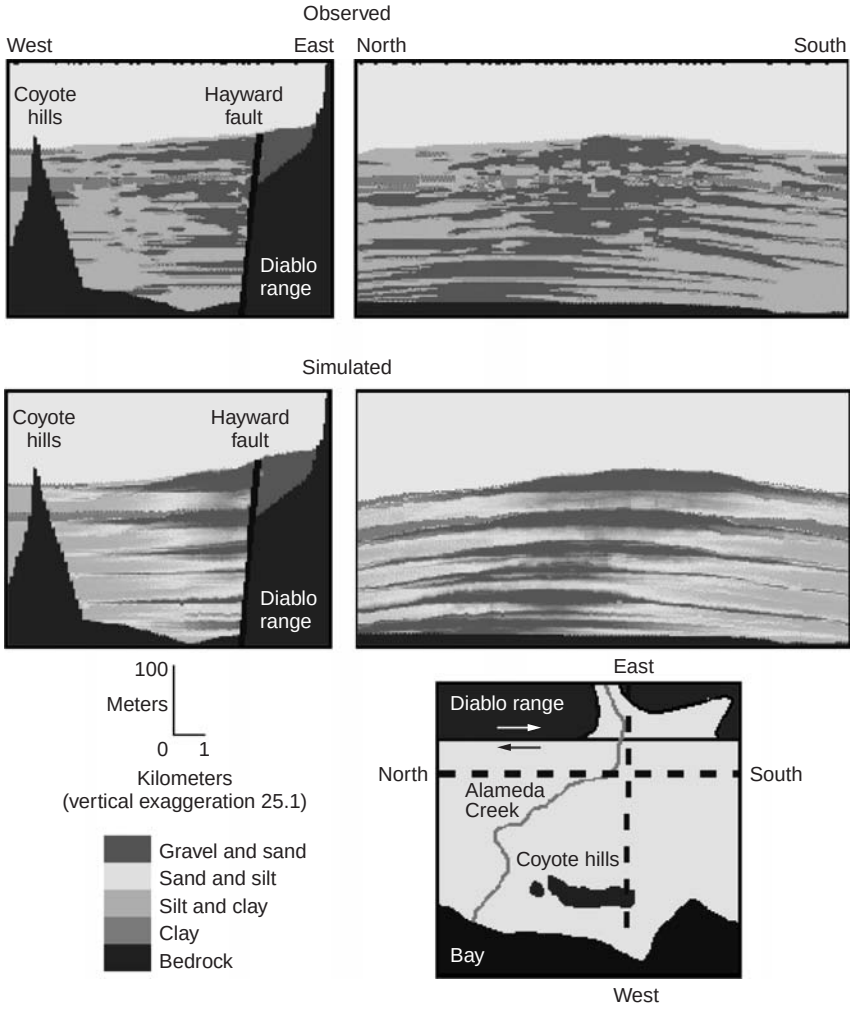

Figure 14 Reconstruction of the internal architecture of the sedimentary complex of the San Francisco Bay, California by a process-imitating model (Reprinted with permission from Koltermann, C. E., and S. M. Gorelick. 1992. Paleoclimatic signature in terrestrial flood deposits. *Science* 256, 1775–1782. © 1992 AAAS) A color version of this image is available at http://www.mrw.interscience.wiley.com/ehs

GENETIC MODELS

Genetic models, which should not be confused with the genetic algorithms used in global optimization, assign parameter values to the elements of the model by simulating the genesis of the aquifer. One of the first models capable of generating realizations of facies is SEDSIM. This program was developed by Tetzlaff and Harbaugh (1989), and it simulates the genesis of a sedimentary basin by modeling the processes of erosion, transport, and sedimentation. SEDSIM moves fluid particles over a 2-D grid, in which sediments from multiple types continuously mix. The basic principle of SEDSIM is that a fluid element moves down the slope as velocity increases its capacity to erode and pick up sediments, then when it finishes descending the slope, it slows down, its transport capacity decreases, and the sediments are deposited.

These models are mechanicist, in the sense that they reproduce the mechanical processes involved in the genesis of sedimentary basin. They must be run over tens of thousands of years, and require initial and boundary conditions that are difficult to estimate, as well as identifying of the external stresses that drive the processes. For example, information of the initial spatial distribution of the material that will be eroded is needed, as well as information about pluviometry over the entire simulation time. Because most of these inputs are impossible to determine and, at most, they are drawn from predefined probability distributions, these models cannot be called deterministic, even though they use deterministic models to obtain the spatial representation of the parameters.

One of the successful applications of the method (Figure 14) was performed by Koltermann and Gorelick (1992). They simulated the genesis of an alluvial fan-aquifer

system in north-central California (US). For this purpose, they had to collect local and regional geologic and climatic data, and hydrologic history of the study area. They also had to address sea level change, fault motion, sediment loading, compaction, porosity relations, and paleoclimate-driven fluctuations in floods and sediment loads. In addition, they had to simulate flood events using a stochastic streamflow time series. The geometry and geology of the fan-aquifer was simulated for 6 00 000 years. The output grain size distributions from the process model were transformed into porosity and hydraulic conductivity values using petrophysical relations.

Genetic models such as the ones described here are computationally intensive; however, they produce realistic images of large-scale sedimentary structures provided the model inputs are carefully constrained. The realizations are realistic at a large scale; however, locally it is very difficult to condition them to specific porosity or conductivity values at certain locations. This last caveat of genetic methods could be their major drawback. Lately, some researchers have been working on the problem of conditioning, such as Karssenberg *et al.* (2001). Others have developed agent models in order to trigger the behavior of the sediments while reducing the computational load (Teles *et al.*, 2001).

INVERSION METHODS

Inverse theory is concerned with the problem of making inferences about physical systems from data (directly measured or remotely sensed). Since nearly all data are subject to some uncertainty, these inferences are usually statistical. Further, since one can only record finitely many (noisy) data and since physical systems are usually modeled by continuum equations, no inverse problems are really uniquely solvable: if there is a single model that fits the data, there will be an infinite number of them. Our goal then is to characterize the set of models that fit the data and satisfy our prejudices as well as other information. This section describes how to determine model parameter values. Models are assumed to be valid; the only unknowns are parameter values that define the models. For completeness, we introduce some concepts and terminology commonly used in inverse/forward problem community. Detailed coverage of the inverse problem using deterministic tools and stochastic tools is given in **Chapter 156, Inverse Methods for Parameter Estimations, Volume 4** and **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4** respectively.

Well-posed versus Ill-posed Problem

Prediction based on a given set of parameter values is called *forward modeling*. Determination of parameter value from observed data is called *inverse modeling*. Inversion requires minimizing the discrepancy between predictions and observations. Inversion can be achieved in two ways. On one hand, a modeler iteratively modifies parameter values (such as hydraulic conductivity), and runs a forward model (i.e. ModFlow, FeFlow) until attaining best "fit" or "match". This kind of process falls into the trial and error methods. Such forward modeling is sometimes tedious and time consuming. On the other hand, an inverse algorithm can be adopted to automatically or semiautomatically obtain the parameter values from the observed data and an initial set of trial parameters values. The procedure also provides an estimate of parameter uncertainty and resolution.

A well-posed inverse problem requires "existence" of the problem, the "uniqueness", and the "stability" of the solution or algorithm. Obviously, in view of the observed data and our understanding of a real-world physical system, a problem is presumed to exist, for example, detection of contaminant plume in groundwater suggests that contamination must have happened in the past. The question then is how to relate the observation to the migration history of the contaminant. A cause generally has an effect. Can an effect result from different causes? Is it unique in theory or model? Even if it is, have we counted and resolved all parameters that define a model?

Inverse uniqueness has two levels: the model itself and the model-defining parameters. The latter is related to the stability of a solution algorithm. How sensitive are parameters to uncertainty of observed data? Are the errors amplified during inversion? Is the inversion algorithm efficient in terms of ease of usage and cost of running the inversion program (complexity)?

Deterministic versus Stochastic Inversion

An inverse model attempts to obtain a spatial distribution of the parameter values, so that the simulated state of the system, using forward flow and transport models, reproduce the observed state of the system at those locations. Because the relationship between state variables and parameters is not linear, conditioning parameter realizations to state variable data is not trivial, and, in general involves nonlinear optimization algorithms, in which the objective function and its gradient are very expensive to evaluate.

To address the inverse problem, two main frameworks have been developed and they are either deterministic or stochastic. In the deterministic framework, the structure of the spatial variability of the parameters is fixed. For example, the aquifer is divided into a number of zones, and each zone is supposed to have a constant hydraulic conductivity; then, the algorithm seeks the best hydraulic conductivity values for which the solution of the flow equation reproduces the state data (Carrera and Neuman, 1986).

However in a stochastic framework, the spatial variability of the parameters is statistically mapped. For example, the overall average and variance, and the variogram of the final realization are specified; this characterization is not enough to fully determine the parameter values at every cell. Then, a spatial realization is sought meeting the statistical constraints, conditional to the parameter values, and so that the forward model of the state of the system matches the observed values. Many alternative realizations can meet the statistical constraints and reproduce the state data. The self-calibrating method by Gómez-Hernández *et al.* (1997) was developed for this purpose. To make these inferences quantitative in either deterministic or stochastic framework, one must answer three fundamental questions:

1. How accurately is the data known, that is, what does it mean to "fit" the data?
2. How accurately can we model the response of the aquifer system? In other words, have we included all the physics in the model that contribute significantly to the data?
3. Finally, what is known about the system independent of the data? This is called *a priori* information and is essential since for any sufficiently fine parameterization of an aquifer system there will be unreasonable models that fit the data too. Prior information is the means by which we reject or down-weight unreasonable models.

Examples of Stochastic Inversion Methods

It has already been pointed out that the final hydraulic property realization cannot disregard the measurement data; they are the only factual knowledge available about the aquifer. However, aquifers are systems, the state of which is described by the spatial distribution of piezometric heads, and by the concentration of the solutes dissolved in water. In general, there is more information about the state of the system than about the parameters that controls it. Therefore, it appears necessary to generate spatial distributions of the parameters that are not only conditional to parameter values, but also consistent with the (partial) knowledge about the state of the system. We will illustrate this stochastic inversion by constraint through three examples (*see* **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4** for more details).

Cokriging methods. Rubin and Dagan (1987a, b) used the analytical approach to solve the perturbed flow equation. They calculate $h' = h - E[h]$ and $Y' = Y - E[Y]$ at the points of h, head, and Y, log of transmissivity, measurements and determined analytically the covariance function of h' and the cross-covariance (h', Y') as a function of the covariance of Y. The covariance of Y is function of a set of parameters q (integral scale of Y and its variance). This is actually sufficient to estimate the transmissivity field by cokriging. The cokriging estimator then gives the optimal estimation of Y at any point as follows:

$$Y(x) = \sum_{i=1}^{n_Y} \lambda_i Y_i + \sum_{j=1}^{n_H} \upsilon_j (h_j - E[h_j]) \qquad (3)$$

where the λ_i and the n_j are optimal weights that depend on the position x. The cokriging equations that provide the value of the optimal weights simply require that the covariance functions of Y, of h, and of $h - Y$ be known. They are developed by Rubin and Dagan (*see* **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**). Rubin and Dagan then calculate by cokriging all the values of Y at the measurement points where Y is known and where it is therefore possible to compare the known value with the one estimated by cokriging – without using the known value of this point in the cokriging equations. As the cokriging estimator is a function of the q parameters, these parameters can thus be optimized to minimize the errors between the estimated and measured Y values. The Maximum Likelihood method was used for their optimization (*see* **Chapter 154, Stochastic Modeling of Flow and Transport in Porous and Fractured Media, Volume 4**). Once the q parameters are known, the cokriging equations give an estimation of Y at all points and a map of Y is obtained (Figure 15).

Bayesian Inversion. For a statistician, an inverse problem is an inference or estimation problem. The data are finite in number and contain errors, as they do in classical estimation or inference problems; the unknown typically is infinite dimensional, as it is in nonparametric regression. The additional complication in an inverse problem is that the data could be directly and indirectly related to the unknown. Bayesian techniques have become more attractive for the hydrogeological communities through the elegant work of Tarantola (1987). One of the fundamental tenets of Bayesian inference is that uncertainty always can be represented as a probability distribution; in particular, the Bayesian approach treats the model as the outcome of a random experiment. The essential defining property of a Bayesian is to talk about the probability $P(H|E)$ of a hypothesis H, given evidence E. Whether one adheres to a Bayesian view, estimators that arise from the Bayesian approach have an attractive property, that is, the posterior pdf is at least as informative as prior one. In this case, the likelihood function is called *diffusive* or totally noninformative, and the prior estimates are exactly equal to the posterior estimates. It is emphasized that the method does not always guarantee better estimates for a couple of reasons. First, the Bayesian approach

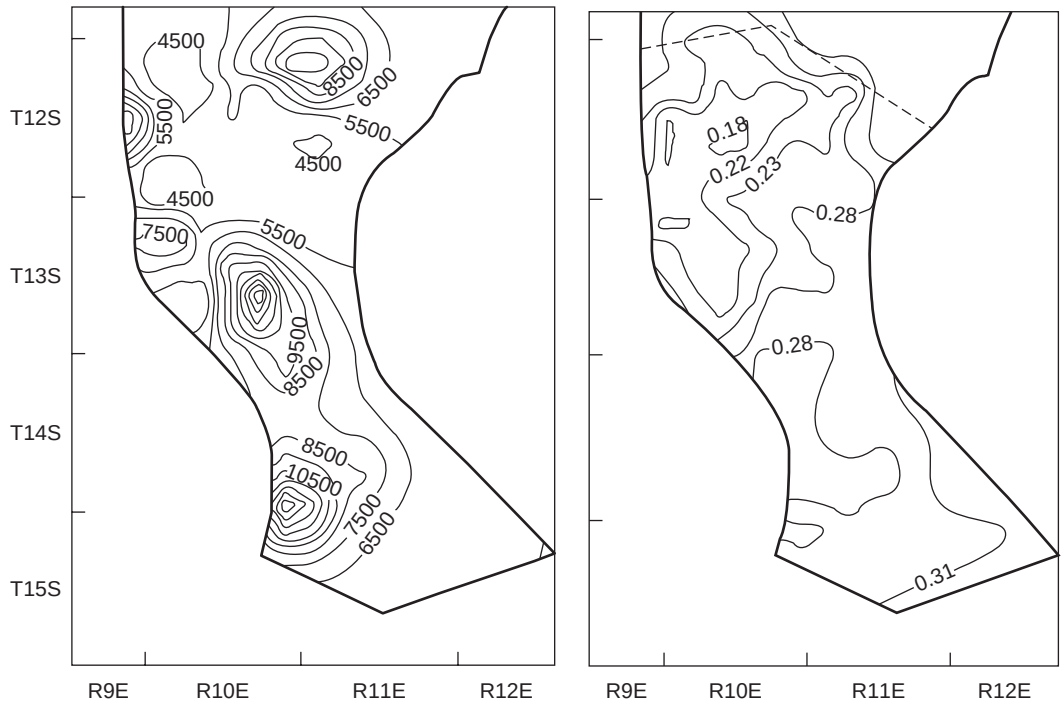

Figure 15 Estimated transmissivity T in ft^2 day^{-1} (a) and the conditional variance of ln[T] (b) based on cokriging and maximum-likelihood estimation (Reproduced from Rubin and Dagan, 1987b by permission of American Geophysical Union)

provides a pdf, not a single-valued estimate. Second, the improvement achieved in the posterior pdf is dictated by the quality of external factors such as the accuracy of the geophysical survey and the petrophysical model in the case of geophysical–hydrogeological stochastic joint inversion.

Bayesian inversion is illustrated in Ezzedine *et al.* (1999). Their hierarchal approach is intended to integrate and transform the well log data to a form in which it can be updated by the geophysical survey, and this tends to be a convoluted process. They started with generating images of the lithology, conditional to well logs. Each lithology image is then used as the basis for generating a series of shaliness images, conditional to well log data. Shaliness images are converted to resistivity images using a site-specific petrophysical model relating between shaliness, resistivity, and lithology, to create the necessary interface with the cross-well resistivity survey. The lithology and resistivity images are then updated using cross-well electromagnetic resistivity surveys. They explored the limits of the approach through synthetic surveys of different resolutions and error levels, employing the relationships between the geophysical and hydrological attributes that are weak, nonlinear, or both. The synthetic surveys closely mimic the conditions at the Lawrence Livermore National Laboratory (LLNL) Superfund site. Ezzedine *et al.* (1999) showed that the proposed stochastic Bayesian approach improves hydrogeological site characterization even when using low-resolution resistivity surveys (Figure 16).

Self-calibrating Stochastic Inversion

The self-calibrated algorithm (Gómez-Hernández *et al.*, 1997) is the first algorithm specifically aimed at the generation of hydraulic conductivity fields conditional to hydraulic conductivity and transmissivity data without resorting to any approximation of the state equation or linearization of the relationship between head and conductivity. It has been later extended to the generation of realizations conditioned to concentration data by Sahuquillo *et al.* (1999) and Hendricks Franssen *et al.* (2003).

In the self-calibrating approach, multiple realizations of the parameters controlling groundwater flow movement and mass transport, that is, hydraulic conductivity, transmissivity, or specific storage, are generated conditioned to values of the parameters and of the state variables. That the realizations are conditioned to the parameter values means that all realizations display the patterns of variability and cross-correlation observed in the field and modeled by a random function, and, at the same time, each realization honors the measured parameter values at their measurement locations. That the realizations are conditioned to the state variables means that the solution of the groundwater flow and mass transport equations with the parameter realizations generated results in the prediction of the state of the system that

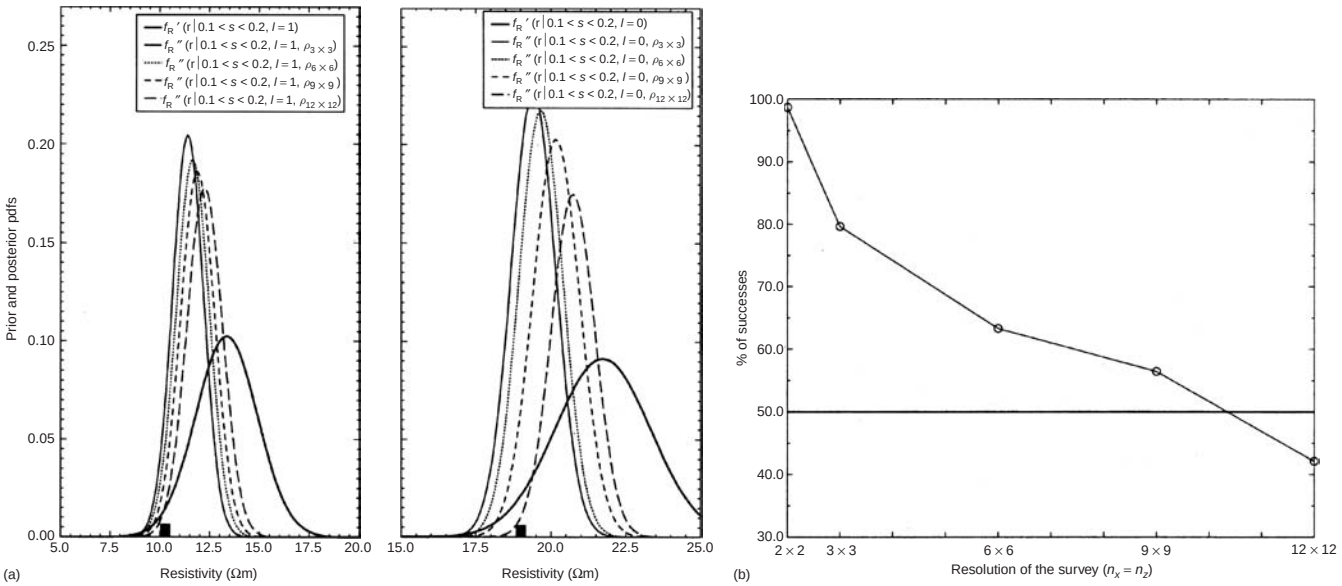

Figure 16 (a) Effect of the block resolution of the $n_x \times n_z$ resistivity survey on the posterior pdf's (prior pdf's are also plotted). The bias in the variance and the mean decrease with the increase of the resolution of the resistivity survey (from 12×12, 9×9, 6×6, to 3×3). The black box denotes ''true'' resistivity values. Prior and posterior pdf's for shaliness between 0.1 and 0.2 in silt (left) and sand (right). (b) Percentage of number of successes of the Bayesian updating approach for different survey resolutions and different errors in the surveys (Reproduced from Ezzedine *et al.*, 1999 by permission of American Geophysical Union)

honors the spatiotemporal measurements of the state variables. Achieving such a dual conditioning amounts to solve a deterministic inverse problem for each realization, something that can only be done after a careful parameterization of the spatial variability of the realizations and efficient computational algorithms.

CONCLUSION

Looking back at the models described here, it is concluded that the best alternative to characterize the spatial variability of a given parameter is through the use of hybrid models. It is important to capture the architecture of the different facies in the aquifer, as it is to capture the variability of the parameters within each facies. Hybrid models start by using a genetic model, an object-based model, or any of the geostatistically-based models capable to generate facies realizations, to generate the spatial distribution of the different facies present in the aquifer; then a geostatistical model (either Gaussian or non-Gaussian) is used to fill in each facies with spatial distributions of the parameters. An example of this approach can be found in Cox *et al.* (1994), who used the cross-sectional geologic images created with a genetic model to estimate the parameters of an indicator-based spatial statistical model. Then, conditioning and generating multiple realizations of hydraulic conductivity were achieved with a geostatistical model.

148: Aquifer Characterization by Geophysical Methods

HARRY VEREECKEN, ANDREAS KEMNA, HANS-MARTIN MÜNCH, AXEL TILLMANN AND ARRE VERWEERD

Agrosphere Institute (ICG-IV), Forschungszentrum Jülich GmbH, Jülich, Germany

Geophysical methods are increasingly being used to characterize the subsurface. They offer the potential to derive basic characteristics, state variables, and properties of geological formations. In this article, we focus on the application of geophysical methods to derive properties and state variables of aquifer systems. Special attention is given to the assessment of hydraulic conductivity, porosity, and water saturation. Three different groups of methods (seismics, electrical techniques, and electromagnetics) and their combined use are discussed. For each method, relationships between geophysical and hydrogeological quantities are outlined and applications are presented. A separate section is devoted to the development and application of combined approaches in hydrogeophysics.

INTRODUCTION

The shallow subsurface is an extremely important zone that yields much of our water resources (*see* **Chapter 145, Groundwater as an Element in the Hydrological Cycle, Volume 4**). It also serves as the repository for municipal and industrial waste. As sustainable and effective use of the subsurface environment is a major challenge facing modern societies, there is a great need to improve our understanding of the shallow subsurface and, in particular, groundwater systems. In this respect, geophysical methods can contribute in a significant manner.

In the past, application of geophysical methods in groundwater hydrology has focused on mapping geological structures (e.g. clay/sand layers, bedrock valleys), delineation of aquifer boundaries, mapping of fracture zones and chemical pollution plumes, delineation of water-saturated zones, and seepage flow in landslide bodies. For these purposes, standard methods are presently available and well documented in the geophysical literature (e.g. Parasnis, 1997; Reynolds, 1997).

In recent years, increased attention has been given to the use of geophysical methods to derive parameters and state variables characterizing especially near-surface groundwater systems and soils. Research in this direction is mainly driven by the fact that geophysical methods allow continuous mapping of geophysical properties, which can be transferred to parameters or variables characterizing the aquifer system (e.g. water content, porosity, flow velocity, and their changes in time). Classical approaches like drilling, coring, and well testing (*see* **Chapter 151, Hydraulics of Wells and Well Testing, Volume 4**) have shown their limitations in constraining spatial and temporal variabilities of these quantities. Characterizing such variabilities is however of utmost importance for, for example, determining the success of water management strategies or predicting pollution risks for water supply systems.

In this article, we will present the application of geophysical methods to derive parameters (e.g. hydraulic conductivity, porosity, dispersivity) and state variables (e.g. water saturation) of aquifer systems relevant for water flow and solute transport (*see* **Chapter 149, Hydrodynamics of Groundwater, Volume 4**). This area of research is today referred to as hydrogeophysics (e.g. Vereecken *et al.*, 2002; Rubin and Hubbard, 2005). Hydrogeophysics is a rapidly evolving discipline aiming at integrating hydrological, hydrogeological, and geophysical methods and concepts to characterize the subsurface. Rather than covering the whole range of available geophysical methods, we

Encyclopedia of Hydrological Sciences. Edited by M G Anderson.

focus on selected methods that are promising in terms of site-specific hydrogeophysical characterization of aquifer systems. Three groups of methods will be discussed: seismics, electrical techniques, and electromagnetics, the latter including ground-penetrating radar. In the last section, we will address the combined use of geophysical and hydrogeological data to characterize aquifer properties.

SEISMIC AQUIFER CHARACTERIZATION

Seismic characterization of the subsurface is based upon the propagation of elastic waves generated through a seismic source at the surface or in boreholes. Owing to the nature of elastic media, there exist different wave types propagating with different velocities. The primary information derived from seismic methods comprises the wave velocities and wave attenuation. From these quantities information can be derived about material properties of the subsurface like porosity, hydraulic conductivity, elastic moduli, and water saturation.

Seismic-Hydrogeological Relationships

Seismic velocities are dependent on aquifer properties (e.g. grain material, texture, and porosity) and state variables (e.g. water saturation). The fast compressional wave (also known as primary wave or P-wave) is related to the bulk and shear moduli of a medium, and its propagation velocity, v_p [m s^{-1}], is

$$v_p = \sqrt{\frac{K + \frac{4}{3}G}{\rho_b}} \tag{1}$$

where K [Pa] and G [Pa] are the bulk and shear moduli, respectively, and ρ_b [kg m^{-3}] is the bulk density. P-waves occur in solids, fluids, and gases. The slower shear wave (secondary or S-wave) does not depend on the bulk modulus; its velocity, v_s [m s^{-1}], is given by

$$v_s = \sqrt{\frac{G}{\rho_b}} \tag{2}$$

Shear waves do not exist in fluids and gases since their shear moduli are zero.

The elastic moduli of sediments depend on the characteristics of the solid matrix, the porosity, and the properties of the pore space. The effect of water saturation on the seismic velocities is well-known and subject of many theoretical (Gassmann, 1951; Biot, 1956a,b; Kuster and Toksöz, 1974a) and experimental (Wyllie *et al.*, 1956; Kuster and Toksöz, 1974b) investigations. Under the constraint that mineral composition and porosity are the primary factors controlling the dry-frame elastic moduli, Nolen–Hoeksema (1993) derived a first-order approximation of the relation between porosity and the dry-frame bulk and shear moduli, K_{dry} [Pa] and G_{dry} [Pa], respectively:

$$K_{dry} = K_{solid}\left(1 - \frac{n}{n_0}\right), \quad G_{dry} = G_{solid}\left(1 - \frac{n}{n_0}\right) \tag{3}$$

Here, K_{solid} [Pa] and G_{solid} [Pa] are the bulk and shear moduli of the solid matrix material, n [−] is the porosity, and n_0 [−] denotes the precompaction porosity, which defines the transition from unconsolidated ($n > n_0$) to consolidated ($n < n_0$) sediments. For media consisting of spheroidal grains, n_0 is in the range of 0.35 to 0.40. A typical rock contains a mixture of grain/pore sizes and shapes, leading to a more complicated relationship between elastic moduli and porosity (see e.g. Toksöz *et al.*, 1976).

For sediments with a homogeneous and isotropic pore space, Gassmann's equation (Gassmann, 1951) describes the influence of fluids on the bulk modulus for low-frequency elastic waves:

$$K = K_{solid}\frac{nK_{dry} + Q}{nK_{solid} + Q} \tag{4}$$

with

$$Q = K_{fluid,eff}\frac{K_{solid} - K_{dry}}{K_{solid} - K_{gas}} \tag{5}$$

where K_{gas} [Pa] denotes the bulk modulus of the gas phase, and $K_{fluid,eff}$ [Pa] is the effective bulk modulus of the fluid–gas mixture. Equations (4) and (5) are valid for consolidated materials, that is, $n < n_0$, and therefore, from equation (3), $K_{dry} > 0$. For a homogeneous fluid–gas mixture in the pore space, $K_{fluid,eff}$ is given by

$$K_{fluid,eff} = \left(\frac{S}{K_{fluid}} + \frac{1 - S}{K_{gas}}\right)^{-1} \tag{6}$$

where S [−] is the fluid (water) saturation and K_{fluid} [Pa] the bulk modulus of the fluid phase. According to equations (4) to (6), an increase of water saturation gives rise to an increase of the bulk modulus of sediments, while water does not contribute to the shear modulus. Therefore, the P-wave velocity (equation (1)) shows a stronger variation caused by saturation changes than the S-wave velocity (equation (2)), which is only influenced through changes in bulk density

$$\rho_b = (1 - n)\rho_{solid} + nS\rho_{fluid} \tag{7}$$

where ρ_{solid} [kg m^{-3}] is the mass density of the solid matrix and ρ_{fluid} [kg m^{-3}] the water density. Accordingly, the v_p/v_s ratio is suitable to distinguish dry from saturated sediments and detect phreatic surfaces, that is, water tables.

For illustration, Figure 1 shows the P-wave and S-wave velocities modeled for a porous medium consisting of

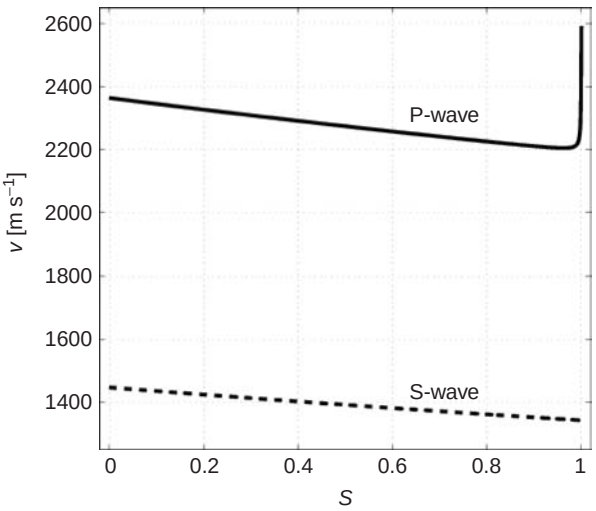

Figure 1 Seismic P- and S-wave velocities as function of water saturation modeled for a porous medium consisting of quartz grains (*see* Tillmann, 2001)

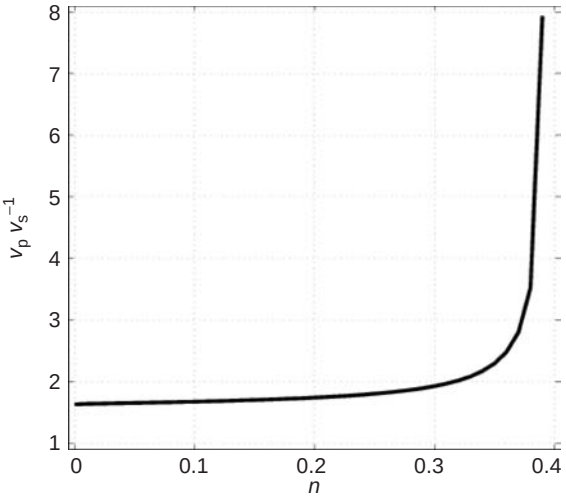

Figure 2 Seismic P-wave to S-wave velocity ratio as function of porosity modeled for a porous medium consisting of quartz grains (*see* Tillmann, 2001)

quartz grains with $n = 0.3$ (for more details, see Tillmann, 2001) as a function of water saturation. The slight decrease of the velocities with increasing saturation at lower to medium saturation degrees is due to the dominant effect of the increase of bulk density with increasing water saturation in the pore space. Near full saturation, the complete filling of pores with water causes a rapid increase of the bulk modulus and the P-wave velocity. Equations (3) to (6) lead to the conclusion that this P-wave velocity increase is larger for high porosities and negligible for low porosities compared to velocity perturbations owing to changes in soil material. The v_p/v_s ratio of the quartz grain model at full saturation as a function of porosity is shown in Figure 2. For n approaching the precompaction porosity, here $n_0 = 0.4$, the ratio becomes infinite since the dry matrix shear modulus becomes zero. Figures 1 and 2 illustrate the potential of seismic methods to detect the transition zones to full saturation and to estimate porosity using a combined interpretation of P-wave and S-wave data.

Empirical relationships between P-wave velocity, porosity, permeability, clay content, bulk density, and water saturation for sandstones and carbonate rocks were derived for example by Koesoemadinata and McMechan (2003) using correlation analyses between the different quantities. Marion *et al.* (1992) obtained velocity-porosity relationships for sediments on the basis of a simple geometric-mechanical model for sand–clay mixtures. From porosity, in turn, permeability can be estimated using the Kozeny–Carman relation (Kozeny, 1927; Carman, 1937).

Seismic Methods

Seismic methods are based on the propagation of elastic waves in the earth. From the experimental setup, different methods can be distinguished (for an overview, *see* e.g. Telford *et al.*, 1990). In the seismic refraction method, the first arrival times of the seismic waves are measured. The derivation of seismic velocities from measured travel times (inversion) is based on Snell's law from ray theory, which implies the assumption of a layered earth. The method is sensitive to velocity changes between two layers as long as critically refracted waves are generated at the layer boundaries. Therefore the method requires an increase in seismic velocity with depth, which is a severe constraint for many shallow applications where low-velocity layers may be encountered.

In contrast to seismic refraction, seismic reflections occur owing to changes in the elastic impedance of the medium, that is, the product of velocity and density in a layer. Therefore, low-velocity layers and density changes can be detected too, as long as the wavelength of the seismic signal is small compared to the layered structure. From this it follows that measurements in shallow sediments have to be performed using signals in the kHz range, which unfortunately are affected by high attenuation.

In seismic crosshole tomography, travel time measurements for a large number of ray paths are collected providing information on the seismic velocity distribution. While the application of this technique in the field involves P-wave travel time measurements between boreholes, in the vertical seismic profiling (VSP) method it is common to use surface-to-borehole shot-receiver configurations. Seismic crosshole tomography gives a relatively detailed velocity model between the boreholes, and does not require the assumption of a layered earth.

Surface wave analysis exploits the fact that a particular wave type is formed owing to the free boundary condition

at the Earth's surface, the amplitude of which drops exponentially with depth. Surface wave interpretation is normally based on the assumption of a horizontally layered earth (Haskell, 1953). Surface waves are dispersive, that is, the propagation velocity as well as the penetration depth depends not only on material parameters but also on frequency. The analysis of this dispersive behavior leads to information about all elastic parameters and the depths of shallow layer boundaries.

Hydrogeological Applications

As pointed out in Section "Seismic-hydrogeological relationships", the typically wide range of elastic properties of sediments normally exceeds any perturbations caused by the presence of water, which makes near-surface water detection by means of seismic methods difficult. Nevertheless, seismic methods have been successfully used for mapping water table depths in aquifers (e.g. Birkelo *et al.*, 1987; Bacharach and Nur, 1998; Baker *et al.*, 2000; Bradford and Sawyer, 2002). However, the water table is not a trivial boundary in seismic terms. Generally, it is defined through the pore fluid properties (such as compressibility, density, and viscosity) and the degree of water saturation (depending on pore pressure and pore-size distribution). Therefore, its location may vary over a relatively short distance in both space and time. Seismic methods can be used to monitor temporal groundwater variations by detecting associated changes in seismic velocity. For instance, Bacharach and Nur (1998) followed this approach for monitoring the water table at a beach under tidal influence. On a longer time scale, Baker *et al.* (2000) monitored seasonal water table changes over one year. Tillmann and Stöcker (2001) presented a joint inversion approach for seismic and electrical data (*see* Section "Electrical aquifer characterization") taking lithological and hydrological parameters into account. In contrast to conventional joint inversion methods (e.g. Hering *et al.*, 1995), their approach can handle the presence of a water table.

As a field demonstration we present the results of a seismic crosshole tomography survey performed to resolve the porosity distribution in a near-surface aquifer. The survey was conducted at the Krauthausen test site, which is located close to Jülich in the western part of Germany. More details about the site can be found in Vereecken *et al.* (2000). In 1997, a series of tomographic measurements was made to characterize the spatial variability of porosity. Figure 3(a) shows the reconstructed P-wave velocity image along a cross section containing several boreholes. Details on the used tomographic reconstruction technique and further results are reported in Dietrich and Fechner (1997). Taking into account additional information from borehole

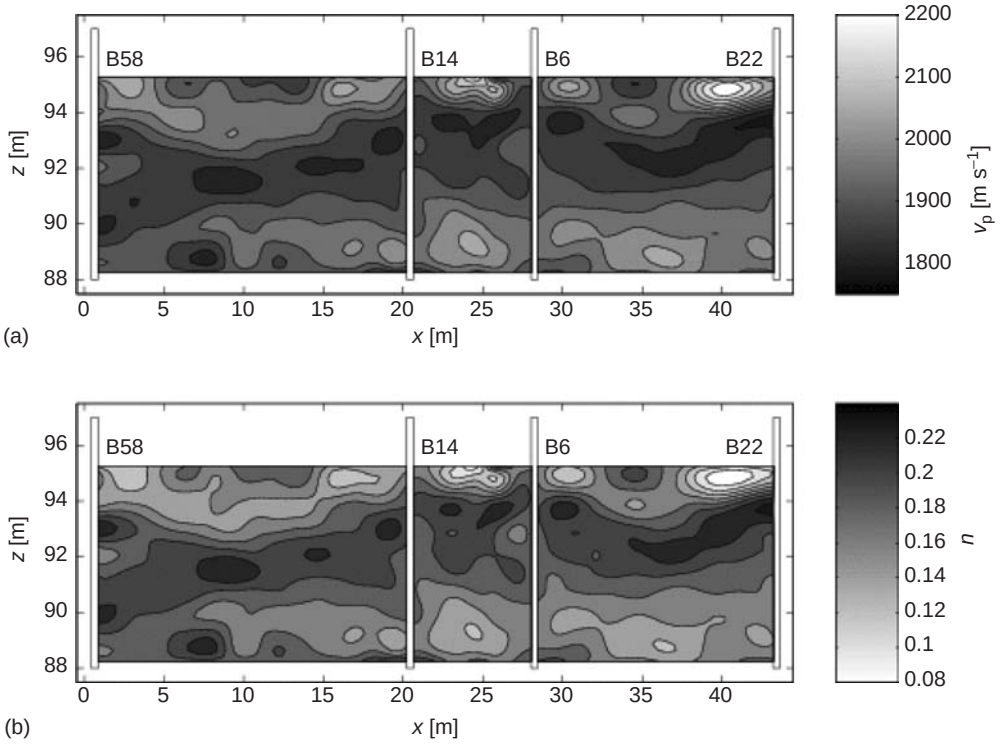

Figure 3 Results of a crosshole seismic tomography survey conducted at the Krauthausen test site along a transect containing four boreholes (B58, B14, B6, B22) to characterize a near-surface aquifer: (a) P-wave velocity distribution, (b) estimated porosity distribution

measurements, the porosity was derived from the P-wave velocity using the approach of Yamamoto *et al.* (1994). The resultant porosity distribution is shown in Figure 3(b). The porosities derived from the seismic data showed good correlation with those determined on cores from the well locations.

ELECTRICAL AQUIFER CHARACTERIZATION

It has been recognized for a long time that measurements of subsurface electrical properties can be used for the investigation of the underground, in particular concerning groundwater resources (e.g. Vacquier *et al.*, 1957). Since solid and aqueous phases of a porous soil/rock system electrically act in a different way, electrical properties of soils and rocks are closely related to the underlying structure. Importantly, in predominantly ion-conductive systems electrical and hydraulic conduction follow similar pathways through the interconnected saturated pores – a circumstance that makes electrical methods particularly attractive for hydrogeological aquifer characterization.

Electrical-Hydrogeological Relationships

In addition to electrolytic conduction in the saturated pores, described by an electrolytic conductivity contribution σ_{el} [S m^{-1}], electrical surface conduction can exist along the interfaces between solid and aqueous phases owing to the presence of electric surface charges and the involved formation of electrical double layers, leading to a surface conductivity contribution σ_s [S m^{-1}]. Following the conceptual model that both conduction mechanisms act in parallel (e.g. Waxman and Smits, 1968; Rink and Schopper, 1974), the bulk electrical conductivity, σ [S m^{-1}], of sediments is given by

$$\sigma = \sigma_{el} + \sigma_s \tag{8}$$

For clay free, saturated formations, the bulk electrical conductivity may be expressed as

$$\sigma_{sat} \cong \sigma_{el,sat} = \frac{\sigma_w}{F} = n_{eff}^m \sigma_w \tag{9}$$
