Proliferation is characterized by enlarged cells with great variability in the size of the nuclei (= anisonucleosis), occurrence of hepatocytes with two to three nuclei, and cell plates of varying thickness. The parenchyma which has remained undamaged is capable of regenerative proliferation. The vulnerability of the acinus structure is the prerequisite for the criterion "*transformation*", and the tendency to proliferate is the criterion for "*nodes*". • The **blood vessels** are also involved in this process: (1.) reduction in the distance between presinusoidal and post-sinusoidal vessels, (2.) development of shunts, and (3.) formation of a perinodular plexus (E. GAUDIO et al., 1993). This plexus consisting of arterioles guarantees the arterial blood supply within the nodes. Due to the displacement effect of the nodes, arterial vessels also become compressed. This is particularly critical since the cirrhotic liver is almost exclusively supplied by arterial blood, so that some areas become increasingly hypoxic and are thus more prone to *coagulation necrosis*. This happens mainly under conditions of circulatory collapse caused, for instance, by haemorrhage or toxicosis. • In contrast, a favourable local arterial blood supply may lead to the formation of **gigantic regeneration nodes** similar to "proliferations". (s. fig. 35.1)

The following forms of cirrhosis are differentiated according to the **size of the regeneration nodes**: (1.) micronodular (granular), (2.) coarse-nodular (nodular),

Fig. 35.1: Atrophic liver cirrhosis with pronounced, thick capsule callosity. Gigantic regeneration node “proliferating” from the underside of the right liver lobe, displacing the (duplicated!) gall bladder

(3.) coarse-bulbous (lobular), and (4.) mixed-nodular. The classification into granular, nodular and lobular forms was proposed by A.H. BAGGENSTOSS et al. (1952). Despite complete transformation processes, cirrhosis with a smooth surface, completely or largely without intrahepatic nodes, is occasionally found. Various synonyms have been used for this kind of classification according to the type and size of the nodes. (quot. 89, 91)

Macronodular cirrhosis: In *multilobular cirrhosis*, the nodes develop from parts of several lobules or from larger parenchymal areas with intact lobular architecture. This group with nodes of >0.3 cm up to the size of a walnut is also called postnecrotic cirrhosis or Nagayo type A (M. NAGAYO, 1914). The liver is predominantly atrophic. The pseudolobules contain parts derived from several acini (= multiacinar or multilobular cirrhosis). Portal fields and central venules are present, however, in an abnormal topography. (s. figs. 35.2, 35.3)

A special form is **incomplete septal cirrhosis**; it is found especially as a result of chronic hepatitis B or in Wegener’s granulomatosis. (190) The thin septa, which invade the parenchyma from the portal fields, contain no or only very few inflammatory infiltrates (= passive septa). (s. p. 414) • Lobular **coarse-bulbous cirrhosis** can likewise be assigned to this group, which, as posthepatic cirrhosis, is also called Nagayo type B or may be referred to as *Marchand’s hyperplasia* (F. MARCHAND, 1895) or *potato liver* (H. KALK, 1957) in the literature. Lobular nodes can reach such a size that they are mistaken for a normal hepatic lobe. (s. fig. 35.1) Macronodular forms may follow chronic viral hepatitis, chronic autoimmune hepatitis, metabolic diseases, toxic-necrotizing processes and alcohol abuse. (s. fig. 35.4)

Fig. 35.2: Complete, coarse-nodular liver cirrhosis due to chronic viral hepatitis B

Fig. 35.3: Stationary macronodular liver cirrhosis in chronic non-active hepatitis C (Sirius red)

Fig. 35.4 Complete, coarse-bulbous cirrhosis after years of alcohol abuse and superimposed acute viral hepatitis B, showing a chronic course. Mild tendency towards cholestasis; pronounced subcapsular vascularization and vascular stasis. Occasional funnel-shaped parenchymal depressions

Micronodular cirrhosis: Monolobular (monoacinar) cirrhosis consists of individual hepatic lobules separated by connective tissue, with the central vein maintained in the interior. In *pseudolobular cirrhosis*, no elements of the lobular architecture and no central vein can be detected; the nodules in this type of cirrhosis are small. The monolobular and pseudolobular forms are classified as micronodular cirrhosis, or Nagayo type C (with node size <0.3 cm). A striking feature is the uniformity of the nodules. (s. figs. 35.5, 35.6)

Fig. 35.5: Micronodular, alcohol-related liver cirrhosis with "simian cleft"; (s. figs. 2.3; 31.22) right lobe with rounded edge and thin fibrotic margin; numerous small scars (brandy drinker)

Fig. 35.6: Complete, micronodular to medium-nodular liver cirrhosis after chronic viral hepatitis B (section, native preparation)

The micronodular form can develop into a macronodular form, but not vice versa. Generally, micronodular cirrhosis contains more fibrosis than parenchyma; therefore it is firmer than macronodular cirrhosis. The development of micronodular cirrhosis, e.g. in alcohol abuse, may be caused by the fact that continuous alcohol intake blocks the protein synthesis, and thus the parenchyma has no time or chance for cellular proliferation. This form of cirrhosis mainly results from alcohol abuse, but may also be found in haemochromatosis, congestive liver, biliary cirrhosis, toxic liver damage due to pharmacons, metabolic diseases and chronic viral hepatitis. The liver is generally enlarged.

Mixed-nodular cirrhosis is considered to be a transitional form between micronodular and macronodular cirrhosis (V.J. DESMET et al., 1990). Due to variations in the regenerative capacity of the cirrhotic liver, 50% of micronodular forms with a diameter of 1.5 mm develop into macronodular forms after 2–4 years, whereas after 10 years, the rate is as high as 90%. • *Atrophic cirrhosis* is the most common form with regard to size (s. figs. 35.1, 35.14),

Fig. 35.7: Complete, micronodular, progressive liver cirrhosis with formation of pseudoacini (Sirius red)

Fig. 35.8: Complete, mixed-nodular (toxin-induced) liver cirrhosis due to years of alcohol abuse and long-term oxyphenisatin abuse

whereas *mixed-nodular cirrhosis* is the most common form with regard to nodes. (s. tab. 35.1) (s. fig. 35.8)

4.3 Morphological course

Progression: The question as to the progression of cirrhosis is of crucial importance clinically and can only be answered by means of histology. There is evidence of dense, chronic inflammatory infiltration of the connective tissue; the boundary between connective tissue and parenchyma is blurred. Groups of damaged hepatocytes, liver cell necroses as well as nodules formed from the proliferation of Kupffer cells and round cells are found within the parenchyma. In places, piecemeal necroses infiltrate the parenchymal islands. Many cirrhoses only take a progressive course because of circulatory disturbances. *Clinical progression* frequently, but by no means always, corresponds to morphological progression. • **Stationary cirrhosis** is predominantly found in macronodular forms. It frequently exhibits round, clearly defined, nodular parenchymal areas within scar tissue. The boundary between the parenchyma and connective tissue is (relatively) clear-cut. (s. fig. 35.2) The scar tissue contains a small number of chronic inflammatory infiltrates of moderate and slightly varying density. The hepatocytes are conspicuously enlarged. Fully developed stationary cirrhosis may result, which is defined morphologically as defective healing. The morphological dynamics of progression or full-scale stationary cirrhosis has to be strictly differentiated from the respective clinical course. • **Remission** of the cirrhosis is possible, provided the cause of the disease is eliminated (e.g. abstention from alcohol, iron depletion in haemochromatotic cirrhosis, removal of biliary obstruction). However, nodular transformation processes cannot be reversed – restoration of normal lobular architecture is no longer possible.

4.4 Completion

Another important criterion is to determine whether the nodular transformation in the liver is complete or incomplete. This morphological characteristic can be found both in progressive and stationary cirrhoses. • In **complete cirrhosis**, the parenchyma is completely partitioned by connective tissue septa. The collapse of fibres (due to portocentral bridging necroses) results in the development of portocentral septa (= *passive septa*). Due to the spreading of the inflammation to the periportal parenchyma, septa develop and branch out from the portal fields (= *active septa*). Generally, they lead to capillarization of the sinusoidal walls as well. (s. fig. 35.9) **Incomplete cirrhosis** only displays the formation of short septa (= *subsepta*), with the result-that there are occasional areas of incomplete (partial) subdivision of the parenchyma.

Fig. 35.9: Scheme of possibilities for hepatic transformation after parenchymal necroses: (1) formation of pseudolobuli, (2) nodes with enclosed portal field, (3) formation of parenchymal garlands, (4) development of a coarse node from several hepatic lobules which are, in part, completely intact, (5) scar formation after total lobular necrosis (H. THALER, 1975) (169)

4.5 Pathogenetic development

The development of cirrhosis can easily be understood by analysing the morphological findings. Differentiation is made between: (1.) *regular cirrhosis* (where the cause has a constant, long-term and strong effect, e.g. in alcohol abuse, haemochromatosis, Wilson's disease), (2.) *irregular cirrhosis* (where the cause has an intermittent effect interposed by inaction), (3.) *mixed forms*, (4.) *biliary forms*, and (5.) *vascular forms*.

4.6 Postdystrophic cirrhosis

In the course of massive subacute liver necrosis (or hepatic dystrophy), large parts of the hepatic parenchyma can be destroyed within a few months. Extensive regenerative nodes form from the remaining epithelium. Within these regenerations, the lobular architecture is either still maintained or has been partially restored. Areas of parenchymal loss are converted into fibrous scar tissue with embedded pseudoductuli and duct proliferations as well as irregularly located residual hepatocytes. This course is extremely rare. In the literature, it is also called *incomplete postnecrotic cirrhosis*.

4.7 Necrosis, fibrogenesis, regeneration

The mechanisms leading to *cell degeneration* and *cell death* have been described in detail. (see chapter 21.3.4) The processes of *regeneration* (see chapter 21.3.5) and *fibrogenesis* (see chapter 21.3.6) have also been discussed in depth. These three important events – cell death, regeneration and fibrogenesis – are involved in the development of cirrhosis.

Fibrogenesis commences with the activation of Ito cells by cytokines such as TGF β 1, PDGF, TNF α , IGF1. This induction of Ito cells leads to quantitatively increased (up to ten times the norm) and qualitatively altered synthesis of the extracellular matrix, which consists of collagens, glycoproteins, proteoglycans and glucosaminoglycans. • Degeneration of the matrix is

reduced by a decrease in matrix metalloproteinases (MMP) with a simultaneous increase in the tissue inhibitors of metalloproteinases (TIMP). Both factors reduce further degradation of connective tissue. • The hepatocytes are now multilayered instead of normal single-layered cell plates and lose their microvilli. Fenestration of the sinusoids disappears, whereas the sinusoidal extracellular matrix increases, leading to **capillarization of the sinusoids**. (s. pp 410, 540) In this way, the distance between the hepatocytes and the blood becomes greater, and the clearance of macromolecular substances is reduced. Stronger flow resistance in the liver leads to portal hypertension. • Portoportal and portocentral bands of connective tissue form, in which portosystemic intrahepatic shunts develop.

Regeneration after liver resection follows a coordinated and limited course. This is not the case in cirrhosis: isolated and excessive regenerations of hepatocytes and bile ducts are formed, from which *adenomas* and *carcinomas* may develop.

4.8 Morphological diagnostics

In order to evaluate cirrhosis in terms of morphology, certain **requirements** have to be fulfilled. Occasional *diagnostic uncertainty* or *divergent classification* may arise from the fact that the biopsy material is insufficient and therefore not representative. This, in turn, is probably due to the fact that the techniques used in obtaining these inadequate samples were faulty or unsuitable. (s. pp 168, 169, 415, 750)

5 Epidemiology

Cirrhosis of the liver is a disease found all over the world, affecting all races, age groups and both sexes. • However, there are **geographical differences** regarding the most important causative factors: (1.) rate of alcohol consumption, and (2.) frequency of viral hepatitis. Few reliable figures concerning its incidence and prevalence are available, since cirrhosis is often symptom-free. Autopsy examinations suggest a **prevalence** of 4–10%. The **incidence** is about 240/million inhabitants/year. • The number of people suffering from cirrhosis in Germany is estimated at 600,000–700,000; some 25,000 patients die of cirrhosis every year, with **mortality** being twice as high in men as in women. Thus cirrhosis ranks ninth as a cause of death overall, and fifth for the age group 45–65 years. • Generally, the increasing mortality rate runs parallel to regional alcohol consumption. This correlation between alcohol consumption and cirrhosis-dependent mortality or morbidity applies equally to men and women. • The slight decrease in mortality in some countries observed during the past 10–15 years may be due to more effective prophylaxis and improved treatment options for complications. (65, 149)

6 Aetiology

The causes of “liver cirrhosis” are numerous; some of them are rare, appearing even in childhood (e.g. drinking water from copper pipes). Cirrhosis can be acquired or genetically based. Aetiological clarification, particularly with early diagnosis, should always be a priority, since it may aid treatment and thus prognosis. *Cirrhosis comes in many different forms!* • There is still no unequivocal answer to the question as to why these causal factors are responsible for the development of cirrhosis over such a widely varying period or why they may not cause cirrhosis at all in some individuals. There are even cases where cirrhosis develops despite effective elimination of the causes – probably as a result of self-perpetuation due to induced immunological mechanisms. • Although there are numerous causes with varying pathogenesis, it is possible to differentiate between three forms of cirrhosis from an aetiological viewpoint: (1.) parenchyma-related cirrhosis, including the so-called “common” cirrhosis (H.W. ALTMANN et al., 1986) and metabolic cirrhosis, (2.) bile duct-related cirrhosis (= biliary cirrhosis), and (3.) vessel-related cirrhosis (= vascular cirrhosis). (s. tab. 35.2)

Biliary cirrhosis: Biliary cirrhosis can be detected in 5–15% of cases. (s. pp 415, 673, 679, 696, 739, 743) (s. figs. 32.5; 35.10, 35.11)

Fig. 35.10: Biliary liver cirrhosis after long-term chronic-recurrent cholangitis

Alcohol abuse: Alcohol abuse is the most common cause of cirrhosis. Nevertheless, no more than 40–60% of alcoholics contract the disease. Thus genetic factors must also be involved in the development of alcoholic cirrhosis. Alcohol itself can be a facilitative factor or cofactor. Moreover, “additives” contained in various alcoholic beverages in widely different quantities may be of greater importance than hitherto assumed. (99, 162, 175) (s. pp 542, 546) (s. figs. 28.13, 28.14; 35.3)

Fig. 35.11: Liver cirrhosis due to chronic-recurrent, ascending cholangitis (Sirius red)

Chronic autoimmune hepatitis: If untreated, AIH (especially type 2) develops almost inevitably into cirrhosis; the condition is further aggravated by the presence of multilobular necrosis and bridging necrosis. In bridging necrosis, development of cirrhosis is more rapid between the portal fields and the central vein than between the portal fields themselves. (s. p. 662) (s. fig. 32.4)

Chronic viral hepatitis: Within a period of five to six years, cirrhosis is caused by chronic viral hepatitis B in 15–30%, chronic viral hepatitis C in 20–50% and chronic viral hepatitis B/D in up to 60% of cases. The risk of cirrhosis is 4.2 times higher in HBsAg carriers and 2.3 times higher in carriers of anti-HCV than in people without these serum markers. (71, 81, 137)

Haemochromatotic cirrhosis: Untreated idiopathic haemochromatosis has an insidious course and, as a rule, leads to (micronodular) cirrhosis. Spontaneous remission has not been observed. The survival rate in haemochromatotic cirrhosis is 60–65% after ten years. (s. pp 639, 642) (s. figs. 31.24–31.26)

► We do not consider the terminological demarcation of “primary” cirrhosis or the differentiation into “primary” and “secondary” cirrhosis to be acceptable, because any kind of biliary cirrhosis constitutes the final stage of a preceding chronic biliary disease. (s. p. 679!)

Cryptogenic cirrhosis: Cirrheses which cannot (yet) be clarified by means of current investigation techniques are subsumed under the term cryptogenic cirrhosis. (33) Earlier data regarding its frequency no longer apply. As a result of the methods of detailed diagnosis used nowadays, only a small number of cirrheses remain truly “cryptogenic”. (17) Modern hepatological detailed diagnostics yield an aetiological clarification rate of nearly 95% of all patients! (s. tab. 35.2) • In most of the remaining cases, **chemical substances** which are still unknown or which have not yet been identified as hepatotoxins are probably involved, so that the patient concerned

1. **Alcohol** (see chapter 28)
2. **Infections**
 - Congenital syphilis (see chapter 24)
 - Schistosomiasis (see chapter 25)

12. **Cryptogenic cirrhosis (<10%)**

Tab. 35.2: Possible causes of liver cirrhosis

remains unaware of them; furthermore, such substances might occur in combination with other noxae that cannot be identified. (*see chapter 30*) **Medication** may likewise cause chronic hepatitis and cirrhosis. This also applies to herbal remedies, e.g. wild germander. (*see chapter 29*) Knowledge in this field has been greatly improved by cooperation between clinicians, toxicologists and specialists in industrial and environmental medicine. **AIH** was the cause of cryptogenic cirrhosis in 20–25% of cases. • **Non-alcoholic steatohepatitis** is of particular aetiological importance in cryptogenic cirrhosis, especially in cases where obesity and diabetes coexist (30–35%). (17, 132, 136) (*see chapter 31.3.6*) • *Owing to modern diagnostic options (and assuming the patient co-operates!), cryptogenic cirrhotoses today constitute no more than 5–10% of cases.*

7 Clinical classification

The following stages or courses of cirrhosis can be differentiated according to clinical criteria:

1. *Latent cirrhosis*
2. *Manifest cirrhosis*
 - active form
 - inactive form

Latent cirrhosis: There are no subjective complaints or clinical symptoms. This stage is identified by laboratory parameters, imaging procedures or histological examination of the liver. Frequency is between 10 and 20%.

Manifest cirrhosis: Manifest cirrhosis is characterized by subjective complaints and clinical findings. Hepatic haemodynamics are significantly altered, and other organs and organ systems as well as hormonal and humoral functions are affected. *Liver cirrhosis orchestrates a complex array of altered biochemical and physiological processes.* • Manifest cirrhosis can present in two forms:

1. *Stage of compensation*
2. *Stage of decompensation*
 - portal decompensation
 - metabolic decompensation

Apart from **histological activity** (= progressive) or **in-activity** (= stationary), **biochemical activity** must also be defined. The latter is determined by (1.) *enzymatic activity*, (2.) *mesenchymal activity*, and (3.) *immunological activity*. (s. p. 127) • Compensated cirrhosis may be either active or inactive. Even decompensated cirrhosis can sometimes be kept in an inactive (stationary) stage for a limited period of time. Jaundice (>3 mg/dl) is a typical sign of decompensation.

Portal hypertension derives from *microcirculatory disorders*, with increasing flow resistance in the sinusoids and

postsinusoids. This condition is a consequence of the narrowing, rarefaction and compression of the sinusoids or central veins due to collagen deposition, fibrosis and nodulation as well as the presence of intrahepatic arterio-portal shunts. Elevated endothelin levels are involved in these processes. (15) Portal hypertension is also evoked or increased by (relatively common) **portal vein thrombosis**. (8, 22, 121, 183) Nitric oxide (5, 14, 21), endotoxins (36, 39), platelet-activating factor, prostacyclin, histamine, adenosine, serotonin, bile acids, secretin, glucagons, etc. are all considered to be mediators of **hyperdynamic splanchnic circulation**. (s. p. 762) The resulting portal hypertension with splenomegaly and collateral varicosis become detectable with progressive cirrhosis of the liver. An important factor is that in alcohol-induced liver diseases, portal hypertension may be present before cirrhosis develops. (*see chapter 14*)

Portal decompensation: Various forms manifest as (1.) hypersplenism, (2.) increasing collateral varicosis with a simultaneous rise in the splanchnic flow due to hyperdynamic circulation and vasodilatation in the area of the splanchnic vessels, (3.) hepatic encephalopathy, and (4.) oedema and ascites. (*see chapters 14, 15 and 16*)

| Portal decompensation |
|--|
| <ul style="list-style-type: none"> • Hypersplenism • Collateral varicosis • Portal hypertensive gastropathy • Hepatic encephalopathy • Oedema and ascites |

Tab. 35.3: Possible forms of portal decompensation in liver cirrhosis

By fulfilling a multitude of **metabolic functions**, the liver guarantees the survival of the organism. Some 70 metabolic partial functions grouped into 12 main metabolic areas need to be constantly maintained with the help of *some 500 biochemical processes* carried out separately within the hepatocytes. (s. p. 36)

Metabolic decompensation: Pronounced functional decrease or dysfunction in several metabolic areas result in *partial metabolic insufficiency*. With the failure of additional metabolic functions, there is a risk of *global metabolic insufficiency*. Development of metabolic insufficiency (also known as *cellular decompensation*) is due to a significant loss of hepatocytes (e.g. mass necroses) and/or a loss of function of the hepatocytes (e.g. insufficient numbers of hepatocytes and accumulation of waste products in cirrhotic transformation with the development of shunts).

Complications: Generally, complications can occur during the stages of compensation and decompensation. Some complications predominantly arise from a decompensated situation, whereas others do not necessarily occur at all in the natural course of cirrhosis. However, in view of the cirrhosis-induced lability of the metabolic

functions, they may easily be provoked by the patient's inappropriate behaviour or by iatrogenic measures. Viruses, such as CMV or influenza A (55), can cause deterioration of the liver function or decompensation. (149) (s. tab. 35.4)

| Metabolic decompensation |
|---|

Tab. 35.4: Possible forms of metabolic decompensation in liver cirrhosis

8 Diagnosis

Liver cirrhosis is the final stage of a hepatic disease which has generally run a chronic course for several years. • Some 60–65% of cirrhoses are alcohol-induced (long-standing alcohol abuse does not go unnoticed!). Some 25–30% of cirrhoses are thought to be posthepatic events. Although a very small number of anicteric HBV and particularly HCV infections remain unrecognized (the exact figure is impossible to estimate), most acute and icteric courses are diagnosed. • With today's diagnostic possibilities, **chronic liver disease** is mostly detected at an early stage, either due to general complaints by the patient or during medical examinations. Its course is then carefully monitored. • The point at which a chronic liver disease, particularly cirrhosis, is

first detected depends on the patient's general attitude and the diagnostic interview, *which nowadays is far more effective than the standard was 20–30 years ago!*

Thus (subjectively and clinically symptom-free) **latent cirrhosis**, with a frequency of 10–20% of cases, need not remain undetected. Looking back on 40 years of experience, we can state that cirrhosis itself constituted the *first diagnosis* in no more than 10% of cases. The first diagnosis of cirrhosis at such a complicative stage as oesophageal varix bleeding or decompensation has fortunately become a rare event. • *The course of cirrhosis (progressing, stationary, or regressing) is monitored by clinical findings, liver function tests and sonography.*

8.1 Anamnesis

Targeted anamnesis can yield valuable diagnostic information as soon as liver disease is suspected. This may require insistent and intense questioning, involving additional consultations. Such an approach is especially helpful in determining risk factors concerning viral hepatitis infection and toxic effects. (s. p. 80) (s. fig. 4.21)

8.2 Complaints

Subjective complaints of cirrhosis are non-characteristic and ambiguous. Even determination of the severity of cirrhosis is only possible to a limited extent. *Fatigue* (= "pain of the liver") (60–80%), sleep disturbance (possibly due to an impaired melatonin rhythm) (44, 164), gastrointestinal complaints (50–60%) and mental disorders are sometimes mentioned. The most important subjective complaints are best noted on a **check list**. (s. p. 81) (s. fig. 4.21) • Frequently, however, the patient does not feel any noteworthy discomfort.

8.3 Clinical findings

As a rule, all cirrhosis-typical findings occur in the late course of the disease. Occasionally, patients report striking findings, such as changes in the consistency, colour or smell of *faeces*, cutaneous or mucous *bleeding* and unexplained *febrile episodes*. The senses of *taste and smell* are both impaired. (28) Eyelid retraction and eyelid lag are often increased. • The *liver* becomes harder; hepatomegaly is present in some 60% of patients, while in about 20% of cases, the liver is atrophic and therefore usually no longer palpable. Single nodes are sometimes detectable. • *Splenomegaly* is present in 50–75% of cases. Splenic infarction may also be detected (e.g. laparoscopically). (s. fig. 35.12) Generally, there is development of *hypersplenism* (= reticuloendothelial hyperplasia with increased fibrosis and hyperaemia). • *Muscle cramps* (F. KONIKOFF et al., 1985) may occur. Zinc deficiency or the administration of diuretics are not considered to be possible causes. These painful cramps happen mostly at night and mainly affect the gastrocnemius muscle and

Fig. 35.12: Splenic infarction in splenomegaly due to complete liver cirrhosis. (Postpartum blood transfusion into the umbilical vein, with subsequent severe viral hepatitis B and rapid transition into early infantile cirrhosis.)

small muscles of the foot. Sometimes they are accompanied by increased activity of the renin system with a decrease in the effective blood volume. They usually respond to BCAA supplements in the late evening (143), quinine sulphate (oral application) or i.v. albumin infusion (1 x per week). (10) Hepatic *myelopathy* with spastic paraparesis is a rare event, especially in the advanced stage of cirrhosis. Pathogenesis is not yet clarified. Liver transplantation leads to complete recovery. • Symptoms of peripheral *neuropathy* have also been observed. (18, 85, 163) There is often *meteorism* (“first the wind ...”), and in many cases *ascites* develops (“... and then the rain”). Tachycardia, hypotension and systolic murmur point to a *hyperdynamic circulation*. Pronounced spider naevi points to a significant disturbance of the systemic and pulmonary circulation. (21, 109) Occasional murmurs may be perceptible in the umbilical area (= Cruveilhier-Baumgarten syndrome). Men can display symptoms of feminization, while women display symptoms of hypogonadism. • Numerous **skin stigmata of liver disease**, which may be partially pathognomonic, are visible in varying intensities and combinations; they are best documented on a **check list**. (s. tab. 4.3) (s. figs. 4.6–4.11, 4.18–4.21) (s. pp 83–92)

8.4 Laboratory findings

Enzymatic activity: The enzymatic activity depends upon the extent of (1.) inflammatory or necrobiotic damage to the hepatocytes, and (2.) residual parenchymal mass. Accordingly, subnormal, normal or differently increased values of *GPT* and *GOT*, and in some cases also of *GDH*, are found. *Enzyme quotients* may be used for establishing the diagnosis. (s. tabs. 5.6, 5.7)

Cholestasis parameters are moderately elevated; in biliary diseases, however, the rise is significant. A progressive increase in γ -*GT* and *AP* suggests hepatocellular carcinoma and requires determination of α ₁-*foetoprotein*. Disproportionally elevated γ -*GT* values generally indicate alcoholic or chemical-toxic aetiology or even HCV infection – but sometimes also regeneration of the hepatocytes. (89, 91, 160) With the progressive loss of liver parenchyma, the transaminase values fall to the normal range, and occasionally even to subnormal levels. This prognostically unfavourable sign correlates with a deterioration of the liver function test.

Mesenchymal activity: Mesenchymal activity is accompanied by an increase in γ -*globulins* and *immunoglobulins*. There is a broad-based, often dromedary-like humped γ -globulin peak (typically 22–35 rel.%). Albumins can be reliably determined by means of immunonephelometry. Generally, IgA is elevated in alcoholic cirrhosis, IgG in autoimmune cirrhosis and IgM in primary biliary cholangitis or CDNC-related cirrhosis. The rise in γ -globulins is due to reduced clearance of bacterial antigens in the RES, with increased antibody formation against intestinal bacteria, mainly *E. coli*. At the same time, elevated γ -globulins have a depressor effect on albumin synthesis and are indicators of the degree of portacaval anastomoses. The serum value of *copper* may be increased. In correlation with the dynamics of fibrogenesis, there is often a rise in *P-III-P* and hyaluronan. (88) • Increased γ -globulins and decreased cholinesterase may point to cirrhosis. (89, 91)

Liver function parameters: The most common endogenous liver function parameters, such as lowered *cholinesterase*, *albumin* (19) and *Quick's value*, are helpful for diagnosis. Since 1982, we have included the determination of *bile acids* as a relatively sensitive and specific follow-up procedure. Abnormal *coagulation factors* and *fibrinolysis values* are of particular diagnostic and prognostic importance. Factor 5 has a short half-life. (s. tab. 35.5) • These endogenous parameters can provide additional help in assessing the remaining liver function, especially when used in combination, and may thus facilitate prognostic evaluation. An increase in bilirubin and subsequent permanent *jaundice* are unfavourable prognostic signs. *Urobilinogenuria* is mostly present. • *Galactose elimination capacity* (141, 144) and the *indocyanine green test* are reliable exogenous liver function parameters. (69, 158) Good results have also been obtained using the *caffeine test*, *aminopyrine breath test* (47) and *MEGX test*. (118, 154) The formation of portosystemic collaterals can sometimes be assessed with the help of the *ammonium tolerance test*. (s. pp 113–116) • In more advanced cirrhosis, there is a decrease in BCAA (valine, leucine, isoleucine) and an increase in AAA (phenylalanine, tyrosine, methionine).

Additional parameters: Decreased serum values of *zinc* (103, 185) and *selenium* (30), *thrombopenia* or *thrombopa-*

| Coagulation factors | | Coagulation inhibitors | | Fibrinolytic system | |

thy (122) as well as increased values of *endotoxins* (36, 39) and *homocysteine* are also considered to be important laboratory parameters. Increased values of anticardiolipin antibodies are a hint of existing portal vein thrombosis. • Determination of *α₁-foetoprotein* (s. pp 112, 803) or *des-gamma-carboxy prothrombin* (s. p. 804) should be carried out to obtain a basic value, then checked at longer intervals; if values increase, they must be monitored at shorter intervals. This also applies if there is a progressive rise in AP and *γ-GT*.

8.5 Imaging procedures

Imaging techniques have greatly improved the diagnosis of cirrhotic diseases. They supply *detailed information* on (1.) structural changes in the liver, (2.) development of portal hypertension and formation of collaterals, (3.) occurrence of ascites at a very early stage, (4.) haemodynamics, and (5.) vascular changes. (s. tab. 35.6)

8.5.1 Sonography

Portal hypertension can be reliably detected and evaluated by way of sonographic criteria. (s. pp 139, 259) The sensitivity of sonography is limited by the extent of the cirrhosis-induced changes and reaches 85–90% in pronounced stages of cirrhosis. Specificity is high. The nodularity of the liver surface is, in general, easily visible, especially using a 7.5 MHz annular-array transducer. (114) Occasionally, however, the surface is so finely undulant that it appears smooth in sonography. The reflex echo is inhomogeneous, irregular and coarse; the vessels are rarefied, compressed and tortuous. A double-barrelled pattern (= prominent arteries) is sometimes evident. Splenomegaly and dilated portal vessels with

| 5. Angiography | (+) | +++ | +++ | +++ | +++ |

Tab. 35.6: Diagnostic reliability of imaging techniques in liver cirrhosis

collaterals can be observed. Any reduction in size of the quadrate lobe (segment IV) (<3 cm in diameter) is an important indicator. The caudate lobe (= segment I) is enlarged (especially in alcoholic cirrhosis) in relation to the right lobe. Regeneration nodes can appear as focal lesions; they may be misinterpreted as malignant foci. (s. figs. 6.6; 35.13, 35.14)

Sonography is also used as a routine technique for assessing the course of *cirrhosis*, but it does not, provide information about the activity of disease or initial stage of a malignant process. The development of cirrhosis is best monitored by measuring liver stiffness with elastography. (60) (s. p. 135) (16, 42, 53, 83, 93, 94, 114, 159, 180) • EUS has proved successful in evaluating varices in the distal oesophagus and cardia area. (25) (s. pp 135, 360)

8.5.2 Colour-encoded duplex sonography

Colour-encoded duplex sonography facilitates characterization of the portal and hepatovenous haemodynamics and differentiation between the hepatofugal and hepatopetal direction of flow. (59) The flow wave flattens in hepatic veins. CEDS can show a shortened liver transit time (using sonographic contrast medium), collaterals, thrombosis or reopening of vessels, spontaneous portosystemic shunts (64, 139) and arteriportal fistulas (24) as well as determining the portacaval pressure gradient. (24, 64, 139, 160) (s. figs. 14.13; 35.15) (s. p. 134) • Colour-encoded duplex sonography is indispensable for establishing indications and excluding contraindications regarding TIPS; in addition, it can also be used for monitoring a TIPS placement.

Fig. 35.15: Periumbilical venous convolutes (V) in abdominal wall (= caput Medusae) and subperitoneal area (P = peritoneum)

8.5.3 Computer tomography

CT scanning basically provides the same information as sonography, but the surface tubers or inhomogeneous

Fig. 35.16: Cirrhosis with regenerative node (↔), recanalized umbilical vein (= caput Medusae) (←) and ascites (↔•••) in CT

internal structure are usually represented more clearly. Generally, regeneration nodes cannot be differentiated. The portal system and hepatic veins as well as collateral vessels are discernible. (86) Even small collections of ascitic fluid and some increases in density are recognizable. The caudate lobe is enlarged more in compensated than in decompensated cirrhosis. (83, 184) CT is useful in detecting small hepatocellular carcinomas. (26, 82, 101)

8.5.4 Magnetic resonance imaging

No further diagnostic information is gained by MRI, even though histological results can be improved to a certain extent by applying special techniques. By measuring the signal intensity of the liver, it is generally possible to quantify the extent of liver cirrhosis. Even the uptake of contrast medium as an expression of the still functioning proportion of the parenchyma may facilitate quantification. As a rule, liver perfusion is reduced in relation to the increase in arterial blood flow. The relative reduction in the volume of the right lobe of liver compared to the caudate lobe correlates closely with the extent of the cirrhosis. However, this has no relevance in the context of cirrhosis. (79, 82, 83, 101, 104, 163, 181)

8.5.5 Radioisotope scanning

This technique reveals decreased uptake of the radioisotope with an irregular pattern. Regeneration nodes cannot be visualized. There is enhanced storage in the spleen and bone marrow. (s. fig. 9.1)

8.6 Liver biopsy and laparoscopy

Laparoscopy: Direct visualization of the nodular liver by laparoscopy is the procedure of choice for primary morphological diagnosis. The diagnostic margin of error regarding percutaneous biopsy in cirrhosis is so high

that there can be no indication for biopsy using a Menghini needle! *Only a compact biopsy sample turns histology into a diagnostic gold standard; furthermore, such a sample allows all other specific evaluation techniques to be carried out, if necessary.* • It is particularly important to obtain **photolaparoscopic documentation** of the liver surface, regeneration and scar areas, portal hypertension, spleen (or splenic infarction) (s. fig. 35.12) and other relevant, individual, abdominal findings. (90, 92, 123, 131) Although percutaneous biopsy using a Vim-Silverman needle usually produces a compact biopsy punch, it entails a higher and less controllable bleeding risk. Only an **adequate biopsy sample** yields the necessary results: (1.) confirmation of diagnosis, (2.) assessment of the degree of activity (= grading), (3.) evaluation of the extent of fibrosis (= staging), and (4.) specific histochemical examinations if a certain aetiology of cirrhosis is given.

Connective tissue collagen in biopsy specimens can be shown, for example, by the following staining:

| | |
|---------------------------------|--------------|
| elastic fibres (e.g. sinusoids) | = elastin |
| reticulum fibres | = silver |
| portal and central zones | = van Gieson |
| basal membrane | = PAS |

Both the risks and the possibility of obtaining uncertain results are far greater with percutaneous biopsy than with laparoscopically directed biopsy. The latter produces a detailed diagnosis in 97–100% of cases, a result also confirmed by our own observations. (50, 51, 91, 117, 123) • Insufficient training in laparoscopy or the non-availability of this examination technique do not constitute an indication for percutaneous biopsy in liver cirrhosis, at least for initial diagnosis. (s. figs. 7.8, 7.15; 16.5; 28.13; 35.2, 35.4, 35.5, 35.8)

8.7 Endoscopy

Gastroscopy (s. figs. 14.10, 14.14; 19.7, 19.9), rectocolonoscopy (s. fig. 19.13) and, in certain cases, rectal endosonography are required for evaluating oesophageal varices, portal hypertensive gastroenteropathy (45, 68, 124,

127, 134, 179), gastric antral vascular ectasia (127), peptic ulcer (128, 161, 179), intestinal (23, 150) and anorectal (74) varices, etc.

9 Prognostic classification

The clinical picture of liver cirrhosis displays a great variety of forms. This makes it very difficult to judge the prognosis and to establish an appropriate treatment plan, particularly with regard to surgical intervention. It was indeed surgeons who proposed a classification suitable for improved evaluation of the risks involved in surgery (C.G. CHILD, J.G. TURCOTTE, 1964). By means of simple parameters, it is possible to assess the functional reserves of the liver with sufficient reliability. Some parameters show the severity of portal hypertension (e.g. ascites, encephalopathy), while others yield information about the metabolic functions of the liver (e.g. jaundice, albumin value, hyaluronan) (19, 88); these criteria were extended by the addition of Quick's value (R. N.H. PUGH et al., 1973). Clinicians hope to improve the value of this classification by multiplying the criteria of class A by 1, of class B by 2 and of class C by 3, so that an overall score ranging from 5 (= most favourable prognosis) to 15 (= worst prognosis) is achieved. A close correlation between the deterioration of the Child-Pugh grade and the increasing size of the oesophageal varices could be shown. (2, 39, 51, 81, 133, 137, 146, 149, 166, 192) (s. tab. 35.7)

Criteria: Criteria such as ascites, encephalopathy and nutritional status are obviously blurred and, to a certain extent, may be interpreted subjectively. For example, the degree of **ascites** (depending on the examination method chosen) and the determination of patient response to treatment (depending on the medication used) are criteria that are hard to standardize. By contrast, **encephalopathy** can be easily classified according to its stages. (s. tab. 15.5) • The occurrence of **hyponatraemia** is a severe complication with a worse prognosis, especially if it progresses into HRS. (11) • **Liver function tests**

| Child-Turcotte stage and Pugh modification | A 1 point | B 2 points | C 3 points |
|--|--------------|-----------------|--------------------|
| 1. Bilirubin (mg/dl, $\mu\text{mol/l}$) | <2.0 < 35 | 2–3.0 35–51 | > 3.0 > 51 |
| 2. Albumin (g/dl) | > 3.5 | 2.8–3.5 | < 2.8 |
| 3. Ascites | none | easy to treat | difficult to treat |
| 4. Encephalopathy | none | stages I, II | stages III, IV |
| 5. Quick's value (%)*) (or INR) | > 70 (<1.7) | 40–70 (1.8–2.3) | < 40 (> 2.3) |
| Points score (used by Pugh) | 5–6 | 7–9 | 10–15 |
| Survival rate: 1 and 2 year(s) | 100%; 85% | 80%; 60% | 45%; 35% |

Tab. 35.7: Classification of hepatic cirrhosis according to Child-Turcotte (1964) and Pugh (1973) (stage A = good compensation, stage B = significant functional loss, stage C = decompensation) *) Quick's value is additionally used by Pugh (INR = international normalized ratio)

may provide information about the severity of the functional disorder at an early stage of cirrhosis. We have always preferred to use the two liver function tests *GEC* and *ICG* as additional methods of evaluation, whereby ascites was determined sonographically and subjected to largely standardized treatment. Reproducible functional values make it much easier to distinguish between class A and B as well as between the scores 5–7 and 8–10. They are no substitute for classification (s. tab. 35.7), but may provide valuable information in individual cases. These two function tests are reliable in quantifying the **liver cell mass** (e.g. by means of *GEC*) as well as the effective **liver blood supply** (e.g. by means of *ICG*) as prognostically useful parameters.

10 Differential diagnosis

Differential diagnosis of liver cirrhosis is concerned with two questions: (1.) *confirmation of the diagnosis*, and (2.) *clarification of the aetiology*. (71, 91)

Diagnosis with an accuracy of almost 100% is guaranteed using **laparoscopy** and **biopsy**, whereby in the latter technique, samples are taken from both liver lobes, if necessary. It is important to obtain a compact biopsy sample – albeit in larger fragments. Crumbly material is of no use! If such tissue crumbs have been obtained by using a Menghini needle, the *Vim-Silverman needle* has to be used for a second biopsy (and should have been used in the first place in targeted biopsy in liver cirrhosis!). A reticulin preparation, which reveals the extent and distribution of connective tissue more clearly, is diagnostically valuable. • Differentiation has to be made between: (1.) **focal nodular hyperplasia**, which

Fig. 35.17: Postnecrotic scarred liver after severe viral hepatitis B. Atrophy of the left liver lobe with regenerations, broad cicatricial areas and scarred furrows (s. figs. 21.13; 22.16; 35.11)

does not show any lobular areas cut off by connective tissue, (2.) **liver fibrosis** (s. figs. 7.16; 21.14; 22.15; 28.6, 28.7), and (3.) **scar tissue** within cirrhosis, e.g. in a scarred liver. (s. p. 412) (s. fig. 35.17)

Clarification of the aetiology of cirrhosis is no problem as long as the potential causes are investigated carefully. In this context, an overview of the numerous causes of cirrhosis as a check list in chart form is very useful. (s. tab. 35.2) The necessary diagnostic parameters can then be applied efficiently. Specific histochemical investigations (e.g. in storage diseases) are carried out accordingly. It is important to categorize cirrhosis based on its aetiology, since some forms can then be treated more effectively. • Several sequelae or complications which impede a differential diagnosis are prevalent in certain types of cirrhosis; they are often the primary reason why the patient consults a physician. (s. tab. 35.2)

11 Consequences and complications

During the course of cirrhosis, it is almost impossible to differentiate between *metabolic consequences* and *complications* due to the fact that transitions are fluid both in terms of terminology and clinical features. Metabolic consequences may be complications in themselves, or play a special role in the occurrence of acute sequelae, or even turn a complicative event into a deleterious situation. The initial cause of such developments often remains unknown. Usually, a vicious circle of impaired mechanisms precedes relevant metabolic insufficiency or other complications. • The development of such events can be triggered by the course of disease itself or by the patient's behaviour, or even by therapeutic interventions.

The clinical picture of cirrhosis is overlapped by the symptomatology of the respective metabolic sequelae, or in some cases the complicative event predominates. Occasionally, a wide spectrum of symptoms and findings may be observed. This calls for detailed diagnostic clarification and varied medical treatment by an internal specialist as well as intensive care or sometimes invasive measures.

► In cirrhosis, both the overall hepatic *intermediary metabolism* (s. p. 36 and footnote *); s. tab. 3.1) and the *microcirculation* are severely impaired.

11.1 Negative energy balance

Cirrhotic patients often suffer from a negative energy balance even at an early stage, mainly due to protein deficiency, which is called *protein-energy malnutrition* (PEM). This pathological metabolic situation found in

70–80% of cases can be recognized by reduced oxygen consumption. The administration of β -blockers in patients with cirrhosis causes a favourable metabolic effect, whereby energy expenditure and catecholamine levels are decreased.

The energy required for hepatocellular metabolism is mainly provided by **oxidation** of short-chain fatty acids and amino acids via the citric acid cycle, usually in the mitochondria. Fructose and ethanol are also available for oxidation. In this process, **O₂ partial pressure** falls from 13% in the periportal area to 6% in the pericentral area, which means that the latter region is the most prone to hypoxic cellular damage.

The **energy supply** required by cirrhotic patients is achieved by mobilizing fats: the patient's fatty tissue is reduced and body weight decreases; the continuing energy requirement is met by the breakdown of muscle proteins with the result that amino acids are formed, which in turn are used for gluconeogenesis in the liver. Catabolism increases and leads to muscular atrophy, which is known as the *wasting syndrome*. (32, 35, 66, 87, 102, 110, 111, 120)

11.2 Carbohydrate metabolism disorders

The central role of the liver in carbohydrate metabolism is underlined by the term **glucostate** (K. JUNGERMANN, 1986). The ingestion of carbohydrates leads to the production and storage of glycogen; it is produced mainly in the pericentral area. A large amount of the glucose absorbed passes directly through the liver to the peripheral organs, where it is primarily utilized. The remaining C₃ bodies (alanine, lactate) are returned to the liver, where glycogen synthesis takes place predominantly in the periportal zone. Gluconeogenesis, i.e. hormone-regulated neoformation of glucose from lactate and glucoplastic amino acids, and glycolysis occur simultaneously and continuously in the same hepatocyte. Usually, about 80% of the glucose released comes from glycogenolysis and some 20% from gluconeogenesis. The energy yield from oxidative breakdown of fructose and glucose, for instance, is 34 and 38 ATP respectively; the energy from the β -oxidation of fatty acids, such as hexanoate or palmitate, is 44 and 129 ATP respectively. (s. p. 45) (s. figs. 3.6, 3.7) • In liver cirrhosis, **three forms** of *carbohydrate metabolic disorders* may be expected: (1.) hypoglycaemia, (2.) hepatogenic diabetes mellitus, and (3.) impaired glycogenolysis and gluconeogenesis (T. YOSHIDA et al., 1998).

11.2.1 Hypoglycaemia

Hypoglycaemia is a rare event. It is usually due to reduced gluconeogenesis, mainly following loss of parenchyma (>80%). Chronic alcohol abuse or acute alcohol intoxication can lead to hypoglycaemia. (s. p. 534)

11.2.2 Hepatogenic diabetes mellitus

Glucose intolerance is found in 50–80% and manifest diabetes in 10–15% of cirrhotic patients. Depending on the severity, glucose intolerance or manifest diabetes may also be observed in fatty liver in 40–70% and 10–40% of patients respectively; in haemochromatotic cirrhosis, the frequency of diabetes is 60–70%. The corresponding liver disease is generally the cause of the disturbed carbohydrate metabolism, which it precedes. • At the same time, increased insulin and glucagon values (two or three times above normal) can be detected; administration of insulin only causes a minor decrease in the glucose serum values. Thus there is no insulin deficiency, but *insulin resistance* (W. CREUTZFELDT et al., 1970); this may be caused by a TNF-induced disturbance in the tyrosine phosphorylation of the insulin receptor. Insulin resistance in cirrhosis is a multifactorial process. *Hyperinsulinaemia* is due to a reduced breakdown of insulin in the liver and may, among other things, be caused by increased insulin secretion stimulated by hyperglycaemia. In this process, however, hyperinsulinaemia is not sufficient to overcome peripheral insulin resistance; there is a reduction in insulin-dependent glucose absorption and its turnover in the skeletal musculature and fatty tissue. • *Treatment* of hepatogenic diabetes is by dietary measures or, depending on the case, by sulphonylurea (G. MARCHESINI et al., 1998) or (preferably) benzoic acid derivatives, e.g. repaglinide. Zinc leads to an improvement in glucose metabolism. Biguanides are contraindicated. (103, 132, 157, 167)

11.2.3 Glycogenolysis disorders

The glycogen content of the liver and glycogenolysis are reduced to 20–30% of the normal level. The clearly decreased glycogenolysis is compensated by increased gluconeogenesis (three or four times above normal). This requires amino acids from the breakdown of muscle protein. Absorption of glucose in the liver is reduced, particularly in portacaval anastomoses, while the release of glucose is unaffected.

11.3 Protein metabolism disorders

The protein and amino-acid metabolism of the liver is characterized by **three essential functions**: (1.) production and breakdown of proteins, (2.) production and breakdown of amino acids as well as regulation of their concentrations in the blood, and (3.) detoxification of ammonium via the synthesis of urea (= excretory form) and glutamine (= non-toxic transport or storage form) with simultaneous regulation of the acid-base balance. The breakdown of branched-chain amino acids occurs exclusively in the muscular system by way of deamination. (s. pp 42, 48)

11.3.1 Catabolism

In cirrhotic patients, a reduced synthesis rate of most proteins is found at an early stage, with albumin synthesis being the least compromised factor. Fat storage, muscle mass and protein turnover are reduced. This ultimately leads to *catabolism* (= stress metabolism) and increasing *muscular atrophy* (= wasting syndrome). The latter condition can also result from sympathicotonia with elevated catecholamine values; similarly, decreased values of IGF1 inhibit the formation of muscle tissue.

11.3.2 Amino-acid imbalance

The regulation of the amino-acid values in the blood plasma is increasingly disturbed, leading to significant changes in their distribution pattern. There is a decrease in **branched-chain amino acids**, probably due to greater absorption in the muscles and increased metabolic degradation (possibly as a consequence of hyperinsulinism). This can be prevented by the administration of β -blockers. • The rise in **aromatic amino acids** is thought to be caused by their reduced breakdown in the liver. They are the initial products for the formation of neurotransmitters and mediators; this explains the increase in serum values, e.g. of serotonin and noradrenaline, in liver cirrhosis. The plasma value of methionine is also elevated due to S-adenosylmethionine synthase deficiency, with simultaneously reduced methionine clearance. As a result, there is insufficient formation of glutathione; the phospholipid synthesis required for the biomembranes is reduced, and decreased polyamine synthesis compromises regeneration. (37) • A reduction in urea synthesis (by some 30%) results in hyperammonaemia and metabolic alkalosis. The turnover and concentration of alanine remain unchanged in cirrhosis; glutamine values are increased. Moreover, hyperinsulinism leads to a decrease in urea synthesis, as does zinc deficiency. (110, 111) (s. p 274)

11.4 Lipid metabolism disorders

The role of the liver in lipid metabolism is characterized by **five important functions**: (1.) β -oxidation and ketogenesis, (2.) lipogenesis, (3.) lipoprotein metabolism, (4.) cholesterol metabolism, and (5.) bile acid metabolism. • Short-chain fatty acids from the food are released in the intestine by lipolysis and transported to the liver. Beta-oxidation takes place in the mitochondria. In this process, acetyl coenzyme A is produced, which is oxidized to form CO_2 via the citric acid cycle or used to form **ketone bodies** in carbohydrate deficiency. After being resorbed in the enterocytes, long-chain fatty acids from the food are again incorporated into the triglycerides; they are passed on via the lymph to the periphery in the form of chylomicrons or transported to the liver as chylomicron remnants. They may also be β -oxidized in the mitochondria. • In **lipogenesis**, carbohydrates are

converted via acetyl-coenzyme A, mainly on the cytoplasmic side of the endoplasmic reticulum. Lipogenesis is mainly controlled by the insulin-glucagon quotient. • **Lipoproteins** are required in order to transport water-insoluble lipids from the site of their synthesis to the site where they are used or broken down. (s. p. 46)

In **liver cirrhosis**, there are several changes: reduction in LCAT (with “cholesterol ester fall”), HDL, LDL and VLDL, with a corresponding change in their distribution pattern; occurrence of hypertriglyceridaemia and atypical lipoproteins; reduction in phospholipid synthesis (31), possibly with greatly impaired structure and function of the biomembranes. Hepatic extraction of bile acids is reduced with the result that they reach the peripheral circulation – even in the early stages of cirrhosis! – and give rise to increased serum values. Bile acids have cholestatic and cytotoxic effects. When bile acid metabolism is markedly compromised, enteral absorption of fat-soluble vitamins is impeded, so that *A, D, E* and *K hypovitaminoses* may be observed.

11.5 Hypovitaminoses

The manifold relationships between the metabolic functions of the liver and the vitamins fulfil vital tasks in helping the organism to stay healthy. Nutrition low in vitamins or age-related reduction in intestinal vitamin resorption as well as chronic alcoholism may be responsible for the development of hypovitaminosis. Standard values of vitamins (including fat-soluble vitamins) in the serum do not exclude a deficit. Deficiency is often recognized for the first time owing to the manifestation of clinical symptoms, and now requires substitution. **Substitution therapy** may be recommended even if no vitamin deficiencies have become manifest at this stage. (s. p. 51) (s. tab. 28.2!)

Deficiency of **water-soluble vitamins** is far less precarious than a deficit of fat-soluble vitamins. While the first condition is generally rare, it can nevertheless often be observed in severe alcoholism. In liver cirrhosis, it was possible to detect a reduced amount of vitamins B_2 , B_6 , B_{12} , C and niacin or pantothenic acid in the liver as well as hypofunction of vitamins B_1 , B_2 , B_6 , C and folic acid. Hypovitaminosis may develop due to the reduced formation of specific transport proteins or the decreased activation or secretion of vitamins despite the sufficient supply of water-soluble vitamins through food intake.

The **fat-soluble vitamins** D and K are activated in the liver, and vitamin A is stored there. Their cellular effect is seen in the cytosol (vitamins E, K) or in the nucleus (vitamins A, D). Transport to the target organs is facilitated by specific carrier proteins (vitamins A, D) or VLDL (vitamins E, K).

Hypovitaminosis A: The vitamin A content of the liver and plasma as well as of the retinol-binding protein (RBP) is reduced in cirrho-

sis. The decreased plasma value of zinc, particularly in existing portacaval anastomoses, correlates with these findings. The **symptoms** observed in hypovitaminosis A and zinc deficiency are largely the same: night blindness, labyrinthine deafness and/or vertigo, disturbed sense of taste and smell (25), skin changes. Such deficiency symptoms in hypovitaminosis A should be treated primarily by substituting zinc. Possible **causes** of vitamin A deficiency are (1.) disturbed resorption, (2.) reduced formation of RBP in the endoplasmic reticulum, (3.) zinc deficiency, and (4.) increased breakdown of retinoids due to the enhanced activity of cytochrome P450.

Hypovitaminosis D: Some 20% of the daily vitamin D requirement are supplied by food intake, while about 80% are produced via endogenous synthesis through transformation of 7-dehydrocholesterol under the influence of ultraviolet light. Within the liver, D₃ (= cholecalciferol) is activated by 25-hydroxylation. It is excreted into the bile to become part of an enterohepatic circulation. In liver cirrhosis, and particularly in cholestasis, this circulation is impaired, so that vitamin D metabolites are activated in larger amounts and excreted in the faeces. The resulting clinical picture is usually a mixture of osteoporosis and osteomalacia.

Hypovitaminosis E: Vitamin E plays a key role in cell metabolism as an antioxidant for eliminating reactive oxygen intermediates. Subsequent to intestinal resorption, vitamin E is transported in chylomicrons into the liver, from where it reaches other organs together with VLDL. • Vitamin E deficiency is observed in chronic liver diseases caused by alcohol, Wilson's disease, haemochromatosis and abetalipoproteinaemia. In vitamin E deficiency, neurologic disturbances (areflexia, dysbasia, ocular palsy, reduced perception of vibration) occur; haemolysis can likewise be induced or become more pronounced due to epoxide formation of unsaturated fatty acids within the erythrocyte membranes.

Hypovitaminosis K: Vitamin K is necessary for the formation of coagulation factors II, VII, X and XI as well as of proteins C, S and M; in addition, it is indispensable for the production of osteocalcin, which stimulates osteoblast activity. It is transported from the liver to the bloodstream in the VLDL. • A deficiency is characterized by symptoms similar to those observed in haemorrhagic diathesis. It can be caused by intestinal resorption disturbance or loss of hepatocellular function (reduced carboxyl transfer to specific vitamin K-dependent proteins).

11.6 Endocrine disorders

Liver metabolism is controlled by hormones, and the plasma values of numerous hormones are controlled by the liver. The essential interactions of steroid, effector and thyroid hormones with the liver have already been discussed. (*see chapter 3.9*) (s. tabs. 3.9–3.12)

Patients with liver cirrhosis often suffer from endocrine disturbances, such as latent or even manifest diabetes mellitus; in most cases, the plasma levels of the growth hormone (STH) are increased; **low-T₃ syndrome** (with T₄ in the normal range) is generally accompanied by euthyroidism. Substitution therapy is not indicated in a euthyroid metabolic condition. • A disturbed sexual function is particularly significant. In the **hepatotesticular syndrome**, gynaecomastia (s. fig. 4.10) is found in about 50% and impotency or infertility in about 80% of cases. Such disturbances (especially testicular atrophy, which is often a direct consequence of alcohol abuse) are more frequent and more severe in cases of haemochromatotic and alcoholic cirrhosis. Feminiza-

tion takes place. The analogous **hepato-ovarian syndrome** corresponds with an early onset of dysmenorrhoea or amenorrhoea and loss of libido. • The last two syndromes can be subsumed under the term **Silvestrini-Corda syndrome** (L. CORDA, 1925). Findings include a reduced breakdown of oestrogens and decreased testosterone synthesis or secretion.

11.7 Bacterial and viral infections

Bacterial infections are detected in 45–50% of patients with cirrhosis. Some 7% of fatalities in compensated cirrhosis and 20% of fatalities in decompensated cirrhosis are due to infections. The bacterial translocation to mesenteric lymph nodes is increased in relation to the Child stage. • The following *organic manifestations* predominate: (1.) spontaneous bacterial peritonitis in ascites, (2.) infections of the urogenital tract, and (3.) infections of the bronchopulmonary system. Tuberculosis (lungs, peritoneum, kidneys) and bacterial meningitis (108, 126) must also be taken into account in differential diagnosis. Diagnostic difficulties are often due to a lack of fever or leucocytosis. • This weakness of the endogenous immune system is likewise involved in **viral infections**: in 63% of patients with cirrhosis, for example, cytomegaly infection was observed prior to liver transplantation, while the infection rate was only 2.5% in the control group. (34, 57, 100, 116)

Causes: The following causes are seen as being responsible for an acquired immune deficiency syndrome in liver cirrhosis (B.A. RUNYON, 1995): (1.) hypofunction of the RES (a decrease in the filter or clearance function and phagocytosis capacity as well as reduced formation of immune modulators) (s. p. 69), (2.) reduction in hepatic synthesis of opsonins (s. p. 70), (3.) compromised function of leucocytes, (4.) impaired proliferation and activation of T lymphocytes, and (5.) increased mucosa permeability to bacteria. Both bacteria and bacterial lipopolysaccharides enter the organism in large numbers. They are responsible for increased serum levels of the cytokines (e.g. interleukins 1 and 6, TNF, γ -interferon), and there is increased production of these substances together with their reduced breakdown in the cirrhotic liver. Cytokines are formed in the monocytes of blood and in the mononuclear cells of various organs (above all in ascites).

11.8 Hepatic osteopathy

11.8.1 Definition

Osteoporosis is defined as an imbalance between the breakdown and neoformation of osseous substance, resulting in bone loss. Ostalgia is evident, and later, fractures of the vertebral bodies, femoral neck and antebrachial bones are observed.

In **osteomalacia**, the bone matrix is quantitatively and qualitatively normal, while the bones show a reduced content of minerals. There is ostalgia and muscle weakness as well as arcuation of the long tubular bones. X-ray imaging shows band-shaped zones of decalcification, usually in symmetrical arrangement, particularly at the ribs, femoral neck and pelvis (= *Looser-Milkman's syndrome*).

The term **hepatic osteopathy** (J.E. COMPSTON, 1986) describes skeletal changes in chronic liver diseases, including osteoporosis, which is by far the most prevalent form, and osteomalacia, which is detected very rarely, as well as their respective mixed forms.

11.8.2 Frequency

In cirrhosis, reduced bone density of the vertebral bodies could be observed in 16% and of the antibrachial bones in 23% of patients (compared to 7% and 5% respectively in the control group). Fractures of the vertebral bodies were detected in 16% and of the antibrachial bones in 21% of cases (compared to 8% and 8% respectively in the control group). Hepatic osteopathy usually occurs independently of the cause and type of the chronic liver disease. However, alcoholism, haemochromatosis and Wilson's disease result in osteoblastic hypofunction, so that osteopathy is more likely to appear in these patients, even prior to the development of cirrhosis. The occurrence of osteopathy is closely correlated with the severity of the liver disease and with hypogonadism. In liver cirrhosis, the prevalence of osteopenia is about 30%. (54, 77)

11.8.3 Pathogenesis

The pathogenesis of hepatic osteopathy is primarily characterized by disturbed bone formation due to (1.) reduced osteoblast surface (with the number of osteoblasts being in the normal range), and (2.) reduction in osteocalcin. The latter substance is a bone-matrix protein formed by the osteoblasts. Therefore, the serum value is seen as a marker of osteogenesis. There is no increase in osteoclasts. The causes and risk factors of disturbed bone metabolism are manifold and not totally understood as yet. (63)

► To date, we do not know what kind of changes in **vitamin D metabolism** or in the binding proteins may be (partially) responsible for these disturbances. Moreover, there are no reliable findings as to the role of **parathyroid hormone** and **calcitonin** in the development of hepatic osteopathy; this is also true for **gastrocalcic**, which (like calcitonin) makes the serum level of calcium decrease. Reduced enteral resorption of calcium is only observed in severe cholestasis, which causes no osteopathy however. While a deficiency of vitamin D can have pathogenetic effects, it does not in itself lead to osteopathy. An increased value of D₃ may be a predictor of a developing osteopathy. In addition, there is a correlation between the serum values of **gastrin** and osteopathy – but nothing else is known about this. • The intake of **antiepileptics** over a longer period of time triggers an induction of the cytochrome P 450 system, so that vitamin D is increasingly broken down, a loss which can, however, be substituted. • **Glucocorticoids** cause a

reduction in enteral calcium resorption and the serum level of oestrogen; they are also responsible for calciuria and impeded osteoblast activity. These factors lead to a decrease in bone density and create what is called the *cortisone effect*. • By contrast, **cyclosporine** increases osteoblast activity.

11.8.4 Clinical symptoms

Hepatic osteopathy remains latent for a long time. *Backache* is considered to be the earliest hint of this type of complicative development in cirrhosis. The further course is characterized by trabecular osteopenia with loss of the cancellous bone structure. This causes *compression fractures* of the vertebral bodies with increasing kyphosis and a corresponding decrease in body height. Further sites susceptible to *fractures* are the femoral neck and the antibrachial bones. • Osteopathy does not yield any *biochemical findings*: the serum values of calcium, phosphate, parathyroid hormone, 25-hydroxycholecalciferol, osteocalcin and alkaline phosphatase are within the normal range. • Osteoporosis cannot be detected by *X-ray imaging* until the late stages. CT scanning allows density measurement of the skeleton. New radiological techniques (e.g. dual energy X-ray absorption) may provide an earlier diagnosis in the future.

Osteomalacia, a rare manifest form of hepatic osteopathy, causes pain mainly in the muscles, but less so in the bones. *Biochemically*, AP is markedly increased; there is a deficiency of calcium, phosphate and 25-hydroxycholecalciferol. *Radiologic diagnosis* shows signs of Looser-Milkman's syndrome: coarsening of cancellous bone structure, narrowing of the compacta in the tubular bones, reduced density of the skeletal system, and band-shaped zones of decalcification.

11.8.5 Treatment

The most important **prophylactic measures** for preventing the development of hepatic osteopathy are (1.) avoidance of harmful *noxae* (alcohol, nicotine), (2.) *avoidance of risk factors* (e.g. overweight; calcium, phosphate or vitamin D deficiency; use of glucocorticoids, cholestyramine and antacids containing aluminium), (3.) administration of vitamin K₂ (menatetrenone) in women with risk factors, and (4.) routine **physical exercise**. (s. pp 551, 683, 765) Chronic liver patients should carry out the following exercises on a regular basis:

Two or three times per day: 10–15 slow knee-bending (= thigh muscles), 10–15 standing on tiptoe (= calf muscles), 10–15 upper arm flexing (= biceps), and 10–15 bending from the waist (= back muscles). This guarantees that about 60% of the musculature is trained under simple conditions at home.

The **drug therapy** used to date aims to achieve broad substitution. Therapy should be carried out for up to 24 months. • (1.) *Daily calcium requirement* is 1.2–1.6 g. Nutrition usually contains about 0.6 g, so that 3 x 200 mg

to 3 x 300 mg per day should be substituted (e.g. with calcium carbonate). • (2.) In order to avoid *hypogonadism*, we recommend a daily administration of conjugated oestrogens (e.g. 2 mg, twice a week, applied dermally to avoid passage through the liver), possibly combined with gestagens. The daily requirement of oestrogen is about 0.6 mg. In men, the administration of testosterone may be indicated. • (3.) *Vitamin D* is only indicated when hypovitaminosis has been detected (e.g. as cholecalciferol, 1 α - or 25-hydroxylated derivatives, or 1,25 dihydroxylated derivatives). These substances should only be applied as substitution therapy when there is a corresponding deficiency. • (4.) In individual cases, *calcitonin* (as nasal spray) and *biphosphonates* are further options. • In the osteomalacic form of osteopathy, treatment with calcium and vitamin D or its derivatives may be required. However, the serum value of calcium must not exceed 11.0–11.5 mg/dl.

11.9 Hepatic encephalopathy

Disturbances of personality, consciousness and intellectual functions are often observed in acute or chronic liver diseases. In 50–80% of cirrhosis patients, such neuropsychiatric signs of HE are found with varying intensity and duration (even with symptom-free intervals) as well as in different combinations. (s. tab. 10.1) While it is relatively easy to **diagnose manifest HE** (stages I–IV) (s. tab. 15.5), other potential causes of this clinical picture have to be excluded by differential diagnosis in each individual case (e.g. intracerebral bleeding, infections, metabolic imbalance, cerebral diseases). There is a close correlation between liver function and severity of HE – and thus also with quality of life. (13) Diagnosis of *latent HE* (stages 0, 0–I) can only be made with the help of psychometric test procedures (8) or special EEG techniques. Nuclear resonance imaging and SPECT (163) have been used in scientific studies. (see chapter 10!)

Numerous **biochemical factors** can be causal agents in HE. It may also be attributable to an increase in serum ammonia resulting from *Helicobacter pylori*. (s. tab. 15.2) Avoidance of causative factors is always the most important measure for the prevention of HE and their elimination is seen as a prerequisite for successful treatment. (s. p. 289)

The **pathogenesis** is multifactorial. In cirrhotic patients with latent HE, regional differences in cerebral ammonia uptake are present; this corresponds to histopathological changes in HE. Although increased ammonia values have a primary pathogenetic significance, other neurotoxins, neurotransmitter disturbances, amino-acid imbalances, high levels of benzodiazepines, zinc deficiency, increased manganese concentration, etc. also figure prominently. With the help of spin-lattice (T_1) relaxation time, significant correlation has been demonstrated between HE severity and the putative deposition of manganese in the globus pallidus, caudate nucleus and posterior limb of the internal capsule. (156) • Values of enterocyte phosphate-activated glutaminase are increased in cirrhosis and correlate closely with latent HE (stages 0, 0–I). *H. pylori* infection is not correlated with HE. (155) • *None of these substances or disturbances on its own has a comagenic effect. It is*

probable that the astrocytes are the pathogenetic end point upon which the cascade of causes has its impact. (s. pp 273–278!)

The **clinical picture** comprises both *acute* and *chronic HE*. In addition, routine application of a simple test programme used for practical and clinical purposes (s. tab. 10.7) has repeatedly shown “*acute-on-chronic*” stages during long-term monitoring. Starting with the normal finding of “no HE”, the stages are grouped, depending on their individual variability, as 0, 0–I (= latent HE) and I, I–II, II (= manifest HE). Furthermore, there is a link between extrapyramidal signs and the latent HE. Since HE can be detected quite reliably at an early stage during its latent period, therapeutic measures are also recommended in addition to the elimination of the causal factors. (s. pp 278–283)

Treatment is based on (1.) elimination of the causal factor(s) (s. tabs. 15.1, 15.2) and (2.) reduction or normalization of the ammonia level. The latter consists of: *intestinal detoxification* using lactulose (52, 98, 113), paramomycin, neomycin or metronidazole; *protein restriction* (0–30 g for the first to third day, gradually increased up to 1 g/kg BW/day) (despite some controversial results); sufficient *calorie* intake (glucose), *application of urea cycle intermediates* (138), administration of *zinc* (103, 185) and, if necessary, of *branched-chain amino acids* and *flumazenil*. Elimination of gastric infection due to *Helicobacter pylori* has proved effective for normalizing hyperammonaemia (caused by this condition). A decrease in ammonia is also achieved by *acetohydroxamic acid*, which is a powerful inhibitor of bacterial ureases of *H. pylori*. (155) Animal experiments have demonstrated that N-carbamoyl-L-glutamate plus L-arginine protects rats with cirrhosis from acute ammonia intoxication. Experience has shown that the very frequent occurrence of latent HE (stages 0, 0–I) can largely be avoided by careful prophylactic measures and that early treatment helps to prevent the latent phase from developing into a manifest one (stages I–IV), i.e. there is no necessity for inpatient treatment! (see chapter 15.9!)

11.10 Ascites

Impairment of **cerebral functions** and disturbances of the **water and electrolyte balance** are the two most important and most common manifestations of decompensated liver cirrhosis. • They may be reliably detected at an early stage by means of daily *body weight control* and simple *psychometric tests*. A **documentation sheet** filled in by the patient has proved to be worthwhile: latent oedemas, onset of ascites and latent encephalopathy can be detected in this way and thus treated at an early stage. **Long-term standing** leads to reduction of natriuresis with subsequent water retention and deterioration of renal blood flow (like a vicious circle). This is caused by activation of the RAAS and the sympathetic nervous system. Such

a dangerous situation (which can arise for example after two hours of standing at a sports event with excessive emotional participation) is often underrated, as we ourselves observed in several patients! (s. p. 298) (s. fig. 16.3) (*see chapter 16!*)

About 50% of patients with cirrhosis develop ascites within ten years. In the case of a “simple” ascites (s. tab. 16.8), a therapy with diuretics is generally successful – in contrast to a “problematic” or refractory ascites.

Complications: The development of ascites causes many complications which greatly worsen the prognosis of cirrhosis. (s. tab. 16.9) • Every day, 40–80% of the ascitic fluid and 4% of the ascitic albumin are exchanged between the plasma and the ascites. In the absence of oedema, 400–500 ml (max. 750 ml) ascitic fluid can be removed from the abdominal cavity by diet and medication. (s. p. 312) • **Side effects** due to diuretic agents (hypovolaemia, hyponatraemia, hypokalaemia, disturbances of the acid-base balance) must be avoided. (s. p. 314) • The occurrence of **spontaneous bacterial peritonitis** is life-threatening. Prognosis could be markedly improved by early diagnosis, elimination of risk factors and efficient antibiotic treatment (e.g. amoxicillin-clavulanic acid) accompanied by simultaneous intestinal decontamination. (s. p. 310)

A step-by-step plan has proved effective for the **treatment** of ascites, with *therapeutic steps 1–4* being employed successively if the previous stage was unsuccessful. (s. tab. 35.8) However, progressing from step to step not only increases the effectiveness of the treatment, but also the frequency and severity of side effects. Nevertheless, a single paracentesis, during which an average of five litres of ascitic fluid were evacuated, resulted in normal cardiac, renal and hormonal parameters within two days. Paracentesis is considered to be a safe and efficient method. (129) (*see chapter 16.8*)

1. Basic therapy (s. tab. 16.11) (s. p. 311)
2. Diuretic therapy (s. tab. 16.12) (s. p. 312)
3. Osmotic diuresis (s. p. 314)
4. Paracentesis (s. p. 315)

Tab. 35.8: Therapeutic steps used in the treatment of ascites

Furosemide can cause hypovolaemia due to its rapid effect with subsequent unfavourable activation of the RAAS, especially after i.v. injection. Nevertheless, i.v. furosemide may be indicated in dilutional hyponatraemia (s. p. 314). Generally, however, spironolactone on its own has proved more effective than in combination with (RAAS-activating?) furosemide. (147) We actually prefer a *combination* of spironolactone with xipamide, torasemide or clonidine. (s. p. 313)

Paracentesis should be combined with an i.v. solution of albumin (our own experience has shown that an i.v. solution of 20–40 ml plasma expander directly before i.v. albumin administration increases the oncotic pressure, so that albumin remains efficacious for a longer time in the blood circulation). • Apparently, 3 mg terlipressin is as effective as i.v. albumin in preventing a decrease in effective arterial blood volume. (s. p. 315)

Hydroxyethyl starch (HES) in repeated administration may be the cause of increased portal hypertension; liver insufficiency or sepsis can occur due to lysosomal storage of HES in Kupffer cells and hepatocytes.

Losartan is a highly selective angiotensin-2-receptor (type 1) antagonist; it decreases portal hypertension as well as improving glomerular filtration and natriuresis with good aquaretic response. (189) (s. p. 367)

When diuretics are administered at the same time, it is not absolutely necessary to adhere to strict **salt restriction**. We followed the recommended 6–8 g/day. Indeed, such a moderate restriction is usually observed more reliably by the patient. • Reducing **water intake** to 1.5–2.0 l/day is also sufficient. Only a hyponatraemic condition of <130 mmol/l requires a reduction in fluid intake to <1,000 ml/day. • Determination of **fractional sodium elimination** (FE_{Na}) may point to potential success even before treatment has begun: with a value of >0.5%, treatment steps 1 and 2 (see above) will achieve a probable success rate of about 95%. This favourable initial situation is supported by a still sufficient spontaneous **sodium excretion** of >40 mmol/day. Therapy resistance must be anticipated when fractional sodium elimination is <0.1% and sodium excretion is <10 mmol/day. • If treatment steps 1–4 are unsuccessful or renal function is clearly impaired initially and FE_{Na} is <0.1%, the insertion of a **peritovenous shunt** (PVS) should be considered. This procedure is designed to make use of the principle of ascites reinfusion for as long as possible. (s. tabs. 16.14–16.18) (s. p. 317) • **TIPS** may also prove to be an alternative to PVS, especially when using a polytetrafluoroethylene-covered stent to prevent occlusion. (107) (s. fig. 16.15) (s. pp 267, 320, 336, 368, 897)

Chronic hepatitis C is occasionally associated with cryoglobulinaemia and glomerulonephritis. • In all forms of cirrhosis, the intrarenal circulation is impaired and there is a redistribution of blood flow away from the cortex. A thickening of the mesangial stalk and capillary wall (= *cirrhotic glomerular sclerosis*) is often evident. These changes predispose to the hepatorenal syndrome. • It is essential to prevent the occurrence of the (particularly iatrogenic) **hepatorenal syndrome** with the following findings. (39, 96, 107) (*see chapter 17!*):

| | | |
|-----------------------------|---|-------------------|
| Creatinine clearance | < | 40 ml/min |
| Proteinuria | < | 500 mg/day |
| Natriuresis | < | 10 mmol/l |
| Hyponatraemia | < | 130 mmol/l |
| Oliguria | < | 500 ml/day |

11.11 Pleuropulmonary complications

In the course of primary **liver diseases** as well as during any requisite invasive measures, numerous pleuropulmonary disturbances or diseases may appear due to functional and/or mechanical conditions. They are closely associated with each other. Pleuropulmonary complications can have considerable adverse effects on the basic liver disease and thus worsen its prognosis. (3, 6, 72, 112, 151, 152) (s. tab. 35.9)

| Pleuropulmonary complications | Liver disease |
|---|--|
| 1. Hepatopulmonary syndrome (HPS) | Acute liver failure Chronic hepatitis Liver cirrhosis |
| 2. Portopulmonary hypertension (PPH) | Alagille's syndrome Chronic hepatitis Focal nodular hyperplasia Hypoplastic portal vein Liver cirrhosis Schistosomiasis |
| 3. Pleural effusions | Acute viral hepatitis After liver transplantation After varicosclerosis Chronic hepatitis Echinococcosis Liver abscess Liver cirrhosis |
| 4. Pulmonary emphysema | α_1 -antitrypsin deficiency |
| 5. Chronic obstructive respiratory disease | α_1 -antitrypsin deficiency Mucoviscidosis Sarcoidosis |
| 6. Interstitial pneumonia | Autoimmune hepatitis Overlap syndrome PBC Sarcoidosis |

Tab. 35.9: Common pleuropulmonary complications in the course of certain liver diseases

Primary **pulmonary diseases** (e.g. primary pulmonary hypertension, pulmonary fibrosis, chronic obstructive respiratory diseases) cause chronic **hepatic congestion** due to chronic pulmonary heart disease, possibly leading to insufficiency. • **Hypoxaemia** as a result of acute or chronic respiratory insufficiency can impair metabolic liver functions considerably. In 40–70% of patients with cirrhosis, hypoxaemia is found; in about 50% of cases with advanced cirrhosis, a reduced diffusion capacity for CO is detectable. • Furthermore, pulmonary tissue contains a high level of glutamine synthetase, so that **ammonia detoxification** is possible (ultimately by perivenous hepatocytes) before the blood reaches the systemic circulation. In existing pulmonary diseases, localized ammonia detoxification is impaired.

11.11.1 Hepatopulmonary syndrome

The hepatopulmonary syndrome (HPS) may occur in patients with chronic liver disease or in the course of acute liver failure. It is characterized by the following **criteria**: (1.) exclusion of an underlying pulmonary or cardiac disease, (2.) increase in the alveolocapillary oxygen difference with or without arterial hypoxaemia (<70 mm Hg O₂ partial pressure) and with a marked decrease in the O₂ value when the body position is changed from lying to standing, and (3.) evidence of intrapulmonary vascular dilatations and **arteriovenous shunts**, resulting in **ventilation-perfusion disturbance**. • The frequency of

pulmonary gas exchange disturbance is 30–50% in cirrhosis patients. The most important clinical finding concerning HPS is **hypoxaemia**. Hypocapnia is also a frequent symptom and is generally associated with pulmonary vasodilation. (3) • Hypertrophic **osteoarthropathy** (hour-glass nails, drumstick fingers) (s. fig. 4.18) likewise belongs to this complex in terms of aetiopathogenesis. (see chapter 18!)

11.11.2 Portopulmonary hypertension

Definition

Portopulmonary hypertension (PPH) is characterized by (1.) elevated pulmonary artery pressure (> 25 mm Hg), (2.) increased pulmonary vascular resistance (> 120 dyne/sec/cm⁵), and (3.) normal pulmonary capillary wedge pressure (< 15 mm Hg). • *The presence of portal hypertension is considered to be a prerequisite for the development of PPH.*

Frequency and causes

PPH was detected in 2.0% of patients with liver cirrhosis, compared to 0.1% in the control group, i.e. *the risk of PPH is 20 times higher in cirrhosis patients*. The prevalence of PPH in liver cirrhosis with portal hypertension was 0.73% in autopsy examinations, compared to 0.13% in all other autopsies. • PPH has not only been described in portal hypertension due to liver disease (cirrhosis, chronic hepatitis, fibrosis, etc.), but also (with or without portal hypertension) in *focal nodular hyperplasia*, *schistosomiasis*, *Alagille's syndrome* and *portal vein thrombosis*. Important extrahepatic causes of PPH include portal hypertension due to *hypoplasia of the portal vein* and *lupus erythematosus*. (112, 140) (see chapter 18.7!) (s. tab. 35.9) (s. fig. 35.18)

Morphology and pathogenesis

Morphology: In PPH, there is evidence of medial hypertrophy in the area of the pulmonary arteries and arterioles, intima fibrosis (= *plexogenic arteriopathy*) and fresh or recanalized thrombi. These changes are unevenly spread throughout the lung; they do not correlate with the severity of PPH. Plexiform damage of the small (50–300 μ m) pulmonary arterial vessels is prevalent in patients who are also suffering from portal hypertension (J.R. RUTTNER et al., 1980).

► **Pathogenesis:** The mechanism responsible is based on the effect of vasoactive or toxic substances arriving directly at the pulmonary vascular system from the portal vein system by circumventing the liver (e.g. NO). Thus pulmonary hypertension is also detected surprisingly often in patients with shunt surgery. Endothelin-1 is considered to be a strong vasoconstrictor; this substance has been detected in high concentrations in the pulmonary vascular endothelia of PPH patients. In addition, microembolisms entering the pulmonary arterioles may also play a pathogenetic role; such emboli can reach the lungs via spontaneous or surgical portosystemic shunts (R.M. SENIOR et al., 1968). A similar mechanism may

be responsible for this condition in drug addicts suffering from PPH who have developed pulmonary microembolisms due to water-insoluble drug components injected intravenously. (s. fig. 35.18) (see chapter 18.7!)

Complaints: In 80–85% of patients with PPH, there is stress dyspnoea and occasional syncopes, thoracic pain on palpation with a feeling of tightness, marked fatigability, lack of concentration and vertigo.

Findings: In 80–85% of cases, a loud P₂ heart sound and systolic murmur can be heard on auscultation. Occasionally, there is haemoptysis or oedema; ascites is rare. • The ECG shows the signs of right ventricular overload (e.g. right bundle-branch block, P pulmonale). *Thoracic imaging* often displays prominent pulmonary arteries and cardiac hypertrophy. *Echocardiography* is of great diagnostic value. The diagnosis is confirmed by *right cardiac catheterization*.

Prognosis for PPH is poor: the mean survival time is about 15 months with a six-month mortality of 50%. The most common causes of death are right heart failure, dysrhythmia and infections.

Treatment still remains difficult, because few clinical studies are available. High doses of **calcium antagonists** are recommended, but their frequent side effects have to be taken into account, particularly with a cardiac output of <2 l/min. In severe cases, pulmonary pressure reduction by permanent infusion of **epoprostenol** over several weeks or long-term administration of **oxygen** may be helpful. Good experience has been made with the endothelin-receptor antagonist **bosentan** (2 x 125 mg/day). (40) (s. p. 344!) • On retrospective assessment of a large number of cirrhotic patients, some of whom we treated for more than ten years, it is our impression

that long-term administration of **spironolactone + molsidomine + β -blocker** is of therapeutic value for portal hypertension and, at least as far as this problem is concerned, also for primary and progressive pulmonary hypertension. Such combination therapy is also pharmacologically plausible. (s. p. 767)

11.11.3 Hydrothorax

Hepatic hydrothorax (= absence of a non-hepatic cause) has been detected in 4–10% of patients suffering from **liver cirrhosis**. Two thirds of the pleural effusions were isolated and localized on the right side, whereas the remaining one third were found on the left side or on both sides with equal frequency. Ascites is present in almost all cases, but is not obligate. (35, 41, 58, 67) Hydrothorax is usually caused by small diaphragmatic defects through which ascitic fluid can penetrate into the pleural cavity (41); diaphragmatic lymphatic vessels may also play a causal role. An ascites-related pleural effusion can be confirmed by intraperitoneal injection of methylene blue or ^{99m}Tc-sulphur colloid due to the subsequent, rapid migration of the substrate into the hydrothorax. *Bacterial infection*, similar to spontaneous bacterial peritonitis, is possible. • Hydrothorax is sometimes observed in **acute viral hepatitis**. The frequency is 0.16%. We have encountered a total of six cases. (s. pp 304, 305) (s. tab. 35.9) (s. fig. 16.8)

Therapy includes paracentesis + thoracocentesis + i.v. albumin solution, pleural drainage or pleurodesis with talc. Recently, pleurodesis using argon beam coagulation + minocycline hydrochloride has been recommended. In the case of refractory hepatic hydrothorax, TIPS or liver transplantation may be indicated. (58)

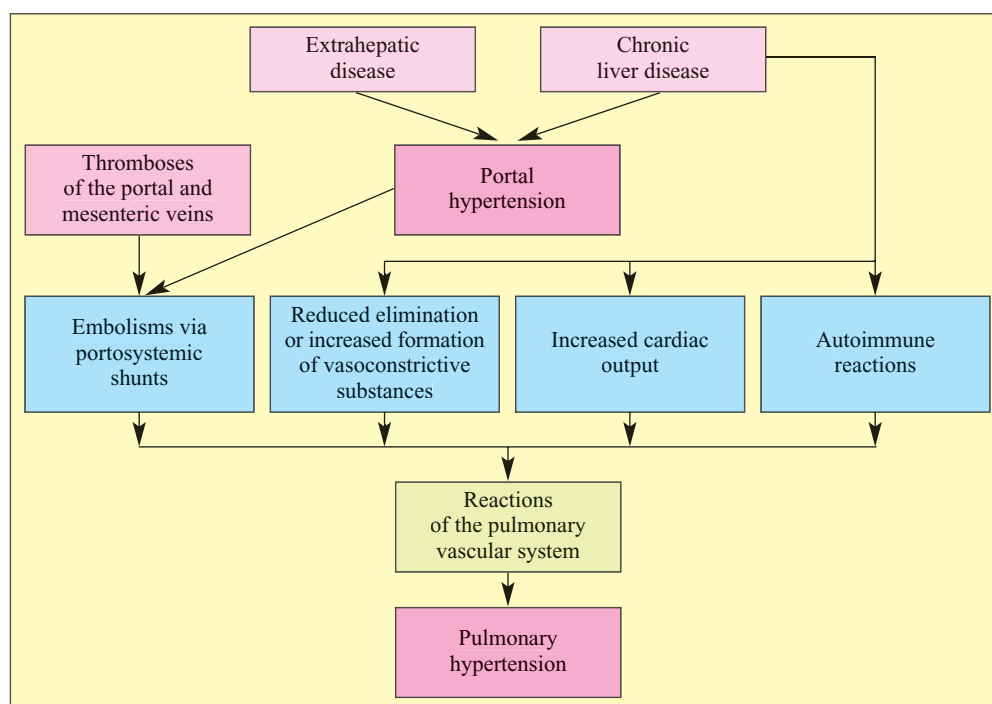

Fig. 35.18: Potential pathogenetic mechanisms associated with the coexistence of portal and pulmonary hypertension (based on B.J. ROBALINO et al., 1991 and M. WETTSTEIN et al., 1995)

► An evaluation of **25,682 clinical data sheets** from 1952–1963 (Dept. of Internal Medicine, University Hospital, Giessen) revealed the existence of pleural effusions (combination of “banal” effusion and hydrothorax) in 9.8% of cases (confirmed by X-ray imaging or autopsies). In 4.3%, pleural effusion was found to be hepatogenous. • *Localization was bilateral in 69.0%, left-sided in 18.7%, and right-sided in 12.3% – a controversial result when compared with some statements made in the literature.* (s. p. 304 and footnote*)

11.12 Gastrointestinal bleeding

Acute upper or lower gastrointestinal bleeding is a common complication in liver cirrhosis and is often life-threatening. Several **bleeding sources** have to be taken into account, which may occur in combination in the individual case. (see chapters 19.2–19.4!)

1. Gastric antral vascular ectasia (GAVE)
2. Portal hypertensive gastroenteropathy
3. Oesophageal and/or fundus varices
4. Ectopic varices
5. Anorectal varices

Peptic ulcer is not cirrhosis-related. Duodenal ulcers are more common than gastric ulcers. Frequency of peptic ulceration in cirrhotic patients is 8–10%, but 60–70% of these cases are asymptomatic. Gastric ulcers heal more slowly and recur more frequently than in non-cirrhotic patients. This condition may be due to chronic alcohol abuse, portal hypertension or *Helicobacter pylori* infection (40–50%, with elevated gastrin in the serum). (128, 194) • **Mallory-Weiss syndrome** is often associated with cirrhosis, but there is in fact no causal relationship between the two. • **Gastroparesis** with delayed gastric emptying is sometimes observed. (179)

11.12.1 Portal hypertensive gastroenteropathy

Altered vascular microarchitecture with dilatation and/or narrowing of the capillaries and veins develops as a result of portal hypertension. Gastroscopy reveals a whitish-reticular, mosaic-like pattern of the gastric mucosa, containing limited reddish and oedematous areas. Frequently, there are pink spots and circumscribed red marks. In severe cases, dark pink patches are present. There are lesions of the endothelial cells with increased permeability of the capillaries, so that petechial or striated bleeding is observed in gastric (165) and/or intestinal mucosa (as well as in portal colopathy). (23, 150) These changes due to portal hypertensive gastropathy were previously (but incorrectly) called “erosive gastritis”. They may cause gastric or intestinal paraesthesia or pain, but can also (less frequently) lead to occult bleeding or haematemesis. It is possible to achieve good results with the help of β -blockers. • Regarding the differential diagnosis, it is important to consider *angiodys-*

plasia (s. fig. 19.5) and *gastric antral vascular ectasia*. The latter resembles a watermelon with stripe-like haemorrhages. In the case of bleeding, endoscopic coagulation may be required. (45, 68, 124, 127, 134) (s. pp 357, 358) (s. tab. 19.4) (s. fig. 14.14)

11.12.2 Oesophagofundal varices

Acute bleeding must be anticipated in about 30% of patients with oesophagogastric varicosis and a pressure rise to >12 mm Hg. Physical overexertion can increase the portal vein pressure to dangerous levels. (20) Haemorrhaging mainly occurs in the lower third of the oesophagus and in the oesophagogastric transition zone, mostly due to venous anastomoses in the mucosa. Patients with small varices have a correspondingly lower bleeding risk. (s. figs. 14.8–14.10!) (see chapter 19.3) • There is a close association between **liver function** and relapse bleeding rate or mortality. Thus, all measures designed to improve **liver function** are beneficial, even though they are polypragmatic and perhaps of limited success. • **Primary prophylaxis** is indicated in patients with an increased bleeding risk (s. tab. 19.6); the portal vein pressure should be reduced by means of long-term pharmacological treatment. (73) In this context, the following drugs are recommended: propranolol (occasionally in combination with nitrate (62) or octreotide), nadolol (106), carvedilol (172), irbesartan (46), molsidomine and spironolactone. (s. p. 312) Primary prophylaxis using ligation (153) or sclerotherapy (119) ought to be started when small oesophageal varices are present. Primary shunt surgery is not indicated. • Mortality due to **initial bleeding** is 20–50%. The goal must be rapid and complete haemostasis. In principle, sclerotherapy and ligation are equally effective; the results depend upon the site of bleeding and the nature of the varices as well as upon the clinician’s experience. A balloon tamponade is a valuable tool in guaranteeing the patient’s transportability, bridging massive bleeding or coping with an emergency. A reduction in portal pressure by *previous (!) administration of medicaments* (20, 62, 76, 78, 109, 142, 153) (e.g. terlipressin bolus 1–2 mg and then 1–2 mg every 4–6 hr; octreotide bolus 50 μ g, 25–50 μ g/hr; propranolol 2 x 10–160 mg/day; molsidomine 2 x 8 mg/day) is helpful. (s. pp 366, 892) • About 70% of patients whose initial bleeding was successfully dealt with suffer another haemorrhage within the first year. **Relapse prophylaxis** is effected pharmaceutically in order to reduce the portal vein pressure (20, 109), by careful monitoring using (long-term) endoscopy and by eradicating any new varices. The insertion of **TIPS** reduces the rate of recurrent bleedings considerably and may help to bridge the time gap until **liver transplantation** can be carried out. (29, 148, 177)

11.12.3 Ectopic varices

Ectopic **intestinal varices** usually occur in combination with oesophagogastric varices. If gastroscopy shows no

bleeding source, (rare) bleeding from ectopic intestinal varices should be suspected. Diagnosis is established by *scintigraphy* (accuracy is 90–95%). For more exact localization of bleeding detected by scintigraphy, *angiography* is subsequently used. In this context, CT angiography also provides much better diagnostic results. • This is also true of the (very rare) ectopic **peritoneal varices**, which can cause intra-abdominal haemorrhage. (s. pp 264, 265)

11.12.4 Anorectal varices

Anorectal varices originate from the **superior rectal vein**, which is connected to the portal vein system. This portacaval anastomosis drains the blood into the *iliac vein*. Occasionally, there is massive bleeding from rectal varices. Endoscopy is required for diagnosis and sclerotherapy. (74) (s. p. 264)

11.13 Febrile phases of disease

Patients suffering from cirrhosis often report fever episodes, similar to those observed in inpatients. Such episodes not only cause additional physical weakness and increase suffering, but also present a considerable **danger** for the patient. Among other things, fever causes (1.) catabolic metabolism, (2.) increased sympathicotonia, (3.) disturbed water and salt balance (some 500 ml liquid and about 25 mmol salts are lost in 24 hours per degree of temperature rise!), and (4.) hypoxia of the hepatocytes. • This may lead to hepatic encephalopathy, portal ascites or hyperdynamic circulatory disturbance, with significant negative effects on renal function and hypoxia-induced metabolic liver insufficiency. The frequency of “cirrhosis-related fever” is 20%.

Cirrhosis patients often suffer from **bacterial infections**. (s. p. 754) The respiratory tract and urogenital system are mostly affected. Interleukin 6 may often increase in decompensated cirrhosis. Directed bacteriological diagnosis is required immediately; depending on the case, administration of antibiotics is recommended even before any evidence of bacteria has been obtained. (34)

Viral infection may likewise cause fever in cirrhosis. Even a mild viral infection can trigger viral hepatitis concomitant with underlying cirrhosis and produce a virotoxic effect with the risk of decompensation – in addition, the “fever” is in itself responsible for typical biochemical reactions in this condition.

Endotoxins are a further cause of fever episodes, particularly from gram-negative bacteria. The *spill-over effect* (*prehepatically* via portacaval anastomoses, the lymphatic system or mastocytes, and *intrahepatically* in RES insufficiency) leads to *endotoxaemia*, which is responsible for numerous, even dangerous, biochemical reactions, e.g. hepatic encephalopathy and the activation of the coagulation cascade. • Long-term admin-

istration of *lactulose* can suppress a gram-negative intestinal flora and thus prevent the onset of endotoxaemia.

Protein degradation products may also trigger a febrile episode; aetiological differentiation of the fever caused by such metabolic products is usually impossible. There are no effective therapeutic measures. Differential diagnosis of “fever of unexplained origin” (R.G. PETERSDORF et al., 1961) can be very difficult in cirrhosis, a situation which presents an additional risk to the patient. • *In unexplained fever, laparoscopy is indicated.* (s. tab. 7.10)

Aetiocholanolone: The degradation products of androgenous steroids are a further suspected cause of febrile episodes, since severe fever could be induced by i.m. injection of *aetiocholanolone* (3 α -hydroxy-5 β -H-androstane-17-on) (A. KAPPAS et al., 1957). In 1958 P.K. BONDY et al. for the first time detected an increase in aetiocholanolone in the plasma of patients with unexplained fever episodes, and thus they coined the term **aetiocholanolone fever**. Other steroids of the 5 β -H configuration also revealed this pyrogenic feature. Aetiocholanolone may be the product of disturbed hepatocellular metabolism. Further observations and examinations have meanwhile been reported. (56, 130)

► *We detected markedly increased aetiocholanolone plasma values in numerous patients with liver cirrhosis and sudden febrile episodes – but we could not show a direct correlation.* • In 1966 F. SCHILLING reported that **aetiocholanolone fever** could be cured by *administration of indometacin*. *We were able to confirm this result (which had also been reported by M. VLAHO et al. in 1976) in those patients who had received indometacin as a suppository.* Indeed, we made use of this effect as differential therapy, but did not seek the underlying causes of a febrile episode unless the rectal administration of indometacin had been unsuccessful after one to three hours. Glucocorticoids, even when administered in a higher dosage, mostly proved ineffective, whereas a subsequent dose of indometacin caused the fever to subside within a very short time. While these may be *clinical observations*, they are remarkable enough to be reported. We suggest administering indometacin prior to any treatment with antibiotics. To our knowledge, renal insufficiency, as is known in cirrhosis (187), has not been observed following a single dose of indometacin.

11.14 Cholelithiasis

Cholelithiasis is found four to five times more often in patients with liver cirrhosis than in healthy persons. Follow-ups showed the development of cholelithiasis in 11.5% or 23.3% (–59%) of cases with women being mainly affected (δ = 15–20%, ♀ 30–35%). In stages Child B and C, frequency is 35–45%. In more than 80% of cases, asymptomatic cholelithiasis is observed. (1, 7, 43, 48) Predominantly brownish-black bilirubin concretions (= calcium bilirubinate) are detectable. (s. figs. 35.19, 35.20) The duration and degree of severity of cirrhosis as well as prior alcohol abuse are important risk

factors. Cholelithiasis has no influence on survival in cirrhosis. Surgical intervention poses a high risk and is therefore only indicated in life-threatening situations. • The cause is believed to be reduced contractility of the gall bladder in cirrhosis with disturbed emptying. (This can be checked with ^{99m}Tc -mebrofenin.) Hypersplenism, which is responsible for increased haemolysis and a reduction in UPD glucuronyltransferase activity in the liver, is assumed to be a further cause of this close association between cirrhosis and cholelithiasis. Hepatic secretion of unconjugated bilirubin is twice as high as normal and bile acid concentration is reduced, whereas the bile itself is oversaturated with cholesterol.*)

Fig. 35.20: Pigment calculus in liver cirrhosis, grid microscopy displaying characteristic plate-like bilirubin bodies

*) Kuntz, E.: Erkrankungen der Gallenblase und Gallenwege. (Diseases of the gall bladder and biliary tract) J.F. Lehmanns Verlag München, 1974. 344 pages, 126 figures.

11.15 Hepatocardiovascular syndrome

Apart from lung and kidney, heart and circulation are often involved, either primarily or secondarily, in liver diseases; this applies especially to cirrhosis.

Hyperdynamic circulation has a close correlation to portal hypertension, which results in (1.) reduction in vascular resistance and (2.) vasodilation of the splanchnic arteries and arterioles with increased blood volume in the vascular system. This leads to underfilling of the heart and reduction of the arteriovenous oxygen difference. The consequences are adaptive tachycardia, increased cardiac output and arterial hypotension. As a result of such a hyperdynamic circulation, there is a decrease in the *effective blood volume* (= central and peripheral blood volume in the cardiac ventricles, lungs and main arteries). The splanchnic hypervolaemia, in turn, increases the portal hypertension. The relative hypervolaemia in the arterial system and the hypotension cause a compensatory activation of the RAAS and the sympathetic nervous system. This is followed by an increase in the intrahepatic vascular resistance with continuous deterioration of the haemodynamics. This vicious circle finally leads to an enlargement of the collateral vessels with development of varices as well as to ascites and the hepatorenal syndrome.

Pathogenesis of vasodilation is multifactorial. The systemic or local vasodilators include: NO, glucagon, substance P, VIP, TNF, calcium-gene-related peptide, prostacyclin, etc. (14, 21, 36)

Clinical findings comprise: resting tachycardia and hypotension with large amplitude; dry and warm skin; flushed extremities, bounding pulses and capillary pulsations in the fingers; occasionally, an ejection systolic murmur is audible; QT time is often prolonged in correlation to the severity of cirrhosis. (171) • These cardiovascular findings are usually not a cause of heart insufficiency. After liver transplantation, there is complete regression. • Beta-blockers are recommended as therapy.

Cirrhotic cardiomyopathy: This term is defined as a left ventricular functional disorder due to stress (e.g. hyperdynamic circulation) or as pharmacological stimulation. But also the possibility of (toxically induced?) subclinical myocardial damage is discussed, especially because elevated troponin I serum values are detectable in every third patient. (4, 84, 135, 176) (Troponin is connected with propomyosin in the actin filaments at regular intervals and, as a “relaxing protein”, has an important function in muscle metabolism, also in the heart).

Pericardial effusion: In ascites, there is often (50–60%) a generally small pericardial effusion, which can be recognized reliably with the help of echocardiography.

11.16 Hepatocellular carcinoma

HCC is the fourth most common tumour worldwide. In 68–89% of patients with HCC, cirrhosis was also

detected, i.e. about six times more often than in non-cirrhotic patients. The incidence of HCC in cirrhosis is between 4% and 55% (2–5% per year), depending on (1.) aetiology of cirrhosis, (2.) type of cirrhosis, and (3.) observation period. Men are affected about eight times more often than women. (53, 95, 170) (*see chapter 37.3*)

Aetiology of cirrhosis: Cirrhosis due to hepatitis B, C and D as well as haemochromatosis, alcohol, NASH and α_1 -antitrypsin deficiency increases the risk of developing HCC considerably; there is a less obvious association with primary and secondary cholangitis or with autoimmune hepatitis. (136, 168)

Type of cirrhosis: Macronodular cirrhosis (which is usually a posthepatic form of cirrhosis) is the type most often associated with HCC (about 55% of cases). Compared to micronodular cirrhosis (usually alcohol-induced), development of HCC must be anticipated in 5–10% of patients. In this context, the actual presence of coarse-nodular cirrhosis seems to pose a greater risk of HCC than the aetiology of the underlying cirrhosis. • The adenomatous and hyperplastic transformations frequently found in cirrhosis tend to develop into HCC.

Observation period: The time lapse between the onset of cirrhosis and that of HCC is unpredictable. Small cancerous foci may be observed at an early stage of cirrhosis, which can only be demonstrated by SPECT *in vivo*. Clinically recognizable HCC is reported to take about four years on average to develop into HBV-induced cirrhosis (H. OBATA *et al.*, 1980) and about eight years into alcoholic cirrhosis (C.M. LEEVY *et al.*, 1964).

Diagnosis: Long-term monitoring of a cirrhotic patient is achieved by determination of α_1 -foetoprotein (s. p. 112). As soon as the initial value has been established, follow-ups are carried out at long intervals (usually every six to twelve months if the values are normal) and at short intervals if the values are elevated. However, sensitivity is only about 60%, so that a normal value does not necessarily exclude HCC. Specificity is 75–90%. Despite unsatisfactory sensitivity, AFP determination is still useful for monitoring the development of “still normal” or “already moderately elevated” values. • The simultaneous determination of **des-gamma-carboxy prothrombin** (DCP) (sensitivity 50–60%, specificity 80–100%) can improve diagnostic value or assessment of the course. (s. p. 748) • **Sonography** serves as a tool in monitoring cirrhosis simultaneously, yet it should be noted that the sonographic differentiation of small-sized malignant foci is quite difficult in the cirrhotic liver. Sensitivity is 70–80% and specificity 90–95%. Follow-ups are recommended at six- to nine-month intervals. Regular monitoring at short intervals with the help of AFP determination and sonography is recommended in macronodular cirrhosis or in the presence of HCC risk factors. (94) • Suspected development of HCC is an indication for contrast-medium (= lipiodol) **computer tomography** (or spiral CT) in order to guarantee a rela-

tively early diagnosis. (s. fig. 37.6) **MRI** (or spiral CT) has been used to distinguish between adenomatous hyperplastic nodes and HCC in cirrhosis. (82, 101, 186) • Cytologic confirmation of HCC can be substantiated by US/CT-guided **fine-needle biopsy**; this is especially true for intrahepatic foci. • In view of the bleeding risk, we would discourage clinicians from resorting to percutaneous biopsy and consider using **laparoscopy** instead. (s. figs. 37.1, 37.7, 37.8) The primary use of laparoscopy as a morphological tool (subsequent to imaging diagnostics) has the following *advantages*: (1.) inspection of the total liver surface facilitates a more reliable detection of foci, (2.) practically any superficial focus can be accessed by forceps biopsy, (3.) use of Robber’s forceps is far less dangerous than any needle biopsy of the liver, (4.) explorative laparoscopy provides the required staging result, and (5.) any kind of “blind” percutaneous biopsy is more dangerous than forceps biopsy, which is carried out under visual control with the possibility of monitoring potential rebleeding and applying respective coagulative measures. (*see chapter 37.3*)

12 Prognosis

The prognosis for cirrhosis patients depends upon the respective complications. The underlying morphological processes, such as necrosis, fibrosis and regeneration, combine to widely differing degrees in the single cirrhotic patient. There are also individual divergencies in haemodynamic responses and the corresponding effects on the kidneys, lungs and liver, etc. Thus it is very difficult to give an accurate prognosis in each case. Furthermore, such a prognosis only covers a relatively short period of time (a few months up to a year). (2, 51, 81, 133, 137, 149, 166, 192, 193)

Various indices have been developed using weighted parameters to calculate the probability of fatality or survival in each case. **Classification** of cirrhosis according to the *criteria* devised by CHILD and TURCOTTE (1964) and the *modification* established by PUGH (1973) has been widely accepted. Our experience shows that the additional use of the *GEC* test and the *ICG* test makes the classification more reliable, particularly in stages A (= score 5–7) and B (= score 8–10). (s. tab. 35.7)

The prognosis of cirrhosis caused by toxins (alcohol or medicament abuse, chemical agents, iron storage, etc.) is much improved by *eliminating the causal noxa*. Recognition and treatment of *secondary immunoreactions*, which may occur concomitantly, are also important. Such reactions reduce the prognostically favourable effect of abstinence (e.g. alcohol, pharmacons) if they are not adequately treated with corresponding drugs.

In compensated cirrhosis, the ten-year survival rate is 45–50%. Long-term compensation (for many years)

can only be maintained in 40–45% of cases. Of the compensated patients, severe complications develop in 55–60% and decompensation occurs in 45–50% of cases. The mean survival rate for compensated cirrhosis is 8.9 years, for decompensated cirrhosis 1.6 years only. (133, 137, 166)

Complications such as variceal bleeding, hepatic encephalopathy, ascites, infections and reduced renal function also influence the **mortality rate** of liver cirrhosis (in Germany some 25,000/year). The main causes of death are hepatic coma or liver failure (25–40%), bleeding (20–30%), infections (about 10%) and HCC (about 5%). Spontaneous bacterial peritonitis is fatal in 50–70%, and with liver dysfunction in 90% of cases. Occurrence of the hepatorenal syndrome is almost invariably fatal.

Prognosis of liver cirrhosis depends upon preventing complications as far as possible. • At the same time, all options should be used to stabilize compensation and improve liver function.

13 Therapy

In principle, **six treatment forms** can be implemented to combat the complex pathological events in liver cirrhosis, which may be extremely variable due to numerous complications. These are: (1.) causal treatment, (2.) treatment of pathogenetic primary reactions, (3.) treatment to prevent progression of cirrhosis, (4.) treatment of symptoms, (5.) treatment of complications, and (6.) liver transplantation.

13.1 Causal treatment

Once alcohol-induced cirrhosis has been detected, absolute **alcohol abstinence** is essential. This abstinence also includes the concealed amounts of alcohol in drinks and foodstuffs or in pharmaceuticals and tonics as well as the use of after-shave products, which may contain a high volume percentage of alcohol. Even fruit juices contain a certain amount of alcohol due to fermentation in the bottle. And so-called alcohol-free beer is in fact a beverage with a low alcohol content. Apart from that, intestinal fermentation caused by certain fungi may result in the production of considerable amounts of alcohol. All these factors can come together to produce “alarming” quantities of alcohol in the body and may even lead to a situation where a phase of abstinence is followed by renewed addiction. Women in general and patients with cirrhosis who have undergone gastric resection are mainly at risk with regard to this complex problem. All too often, these factors are underrated or go largely unnoticed as far as their cumulative effect is concerned. Beware of *cliché-ridden expressions* designed

to trivialize the matter such as a “sip of wine”, a “sip of beer” or a “nip of brandy” – this form of self-deception is simply not acceptable. (s. pp 64, 534–537)

Likewise, in cirrhosis due to medicaments or toxins, causal treatment entails elimination of the underlying **noxa(e)** (pharmaceuticals, chemicals, drugs) and a simultaneous “ban” on alcohol. Alcohol has an additive and sometimes intensifying effect as a noxa. • In a particular course and stage of cirrhosis due to viral hepatitis B or C, treatment with **interferon** may (still) be used as causal therapy. Hereby, the frequency of decompensation in HCV cirrhosis or of HCV-induced carcinoma could be lowered, although not significantly.

13.2 Treatment of pathogenic reactions

Treating pathogenic primary reactions does not cure the underlying cause of cirrhosis, but is an effective intervention in its pathogenesis. Continuous therapy may result in reduced inflammatory or immunological activity and decreased fibrogenesis despite the (regrettable) development of cirrhosis; thus it can create a tendency towards stabilization or inactivation of the overall process: e. g. *iron depletion* in haemochromatosis, *removal of copper* in Wilson’s disease, *protection against ultraviolet light* in certain forms of porphyria cirrhosis, *immunosuppression* in autoimmune cirrhosis, and reduction in *portal hypertension* by medication.

13.3 Treatment of progression

The above-mentioned measures do not combat the cause(s) or eliminate the primary pathogenetic reactions (with a few exceptions). The general aim is to prevent progression of the disease, ideally until the cirrhosis comes to a halt. When such medication is administered effectively, complicative developments can also be prevented. Pathogenetic primary reactions often initiate a cascade of secondary mechanisms, in particular of a biochemical nature. This is true of the inhibition of concomitant cholestasis during the course of cirrhosis by *ursodeoxycholic acid* (97), the reduction in lipid peroxidation by *silymarin*, the inhibition of fibrogenesis by *colchicine* or *silymarin* (sometimes with improved quality of life), and the elimination of hyperammonaemia by *ornithine aspartate*. (138) (s. p. 287)

Fundamentally, “treatment” of cirrhosis should begin during its chronic precursory stages, i. e. *chronic hepatitis* or *chronic cholangitis*. A chronic disease confirmed by detailed diagnostics usually still responds to effective treatment measures, which are, however, of no help once the cirrhotic stage has been reached.

13.4 Symptomatic treatment

From the subjective point of view concerning the pathological events, it is usually those symptoms which impair

the state of health and lifestyle that are the most obvious. The patients “feel” tired, worn out, lack concentration, are unenthusiastic and unmotivated; they are inappetent and show muscular weakness; occasionally they suffer from pruritus; they “feel ill” or even “chronically poisoned” (as we were often told by such patients who used these words). Above all, the patient seeks advice and help, even polypragmatic help, in view of the often widely varying symptomatology.

► When liver cirrhosis has already been confirmed by detailed diagnosis and its (possible) secondary reactions or complicative developments have been determined (this is the *primary prerequisite* of “the physician”), it is possible to apply symptomatic treatment measures in a more effective and more targeted and thus more efficient way (which is what “the patient” *principally expects*). • In most cases, this forms a basis of mutual trust as it generally guarantees the patient’s readiness to cooperate with regard to strict directions, certain treatment and follow-up measures as well as invasive therapy.

13.4.1 Nutrition

The question “*What can I eat?*” is nearly always of prime importance and it implicitly includes the basic idea of what the cirrhotic patient should avoid or what diet to give preference to. First of all, it should be clear that there is no such thing as a special **liver diet** designed to have instant curative effects on liver disease (despite the fact that many such diets have been extolled). • The diet of a cirrhotic patient is based on the principles of *nutritional physiology*, the *aetiology* of the cirrhosis, the patient’s *body weight* and *age* as well as on any *complications*. (111) (s. pp 550, 878)

The calorie content of the diet should be adapted to the current body weight. As a rule, the percentage ratio between **calories** derived from carbohydrates, protein and lipids is considered well-balanced at 40:20:40 or 50:20:30, with a minimum of 2,000 calories per day. The recommended **protein** intake is about 0.8–1.2 (–1.5) g/kg BW; when there is a tendency towards encephalopathy, the protein content needs to be reduced accordingly, with an intake of mainly lactovegetative proteins. (s. p. 286) In catabolism or muscular atrophy, the protein intake must be increased to more than 100 g/day and/or **branched-chain amino acids** (37, 69, 80, 102, 105, 115, 143, 167, 188) or formula diets are recommended. The nitrogen balance must be in equilibrium. (87, 110) The daily intake of food should always be spread over **five meals** (i.e. three main meals and two snacks, as with diabetic patients): this makes digestion easier, and the catabolic phases become shorter. With regard to energy, a cirrhosis patient is basically in a condition of fasting. **Salt intake** should not exceed 7–8 g/day; as soon as signs of water retention in the tissue appear (s. fig. 16.2), salt consumption should be reduced further. (s. p. 311) • In addition, disease-induced **maldigestion/malabsorp-**

tion (e.g. deficiency of pancreatic enzymes or bile salts, portal hypertensive enteropathy) is responsible for a lack of essential nutritional components (often latent for a long time). In older people, reduced absorption of fat-soluble vitamins (173, 174) and arachidonic acid (125) (among other things) is also to be expected. However, one should not wait for a vitamin deficiency to arise; besides, biochemical evidence of reduced vitamin values is costly and unreliable. Daily intake of *multivitamin tablets* (as a dietary supplement) should thus be considered for obvious reasons. This is also true of a complementary supply of *electrolytes*, *zinc* (103, 185) and *selenium*. (30) • If steatorrhoea is observed, *MCT* (about 3 x 15 ml/day, equivalent to some 400 kcal) are given, possibly coupled with the administration of “*essential*” *phospholipids* to achieve the best results. (31)

I have been told that **raw goat’s milk** (2 x 0.25 l/day, stored in the refrigerator) is used “successfully” to treat liver cirrhosis in some regions. **Ubiquinone** (?) is thought to be the active substance – this agent is also said to have prevented the occurrence of cirrhosis in animal experiments.

Malnutrition, which is observed in 60–80% of cirrhotic patients, may be so severe that **parenteral nutrition** is called for. (32, 111) Glucose infusions as a main source of energy (6–10 g/kg BW/day), amino-acid solutions (1.0–1.5 g/kg BW/day) and lipid infusions (0.3 g/kg BW/day) can be used to guarantee a supply of about 2,270–3,000 kcal. • Parenteral nutrition should guarantee an adequate supply of *vitamins*, *electrolytes*, *zinc* and *choline* as well as *albumin*. (27) In encephalopathy, preference is usually given to *branched-chain amino acids* instead of total amino-acid solutions. Administration of *insulin* may be necessary in impaired glucose tolerance. • In pronounced catabolism, the nitrogen balance can be considerably improved by administering recombinant growth hormones. • *Laevulose*, *xylitol* or *sorbitol* should not be administered as they are not sufficiently transformed into glucose in the cirrhotic liver, with the result that *lactate acidosis* and *hypoglycaemia* occur due to the increased formation of lactate. In addition, these substances lead to a further reduction in energy-rich phosphates, which are generally already decreased.

13.4.2 Physical activity

Appropriate **physical activity** (with anabolic effects) is recommended for cirrhotic patients in order to prevent muscular atrophy and hepatic osteopathy. We had positive experience with a *muscle-training programme* carried out two (or even three) times a day. Almost 60% of the musculature is activated in this way – irrespective of age or weather conditions and without the need for particular clothing or equipment. (s. pp 551, 683, 755) • Swimming or water gymnastics are recommended activ-

ities, if possible. Physical overexertion must be avoided. (20, 61, 145) This also applies to the use of home-training equipment. An unfavourable rise in HVPG due to increased physical exercise can be prevented by propranolol. (20) • We recommend a **horizontal position** for about an hour after each of the three main meals. The positive effects of a recumbent position on numerous biochemical parameters, particularly in disturbed water and salt balance, remain undisputed – and are just as obvious as the negative effects of a long-term upright posture. (145) The latter may even trigger complications when there is simultaneous emotional (sympatheticotonic) excitement (e.g. when watching sports events!). • Vocational **rehabilitation** is the ultimate aim and the patient ought to be given tasks based on physical aptitude. If the physician agrees, patients should continue in their current profession. *The diagnosis “liver cirrhosis” does not automatically mean incapacity for work or vocational disability!* • Utmost care should be taken by the patient in keeping personal **records** (documentation sheet) in order to detect latent HE or latent water retention, which points to a commencement of decompensation. (s. fig. 15.3) (s. pp 283, 311)

13.4.3 Psychological guidance

► *Detailed and confirmed diagnosis* enables the physician to offer reliable guidance, which gives the patient the necessary confidence in the former’s proficiency and experience. This is the first important *prerequisite* regarding active medical care. • The patients, who have various subjective complaints and are usually weakened by malnutrition, besides being severely restricted in their everyday lives, are mainly seeking *tangible help* to ease their own subjective suffering. The patient has more trust and readiness to cooperate if the physician shows understanding for these subjective complaints, takes them seriously and treats them (even if the treatment measures are gradual or polypragmatic). This is the second important *prerequisite* regarding active medical care. • Usually, it is the patient’s desire to be informed in a comprehensible manner about the respective disease. The physician’s patience and readiness with respect to *elucidation*, i.e. explaining the disease itself and the cirrhosis-related circumstances in an understandable manner, or even suggesting that a *second opinion* should be obtained from another hepatologist, reassure the patients that they are in the hands of a competent specialist. This is the third important *prerequisite* regarding active medical care.

Understandably, there are always questions concerning **prognosis**. *Cirrhoses come in many different shapes and sizes!* The individual *aetiology* of cirrhosis – more than thirty different causes are known (s. tab. 35.2) – initially determines the prognosis. This is all the more essential since certain forms respond well to treatment. In addition, prognosis is influenced by maintaining *compensation*, which, in turn, is supported by an *appropriate life-*

style. The patient is fully aware of the fact that any kind of *active participation* is worthwhile, that even phases of decompensation can be overcome and that any early detection of such phases and complications offers the best chance of stabilization, provided that treatment commences as early as possible. The patient experiences how *aetiology* of the cirrhosis, personal *cooperation* and early detection of *complications* form an important **triad**, and that consequently the prognosis of liver cirrhosis need not be as poor as is generally assumed. • *We treated numerous cirrhotic patients over a long period, a large number of whom we accompanied for 10–15 years despite some interspersed “acute-on-chronic” events.*

Even an **infaust prognosis** should not be withheld from the patient, particularly in those cases where specific questions are asked about the true situation. In these conversations, the physician, who is naturally deeply involved, should explain the situation step by step, revealing one unfavourable fact after the other. In this way, all medical and nursing measures can be discussed frankly. The patients also need time to settle their personal and family affairs and to have a chance for contemplation as well as for finding spiritual support.

A joint approach and communal experience concerning cirrhosis require the physician to show empathy and persuasion while discerning the degree to which the patient is able to grasp and understand the medical facts and findings intellectually and emotionally. Time and again, the three prerequisites described above have proved to be mainstays in the relationship between physician and patient.

13.4.4 Drug therapy

► A review of the past 60 years (since 1955), during which time we have experienced numerous developments in hepatology, shows that an unimaginable and fascinating spectrum of treatment options has been established. • This is true especially of the *treatment of pathogenetic primary reactions*, some examples of which have been outlined in the individual chapters describing the corresponding diseases. The same applies to the pharmacological treatment of *progressive tendencies* typical of cirrhosis, e.g. cholestasis, fibrosis, hyperammonaemia, electrolyte imbalance, lipid peroxidation.

Dealing with complications is not what we consider to be the most important aspect of treating cirrhosis. A primary objective should be to carry out prophylactic measures for preventing such complications in the first place, insofar as this is possible.

As we have shown in the case of **encephalopathy** and **ascites** – *the two earliest and thus most common decompensation syndromes* – successful **prophylaxis** for about

one year is less of a financial burden than (just) one week of inpatient treatment after manifestation. Even more important is the absolute danger to the patient inherent in a progressive course. • *Prevention of complications is always better and cheaper – for all parties involved!*

The use of the following substances has proved suitable in terms of pharmacological plausibility and clinical results, provided there are no particular circumstances, forms of treatment, intolerance or individual imponderables to contraindicate their application.

Step 1: (1.) *lactulose* (2–3 stools/day) and (2.) *spironolactone* (50 mg per day or every second day). This therapy is practically free of side effects – even during long-term administration. (s. pp 287, 312, 887)

Step 2: Additional administration of (3.) *ornithine aspartate* (1–3 x 6 g/day). This may be indicated by the detection of latent HE (stages 0, 0–I). Usually, the administration of (4.) *zinc* (15–30 mg/day) is also indicated in this context. (s. pp 287, 885, 890)

Step 3: Reduction in portal pressure (46, 78, 109) and prevention of variceal bleeding are important measures as part of a primary prophylaxis. In our experience, the development of pulmonary hypertension can be delayed (or even prevented). This might be achieved, for example, by administering (5.) *molsidomine* and (6.) *beta blockers* (in combination with spironolactone as in Step 1). The frequent occurrence of portal colopathy (30–40%), even with colitis-like abnormalities, can be reduced by propranolol. (23, 150) • A combination of isosorbide-5-mononitrate with nadolol has been successful in cases where treatment with beta blockers alone did not prove effective. (s. pp, 267, 366)

Fat-soluble vitamins: Oral intake of vitamins A, D and E is usually sufficient – as is the dosage contained in multivitamin preparations when taken daily. Biochemical evidence of deficiency or the occurrence of diseases due to deficiency usually require vitamins A, D, E and K to be supplied parenterally as a compound preparation.

Silymarin: At present, there is no unequivocal confirmation of the positive effects of silymarin as a cytoprotective agent against various noxae; in particular, the scavenger effects attributed to this substance and its alleged regenerative properties have not been confirmed in cirrhosis. (s. p. 895)

Phosphatidylcholine: As is the case with silymarin, there is a vast amount of information in the literature about this substance. Animal experiments have shown that the development of septal fibroses and the occurrence of cirrhosis could be prevented despite chronic alcohol consumption. The studies available to date on cirrhotic patients provide insufficient information. (s. p. 894)

Colchicine: Inhibition of progressive fibrosis in cirrhotic patients with a markedly improved survival time was

reported (dosage: 1 mg/day, 5 days/week). However, this was not confirmed in a later study. We have no information about potential side effects, particularly during long-term treatment (which is usually desirable in cirrhosis therapy). (s. p. 897) • The use of **proline-4-hydroxylase** results in the significant inhibition of collagen synthesis in animal experiments. No clinical data are available to date.

Coagulation parameters: Detection of pathological laboratory values is not an indication for substitution. Such measures are unnecessary before clinical manifestations are observed. Propranolol ameliorates thrombopenia. (142) (s. pp 352, 353)

Liver cirrhosis is the final stage of disease of the largest metabolic organ, with diverse functionally, biochemically and morphologically related complications. Decompensation mechanisms should therefore be avoided with the help of targeted treatment. The aim is to maintain the stage of compensation for as long as possible and to recognize complications at their onset. • The costly and complex treatment strategies for dealing with cirrhotic complications, often involving intensive care, are described in the respective chapters.

13.5 Monitoring

Regular monitoring is essential and should always be carried out in a targeted and economical way. The basic parameters used in the follow-up should be limited to obtaining really informative results!

► In the course of some 40 years, we have accompanied cirrhotic patients for considerable periods of their lives, many for more than 10 years, some even for more than 15 years. This often resulted in experiences that modified and ultimately standardized our follow-up programme. • Basic control parameters, i.e. parameters important in all forms of cirrhosis, are supplemented by more informative investigations (such as iron, copper or phosphatase values) in cases with a particular aetiology.

Such a **standard programme**, which nevertheless leaves room for individual concepts, has proved successful over many years. (s. tab. 35.10)

1. Interim anamnesis: Important events during a certain period of time have to be noted in a concise manner – otherwise the abbreviation n.a.d. (= no abnormality detected) is sufficient.

2. Therapeutic status: The name and dosage of the pharmacons used in the meantime; the name and date of any medicine discontinued or newly prescribed; side effects and intolerances observed, if any. All relevant details concerning the remedies are recorded, which facilitates interim repeat prescriptions.

| Doctor's orders: | | |
| | | |
| | | |

Tab. 35.10: Standardized (uniform and easy-to-document) evaluation programme for the long-term follow-up of compensated cirrhotics. (Time intervals in accordance with the current situation, particular values in accordance with the given cirrhosis aetiology)

3. Clinical findings: Relevant changes in findings are recorded tersely; unchanged status is noted with the abbreviation n.c. (= no changes).

4. Documentation sheet: Presentation of the documentation sheet by the patient containing details of body weight and handwriting specimens during the respective follow-up phase. This form (which can easily be drawn up by the patient) may contain, on the front and back, daily entries for two follow-up months. This patient-own documentation is the *cheapest and most reliable follow-up method* with regard to early detection of the two most sensitive signs of decompensation: latent HE and latent ascites. (s. fig. 15.3) (s. pp 283, 311)

5. Laboratory parameters: These are of *secondary importance* in the long-term follow-up of compensated liver cirrhosis. *GPT* is sufficient for evaluating enzymatic activity, while γ -*GT* is suitable for initial detection of concomitant cholestasis or toxic components (in some cases, there are also hints of malignancy or even regeneration). Depending on the individual situation, these two values have to be checked at intervals of (2–)4 weeks. In order to monitor liver function, *cholinesterase* and *Quick's value* are determined at intervals of (4–)8 weeks, while *electrophoresis* (for evaluating mesenchymal activity and albumin synthesis) is conducted every (3–)6 months. • Control of *sodium* (Na) and *potassium* (P) is carried out according to the individual situation. However, these two electrolytes are nearly always within the normal range if the findings in the above mentioned documentation sheet referring to latent HE or latent oedema are also normal – a fact which can be

explained in terms of pathophysiology. • With specific forms of cirrhosis, one or two *additional parameters* of particular significance are applied.

The aim is to maintain the **stage of compensation** in an undisturbed state for as long as possible, to use all possible measures to prevent negative effects, and to detect and treat the onset of any decompensation mechanisms as early as possible. This is essential and decisive both for prognosis and for structuring a worthwhile daily life. • The requirements of *quality management* are met by adhering to a standardized **follow-up programme**, which can be documented. • This well-established overall concept has also been successful in reducing the expense involved. The **costs** of caring for one cirrhotic patient have been calculated at more than 13,000 US dollars per year (T. Szucs et al., 1997).

13.6 Liver transplantation

All patients with end-stage cirrhosis should be considered for liver transplantation in good time. Selection initially requires a thorough and critical evaluation of the indication with regard to the patient's general physical and mental condition. The **risk factors**, which have to be assessed in advance, include: (1.) cardiac, pulmonary and renal function, (2.) coagulation system, (3.) albumin value, (4.) obesity, (5.) prior complex hepatobiliary surgery, (6.) portal vein thrombosis, (7.) autoimmune disease, (8.) viral infection, (9.) coexisting diseases, (10.) problems relating to addiction, (11.) unfavourable familial and social environment, and (12.) individual unwillingness to cooperate. • These twelve evaluation criteria provide an initial overview of the extent of the risk factors which can be identified in advance and which are of significance for the patient's registration at a transplantation centre. • For many patients in a life-threatening situation, liver transplantation remains the only chance of survival.

36 Benign hepatic lesions and tumours

1 Definition

The term **lesion** denotes a circumscribed impairment of function or tissue structure, while the word **tumour** describes a circumscribed swelling or the growth of body tissue. • **Benign hepatic focal lesions** are circumscribed alterations. They differ markedly from the surrounding hepatic tissue, which shows a normal or diffusely changed structure. Differences in tissue type or chemical composition are revealed by imaging procedures. Benign hepatic coin lesions can appear either in solitary or multiple form. They may be only 1–2 mm in size or cover large hepatic areas, and even a complete lobe.

2 Classification

Benign hepatic focal lesions are usually detected as an incidental finding in sonography. As a rule, there are no subjective or characteristic complaints, no identified neoplastic disease and no objective clinical findings.

2.1 Sonomorphological classification

Sonomorphological differentiation may be helpful in classifying incidentally detected liver foci: (1.) anechoic, (2.) hypoechoic, and (3.) echogenic lesions. (s. tab. 36.1)

| Anechoic lesions | Hypoechoic lesions |
|--------------------------|-------------------------|
| Caroli's syndrome | Adenoma |
| Cysts | Echinococcus alveolaris |
| Echinococcus alveolaris | FNH |
| Fresh haematoma | Focal non-fatty changes |
| Liquefied abscess | Fresh abscess |
| Osler's disease | Hamartoma |
| Echogenic lesions | Lymphoma |
| Fibroma | NRH |
| Focal fatty changes | Old haematoma |
| Granuloma | Peliosis hepatis |
| Haemangioma | Regenerative nodes |
| Hamartoma | |
| Lipoma | |
| Regenerative nodes | |

Tab. 36.1: Sonomorphological classification of benign hepatic focal lesions according to their (predominant) echogenicity

As a typical anechoic focus, a cyst displays a delicate margin, dorsal sound reduction and a completely anechoic lumen. • Focal hepatic lesions or coin lesions are variable in size, number, internal echo (homogeneous or structured), demarcation from the surrounding hepatic tissue and

secondary findings (displacement effects, compression). • *It is important to rule out malignant hepatic tumours.*

2.2 Histological classification

Differential diagnosis of circular hepatic foci helps to decide whether therapeutic measures are necessary, not required, or not feasible. • The histological *classification* of benign coin-like hepatic lesions differentiates between (1.) hepatocellular tumours, (2.) cholangiocellular tumours, (3.) mesenchymal tumours, and (4.) tumour-like lesions. There may also be evidence of (5.) calcareous foci. (2, 3, 6, 11, 14) (s. tab. 36.2)

1. **Hepatocellular tumours**
 - Adenoma
 - Focal nodular hyperplasia
 - Nodular regenerative hyperplasia
 - Regenerative nodes
2. **Cholangiocellular tumours**
 - Bile-duct papillomatosis
 - Biliary hamartoma
 - Caroli's disease/syndrome
 - Intrahepatic bile-duct adenoma
 - Intrahepatic bile-duct cystadenoma
3. **Mesenchymal tumours**
 - Angiolipoma
 - Angiomyolipoma
 - Benign haemangioendothelioma
 - Cavernous haemangioma
 - Chondroma
 - Fibrous tumour
 - Focal fatty changes
 - Glomangioma
 - Leiomyoma
 - Lipoma
 - Lymphangioma
 - Mesenchymal hamartoma
 - Mesothelioma
 - Myelolipoma
 - Myolipoma
 - Myxoma
 - Schwannoma
4. **Tumour-like lesions**
 - Abscess
 - Cyst
 - Granuloma
 - Haematoma
 - Inflammatory pseudotumour
 - Peliosis hepatis
5. **Calcareous foci**

Tab. 36.2: Histological classification of benign hepatic coin lesions

3 Diagnostics

3.1 Anamnesis

In most cases, benign liver tumours are detected by chance during sonography. Any *information* elicited during anamnesis about the long-term use of contraceptives, androgens or medication as well as any possible intake of chemicals, potential infections with parasites or zoonoses, abdominal trauma or febrile diseases and previous episodes of jaundice may be important.

3.2 Complaints

There are usually no subjective complaints – except when there are large space-occupying lesions which cause anorexia, weight loss, upper abdominal pain upon pressure, haemorrhaging in the tumour or tumour rupture. Febrile conditions and pain may point to infection, liver abscess or echinococcosis.

3.3 Findings

Anamnesis and **complaints** are of little diagnostic value. Clinical examination frequently reveals non-characteristic findings, such as hepatomegaly, abdominal pain on pressure, diaphragmatic elevation, right-sided pleural effusion or hepatic vascular murmur (e.g. in large haemangiomas). **Laboratory parameters** are mostly normal. Sometimes the transaminases and γ -GT are elevated; AP and respective values relating to cholestasis can be higher. In an inflammatory process, CRP and BSR are often elevated, while ChE and iron may be lower.

3.4 Imaging procedures

The following imaging procedures can be used for the detection and differential diagnosis of benign hepatic lesions or tumours: (1.) sonography, (2.) computer tomography, (3.) scintigraphy, and (4.) magnetic resonance imaging. These methods show clear differences in their ability to detect tumours of minimum size, in their sensitivity and specificity, and in the costs involved. • Echogenic and anechoic foci can obviously be detected by sonography at a much smaller diameter than hypoechoic foci. In scintigraphy, hepatic tumours in the portal area and in the centre of the liver must have a larger diameter in order to be visualized. By combining scintigraphy and CT, it is generally possible to differentiate FNH from adenoma. In CT and MRI, detection of a tumour depends on its structure. • Sensitivity, i.e. the rate of correct positive results, should be as high as possible, but there are clear differences here. The specificity of these diagnostic procedures is high at 90 to 95%.

Sonography is the method of choice on the basis of the following *criteria*: (1.) it has a high diagnostic yield (including extrahepatic areas), (2.) it is cost-effective, (3.) it can be used in various locations, (4.) it is not time-

consuming, and (5.) it does not burden the patient. The use of new techniques (contrast-enhanced power Doppler sonography, phase-inversion harmonic imaging) can help to make the assessment more reliable in individual cases. US is clearly inferior to CT when it comes to diagnosing metastases. (5) • *It should be noted that the respective diagnostic reliability is highly dependent upon the investigator's experience.* (s. tab. 36.3)

Computer tomography has a greater sensitivity than sonography; however, there are higher costs involved, it takes more time, requires more space and entails exposure to radiation. More sophisticated methods such as helical CT or CT arteriography allow a more differentiated application in certain constellations (e.g. malignant lymphoma, metastases of parvicellular bronchial carcinoma, or breast cancer). Permanent-location CT with administration of bolus contrast medium is suitable for the differentiation of haemangioma. Sonography and CT are considered to be useful complementary techniques in diagnosing hepatic focal lesions, since in this way foci can be detected which are missed by the respective other method. (1) (s. tab. 36.3)

| Criterion | US | CT | MRI | SC | FNB | Lap |
|-------------------------------|-------|-------|-------|-------|---------|---------|
| Detectable size of focus (cm) | >0.5 | >0.8 | >1.0 | >2.0 | >1.5 | >0.1 |
| Sensitivity (%) | 50–70 | 60–90 | 70–95 | 40–60 | 75–90 | ca. 100 |
| Specificity (%) | 90 | >95 | >95 | >95 | ca. 100 | ca. 100 |
| Additional information | + | + | + | ∅ | ∅ | ++ |
| Costs | (+) | ++ | +++ | ++ | (+) | + |

Tab. 36.3: Respective values of the different diagnostic methods regarding the detection of hepatic focal lesions (US = ultrasound, CT = computer tomography, MRI = magnetic resonance imaging, SC = scintigraphy, FNB = fine-needle biopsy, Lap = laparoscopic findings at the liver surface)

Magnetic resonance imaging may provide e.g. extra differentiation of unclarified findings (particularly in diagnosis of haemangioma). Hypovascular lesions are detected more easily with SPIO-enhanced MRI, whereas detection and characterization of hypervascular lesions are best with gadolinium-enhanced MRI. (1, 7, 13) (s. tab. 36.3)

Scintigraphy can be indicated for differentiating an adenoma from FNH (combination of colloid scintigram and hepatobiliary sequential scintigraphy) and for diagnosing haemangioma. (12)

Angiography: Visualization of hepatic veins or arteries is rarely required. Angiography is indicated for diagnosing metastases of active endocrine tumours. This technique may also be necessary in the planning phase of liver surgery. A further possible indication is its use in carrying out therapeutic measures.

3.5 Biopsy and laparoscopy

Reliable differentiation between benign and malignant hepatic tumour is not possible using imaging procedures; thus, an indication is given for US-guided or CT-controlled **fine-needle biopsy**. (s. tab. 36.3) (s. pp 133, 156) However, FNB is diagnostically inferior to thick-needle biopsy (> 1.2 mm) – although the bleeding risk is clearly much lower. The indication for **biopsy** should be viewed critically, particularly when considering the use of a thick needle. (4) • *In all cases where the findings cannot be substantiated by imaging procedures and where treatment implications can be expected as a result of diagnostic clarification, laparoscopy is indicated. The combination of laparoscopy and biopsy yields the highest diagnostic sensitivity and specificity. The diagnostic reliability is almost 100% in focal lesions on the liver surface.* (9, 10) Tissue samples for histological examination can be gained from selected tumour areas by careful, directed **forceps biopsy** (also by FNB). Laparoscopy makes possible the photographic documentation of the findings as well as of any additional important pathological changes in the abdominal cavity – this may prove very helpful. (s. tab. 36.3.) (see chapter 7!)

4 Differential diagnosis

4.1 Adenoma

Epidemiology and aetiology: Adenomas have an incidence of 4–10/100,000 inhabitants/year. They are almost exclusively found in women during their reproductive years. Children are rarely affected. (29) In men, the risk is higher when they take anabolic agents. In about 90% of cases, there is a correlation with the intake of oral contraceptives over many years; this was pointed out for the first time by J.K. BAUM et al. in 1973. (19, 22, 26, 33, 34) There is also an association with the polycystic ovary syndrome. (35) An adenoma can develop in glycogenesis types I and III (with multilobular nodulation) (30) as well as in type IV. (15) The administration of various other drugs (e.g. carbamazepine) has also been associated with adenomas.

Morphology: Adenomas are mostly solitary (75%) and located mainly in the right liver lobe (65–70%). The rare occurrence of multiple adenomas (> 3 lesions) is termed *adenomatosis* of the liver. (20) A familial form has been observed, showing the association with germline hepatocyte nuclear factor alpha. (17) Usually, adenomas develop close to the surface beneath the liver capsule. They vary greatly in size, but have an average diameter of 10 cm (2 cm to > 30 cm); even pediculate nodes have been observed. Adenomas are hypervascularized and have a firm, rubber-like consistency. Due to their bright red to light brown colour, they stand out from the rest of the hepatic tissue. (s. fig. 29.11!)

Histology: The parenchyma is formed from pluricellular trabeculae and two (or three) layers of hepatocytes, the width of which varies from location to location. The hepatocytes are rich in glycogen, often pleomorphic and enlarged, and usually show fine-droplet fatty deposits. No evidence of acinar architecture or Kupffer cells is found; very few preexisting and incorporated portal fields, central veins or bile ducts are detectable. There are numerous arteries and ectatic sinusoids (without Kupffer cells). This is the site of haemorrhages into necroses which are mostly found in larger nodes. These haemorrhages may also penetrate the adjacent liver parenchyma and rupture into the abdominal cavity. There are no fibroses or inflammatory reactions. Reticular fibres are delicate or have disappeared completely. Adenomas often possess a capsule made of fibre tissue or compressed liver parenchyma, so that adenoma nodes are easy to enucleate from their hepatic bed. (20, 23, 25)

► According to recent studies, adenomas can be classified into four forms: (1.) **archtypical adenoma** (monoclonal, no atypias, no inflammation, no ductular structures), (2.) **variant 1** (mutation of HNF α gene, steatosis ++, no atypias, no inflammation), (3.) **variant 2** (mutation of β -catenin gene, minor atypias, slight metaplasias), and (4.) **variant 3** (monoclonal, previously “telangiectatic type of FNH”, ductular structures, inflammatory infiltrates, sinus ectasias). (18)

Diagnosis: Small adenomas do not cause any discomfort. Large adenomas may become palpable or cause pain upon pressure and have displacement effects. **Laboratory parameters** are generally normal, although AP is sometimes increased; the serum value of AFP remains unchanged. The administration of oestrogen results in a subnormal γ -GT value. • **Sonography, CT and MRI** do not show any abnormalities, since the tissue is hepatogenic and thus somewhat hypoechoic or hypodense on a non-enhanced CT scan, but hyperdense in the arterial phase. In some cases, a space-occupying lesion is detectable. There may be evidence of circular vascularization, from which irregular vessels penetrate the adenoma. (16, 28, 32) (s. pp 142, 181) Hypervascularized adenomas can be seen in colour Doppler sonography (as well as in coeliacography or MR angiography). Differential diagnosis of haemangioma, HCC or metastases may be rendered more difficult by haemorrhages. • **Scintigraphy** using ^{99m}Tc sulphur colloid shows no activity enhancement. Functional scintigraphy reveals a normal flow and reduced or no enhancement in the parenchymal and excretory phases. • **Laparoscopy** facilitates a “split-second visual diagnosis”, with histological confirmation by forceps biopsy, if required. (s. tab. 36.3) (s. fig. 29.11!)

Complications: Intense pain may occur due to haemorrhage in the adenoma or haemorrhagic penetration of the neighbouring liver parenchyma. A rupture causes haemoperitoneum with symptoms typical of acute abdomen and circulatory shock. (s. fig. 36.1) • An association between

Fig. 36.1: Spontaneously ruptured hepatocellular adenoma in non-cirrhotic liver tissue (30-year-old woman, 15 year's use of oral contraceptives)

menstruation and adenoma rupture has been reported. The risk of bleeding is 30–40%. Malignant degeneration is a potential danger (approx. 10%). (24, 26, 31, 33) • *We can add one observation of our own regarding malignant degeneration.* (s. p. 563) (s. fig. 29.14!)

Prognosis: All in all, prognosis is relatively good. While some adenomas became smaller or even went into remission as soon as oral contraceptives were discontinued (19), there were other cases in which the tumour maintained its size or indeed continued to grow. Even after regression of the adenoma, there is always a danger of hepatocellular carcinoma developing. Systemic AA amyloidosis or paraneoplastic symptoms are rare complications. (22) Monitoring is effected by US or CT, as appropriate. Determination of hormone receptors could provide an additional prognostic criterion in the future. Alkaline phosphatase, γ -GT and ChE, for example, may serve as laboratory parameters.

Treatment: Imaging procedures cannot exclude the presence of malignant adenoma degeneration. This uncertainty, together with a high risk of haemorrhage and rupture, which increases with further growth of the tumour, provides the basic indication for enucleation or resection of the adenoma, particularly in the event of an unexpected trauma of the liver. Embolization prior to resection leads to a reduction in size of larger adenomas, thus giving better results. Surgery is indicated from the outset: (1.) when an already large adenoma (> 5 cm) is present at initial diagnosis, (2.) in pediculate tumours, (3.) in cases of proven haemorrhage or subcapsular haematoma, (4.) when there is an increased risk of abdominal trauma in everyday life, and (5.) prior to a planned pregnancy. • *As a rule, every resectable adenoma should be removed surgically.* (20, 23, 29, 31, 38, 40)

4.2 Focal nodular hyperplasia

Epidemiology and aetiology: Focal nodular hyperplasia (FNH) was first described by M. SIMMONDS in 1884. It is about twice as common as adenoma and is the second

most frequent type of benign liver tumour. Its incidence is 20 (–30)/100,000 inhabitants/year; in autopsy statistics, frequency is 0.3–8.0%. FNH has also been observed in children (53), as has the simultaneous occurrence of FNH and adenoma. Cigarette smoking is deemed to be a risk factor. FNH affects mainly women (80%); in some 60–70% of women, there is a connection with the long-term intake of oral contraceptives (48) and the Klinefelter syndrome. (56) When the contraceptives are discontinued, FNH (like adenoma) often goes into remission. A hyperplastic reaction to a pre-existing arterial malformation is thought to be one of the pathogenetic possibilities. This view is substantiated by evidence of other concomitant vascular abnormalities (e.g. haemangioma in 20–25% of cases, aneurysm, teleangiectasia) and malformations (e.g. brain tumour) or indeed the occurrence of FNH among family members. FNH is caused by increased arteriohepatic perfusion and additional local portovenous thrombosis, resulting in nodular hyperplasia of the hyperperfused parenchyma. (8, 49) In a recent study, increased values of the genes angiopoietin 1 and 2 have been reported. (51)

Morphology: FNH is usually solitary; multiple nodes of varying sizes (up to 20 cm) are only detected in about 20% of cases. (41, 55) FNH is present mainly in the right liver lobe (50–60%), in individual cases also as a pediculate tumour. There is generally no capsule. FNH has a firm consistency. In two thirds of cases, strikingly large arteries can be seen supplying the tumour. Tumours located close to the surface are reddish-brown to yellowish-brown in colour. (s. fig. 29.12!) • A **progressive type** of FNH is a rare variant; however, this type may recur following partial liver resection. (56) The **teleangiectatic type** of FNH displays a molecular pattern closer to that of adenomas than to FNA; therefore these atypical lesions should be referred to as “teleangiectatic hepatocellular adenomas”. (s. p. 776) (s. fig. 36.2)

► **Histology:** Hepatocytes are rich in glycogen. There is no lobular structure, since portal fields and central veins

Fig. 36.2: Focal nodular hyperplasia: sharply delineated, ochre-coloured, non-encapsulated, nodulated lesion with star-shaped radiating septa

are absent. But there are Kupffer cells and sinusoids with varying dilatations. Many bile-duct proliferations are found, e.g. within the connective tissue septa. These findings may lead to *misdiagnosing* “cholangiocarcinoma in cirrhosis”, since numerous, sometimes chaotic, blood vessels are present. Connective tissue bands originating from a *central scar* and directed towards the periphery contain biliary tract elements, arteries and veins, infiltrates and occasional epithelioid cell granulomas. Thick-walled blood vessels show mucoid media degenerations. These *hypervascular septa* cut off parenchymal areas of varying sizes and form pseudoacini. The result is a wheelspoke-like structure and the clinical picture of *pseudocirrhosis*. (36, 41, 42, 43, 49) (s. fig. 29.13!)

Diagnosis: When FNH reaches a certain size (7–10 cm or more), upper abdominal pain upon pressure, displacement effects and hepatomegaly occur, i.e. FNH remains asymptomatic for a long period of time. Laboratory parameters are normal. Cholestasis is a rare finding. • **Sonography** shows a hypoechoic image corresponding to that of the liver. (s. figs. 6.14; 36.3)

Fig. 36.3: Focal nodular hyperplasia (FNH). (There is also evidence of a small hyperechoic focal lesion, probably haemangioma)

It is often possible to identify a fibrous “*vascular star*” with vessels in a radial or circular arrangement similar to a “*wheelspoke pattern*”. This is clearly visualized by colour Doppler sonography. (s. fig. 36.4) (44, 45, 47, 57) CT usually shows a hypodense tumour with smooth boundaries and short, inhomogeneous, massive enhancement during the arterial phase (12–25 sec), with contrast adaptation to the neighbouring parenchyma occurring after 45–120 sec. There may also be signs of the central scar. Spiral CT increases diagnostic accuracy. (36, 37, 39, 58, 59) (s. fig. 36.5) • Following administration of Gd-DTPA, MRI yields similar results to CT. The

fibrous vascular star appears hyperdense (T_2). (44) • Because of the phagocytosis capacity of the RES, **scintigraphy** shows storage of colloids (in 70% of cases), whereby enhanced storage is seen as pathognomonic. Some 30% remain “cold” due to increasing weakness of the RES. Functional scintigraphy helps to detect hypervascularization as well as (mild to normal) enhancement during the parenchymal phase and retarded excretion (= trapping) as a result of rarefied bile ducts, showing that the remaining liver tissue has long been freed of ^{99m}Tc IDA (= afterstorage). Sensitivity is 87%, specificity is 100%. • **Angiography** displays early central hypervascularization with rapid centrifugal filling of the tortuous, wheelspoke-like arrangement of arteries and delayed venous visualization. • Clear differentiation, e.g.

Fig. 36.4: Colour-encoded Doppler sonography of FNH with wheelspoke pattern (s. fig. 6.14!)

Fig. 36.5: CT in the portal venous phase: FNH with star-shaped scar

from HCC, is often impossible with imaging procedures. An unclear diagnosis calls for **laparoscopy** (9, 10), (s. figs. 29.12, 29.13), possibly with refined forceps biopsy or fine-needle biopsy. (54) • Thick-needle biopsy is contraindicated due to the risk of bleeding (and because FNH does not require histological examination).

Complications: In 10% of cases, there is a potential risk of vein obstruction (52) or bleeding. Portal hypertension can develop, in some cases with pulmonary hypertension. Spontaneous regression has been reported. (50) • Malignant degeneration is extremely rare.

Treatment: Monitoring by imaging procedures suffices in the first instance. A marked increase in size and particularly haemorrhage or rupture are indications for embolization or surgery. (38, 40, 46)

4.3 Nodular regenerative hyperplasia

► The first description was given in 1953 by S. RANSTRÖM, who called this condition “miliary hepatocellular adenomatosis”. The term “nodular regenerative hyperplasia” was introduced by P.E. STEINER in 1959.

In nodular regenerative hyperplasia (NRH), the liver is interspersed with numerous diffuse nodes, which are 1–3 mm in size (occasionally up to 3 cm) and yellow to yellowish brown in colour with blurred boundaries; they consist of hyperplastic hepatocytes. No fibroses or perinodal connective tissue septa are evident. The multi-layered, disordered trabeculae do not have a lobular structure. (69, 72) CD 8⁺ cytotoxic T cells infiltrate the acinus. The nodes lack central veins and bile duct proliferations. The internodular parenchyma becomes atrophied due to pressure. It is possible with reticulin staining to show nodes containing irregular trabeculae, whereas the altered vessels are best seen using elastica staining. The liver surface is smooth. In the course of disease, presinusoidal, and later sinusoidal, portal hypertension with hepatosplenomegaly and oesophageal varices are usually observed. (67, 68, 70) (s. fig. 36.6)

Fig. 36.6: Macroregenerative nodes in liver cirrhosis with Budd-Chiari syndrome

Men and women are affected with the same frequency at almost any age. Familial forms have been described. (65) There is an association with polyarthritis, coeliac disease (60), PSC, PBC (63), sarcoidosis, Budd-Chiari syndrome (s. fig. 36.6), and collagenoses or myeloproliferative diseases. A connection with thorotrast (61), immunosuppressives, cytostatics and contraceptives or androgens as well as with antirheumatics, arsenic, vinyl chloride and the so-called “toxic oil syndrome” is also postulated. • As a pathogenetic factor, disturbance of the microcirculation is discussed: reduced blood perfusion can lead to atrophy of the ischaemic acini with subsequent stimulation of hyperperfused areas, resulting in nodular hyperplasia. (8, 43) • Occasionally, transaminases, AP and γ -GT are increased. Using sonography, it is possible to find an inhomogeneous reflex pattern in the case of larger nodules. CT may show hypodense lesions with peripheral-central enhancement of the contrast medium. Imaging techniques can misjudge the NRH as a micronodular cirrhosis. (64, 71) Diagnosis is confirmed by laparoscopy (62, 66) with forceps biopsy or two to three large biopsy specimens. (9, 10) • As a rule, NRH progresses slowly and has at least one stationary stage. However, ALF has been reported in four patients. • **Therapy** consists of treating portal hypertension (TIPS or surgical shunt); liver transplantation may be indicated. (67)

► **Partial nodular transformation:** This form is characterized by morphological changes similar to those observed in NRH, but with only partial liver involvement. (70) Formation of nodes is limited to the area where the larger vessels begin, i.e. perihilar region. The pale nodes can reach a size of up to 4 cm. Haemorrhage and necrosis may occur in larger nodes.

4.4 Haemangioma

Epidemiology and aetiology: F.TH. FRERICHS (s. fig. 1) described a haemangioma for the first time in 1861. • With a frequency of 2–8% and an incidence of 800/100,000 inhabitants/year, it is the most common benign tumour of the liver and is about 40 (–100) times more frequent than adenoma. It occurs in all ages, but is observed slightly more often in women than in men. There is no association with the intake of oestrogen or progesterone, although a higher frequency has been recorded in multiparous women. Puberty, pregnancy and oestrogens may cause an increase in tumour size. The aetiology is unknown. Haemangiomas have also been detected in children (85); this finding suggests that these tumours are true neoformations. There is no known malignant degenerative tendency. Haemangiomas may become thrombosed, fibrosed or calcified.

Histology: Due to vascular malformation, thin-walled spaces, which are filled with blood and lined with endothelium, develop; they are separated by septa. The blood is thrombosed or the thrombus becomes organized. The surrounding liver parenchyma is unchanged. (s. fig. 36.7)

Fig. 36.7: Cavernous haemangioma: thin-walled spaces lined with endothelium, partially septated, filled with blood. The surrounding parenchyma appears to be unchanged (HE)

Fig. 36.8: Grape-shaped, multi-chambered, livid bluish haemangioma (right liver lobe)

Fig. 36.9: Giant (larger than a fist) cavernous haemangioma with a smooth surface in the left liver lobe. Numerous blood vessels and peliosis-like livid blue foci of up to 0.5 cm in size in the capsule area

Morphology: Haemangiomas appear in solitary or (in some 20–30% of cases) multiple form. (87) They are usually located beneath the liver capsule and are clearly differentiated from the parenchyma by a pseudocapsule. Their usual size is 1–4 cm and they are found in both liver lobes, apparently with a higher frequency in the left lobe. It is worth mentioning that the haemangiomas situated in the right lobe are predominantly found in the usual percutaneous biopsy area (which needs to be taken into account in prepuncture sonography). Haemangiomas continue to grow due to enlargement of the respective cavernous spaces. *Laparoscopically*, haemangiomas appear as bluish red or crimson red structures, sometimes tuberous, usually protruding slightly beyond the liver capsule; a multi-chambered structure is visible in most cases. (s. fig. 36.8, 36.9) • More rarely (about 7%), voluminous tumours, which may spread over the whole liver lobe, develop (= *giant haemangioma*, with a size of > 10 cm). (76, 77, 81, 86, 88, 89, 94) Up to now, only about 20 cases involving *giant pedunculated forms* have been observed.

Diagnosis: Haemangiomas are usually asymptomatic and, as a rule, discovered incidentally. Having reached a particular size, however, they may cause upper abdominal pain, nausea and inappetence. Acute pain results from bleeding in the tumour, thrombosis or rupture. Palpation may suggest hepatomegaly or an unusual kind of resistance. • Laboratory values are within the normal range. Thrombopenia and/or a reduction in fibrinogen may be present in thrombosis. (79, 84, 90, 97)

Sonography shows a hyperechoic structure (60–70%) with smooth boundaries, but no hypoechoic margin or sound shadow (= *white tumour*). There may be an efferent and an afferent vessel. As the size of the haemangioma increases, thrombosis develops, while connective tissue organisation and regressive liquefaction become evident. Inhomogeneous and irregular internal structures result from this, making diagnostic classification difficult. Sensitivity is about 80%. (78, 79, 83, 96, 98) (s. fig. 6.15) • **Computer tomography** shows a hypodense tumour. After intravenous bolus contrast-medium injection, enhancement increases in a peripheral-central direction followed by a focal globular contrast and subsequently a rapid reduction of the contrast-rich zone ("*iris diaphragm phenomenon*"); this occurs in ca. 60% of cases. The haemangioma becomes isodense with the liver parenchyma. The isodense phase may last up to 90 minutes. The sensitivity of this examination is about 90%. (93) (s. figs. 8.5, 8.9) • **MRI** displays a low-signal T₁ time and pronounced hyperintensity in the T₂-weighted picture with well-defined margins, which means that even haemangiomas smaller than 1.0 cm can be detected. The "*cotton wool sign*" is followed by the "*light bulb sign*". The heterogeneous structure points to thrombosis, fibrosis, etc. Both the specificity and sensitivity of MRI are 85–95%. (75, 98) (s. figs. 8.7; 36.10 a–c) • In the blood pool scintigram (Tc^{99m}-

Fig. 36.10: a) Adenoma (↑), (not visible) haemangioma (the same female patient as in b and c)

b) Haemangioma (⇓) in MRI: T₁-weighted axial (portovenous) ("cotton wool sign") (the same female patient as in a and c)

c) Haemangioma (⇓): T₂-weighted ("light bulb sign"), with fat suppression (the same female patient as in a and b)

marked autologous erythrocytes), **scintigraphy** shows the pathognomonically useful filling-in phenomenon. Activity enhancement increases from the periphery towards the centre and is detectable for several hours. By contrast, the haemangioma remains negative both in static and liver-function scintigraphy; this is because the haemangioma has neither hepatocytes nor RES cells. (73, 75, 83, 89) • **Fine-needle biopsy** (82) is occasionally favoured. *We consider percutaneous biopsy, particularly thick-needle biopsy, to be contraindicated because of the risk of bleeding (it is indeed of little help from a diagnostic viewpoint, since better diagnostic tools are available); we also feel that there is no justification in using exploratory laparotomy for diagnostic purposes.* • In order to obtain a definitive diagnosis, **exploratory laparoscopy** is the method of choice, since haemangiomas are usually situated in the subcapsular area, which means that a "split-second visual diagnosis" is possible ("one-second biopsy" is not indicated!). (9, 10) (s. figs. 36.5, 36.6)

Complications: Blunt abdominal trauma increases the risk of rupture, which can also occur spontaneously. The mortality rate is 60–80%. (74) Large shunt volumes may give rise to the development of cardiac insufficiency, particularly during childhood. The development of portal hypertension has also been observed. (97) Anaemia, thrombopenia and hypofibrinogenaemia may occur due to the haemangioma-thrombocytopeny syndrome (= *Kasabach-Merritt syndrome*). (86)

Treatment: A ruptured haemangioma requires immediate surgical intervention; it is often necessary to ligate the hepatic artery. Enucleation is sometimes possible. (80, 90) Resection or arterial embolization are recommended for very large and symptomatic haemangiomas. Inoperable tumours should be reduced in size by external irradiation or interferon- α therapy. Liver transplantation is a rare indication. (91, 92, 95) • All in all, prognosis is good. (97)

4.5 Infantile haemangioendothelioma

This benign infantile tumour is of embryonic origin and usually diagnosed within the first months of life, whereby girls are twice as often affected as boys. In most cases, capillary haemangiomas of the skin and mucosa as well as of other organs are also in evidence. Cardiac and vascular malformations are often found.

Morphology: Haemangioendotheliomas appear in solitary or (seldom) multiple form and may reach a size of some 15 cm. The unencapsulated tumour foci have blurred boundaries. They are sponge-like and reddish brown in colour, but may become firm and grey in bigger tumours. Vascular segments of differing width are connected with each other and embedded in loose, cell-rich mesenchyma. • Two **histological types** can be differentiated: *type I* is characterized by a layer of cuboid

endothelial cells, while *type II* shows papillary proliferations and several layers of pleomorphic cells (which are similar to those found in angiosarcoma). Malignant degeneration of the haemangioendothelioma is possible.

Diagnosis: Hepatomegaly and an occasional systolic vascular murmur above the tumour are clinically detectable. Patients suffer from anorexia, vomiting, weight loss and lethargy. Laboratory investigation often reveals thrombopenia, haemolytic jaundice and anaemia. Disseminated intravascular coagulopathy (= *Kasabach-Merrit syndrome*) can occur. Signs of cardiac insufficiency are present at an early stage due to arteriovenous shunts with cardiac volume overload. Acute pain is a sign of haemorrhage in the tumour or of a ruptured tumour. Diagnosis is established by imaging techniques; angiography has been widely replaced by colour Doppler sonography or angio-MR. Occasionally, laparoscopy has also been used. (99–105)

Treatment: If it is possible, elective resection is indicated. (103) However, due to cardiac or (increasing) hepatic insufficiency, invasive techniques cannot usually be attempted. External irradiation may be used in an effort to minimize the tumour. Ligature or embolization of the afferent hepatic artery is sometimes indicated. Steroid therapy has proved unsuccessful. The use of interferon- α is a new therapeutic approach: tumour regression is accelerated and cardiac insufficiency is compensated. (106) Liver transplantations have also been carried out successfully. This infantile, benign tumour may regress with increasing age.

4.6 Fat-containing tumours

4.6.1 Focal fatty changes

Circumscribed fatty foci (“yellow spots”) were seen relatively often during laparoscopy in the past. (13) We ourselves also observed them on many occasions. (s. fig. 31.6) • Sonography and CT have shown these rare benign foci to be more frequent than previously supposed. They may occur in focal or segmental form. (s. figs. 8.3, 8.4)

4.6.2 Lipoma

Hepatic lipoma is very rare. Research of the literature shows that S. YOUNG was the first to publish a documented observation of this tumour in 1951. Although lipomas grow slowly, they may reach a considerable size. They consist of fatty tissue (adipocytes) with a lobular structure; according to (rare) observations made to date, there is no capsule. The lipoma is hyperechoic, which usually makes it easily identifiable by sonography and CT. There is no evidence of vascularization and no tendency towards malignant degeneration. Larger lipomas should be removed surgically, particularly when they have become symptomatic. (107, 108)

4.6.3 Myelolipoma

This rare type of mesenchymal tumour, which contains adipocytes and blood-forming tissue, can grow to an enormous size (e.g. 26 x 16 x 12 cm). When reaching a certain diameter in a specific location, it usually becomes symptomatic. It has a yellowish colour and contains fatty tissue as well as myeloid elements. Due to its echogenicity, the presence of this benign focus can be demonstrated by sonography and CT. Angiography shows a tumour that is usually avascular. Large or symptomatic tumours require surgical treatment. • Definitive diagnosis of these forms of fat-containing tumours is provided by biopsy, with thick-needle biopsy being the most reliable technique. (109, 110)

4.6.4 Angiolipoma

This benign mesenchymal tumour consists of fatty cells and numerous blood vessels, which have a tendency to thrombose. In general, angiolipomas occur singly in both liver lobes.

4.6.5 Angiomyolipoma

The first observation of an angiomyolipoma was reported by K.G. ISHAK in 1976. Up to now, about 100 cases have been published. Owing to its fat content, this benign tumour has a yellowish-red colour. The largest tumour reported to date was 36 cm in diameter. Women are mainly affected. (120, 122) The right liver lobe is the preferred location. Fatty cells, blood vessels and smooth muscle cells can be demonstrated histologically. (126) The vessels may be thick-walled and are usually arranged in an island-like configuration. The tumour appears as a hyperechoic focus in sonography and as a hypodense focus in CT and MRI. (111, 121, 124, 127, 129) Hypervascularity is observed in arteriography. Multiple angiomyolipomas have been reported (125), occasionally also in kidneys and lungs. (116) The occurrence of spontaneous rupture (118) or disseminated intravascular coagulopathy was reported as a rare complication. Due to their vascular richness, diagnostic evidence of angiolipomas and angiomyolipomas should be obtained by fine-needle biopsy (114, 121), possibly together with immunohistochemistry. Malignant degeneration has not been observed. (112, 113, 115–117, 119, 123, 128)

4.7 Chondroma

To date, there has only been one single observation of a chondroma in the liver. (130) This tumour was excessively large (19 x 15 x 9.5 cm); it was hypervascularized, had a multilobular structure and did not possess a capsule. Focal calcifications were detectable. Chondrocyte-like cells and a chondroid matrix were found. Such a tumour can be visualized by imaging procedures. Laparoscopically, a hard, nodular surface is detectable. Diagnosis can only be confirmed histologically.

4.8 Leiomyoma

Up to now, only very few cases have been described. These tumours also become symptomatic once they have acquired a certain size and may grow to excessive proportions in the liver (e.g. 19.5 x 12 x 12 cm). (131)

4.9 Schwannoma

Schwannoma (neurinoma) is a benign tumour originating from Schwann cells. It is very rare. (132) Recently, a schwannoma of the bile duct causing obstructive jaundice was reported. (133)

4.10 Glomangioma

Glomus organs are small a.v. anastomoses for thermoregulation of the extremities. Glomangiomas are therefore most frequently located in the toes and fingers. However, they are also found in the respiratory, gastrointestinal and genital organs. A glomangioma was recently reported for the first time as a benign solitary tumour in the liver. This smooth, well-defined subcapsular lesion could be clarified histologically with the help of imaging-guided biopsy and later on confirmed by evaluation of the surgically excised tumour. (134) Malignant transformation of glomangioma is possible.

4.11 Mesenchymal hamartoma

► R. MARESCH described hamartoma as a cystic tumour structure in 1903; it was termed mesenchymal hamartoma by H.A. EDMONDSON in 1956.

This benign tumour is caused by faulty tissue composition of certain organs, including the liver. The tumour is mostly found in the right liver lobe; it grows rapidly and progressively. This type of cystic tumour is mainly observed within the first year of life. Boys are more often affected than girls. In adults, mesenchymal hamartoma is very rare. Pre-existing composition disorders of the liver tissue can be stimulated into growth by steroids. Hamartomas remain asymptomatic until attainment of a certain size results in compressional or displacement phenomena. In their interior, they contain cysts filled with a yellowish, gelatinous substance. The stroma presumably derives from the connective tissue of the portal fields, from which the hamartoma may also originate. Malignant degeneration has been reported. Due to its tendency to grow, early surgical removal of the tumour is indicated. (135–137)

4.12 Mesothelioma

Mesotheliomas of the liver are extremely rare. They consist of parallel bundles of collagenous and reticular fibres as well as fibroplastic and epithelial cells. (138)

The reported observation of a hepatic mesothelioma weighing some 2,800 g remains a rarity. (139)

4.13 Fibrous tumour

A solitary fibrous tumour was first described in pleural tissue by P. KLEMPERER et al. in 1931. Meanwhile, this rare entity has been reported in various organs, with the liver being affected in 26 cases. The tumour shows cellular areas (consisting of bundles of spindle cells arrayed haphazardly or in a storiform pattern) and relatively acellular areas (containing abundant collagen bundles). There is evidence of cellular atypia, mitotic activity and ectatic vessels. This tumour possesses malignant potential with the ability to metastasize. (140)

4.14 Cysts

Liver cysts can occur in solitary or in multiple form. They may be congenital or acquired. The reported frequency varies between 1% and 20%. The cysts are lined with a layer of cuboid cells and mostly filled with fluid. They are usually detected by chance. When cysts compress bile ducts or vessels, they become symptomatic. (142) • In *sonography*, the cyst appears as an anechoic (black) space with well-defined margins and distal sound amplification. (s. fig. 6.10) Haemorrhage into the cyst cavity and debris can mimic a cystadenoma or even cystadenocarcinoma. The presence of septa suggests a neoplastic cyst. (142) • In *computer tomography*, their content can generally be determined at +0 to +15 Hounsfield units. The i.v. administration of a contrast medium shows no evidence of enhancement. (s. figs. 8.6; 36.11) • Cysts are easily detected by *magnetic resonance imaging* (T_1 image = dark; T_2 image = light with high signal intensity). *Laparoscopy* provides a very impressive view of cysts. (s. figs. 36.12, 36.13)

Fig. 36.11: CT with contrast medium: solitary liver cyst. (s. fig. 8.6)

Fig. 36.12: Multiple cysts with several chambers in the area of the right liver lobe

Fig. 36.13: Giant (fist-sized) solitary cyst in the right liver lobe

Four **types of cysts** can be differentiated: (1.) dysontogenetic cysts, (2.) parasitic (or infectious) cysts, (3.) neoplastic cysts, and (4.) post-traumatic cysts. The cause of cystic neoplasms is unknown. Traumatic cysts (C. WHIPPLE, 1898) occur from an injured intrahepatic bile duct after blunt abdominal trauma. (142)

Treatment: *Asymptomatic cysts* do not require treatment; large cysts which might rupture are an exception. • *Symptomatic cysts* (usually > 5 cm) are generally sclerosed. Reliable sclerotherapeutic agents include aethoxysclerol (1%), alcohol (95%) (153), minocycline hydrochloride (141, 156), tetracycline hydrochloride (1 g), and sodium chloride solution (10%). The sclerosing procedure is successful and low in side effects. Percutaneous aspiration of the cysts has a high relapse rate. Sclerotherapy does not prevent relapse, since a sclerotherapeutic agent destroys the cells, but not the cyst walls. Parasitic cysts require specific therapeutic measures. • Under laparoscopy, cysts which prove to be problematic may be treated reliably by fenestration (T.Y. LIN et al., 1968).

Surgical procedures (e.g. cyst excision, resection, cystjejunostomy, cystenterostomy) are rarely indicated and involve a much higher risk. (142, 148, 155)

4.14.1 Polycystic liver disease

The incidence is 1:500 to 1:5,000 births/100,000/per year. The gene responsible is located on chromosome 16; often another gene located on chromosome 4 is also involved. This autosomal dominant polycystic disease of the liver and kidneys can occur in (1.) children and (2.) adults (σ : ♀ = 1:5). The intrahepatic bile ducts are widely dilated and lined with bile-duct epithelium. Each liver segment may be interspersed by cysts of varying sizes which are connected with the biliary duct system. The cysts are surrounded by a fibrous capsule. Both the number and size of the cysts increase in later life. Usually, polycystic degeneration of the kidneys also occurs. (142) (s. fig. 8.6) Pancreatic cysts or colonic diverticulosis are less frequent. Occasionally, the cysts cover the liver in a balloon-like manner. (s. fig. 36.14) Rupture of large cysts may give rise to the clinical picture of acute abdomen. Compression leads to portal hypertension, jaundice (145), cholestasis and leg oedema. • Renal insufficiency is also a dangerous complication.

Fig. 36.14: Polycystic liver with spheroid, balloon-like cysts in the right liver lobe

Treatment may be by laparoscopic or surgical fenestration (143, 144–147, 149–152), injection of alcohol (40%) (153) or minocycline hydrochloride (141, 156), as well as surgical management. (148) Liver transplantation is a rare indication. (154)

4.14.2 Parasitic cysts

The cysts of *Echinococcus granulosus* (cysticus) (s. figs. 25.16, 25.17, 25.19) and *Echinococcus multilocularis* (alveolaris) (s. fig. 25.21) are of particular clinical importance. (see chapter 25.2.3)

4.15 Cholangiocellular tumours

4.15.1 Caroli's disease/syndrome

► This congenital clinical picture was first described in the form of intrahepatic stones by H.R. VACHELL et al. in 1906. • Later on, in 1958, J. CAROLI et al. were able to establish an association between characteristic congenital bile-duct alterations, cholangitis, cholangiolithiasis and renal cyst formation. In 1964 J. CAROLI et al. differentiated a particular form with simultaneous congenital liver fibrosis (which had already been described by D.V.S. KERR et al. in 1961). Both forms are autosomal recessive.

Caroli's disease is characterized by congenital, segmental dilatation of the intrahepatic bile ducts, causing bile sludge formation and the development of gallstones. Clinical findings include hepatomegaly, cholestasis and subicterus as well as cholangitis with upper abdominal pain and biochemical signs of inflammation. (158, 160) (s. tab. 38.2) Diagnosis is by CT (157, 159) (s. pp 182, 696), Doppler sonography (159) and ERC. (s. fig. 36.15)

Fig. 36.15: ERC findings in Caroli's disease: mainly segmental, sack-like dilatations of the intrahepatic bile ducts with some small-diameter connections to the efferent bile ducts

Caroli's syndrome is additionally characterized by congenital liver fibrosis. (s. p. 697) There may be fibroangiomas of the bile ducts and microcysts in the kidneys. The condition can lead to portal (presinusoidal) hypertension. • Choledochal cysts, polycystic degeneration of the liver and kidneys, Laurence-Moon-Biedl syndrome and ectasia of the renal tubules may all appear. • Apart from cholangitis and hepatolithiasis, potential complications include liver abscess, pancreatitis, amyloidosis, malignant tumours and liver failure. • *Treatment* consists of biliary drainage, antibiotics, surgical procedures and liver transplantation. Ursodeoxycholic acid may be used as an adjuvant.

4.15.2 Hepatobiliary cystadenoma

This rare benign tumour probably develops from congenital bile-duct malformations. It is found mostly in

women (>90%), mainly after the age of 45–50 years. The tumour grows very slowly, yet can reach a considerable size (5–25 cm). Cystadenomas occur as solitary, but multilobular cystic tumours. The cysts are frequently separated by septa. The *mucous type* consists of a mucous/gelatinous, bile-coloured fluid, often containing old blood. Occasionally, a *serous type* of cystadenoma without mesenchymal stroma is found. There is evidence of ovary-like stroma together with unilaminar bile epithelium, which is folded in a polyploid or papillary manner in places. (161) (s. fig. 36.16) The collagenic capsule is rich in vessels. Surrounding the tumour, numerous abnormal bile ducts and arterial vascular clusters are evident. • Cholestasis or even obstructive jaundice develops. (162) Diagnosis of this cystic lesion (mainly in the right lobe) is by imaging techniques. Differential diagnosis may be extremely difficult (and is often only possible by means of surgery). • Due to the tendency of cystadenoma towards malignant degeneration, resection should be carried out as soon as possible. (163–167)

Fig. 36.16: Hepatobiliary cystadenoma with ovary-like stroma (HE)

4.15.3 Bile-duct adenomas

Bile-duct adenomas are rare. Usually, they are solitary and <2 cm in size. This type of adenoma is more often detected in men than in women (3:1), and it occurs in patients mainly over the age of 50. It is nearly always localized beneath the liver capsule. Sonography shows roundish, hypoechoic foci of different sizes with relatively unclear contours (s. fig. 36.17). They are visible in MRT as hypotense (T_1 -weighted) lesions (s. fig. 36.18). Imaging procedures do not reveal any characteristic features. With the help of laparoscopic examination, roundish, greyish-white, well-defined foci are visible. The lesions cause slight bulging on the liver surface. The surrounding tissue is unchanged and without vascularization. The biopsy material taken from the foci turned out to be crumbly (!). (s. fig. 36.19) This adenoma has the form of a firm, whitish or whitish-grey node and consists of bile-duct proliferations. It contains biliary acini and tubules which are lined with a layer of cuboid epithelium within loose fibrous, partially hyaline stroma.

Fig. 36.17: Several roundish, hypoechoic foci of different sizes with relatively blurred contours. Unclear aetiology. (50-year-old man; the same patient as in figures 36.18–36.21)

Fig. 36.18: Axial T₁-weighted MRT showing at least three hypointense roundish foci with slightly hazy edges in the right liver lobe. One focal lesions is subcapsular, causing minimal bulging on the surface. There are no signs of any radiological features which might facilitate a diagnosis

Fig. 36.19: Diffusely disseminated greyish-white foci of different sizes in both liver lobes with relatively sharp contours. The liver surface shows slight bulging (about 1–2 mm), but no central dipping; no vascularisation is visible. The perifocal tissue is unchanged

There is evidence of mononuclear inflammatory cells and, occasionally, lymph follicles. (s. figs. 36.20, 36.21) • It is discussed that such biliary adenomas are peribiliary gland hamartomas. (169) There are no clinical or biochemical abnormalities, nor is there any tendency towards malignant degeneration. (168, 170)

Fig. 36.20: Bile-duct adenoma in subcapsular liver tissue (HE)

Fig. 36.21: Bile-duct adenoma composed of small tubules, which are lined by a single layer of slightly irregular epithelial cells. The ducts are embedded in a dense collagenous stroma (HE)

4.15.4 Bile-duct papillomatosis

Bile-duct papillomatosis is a very rare finding (up to now about 50 cases have been reported) which occurs mainly in elderly women. There are papillomatous proliferations in both intrahepatic and extrahepatic bile ducts. Clinically, it is characterized by recurrent epi-

sodes of jaundice and cholestasis as well as ascending cholangitis and haemobilia. The bile ducts can be dilated; their wall surface is irregular. The course is progredient; the prognosis is poor. (173) Recently, encouraging results have been reported following intraluminal iridium¹⁹² therapy (172) and liver transplantation (171). Malignant degeneration into cholangiocarcinoma is possible.

4.15.5 Biliary hamartoma

Benign biliary microhamartomas (= *Meyenburg's complex*) were described by H. VON MEYENBURG in 1918. (s. p. 698 and fig. 33.20) They consist of small cysts developing from dilatations of the small (interlobular) bile ducts and are surrounded by fibrous stroma. The cysts are remnants of ductal plate malformations. Sometimes typical ductal plates are also detected. The hamartomas can reach a diameter of up to 0.5 (–1.0) cm. Macroscopically, they appear as firm, greyish-white nodules which are clearly delineated from the liver parenchyma. Subcapsular nodules may also be detected by laparoscopy. (176) They are sometimes misinterpreted as small metastases. Here, MRI is of great diagnostic value. (175)

- Microhamartomas are often associated with malformations of the small branches of the portal veins. They may represent a transition to the autosomal dominant form of polycystic degeneration. These tumours have a tendency to develop into cholangiocarcinoma. (174–177)

4.16 Abscesses

Depending on their cause, liver abscesses are classified as (1.) pyogenic or (2.) parasitic. This factor largely determines differential diagnosis, diagnosis and therapy. Fresh abscesses usually have blurred margins; following consolidation, they have a round to elliptical form. Evidence of gas bubbles is seen as pathognomonic. The abscesses are generally hypoechoic and hypodense. (*see chapter 27!*)

4.17 Hepatic lymphangioma

This rare, congenital benign tumour consists of multiple, small (1–4 mm in diameter) dilations of intrahepatic lymph vessels, which communicate with each other. They contain chylous fluid. Mostly, there are lymphangiomas in other organs as well. (178)

4.18 Peliosis hepatis

Peliosis hepatis may be caused by various kinds of medication (181) or chemical agents and is associated with numerous diseases (of a viral, bacterial, parasitic or metabolic nature). Its aetiopathogenesis is unknown. It has also been detected in small children. (180, 182) *Histologically*, there are spaces lined with endothelium corresponding to dilated sinusoids and Disse's spaces. They are filled with blood (= "globoid bleeding"). Their size varies from

Fig. 36.22: Hepatic peliosis composed of a network of dark-blue to livid-reddish vessels below a yellowish-red surface of a fatty liver

0.5–2.0 mm and can even reach >1 cm. The hepatocytes and venules are unchanged. (s. p. 404!) (s. figs. 21.8; 36.22)

Clinical findings include fever, abdominal pain and hepatomegaly. *Laboratory values* reveal occasional subicterus and elevated transaminases. (180) *Imaging procedures* often yield no findings or merely uncharacteristic changes. (179) Definitive results are obtained by *laparoscopy* (183): characteristic foci of a livid-reddish to dark-blue colour are found, mostly rounded and subcapsular, often with net-like confluence (s. fig. 36.23). The findings are so typical and distinctive that histological examination is no longer necessary; however, biopsy may be justified under visual control. The most important *complications* are haemorrhages and, especially following trauma, rupture of the liver capsule with bleeding into the abdominal cavity. (180, 181)

Fig. 36.23: Peliosis hepatis: non-endothelialized cavernous blood-filled cavities surrounded by hepatocellular trabeculae (HE)

4.19 Granulomas

It is generally not possible to detect granulomas using imaging procedures. When the foci are densely grouped, it is possible to see an inhomogeneous reflex pattern during sonography and a variable pattern in the CT scan. The

causes are manifold and vary greatly. (s. tab. 21.1) • Diagnosis is facilitated by laparoscopy and forceps biopsy, provided the foci are located on the surface (which is mostly the case). If the surface is free of foci, multiple biopsies from both liver lobes done under laparoscopy yield reliable results. (s. p. 405) (s. figs. 21.9, 21.10; 24.14; 29.6; 38.5)

4.19.1 Sarcoidosis

► A cutaneous form of sarcoidosis (“Mortimer’s disease”), first described by A. HUTCHINSON in 1877, was observed in further courses of disease by E. BESNIER (“lupus pernio”) and C.P. MOELLER-BOECK (“sarcoidosis”, “miliary lupoid”) in 1899. In 1917 these single findings were synthesized by J. SCHAUMANN. Various terms, such as Besnier-Boeck-Schaumann disease, benign lymphogranulomatosis or Boeck’s disease, have been used in the past to describe this condition. However, the term sarcoidosis has gained more and more acceptance.

Definition

Sarcoidosis is a primary multisystemic, granulomatous disease of (still) unknown aetiology with enhanced immunity at the site of manifestation. The lungs and the intrathoracic lymph nodes are nearly always affected. In many cases, the extrathoracic organs are involved as well. Sarcoidosis is characterized by the presence of epithelioid cell granulomas, which do not show caseous changes.

► Since 1964, our study group, consisting of L. MANDI et al. (Debrecen/Hungary) and E. KUNTZ, has been intensively involved in investigating the striking regional differences in sarcoidosis. We postulated an **immune reaction** – with a *genetic disposition* – against a **mycobacterial substrate**. • Among other things, we found **Ziehl-Neelsen positivity** of pollen obtained from numerous trees and plants. A high correspondence of sarcoidosis frequency with certain ZN-positive pollen locations became obvious as we catalogued our findings. This might also explain familial aggregation as a result of similar exogenous exposure. • **Injection** of ZN-positive pollen, embedded in paraffin, into the testicles of guinea pigs resulted in the *dissemination* of histological findings fully corresponding to sarcoidosis. By contrast, ZN-negative pollen did not elicit this reaction in animal experiments.

Frequency: Men and women are affected with the same frequency. Manifestation mainly occurs between the ages of 20 to 40, predominantly in winter. The incidence is highest in Scandinavian countries, the USA and Japan (always with considerable regional variations) at 5–40/100,000 inhabitants/year.

Localization: Based on X-ray findings, *intrathoracic sarcoidosis* can be divided into four stages: 0, I–III. • The *extrathoracic manifestation* of sarcoidosis affects the lymphatic system, bone marrow, bones, skin, eyes, lacrimal and salivary glands, urogenital system, musculature,

nervous system and endocrine glands. Extrathoracic manifestations without thoracic findings are rare. At least two organs must exhibit granulomas to substantiate the diagnosis of sarcoidosis.

Aetiopathogenesis: Development of sarcoidosis has been observed during treatment with *interferon- α* . (187) • Mycobacteria were also seen as a possible cause of sarcoidosis, which was recently reinforced when *mycobacterial DNA* and *RNA* were found in sarcoidosis tissue (H. H. POPPER et al., 1994) and the presence of *acid-fast L forms* was detected in patients’ blood (P. L. ALMENOFF et al., 1996).

Liver: The liver is involved in sarcoidosis in 60–80% of cases. Initially, loosely concentrated *epithelioid cells* are found which combine to form small *epithelioid granulomas* mainly in the portal and periportal area. These small granulomas may join together and form conglomerates up to the size of lentils. Within the epithelioid cell granulomas, there is evidence of one or more *Langhans’ giant cells*, which are rich in the angiotensin-converting enzyme. Epithelioid cells and giant cells release α_1 -antitrypsin and lysozymes as well as other substances; epithelioid cells also release interleukin-I. Within the giant cells (displaying a rosette-like arrangement of nuclei), *asteroid bodies* (5–20 μm) resembling a sea anemone are often found. Moreover, there is evidence of *Schaumann bodies* (25–200 μm) (more frequently in lymph nodes than in the liver) and small *vesicles*. • Inflammatory *cellulation* is low: it consists of eosinophils, T lymphocytes (CD4⁺) and plasma cells. Granulomas may increase in size, but may also heal by way of fibrosis. (190) • Chronic cholestasis (ductopenia, cholate stasis, copper storage) as well as the histological picture of PBC (or less frequently of PSC) can be found in 50–60% of cases. (quot: 188) • *This would suggest a connection with the mycotoxin theory of PBC (E. KUNTZ, 1984), whereby molecular mimicry (M. E. GERSHWIN, 1991) is of potentially pathogenetic significance in sarcoidosis as well.* (s. p. 676) • Pronounced fibrosis leads to *portal hypertension*. Formation of *NRH* was evident in 9% and *cirrhosis* in 6% of cases.

Clinical findings: Usually, there are no subjective complaints. As the lungs become increasingly affected, fatigue and (exercise-related) dyspnoea may occur. Extrathoracic manifestations can cause corresponding symptoms. Hepato(spleno)megaly is observed in 5–10% of cases. In an acute stage, polyarthralgia, erythema nodosum and fever are generally found. Kveim’s test is positive, while the BCG test is clearly reduced or negative. (184–186, 189–191)

Biochemistry: In most cases, eosinophilia and monocytosis are present in leukopenia and lymphopenia. BSR and CRP are normal or only slightly elevated. The γ -globulins may be increased. Cholestasis is often found, whereas jaundice is rare. Hypercalcaemia is a striking feature; occasionally there is evidence of augmented ACE and lysozymes in the serum.

Histology: The best method of obtaining the prominent, whitish granulomas on the liver surface, the size of a pin-head up to a lentil (= *fly agaric liver*), is by *laparoscopy* and *forceps biopsy*; otherwise, *thick-needle biopsies* can be performed on suspicious areas of the right and left liver lobe. The diagnostic accuracy of this procedure is more than 98%, while that of percutaneous liver biopsy is 30–70%. (s. figs. 21.9, 21.10) (s. pp 405, 486, 561) • *Bronchoscopy* used for taking mucosa samples also facilitates histological diagnosis.

Imaging procedures: Enlargement of abdominal lymph nodes can occasionally be detected by sonography, CT or MRI. (185, 189) The liver may exhibit an inhomogeneous reflex pattern due to fibrosis.

Treatment: Intrathoracic sarcoidosis has a high rate of spontaneous remission with possible fibrosis residues. • Extrathoracic manifestations may cause considerable symptoms and secondary disorders, depending on the organs affected. This is also true of the liver. Treatment consists of monitored waiting and administration of glucocorticoids (usually as long-term therapy). Liver transplantation is necessary in some cases.

4.20 Inflammatory pseudotumour

The synonyms used for inflammatory pseudotumour include myofibroblastic inflammatory tumour, histiocytoma, pseudolymphoma, fibroxanthoma and plasma cell granuloma. This condition was first described by G. T. PACK et al. in 1953. It is a rare type of tumour (about 100 reports so far) which can occur at any age (but mainly between 30 and 40), with men being affected three times more often than women. The tumour mostly affects the liver (90%), but also numerous other organs (lung, stomach, parotis, pleura, ovaries, thyroid gland, lacrimal glands, etc.). A tumour size of up to 25 cm has been reported. Its pathogenesis is not clear. (192) Bacterial and viral infections (e.g. EBV) are possible trigger factors. An association with systemic inflammatory diseases, e.g. Crohn's disease (194), has been reported.

Histology: There are obvious fusiform cells, foamy histiocytes, plasma cells and lymphocytes, but no irregular mitosis. Extensive connective tissue may form incomplete capsular boundaries. The pseudotumour is vascularized despite the presence of numerous obliterated vessels. (196) The bile ducts exhibit inflammatory alterations. Fatty degeneration and occasional central necrosis as well as bleeding are evident. This gives rise to simulated HCC. Malignant degeneration is rare. (195) • The main symptoms include fever, epigastric pain, weight loss, elevated transaminases, inflammatory laboratory parameters, cholestasis and increased gamma globulins. (193, 196–198) Sonographically, a hypoechoic space-occupying lesion can be seen. In CT, the tumour is hypodense with a blurred margin; following CM application, it shows mild, heterogeneous and delayed

enhancement. MRI displays low signal intensity in T₁ images and significant signal enhancement in T₂ images. A thick hyperintensive periphery may be present.

Treatment: Spontaneous regression is rare. The administration of prednisolone and antibiotics has been used with controversial results. In general, there is an indication for surgical resection, which is deemed a successful method of treatment.

4.21 Erdheim-Chester disease

This condition is a rare form of non-Langerhans histiocytosis. The foamy histiocytes are lipid-laden and affect the lower extremities, lungs and kidneys, causing progressive disseminated, granulomatous lesions. In a first report of biliary manifestation of ECD, these granulomatous lesions were embedded in extended periductular fibrosis. A remarkable cholestasis was found with moderate increase of the transaminases. (199)

4.22 Calcareous foci

Calcareous foci in the liver are detected incidentally in X-ray or sonographic examination of the abdomen. It may be quite difficult to identify their aetiology, since calcification can be observed in numerous diseases. Diagnostic clarification often has no prognostic or therapeutic implications. However, in many cases, the irrelevance of such a diagnosis can only be determined retrospectively after numerous examinations (imaging procedures, laparoscopy with targeted biopsy) have been

| Calcification of benign lesions |
|---|

| – ovarian cystadenocarcinoma |
| – gastric or colon carcinoma |
| Porcelain liver |

Tab. 36.4: Calcification of benign and malignant liver foci

carried out. (202, 204) Different calcified foci, such as calcified vipoma (201), calcified metastasis (s. figs. 37.24, 37.25), microlithiasis in cystic fibrosis (203) or calcification of the hepatic artery (205), are rare observations. Calcification of an echinococcus cyst is the most common type of calcareous focus. (s. fig. 25.18) (s. tab. 36.4)

A so-called **porcelain liver** should be clarified by differential diagnosis. (200) This condition is characterized by focal calcareous deposits in the liver capsule, which can be detected by X-ray examination as well as by sonography and CT. It may be caused by phleboliths, pseudolipoma, histoplasmosis, calcified larvae, small capsule haematomas, small abscesses, etc.

► A case involving an **unusual calcification of tremendous size** in the right liver lobe was the subject of much speculation. It was not until laparotomy was carried out that this case was resolved (s. fig. 36.24):

What was discovered was a monstrous gall-bladder staghorn calculus which had migrated to and become embedded in the liver parenchyma. In order to be removed, it had to be cut into four parts (which are well-preserved and still at our

Fig. 36.24: Giant gall-bladder staghorn calculus, dislocated into the right liver lobe and embedded in the parenchyma. (*at our disposal*) – **Probably the largest gallstone reported to date: 12 x 5 cm, 120 g dry weight!**

disposal). With a length of 12 cm, a diameter of 4–5 cm and a dry weight (!) of some 120 g, it may well be the largest gallstone ever reported. • Our investigations of the literature revealed a previous maximum weight of 110 g (published in 1917). (s. p. 761, footnote*): E. KUNTZ)

5 Surgical treatment

Most benign tumours are asymptomatic and do not require surgical intervention. A smaller group of benign liver foci are treated conservatively or require interventional treatment. • Other tumours are difficult to differentiate as either benign or malignant, or they tend towards malignant degeneration and should be removed surgically. Surgery is indicated in unresolved findings, or when the tumour increases in size with secondary compressional effects, or if there are complications. Postoperative morbidity is low with negligible mortality; life expectancy and quality of life are not compromised.

It is important that the *preoperative examination* is carried out meticulously and that the tumour can be adequately assessed by imaging techniques regarding its intrahepatic location, size, extent and segmental affiliation. When

1. **Ligature or embolization of the hepatic artery**
 - in acute bleeding
 - in angiomas with large, functionally effective arteriovenous shunts
2. **Atypical liver resection, enucleation, local tumour excision** (without liver hilus preparation)
 - method of choice and relative indication in clearly benign hepatic tumours showing symptoms and a clear increase in size of tumour (haemangioma, FNH, lipoma, etc.)
3. **Anatomical, segment-oriented liver resection** (including liver hilus preparation in most cases)
 - necessary in unresolved or ambiguous hepatic tumours (e.g. suspected adenoma) as absolute indication due to risk of malignancy and in complications (e.g. haemorrhage, rupture). The aim is radical removal of the tumour with a sufficient safety margin (as in malignant tumours)
4. **Partial/total vascular ligation**
 - useful additional technique for better intraoperative control of haemorrhage and haemostasis, particularly suitable for well-vascularized tumours or those close to the inferior vena cava
5. **Various modifications of in/ante/ex situ resection**
 - relatively rare techniques which may, however, be useful (with additional protection of the liver and possible auto-transplantation) for improving technical resectability when the size or location of the tumour presents problems (e.g. confluence of the hepatic veins)
6. **Hepatotomy and allogenic liver transplantation**
 - exceptional techniques applied in multiple tumours, diffuse changes (e.g. haemangiomatosis) or concomitant liver diseases often of a metabolic nature (e.g. glycogenosis). Radical oncological treatment for eliminating the risk of malignant tumour development

Tab. 36.5: Surgical treatment options for benign hepatic tumours (according to B. RINGE et al., 1997) (209)

participation of vascular or biliary structures or involvement of extrahepatic organs is suspected, additional investigations are called for. • The *hepatological status* is determined as follows: enzymatic and mesenchymal activities, cholestasis and jaundice, functional test values (e.g. cholinesterase, albumin, coagulation status, indocyanine-green test, galactose elimination capacity). • The surgical strategy is chosen in accordance with the tumour type and any additional individual factors. Atypical resection, enucleation or excisional separation of the local tumour are considered to be less invasive and therefore less inconvenient for the patient. (205–210) (s. tab. 36.5)

1 Historical review

► C. A. ROKITANSKY (1849) was probably the first author to refer to primary liver carcinoma as an independent disease. Until then, the problem had been to accept the existence of both primary and secondary (metastatic) liver tumours and to differentiate between them histologically. • In 1854 E. NOEGGERATH described a congenital hepatic carcinoma as being a mechanical obstetric obstacle. In 1859 T. BILLROTH reported the presence of hepatic metastases from a cylindroma. A. KELSCH and B. L. KLIENER presented the first case reports of a primary liver tumour in 1876. A short time later, in 1881, C. SABOURIN made significant histological progress by differentiating between hepatocellular and cholangiocellular carcinomas. He reported on four more patients suffering from primary hepatic carcinoma and coined the term “hepatoma”. In 1883 J. A. P. PRICE described the development of carcinoma from cirrhosis, which led to the introduction of the term “*cirrhosis hepatitis carcinomatosa*”. In 1888 V. C. HANOT et al. attempted to differentiate liver tumours according to macroscopic and microscopic criteria.

H. EGGEL (1901) confirmed the association between cirrhosis and liver carcinoma, actually finding cirrhosis in 85% of all liver carcinomas. He distinguished carcinomas according to nodular, massive or diffuse growth, evaluating all cases that had been published since 1865. (5) Primary cystadenocarcinoma of the liver was initially differentiated in 1909 (P. BASCHO). To our knowledge, the first right-sided lobectomy for hepatic carcinoma was carried out in 1911 (W. WENDEL). • In 1932 T. YOSHIDA succeeded in creating a hepatocellular carcinoma in animal experiments by using o-amidoazotoluol: this marks the beginning of the search for chemotoxicological causes. M. M. STEINER (1938) wrote a detailed report on primary liver carcinoma in children. (243) L. LISA et al. (1942) observed that metastases were rarely found in a cirrhotic liver. In 1952 C. BERMAN presented an overview of about 2,000 cases of primary liver cell carcinoma reported up to that time. • In 1950 G. M. FINDLAY postulated an association with chronic viral hepatitis, which he had detected in his epidemiologic examination of soldiers stationed in regions south of the Sahara desert, a finding that was also reported by M. PAYET et al. in 1956. This supposition was confirmed when the hepatitis B virus was discovered (J. B. SMITH et al., 1965; S. SHERLOCK et al., 1970). (4, 13, 149)

2 Classification

Morphologically speaking, the liver is (1.) origin of benign or malignant tumours, (2.) important target organ for metastatic spread, and (3.) susceptible to reactive nodulation due to its ability to regenerate.

Final differentiation between these three types of tissue formation is only possible with histomorphological techniques, and not with imaging procedures. The latter, however, are able to determine small foci (<1.0 cm), which is required for US- and CT-guided biopsies.

Macroregenerative nodules are generally reactive benign tumours without any malignant tendency. They are found in various conditions, e.g. Budd-Chiari syndrome

(s. fig. 36.6), congenital hepatic fibrosis, focal nodular hyperplasia, and appear in different forms: (1.) monoacinar nodules, (2.) multiacinar nodules, (3.) lobar or segmental hyperplasia, (4.) focal nodular hyperplasia, and (5.) monoacinar or multiacinar cirrhotic nodes. • The common pathogenetic principle is a pathological perfusion of the liver parenchyma.

2.1 Systematization

Malignant liver tumours may be grouped as follows: (1.) primary forms, i.e. originating in the liver (s. figs. 29.14; 30.2; 37.1, 37.9, 37.10), (2.) secondary forms, i.e. arising from metastases (s. figs. 37.2, 37.18, 37.19, 37.24, 37.33–37.35), and (3.) extrahepatic tumours infiltrating the liver from the outside (e.g. gall-bladder carcinoma). (s. fig. 37.3)

Primary liver tumours originate in principle from all histogenetic cell elements found in the liver: hepatocytes, bile-duct epithelia, periductal biliary glands, neuroendocrine cells and mesodermal structures (such as endothelial cells, Ito cells, Kupffer cells) as well as fibroblasts, nerve cells and muscle cells. However, they may also occur as mixed forms. In rare cases, ectopic tissue in the liver may be the starting point for malignant tumours. (s. tab. 37.1)

Primary liver tumours can be categorized according to macroscopic criteria. The solitary coarse-granulomatous type is predominantly found in the right lobe, while the

Fig. 37.1: Grey-coloured, medium-coarse tubercular cirrhosis in haemochromatosis with hepatocellular carcinoma: in the foreground, white, flat tumour granuloma of the right hepatic lobe with vascularization at the tumour margin and small “cancer umbilicus”; in the background, two additional tumour granulomas. Carcinomas infiltrating the peritoneal serosa in the right upper abdomen

Fig. 37.2: Liver metastases in the right hepatic lobe in breast cancer with pronounced chaotic vascularization. Dissipated light reflex due to tumourous tubercles on the surface

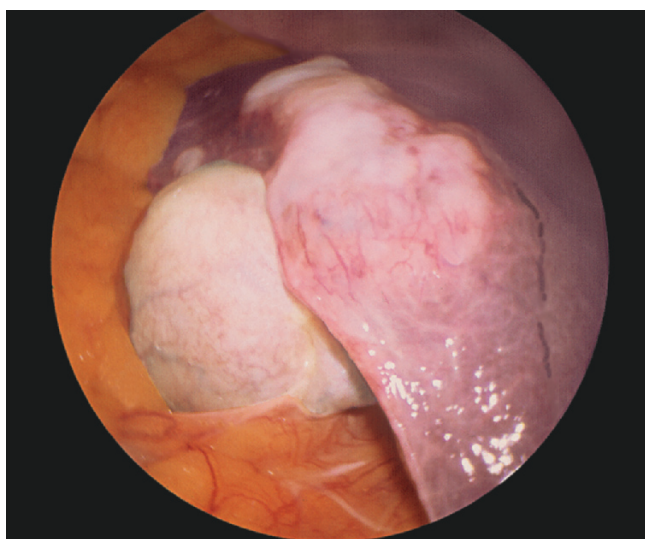

Fig. 37.3: Gall-bladder carcinoma subsequent to cholelithiasis with chronic cholecystitis and shrunken gall bladder. Bulbous carcinoma infiltrating the right lobe of liver

nodular multi-granulomatous type is most common in cirrhosis. The diffuse infiltrative type is relatively rare (5–10% of cases). A combined type is observed on occasions. The right lobe is affected seven times more frequently than the left lobe. Some 3–5% of malignant liver tumours are of primary origin.

Secondary liver tumours: In contrast, 95–97% of all malignant liver tumours are assumed to be secondary liver tumours, so-called *liver metastases*. (s. tab. 37.1)

2.2 TNM staging system

In medical letters/reports, an identified tumour is (correctly) classified according to the TNM staging system. In this process, unclear or incorrect interpretations are sometimes given due to inconsistent use of the terminol-

| Primary malignant liver tumours |

Tab. 37.1: Systematization of primary and secondary malignant liver tumours

ogy or lack of sufficient experience with this kind of classification. Thus it is appropriate to explain this system with interpretations. The anatomical spread of malignant liver tumours is also described according to the TNM staging system. It is important to assess the histologically verifiable invasion of vessels in the preparation and, at the same time, to clarify the question of whether the resected tissue still contains tumourous foci. (s. tab. 37.2)

The TNM staging system comprises the following stages with a respective survival time of three years after resection of HCC:

| | |
|-------------|---|
| stage I | = T ₁ No Mo (83%) |
| stage II | = T ₂ No Mo (70–75%) |
| stage III A | = T ₃ No Mo (45–50%) |

3 Hepatocellular carcinoma

3.1 Definition

Hepatocellular carcinoma (HCC) originates in the hepatocytes; HCC thus resembles liver parenchyma in morphology. It may present as highly differentiated, moderately differentiated or undifferentiated (anaplastic). The most common (and basic) structure is the trabecular aggregation of tumour cells around a capillary vascular bed. Clinically, HCC is seen as an extremely malignant, rapidly progressing tumour. Therapeutic measures remain limited, with surgery being the only potentially curative treatment.

3.2 Epidemiology and frequency

Epidemiology: HCC is one of the most common malignant primary liver tumours worldwide. It ranks fifth in frequency in men and eighth in women ($\sigma = 6\%$, $\text{♀} = 3\%$). Between 500,000 and one million new cases are reported each year. The annual mortality rate is virtually the same as its annual incidence. Its *geographical distribution* varies greatly and correlates almost 100 per cent with the regional incidence rates of HBV and HCV infection. There are areas showing low incidence with $< 5/100,000$ inhabitants/year (e.g. Scandinavia, Australia, USA., Central Europe), moderate incidence with $5-20/100,000$ inhabitants/year (e.g. East/South-East

Europe, Mediterranean region) and high incidence with $20-150/100,000$ inhabitants/year (e.g. Asia, Africa).

Frequency: During the course of the 20th century, the statistical frequency of HCC rose constantly – owing to an increase in autopsies and improvements in diagnostic procedures. • In 1910, for example, autopsy records showed HCC in only 0.04% of cases; in 1930 the figure was 0.13%, in 1960 0.23%, and in 1970 0.6–0.8%. In 1986 the frequency of HCC was given at about 1% of cases based on autopsy findings. The ratio of HCC to liver metastases is about 1 : 50.

Age: HCC affects persons of all age groups. In Asian and African countries, the morbidity peak is reached in adolescence or between the ages of 20 and 40 years, corresponding to predominantly perinatal or postnatal infection with hepatitis viruses. (176) In countries with a low incidence, the morbidity peak is between the ages of 50–60 years. • HCC has also been observed in babies and infants.

The HCC **gender ratio** between men and women is about 3 : 1, but up to 8 : 1 in countries with a high incidence. In a cirrhosis-free liver, however, men and women are equally affected by HCC, i.e. the gender ratio of cirrhosis seems to determine the ratio of HCC. Androgens are thought to be of aetiopathogenetic significance, since carcinoma cells have been shown to carry androgen receptors which display qualities favouring growth, and a carcino-protective effect was observed in animal experiments when androgen was withdrawn. Sex hormones appear to be cocarcinogens. (25, 41, 45, 80)

3.3 Risk factors and causes

► **Animal experiments:** A considerable number of chemical agents have proved to be directly carcinogenic in animal experiments. This is most likely to apply to humans as well (but as yet no supporting evidence has been presented). Both a linear dosage-effect relationship and a respective time-exposure relationship can be observed: the higher the dosage and the longer the exposure, the greater is the likelihood of carcinoma formation. Carcinomatous degeneration occurs predominantly in epithelial or mesenchymal tissues. (s. tab. 37.3)

Risk factors: The figures and observations relating to the epidemiology and frequency of HCC are the result of individual or combined risk factors. The extent of risk correlates with (1.) aetiology, (2.) duration, and (3.) inflammatory activity of the liver disease. In 10–15% of patients, no risk factor could actually be determined in the development of HCC. (s. tab. 37.4)

Genetic mechanisms: A *genetic disposition* is suspected in HCC, as in other malignant tumours. Some 22% of patients suffering from HCC had other organ tumours as well. (133) • Several *hereditary metabolic diseases*, with or without cirrhosis, may increase the risk of HCC considerably. These include tyrosinaemia (type I), glycogenosis (type I), α_1 -antitrypsin deficiency, galactos-

Tab. 37.3: Chemical substances displaying carcinogenicity, as has been demonstrated in experiments or is very probable

aemia, porphyria cutanea tarda, acute intermittent porphyria and idiopathic haemochromatosis. Patients with diabetes mellitus and obesity (30, 62) also have a higher risk of developing hepatocellular carcinoma. • HCC has only rarely been associated with Wilson's disease; copper seems to have a carcino-protective effect. (171) (s. tab. 37.4)

Chemicals: A number of chemicals can cause malignant hepatic tumours, including HCC, both in animal experiments and in the everyday life of humans. These include vinyl chloride, aromatic amines, nitrogen compounds, polycyclic aromatic hydrocarbons and alkylating substances. Similarly, mycotoxins and phytotoxins (aflatoxin, cycasin, ochratoxin, safrol, etc.), betel quid chewing as well as inorganic substances (arsenic, asbestos, cadmium, chromium, etc.) can have a carcinogenic effect. In addition, substances emitting ionizing radiation must be mentioned in this context. (s. tab. 37.4)

Medication: The aetiological relationship between the intake of certain types of medication and the development of HCC is well known. These include methotrexate, methyl dopa, androgens/anabolic steroids, oestrogen derivatives/oral contraceptives and cyproterone acetate. (s. tabs. 29.9; 37.4)

Alcohol and tobacco: Alcohol is seen as a *cocarcinogen*, i.e. it requires additional noxae (e.g. tobacco smoke, aflatoxin) to be able to induce HCC as a carcinogen. The combined effects of alcohol and aflatoxin result in a 35-fold increase in carcinogenicity. Aflatoxin may cause a specific type of mutation within the tumour suppressor gene p53 and thus trigger initiation (i.e. the first step in the development of a tumour). The risk of HCC developing with underlying alcoholic cirrhosis is about 15% or 22.6% (i.e. there is approximately a fourfold increase in the HCC risk); abstention from alcohol does not lower the risk of HCC significantly. (157) • Interestingly, regular coffee intake is probably a protective factor in HCC.

Tab. 37.4: Risk factors (carcinogens and cocarcinogens) regarding hepatocellular carcinoma, which have already been proved (including some references) (s. tabs. 29.10; 37.3)

Hepatitis viruses: In chronic infections, **HBV DNA** may become integrated into the genetic material of the hepatocytes; this has a strong, time-dependent carcinogenic effect. Alcohol speeds up the incorporation of viral DNA into the host genome. HBV carriers (those suffering from liver disease as well as healthy persons) have an HCC risk which is 200 times higher than that of other people. Integration of viral DNA into the tumour cells is well documented. Integrated HBV DNA shows a number of modifications. Genetic damaging of hepatocytes by the integrated viral DNA (also in serologically HBV-negative patients, who may be molecularly biologically positive) is considered to be the initiation

of carcinogenesis. In this process, the HBV subtypes apparently behave like the HBV type itself. HBxAg is undoubtedly of pathogenic significance; possibly it also damages p53. HBV protein (and the core protein of HCV) are able to activate NF-kappa B, which is considered to be important in HCC pathogenesis. *Vaccination* against HBV infection is thought to be an effective prophylactic measure against the development of HCC. • Superinfection with HDV has a potentiating effect, resulting in the earlier occurrence of both cirrhosis and HCC – but not in a higher incidence of HCC. Animal experiments show that HBV can induce HCC without further cofactors. This evidence of the strong carcinogenicity of HBV also explains why, for example, HBsAg-positive men have a risk of developing HCC which is 98 times higher than that of an HBsAg-negative control group of the same age. A higher familial frequency has also been observed. (64, 109, 149, 165) • HCV is equally carcinogenic; in certain regions, its carcinogenicity is actually 2.7 times higher than that of HBV, whereby different molecular mechanisms are responsible for the development of HCC. HCV is not integrated into the hepatocellular genome. Prevalence of HCV antibodies in HCC patients has been shown to be considerable (albeit varying between individual countries), e. g. 27% vs 4%, 55% vs 10%, 30% vs 1%, and 71% vs 5%. This corresponds to a 27-fold increase in the risk of HCC. Genotype 1 b is associated with a higher risk of HCC as well as a decrease in IGF. Simultaneous infection with GBV-C does not increase the HCC risk. The likelihood of HCC occurring subsequent to an HCV infection is 21.5% after 5 years, 53.2% after 10 years, and 75.2% after 15 years. HCV cirrhosis is associated with HCC at a malignant transformation rate of 2–8% per year. (64, 125, 155, 162, 165)

Liver diseases: An association with AIH and with secondary biliary or CDNC-induced biliary cirrhosis has been reported (91, 115, 153), albeit as a rare event.

Cirrhosis: In 70–80% of cases, HCC develops in underlying (mainly multicentred, coarse-granulomatous) liver cirrhosis, i. e. some 20% of cirrhotic patients suffer from HCC. • *Cirrhosis of any aetiology must thus be considered a precarcinogenic factor.* • In Europe and the USA, cirrhosis is mostly alcohol-induced. In HCC patients in Africa or Asia, cirrhosis is less common: generally perinatal, postnatal or juvenile HBV infections, most likely involving large numbers of viruses, result in the formation of HCC before cirrhosis can develop. Chronic viral hepatitis, just like cirrhosis, causes an increase in hepatocellular proliferation. Unless the genetic damage induced by viral DNA can be repaired by enzymes produced in the hepatocytes, it is passed on via mitoses to the daughter cells. An increased DNA synthesis rate within the cirrhosis is accompanied by an elevated risk of malignant transformation. Cirrhosis increases the susceptibility of the liver tissue to other carcinogens. A rise in the mitosis rate thus also results

in an increase in genetic alterations. This causes oncogenes to be activated, while tumour suppressor genes or mutation repair genes become inactivated. (20, 41)

3.4 Pathogenesis

Development of HCC begins in the small diploid hepatocytes, which have a higher growth rate. Pathogenesis is a multifactorial event. The sequential course has three main phases: (1.) **initiation:** various noxae cause a genetic defect, which can be repaired by endogenous mechanisms and is thus reversible; (2.) **promotion:** if the genetic damage is beyond repair, the initiated hepatocytes are stimulated and mitosis begins, with the result that the genetic damage is transferred to the daughter cells; (3.) **progression:** clonal expansion of the altered (“malignatized”) cells occurs.

Tumour-suppressor gene: The tumour-suppressor gene p53 is located on chromosome 17. Noxae may cause mutations of this gene, which results in the loss of its suppressor effect. (6) • *An autosomal dominant mutation of p53 is also encountered in humans, so that a tumour can develop during adolescence, the so-called Li-Fraumeni syndrome.*

Carcinogens are cancer-causing substances which are able to initiate genetic damage of the hepatocytes (or of bile-duct epithelia or sinusoidal endothelial cells) without the assistance of additional noxae. **Cocarcinogens** require other cocarcinogens or carcinogens in order to cause malignant transformation. • The **interaction** between hepatitis viruses, alcohol, chemical agents, hormones, etc. is a crucial factor in the development of manifest HCC. In this context, constituents of tobacco smoke, nutritional factors (e. g. choline deficiency, vitamin B₆ deficiency, aethionine surplus) or occasionally enhanced fatty acid synthesis (128) may act as cocarcinogenic factors.

Growth factors (HGF, IGF, etc.) are also of crucial importance in pathogenesis, as is a compromised immune defence system. Increased expression of angiopoietin 1 and 2 plays an important role in the vascular development of HCC. (163)

3.5 Morphology

► *Aetiopathogenesis is multifactorial as an interaction of genetic, exogenous and/or endogenous factors. In a molecular-biological context, HCC is regarded as an extremely heterogeneous tumour.*

3.5.1 Macroscopic forms

The macroscopic or histologic differences in the morphology of individual hepatocellular carcinoma types are of little epidemiological or clinical significance. • Macroscopically, HCC has a whitish-yellow colour, is

often permeated by bile and shows a soft consistency. There are often haemorrhages in the nodes as well as central necrosis. HCC is mainly supplied with arterial blood. Its doubling time is 30 to 400 days, with an average of 120 days. Occasionally, infiltration into the portal vein system or the hepatic veins occurs (s. fig. 6.16), with intrahepatic metastases and thromboses in the branches of the portal or hepatic veins. (137) HCC may also become manifest simultaneously with cholangiocarcinoma. • **Three forms** (nearly identical with the three forms described by H. EGGEL in 1901) (5) can be differentiated: (1.) expansive type, (2.) infiltrative type, and (3.) combination type. • A rare form is the **pedunculated HCC** (only about 100 cases have been reported). It occurs mostly on the underside of the right lobe and protrudes beyond the upper edge of the liver. This form (occasionally > 1 kg in weight) can be more easily resected, leading to a better prognosis. (123, 177) (s. tab. 37.5)

| 2. Pleomorphic | | 4. Small-cellular | |

Tab. 37.5: Macroscopic forms, microscopic typing and degree of tumour differentiation in hepatocellular carcinoma

3.5.2 Microscopic tissue types

Dysplasia: Dysplasia is defined as variably large, different-shaped hepatocytes, mostly in localized groups, with enlarged, pleomorphic and hyperchromatic nuclei as well as enlarged nucleoli. These dysplastic hepatocytes are often polyploid. Dysplasia can occur as a *macrocellular* (with eosinophilic cytoplasm) or *microcellular* (with basophilic cytoplasm and increased proliferation) variant. The latter is a precancerous stage. • **Dysplastic foci** with a diameter of 1(–2) mm consist of enriched, mainly small-cellular dysplastic hepatocytes. • **Dysplastic nodes** with a diameter of 0.3–1.0 cm have an atypical architecture and cellular atypias; trabecular or pseudoglandular structures are evident. Atypical hepatocytes are often clear-cellular, basophilic or steatotic. Fluent transition into HCC is seen occasionally. (84, 93)

Growth forms: Histologically, there are six growth forms of HCC. (s. tab. 37.5) The most common form is the **trabecular type**, usually comprising highly differentiated carcinomas with polygonal tumour cells similar to hepatocytes; they grow in multilayered trabeculae and enclose blood spaces lined with endothelium (usually without Kupffer cells). • The **pseudoglandular type** is often found in combination with the trabecular form. It is characterized by the formation of gland-like structures containing detritus and bilic or liquid material. • The **scirrhus type** shows excessive deposits of sclerosed connective tissue, which is relatively low in cells. There are no necroses or haemorrhages. The moderately differentiated tumour cells lie between the septa, which resemble connective tissue. This type is mostly found after chemotherapy or radiation therapy. (92) • The **solid type** is an undifferentiated HCC, with the tumour cells displaying considerable cellular polymorphism; the trabecular tissue pattern has disappeared. The tumour is compact due to compression of the sinusoids. • Differentiation is, however, only possible in rare cases, since there is often great heterogeneity within the tumour, i.e. different tissue types may be found in the same HCC. (s. figs. 37.4, 37.5) • **Fibrolamellar HCC** is rare; it consists of solid cell trabeculae with connective-tissue septation and a capsule. (s. p. 813) (s. figs. 37.12, 37.13) • **Spindle cell-like differentiated HCC** is likewise a rare histological form with a fascicular-sarcomatous growth pattern. (110) Prognosis is significantly poorer than with other forms of HCC (S. KAKIZOE et al., 1987).

Tumour differentiation: Histological tumour differentiation ranges from the highly differentiated grade 1 to the undifferentiated grade 4. (s. tab. 37.5) It does not provide sufficiently reliable information for giving a prognosis of HCC. This also applies to the above-mentioned histological growth forms – with the exception of the fibrolamellar type, which has a more favourable prognosis in the majority of cases.

Fig. 37.4: Highly differentiated, macrotrabecular hepatocellular carcinoma with hydropic swelling of the tumour cells (condition after alcohol injection) (HE)

Fig. 37.5: Partly solid, partly pseudoacinar hepatocellular carcinoma with bile pigment in canalicular structures (HE)

3.5.3 Cytological differentiation

Polygonal cells are predominantly found in HCC. They have dense nuclei and lumpy, eosinophilic cytoplasm, which subsequently becomes basophilic. Bile canaliculi are often observed. Sometimes there are haemorrhagic necroses. (s. fig. 37.6) • **Pleomorphous** cells are present in immature tumours. They are generally smaller than the hepatocytes and may vary in their overall cell size as well as in the size of the nucleus; occasionally, they grow to form multinuclear cells or multinuclear giant cells containing bizarre nuclei. • Typical **hyaline inclusion bodies** with autofluorescence are sometimes detected, pointing to disturbed protein secretion; they can be differentiated immunohistochemically, e.g. in the form of ferritin, α_1 -foetoprotein or α_1 -antitrypsin. The detection of **Mallory-Denk bodies** in tumour cells is likewise typical for HCC. (158) They are caused by disturbed metabolism of the intermediate filaments. **Ground glass cells** are also found (due to HBsAg expression or enhancement of fibrin). **Nuclear inclusion bodies** are caused by

Fig. 37.6: Haemorrhage and polygonal tumour cells with hyperchromatic nuclei in HCC (HE)

invaginated cytoplasmic substances. Bile may still be produced, particularly within a highly differentiated HCC; this is expressed in the formation of **bile thrombi**, as is shown by morphology.

The glycogen content in the tumour cells varies. When a large amount of glycogen (and water or lipids) is stored, HCC takes on a **clear-cellular** “hypernephroid” form. • **Small-cellular** carcinomas are also occasionally in evidence. (s. tab. 37.5)

A **grading of HCC** with regard to these different forms is usually without clinical importance: (1.) the forms do not necessarily correlate with the clinical course and (2.) different forms can appear in one and the same patient.

3.5.4 Metastatic spread

HCC metastasizes intrahepatically, haematogenically (50–60%) and lymphogenically (30%) into the regional lymph nodes, mainly (and also initially) below the diaphragm. • Haematogenous metastases affect the lungs (40–50%) and skeletal system; metastases are only rarely found in the kidneys or brain. • However, infiltrating growth affects neighbouring organs (e.g. gall bladder, diaphragm, kidneys, hepatic vessels, bile ducts). (75, 178)

3.6 Symptomatology

3.6.1 Subjective complaints

HCC develops without subjective complaints. Even further tumour growth often remains undetected; alternatively, the complaints are explained as general symptoms relating to cirrhosis or to an existing chronic liver disease. HCC is hence usually detected late. *Complaints* are very varied:

- | | |
|-----------------------------|------------------------|
| • pain in the upper abdomen | • weight loss |
| • bloating, flatulence | • fatigue, weakness |
| • inappetence, nausea | • stool irregularities |

The patient is suspected to be suffering from HCC when the subjective complaints continue to worsen and when an increase in complaints, which may occur quite abruptly in some cases, cannot be explained by the progression of cirrhosis. Most patients are affected by pain radiating into the right side of the back or into the right shoulder and neck area. This is due to an irritation of the phrenic nerve caused by expansion of the tumour towards or even into the liver capsule. Anorexia is more pronounced. Occasionally, the course of HCC is acute, resembling liver failure or liver abscess.

3.6.2 Clinical findings

The clinical situation deteriorates rapidly: febrile temperatures and leucocytosis as well as subicterus are observed; there are also signs of encephalopathy. An arterial murmur can often be heard on auscultation,

since the tumour is mainly supplied with blood from the hepatic artery. A sudden “blossoming” of vascular spider naevi is frequently seen with underlying cirrhosis. *Virchow-Troisier’s lymphadenopathy* may be present. (81) Fever and leucocytosis frequently occur in tumour necrosis. Clinical findings include:

- | | |
|-------------------------|----------------------------|
| • fever | • arterial murmur |
| • subicterus | • tenderness upon pressure |
| • meteorism/ascites | • palpable tumour |
| • latent encephalopathy | • perihepatic friction |

Paraneoplastic findings: Occasionally, there are paraneoplastic symptoms or syndromes which vary greatly from individual to individual, such as erythrocytosis (due to enhanced expression of erythropoietin), polycythaemia, hyperparathyroidism with hypercalcaemia, hyperthyroidism, painful gynaecomastia (14), osteoarthropathy, pseudoporphyria, hypercholesterolaemia, hypertension (16), polyneuropathy, polymyositis (61), water diarrhoea syndrome, dermatomyositis, and an increase in the vitamin B₁₂-binding protein. Large and glycogen-rich tumours cause hypoglycaemia (possibly due to enhanced expression of IGF2).

3.7 Diagnosis

The efficacy of therapeutic measures, particularly the prospect of curative treatment and thus prognosis, depend upon the *early diagnosis* of HCC.

3.7.1 Laboratory findings

While **non-specific signs of inflammation** may also be present in liver cirrhosis, they are much more obvious in HCC. For example, positive CRP values as well as an increase in the BSR, α_2 -globulins, α_1 -antitrypsin and fibrinogen can be found. A constellation of decreased serum iron and elevated serum copper (139) points to a consuming inflammatory process or malignant tumour. (s. tab. 5.10) Usually, the haemogram shows leucocytosis and anaemia. Nitric oxide values in the plasma are elevated in correlation with tumour size. (s. tabs. 37.6, 37.11, 37.12)

Conspicuous **enzyme activities** include a disproportionate increase in γ -GT, AP (especially the Regan isoenzyme, which is identical to the placenta isoenzyme) and LDH. This constellation is thought to be an important indicator of HCC, particularly when HBDH is also elevated. Intrahepatic cholestasis is invariably present in HCC. More and more foetal γ -GT is produced in carcinomatous hepatocytes and is detectable at the biliary pole of the cells. The transaminases rise only slowly; the enzyme quotients may provide revealing information. (s. tab. 5.6) • **Hepatic synthesis capacity** (albumin, cholinesterase, Quick’s value) decreases progressively. ChE is also greatly reduced in cases of malignant ascites. The

indocyanine green test is considered to be conclusive for evaluating the residual liver parenchyma prior to hepatectomy. A combination of the *ICG test* and *galactose elimination capacity* (s. p. 114) is an even more reliable tool, according to our experience.

α_1 -foetoprotein has gained great importance as a laboratory value pointing to HCC. (s. p. 112) First discovered in hepatomas by G. ABELEV et al. in animal experiments in 1963, this type of oncofoetal protein was also detected in human HCC by Y.S. TATARINOV in 1964. AFP is a glycoprotein formed initially within the yolk sac and later in the liver and gastrointestinal tract of the foetus. Serum values of about 70,000 μ g/l are found in neonates, decreasing to the normal value of < 10 μ g/l within 9–12 months. Higher values can be detected in liver cell regeneration (acute and chronic hepatitis, cirrhosis) and particularly in HCC (> 20 μ g/l). Thus, a continuous increase in AFP values arouses suspicion; a value of > 100 μ g/l is highly suspicious for HCC. There is only a moderate correlation between AFP and the respective tumour size and doubling time. A false-negative AFP value is detected in about 20% of patients suffering from HCC. The response to chemotherapy usually corresponds to decreasing AFP values. • Specificity is between 76–91%, sensitivity 39–64% (approx. 85% when ferritin is increased at the same time). Serum values of $> 2,000$ μ g/l may ultimately be reached. Liver metastases usually show values of < 150 μ g/l, with no tendency to rise. AFP values in the normal range exclude HCC in 90–95% of cases. No AFP is produced in very mature or very immature tumour cells. AFP production in elder patients is lower; it is mostly higher in virus-related cirrhosis than in alcoholic cirrhosis. (39, 72, 150, 152)

Diagnostic importance is also attributed to **des- γ -carboxy prothrombin** (60–80% positivity in HCC) (H.A. LIEBMAN et al., 1984). (87, 119, 131, 152) It is synthesized in the normal hepatocytes and therefore also in HCC. The diagnostic accuracy in small hepatocellular carcinomas (<3 cm) could be greatly improved by determining this precursor prothrombin (PIVKA II) in combination with AFP. • A decrease in the **factor-II index**, i.e. (factor VII + factor X) – (factor II) = >15, has proved to be a specific and independent marker of HCC. • In addition, isoferritins, Regan-AP, telomerase activity (97), leptin receptor (168) and L-fucosidase as well as CEA variants may be helpful in the demarcation of HCC. • *Laboratory diagnosis of HCC is indeed much more reliable if various important parameters are added.* (s. tab. 37.6)

3.7.2 Imaging procedures

Sonography: *Sonography is the method of choice in monitoring the course of risk patients, particularly in combination with AFP determination at four- to six-month intervals.* In this way, a longer survival time could be achieved. Under optimal examination conditions with an experienced investigator, foci are detectable at a size of 1 cm. However, demarcation of HCC in a cirrhotic liver is very difficult, if not impossible, due to its inhomogeneous reflex pattern. Small foci (<2 cm) are usually hypoechoic; when they grow, their echogenicity increases (due to deposition of fat, connective tissue formation or necrosis) and a hypoechoic margin with a rather blurred *halo* (= tumour cells plus compressed liver parenchyma) is often in evidence. A *bull's eye* is also detectable (= hypoechoic centre surrounded by a hyperechoic edge). At a size of >4 cm, the reflex pattern becomes inhomogeneous. However, HCC has no typical image. In 50 to 70% of cases, diagnosis is successful at a size of 2 cm and more. Detection of HCC also depends on its degree of differentiation: well-differentiated liver carcinomas are barely distinguishable from normal liver tissue. A hypoechoic halo points to a fibrous capsule and – in combination with a mosaic structure within the focus – arouses suspicion of a carcinoma. (2, 26, 35, 39, 43, 84) • The use of **colour-encoded Doppler sonography** shows hypervascularization even in the early tumour stage and thus provides diagnostic differentiation from regeneration nodes and adenomatous hyperplasia. Visualization of tumour vessels is improved by intravenous injection of a contrast medium. When HCC infiltrates the portal vein, arterial vessels can be identified in the tumour thrombus in 60–70% of cases. (8, 11, 53, 58, 67, 122) • The use of **intraoperative US** as well as **laparoscopic US** (21, 65) results in a 20% higher detection rate of HCC than in preoperative diagnostics. When all space-occupying lesions of the liver are included, the diagnostic results are up to 40% better than those gained by conventional sonography. The haemodynamic pattern “*nodule-in-nodule*” (= a vascular spot in a hypovascular nodule) is a sign of a suspicious node – this could, in turn, be an

early stage of HCC. (88, 181) • Characterization of liver tumours with contrast-enhanced sonography and digital grey-scale analysis offers the possibility of an investigator-independent differential diagnosis. (11)

Fig. 37.7: Thrombosis inside the blood vessels of a diffuse hepatocellular carcinoma resulting from alcoholic cirrhosis (arrows). Spot-like neovascularization in the thrombosed blood vessels. (VP = portal vein)

Computer tomography: The detection of small carcinomas, especially of tumours in cirrhosis, is unreliable using conventional CT scanning. However, when the tumour has reached a certain size, capsule formation, fatty transformation of the tumour mass, vascular infiltration and development of arteriportal shunts are evident. Abdominal lymph node metastases can be found. Sensitivity is about 60%. (s. fig. 37.8) • The introduction of **lipiodol CT** has resulted in a considerable improvement in HCC diagnosis: the oily contrast

Fig. 37.8: HCC: nodular liver surface in cirrhosis. Tumour formation in the right lobe of liver, in parts at the margin; central hypodensity with peripheral hypervascularization (CT after CM)

medium injected into the hepatic artery under angiographic monitoring is stored within the tumour tissue, so that any tumour above a size of 3 mm can be identified in conventional CT scanning in full contrast for a period of one to two weeks. Sensitivity is about 70%, specificity about 80%. (24, 112) • **Spiral CT** has proved to be most effective (sensitivity 90%). This technique offers a biphasic examination supported by contrast medium, with the first (hepatic-arterial) phase showing mainly hypervascularized HCC and the second (portal-venous) phase showing mainly hypovascularized HCC. (10, 37) • **CTAP** (CT following arteriportography) is considered to be a very sensitive method for the detection of HCC in a non-cirrhotic liver (CTAP is not suitable in cases of portal hypertension and portosystemic shunts). The sensitivity of CTAP is 85–90%. • Although **CT arteriography** is an invasive procedure, it shows the highest sensitivity in extensive cirrhosis, because HCC is predominantly supplied with arterial blood.

Angiography: HCC appears as a hypervascularized tumour in angiography via the hepatic artery. The vessels show irregular internal diameters; due to arteriovenous anastomoses, the hepatic veins are rapidly filled, giving retrograde visualization of the portal vein. Poorly vascularized or non-vascularized areas present in the tumour develop due to necrosis or bleeding. Evidence of a hypervascularized “*bush pattern*” in a cirrhotic liver is considered to be an obvious sign of HCC. In terms of sensitivity, angiography is, however, inferior to other imaging techniques. There is no alternative to angiography when assessing surgical strategies or chemoperfusion and chemoembolization; angiography is often combined with simultaneous regional tumour treatment.

Magnetic resonance imaging: Malignant tumours generally show longer relaxation times compared to healthy liver tissue. This results in hypointensity in T₁-weighting and hyperintensity in T₂-weighting – in contrast to healthy liver parenchyma. T₂-signal intensity is more sensitive in the diagnosis of advanced HCC and in the assessment of a tumour capsule; this is prognostically significant. Early stages of highly differentiated HCC are better defined in T₁-weighting. Diagnosis is further improved with contrast medium. (29, 112, 169, 172)

Scintigraphy: The approaches used to date in scintiscanning have proved to be inadequate for diagnosing HCC and are also inferior to other imaging techniques. • New methods (Tc-GSA) as well as immunoscintigraphy, ¹⁸F-FDG PET or SPECT (3, 83, 100, 154, 159) have not yet been evaluated with regard to their diagnostic sensitivity or specificity in detecting HCC or in preoperative staging. Their main value consists in better detection of extrahepatic tumours; they may also have a direct impact on operative management. (1)

Plain X-ray: The rare event of HCC calcification is characterized by the so-called *sunburst sign*.

3.7.3 Morphological diagnosis

Percutaneous fine-needle biopsy: This technique is associated with the risk of tumour cell spreading. The frequency of subcutaneous implantation metastases is reported to be 2%; they mostly appear within three months. When this procedure is indicated, the bleeding risk from the usually hypervascularized tumour must also be taken into account. The cytologic-diagnostic sensitivity is 80–85% of cases; specificity is 97–100%. (32–34, 126)

Percutaneous thick-needle biopsy: We consider this technique to be *contraindicated*, mainly because of the bleeding risk involved: (1.) HCC is usually a densely vascularized tumour, (2.) the tumour tissue does not possess the requisite spontaneous contractility for mechanical closure of the biopsy canal, (3.) local coagulation is usually disturbed in the tumour tissue. Punctures into the necrotic centre of a tumour may cause uncontrollable haemorrhagic oozing. The risk of implantation metastases is the same as in FNB. (34) • This raises the question of whether histological or cytological confirmation of the diagnosis is really necessary. In this context, cytological assessment of the malignancy is equal or even superior to histology. However, cytological delimitation of highly differentiated HCC from adenomatous hyperplasia may be very difficult in certain cases. Diagnosing the tumour type is much more accurate by histological examination than by cytology.

Surgery is indicated if a resectable space-occupying lesion in liver cirrhosis with sufficient evidence of HCC has been determined by imaging techniques and the AFP value is >400 µg/l. Operability in terms of internal medicine as well as hepatology has to be established. • Provided laboratory, sonographic and radiological findings are largely unambiguous, surgery is indicated even without an increase in AFP values; preoperative percutaneous biopsy should *not* be carried out in such cases.

Morphological clarification of the findings is necessary if differential diagnosis of a hepatic space-occupying lesion is unclear. • Cytological or histological confirmation of tumour malignancy is likewise required prior to palliative therapy, even in patients with no chance of curative treatment.

Laparoscopy: This technique should always be used to achieve the required morphological clarification. (s. figs. 37.1–37.3, 37.9, 37.10, 37.18, 37.19) (9, 85, 155) • It initially serves as **explorative laparoscopy** in the careful inspection of the abdominal cavity using various body positions in order to gain as reliable a picture as possible of malignant metastases, particularly in the region of diaphragm, peritoneum and ligaments. (s. figs. 37.33, 37.34) Inspecting large areas of the visible surface of the liver as well as certain parts of the underside when lifted by a probe allows excellent differentiation of all the respective findings – especially in cirrhosis. *Explorative*

Fig. 37.9: Small to medium-nodular, alcoholic cirrhosis with undifferentiated, multilobular hepatocellular carcinoma and subcapsular vascularization

Fig. 37.10: Large-bulbous hepatocellular carcinoma due to alcohol abuse and active chronic hepatitis B with cirrhotic transformation in some places

laparoscopy also facilitates staging, which cannot be achieved as effectively by imaging diagnostics.

All findings are documented by **photolaparoscopy**. (s. p. 164) Sufficiently large and compact tissue particles can be obtained from foci lying close to the surface by using **biopsy forceps**. Highly vascularized areas are thus avoided. The site of extraction can be coagulated immediately, so that prolonged biopsy bleeding or late bleeding is excluded. • Foci that lie at a deeper level or those which cannot be reached with forceps should be evaluated by **fine-needle biopsy**. Assisted by sonography, this can be carried out at the same time as or after deflating the pneumoperitoneum, while the position of the trocar (or alternatively the Veres needle) is maintained. If necessary, a clear view into the abdominal cavity can be regained by quick insufflation using the trocar.

Explorative laparotomy, as is often recommended in older literature, is *contraindicated* in our opinion. • All comparisons with respect to the degree of risk, stress or inconvenience to the patient, expenditure of time, material, staff and the costs involved, and particularly the diagnostic benefits, speak *against* laparotomy and *in favour of* **explorative laparoscopy**.

3.8 Prognosis

The prognosis of HCC is determined by the tumour mass and its speed of growth at the time of diagnosis. Signs of a *poor prognosis* are included in the (p)TNM classification. (s. tab. 37.2)

1. Considerable size of tumour (> 5 cm)
2. Infiltrative or multilobular growth
3. Metastatic spread

The **natural course** of disease shows an average survival rate of five months (2–8 months). Longer courses of HCC have only been observed occasionally; some 3% of patients survive for five years. • The number of tumour nodes and the existing cirrhosis correlate with the likelihood of recurrence. In contrast, the histological degree of tumour differentiation as well as potential capsule or bile formation by the tumour are unlikely or still disputed risk factors for a relapse. This is also true of the biological features of the tumour, such as ploidy, mitosis rate and proliferation marker index. (54, 107)

By including clinical and laboratory parameters (ascites, jaundice, hyperalbuminaemia), K. OKUDA et al. (1985) introduced a **classification** into stages in order to improve prognostic accuracy regarding survival time. (s. tab. 37.7) The survival rate in the untreated course was calculated to be 11 months in stage I, 3 months in stage II, and 1 month in stage III. The corresponding 1-year survival rates are 39%, 12%, and 3%. A survival rate of 29 months can be expected for tumours with <25% invasion of the liver in stage I; the corresponding figure for 25–50% liver invasion is 8 months. With smaller tumours (<3 cm), the survival rates are slightly better: 1 year = 91%, 2 years = 55%, 3 years = 13%. In older patients and in those with moderately increased γ -GT values, tumour growth is retarded. Evidence of antibodies against the tumour suppressor gene p53 point to an unfavourable prognosis.

Another alternative HCC staging system is the so-called **CLIP score** (36). This also combines morphological criteria of the HCC with liver functions (Child-Pugh) and, additionally, with portal vein thrombosis and AFP. (s. tab. 37.8) • **BCLC classification** can be recommended for staging-adapted management of HCC. (106, 107)

Complications: Acute liver failure, arterioportal fistula formation, oesophageal varices (15) and pulmonary

| | 0 points | 1 point |
|------------------------------|------------------------|----------|
| A: Liver invasion | ≤ 50% | > 50% |
| B: Ascites | no | yes |
| C: Bilirubin | ≤ 3 mg/dl | > 3 g/dl |
| D: Albumin | > 3 mg/dl | < 3 g/dl |
| A+B+C+D = 0 points: | stage I = 8.3 | |
| A+B+C+D = 1–2 points: | stage II = 2.0 | |
| A+B+C+D = 3–4 points: | stage III = 0.7 | |

Tab. 37.7: Classification of the stages of hepatocellular carcinoma and survival time in months (untreated) (K. OKUDA et al., 1985)

| Criteria | Points | | |
|----------------------------|------------------------|--------------------------|--------------------------|
| | 0 | 1 | 2 |
| 1. Child-Pugh | A | B | C |
| 2. HCC morphology | solitary <50% of liver | multifocal <50% of liver | multifocal >50% of liver |
| 3. α_1 -fetoprotein | <400 μ g/l | >400 μ g/l | |
| 4. portal vein thrombosis | no | yes | |
| Survival rate | | | |
| points | mean rate | 1 year (%) | 2 year (%) |
| 0 | 36 | 84 | 65 |
| 1 | 22 | 66 | 45 |
| 2 | 9 | 45 | 17 |
| 3 | 7 | 36 | 12 |
| 4–6 | 3 | 9 | 0 |

Tab. 37.8: CLIP staging system of HCC and the respective survival rate (36)

hypertension have been reported as complications. • In most cases, the **cause of death** is anorexia with *tumour cachexia*, accompanied by signs of circulatory and renal failure. Occasionally, there is intraperitoneal haemorrhage, portal vein thrombosis (137, 144) and *tumour rupture* with formation of haemorrhagic ascites. (120)

Spontaneous regression: As far as I know, it was E.B. GOTTFRIED et al. (1982) who first reported spontaneous regression of HCC. In the meantime, further (>25) unusual observations of this kind have been published. However, recurrence after such regression has also been reported. (49, 59, 66, 73, 103, 111, 118, 161, 164)

3.9 Therapy

Surgical, local-interventional, regional and systemic procedures and palliative measures are available for the treatment of HCC. • Longer survival periods can be achieved by surgery, which is seen as the only form of potentially curative treatment for small tumours (<3 cm, or even <5 cm). • At present, merely 5% of patients suffering from HCC have any chance of being cured. Some 25–30% of *inoperable* patients were ren-

dered *operable* by means of preoperative selective irradiation with yttrium⁹⁰ microparticles (intra-arterially) or by several cycles of cisplatin + IFN α_{2b} + doxorubicin + 5-fluorouracil. The results could be further improved by postoperative treatment with lipiodol-J¹³¹. • In this context, the overall chance of recovery is reported to be 15%.

► An **interdisciplinary consensus conference** to decide upon the best therapy possible must be held before any treatment of a carcinoma begins. A gastroenterologist, a surgeon, an oncologist and a radiologist should participate, irrespective of the department in which the patient is being cared for. The treatment plan must then be explained to the patient and (with the patient's consent) also to the closest relatives. • So-called "*virtual liver surgery*" will play an important role in this connection in the foreseeable future.

3.9.1 Surgical therapy

Resection

About 30% of tumours are still resectable by the time HCC is diagnosed. • The following conditions are given as **contraindications** for resection: (1.) multicentric tumours, (2.) metastases, (3.) invasion of the tumour into the portal or hepatic vein, (4.) liver malfunction (jaundice, hypoalbuminaemia, considerable reduction in Quick's value and cholinesterase), and (5.) decompensated portal hypertension (ascites, encephalopathy). • **Surgical techniques** include (1.) right-sided or left-sided hemihepatectomy, (2.) right-sided or left-sided lobectomy, (3.) segment IVb resection, and (4.) atypical resections and wedge excisions. (s. pp 825, 900) Resection of the small left lobe of liver is tolerated best. When the larger right lobe is resected, there is a risk of liver insufficiency due to inadequate residual functional capacity. Preoperative administration of ¹³¹J-lipiodol (60 mCi/injection) showed promising results. (142) • The following procedure was recommended for the safe removal of liver parenchyma: first, embolization of the portal vein branch associated with the tumour is carried out; this results in atrophy of the embolized lobe and hypertrophy of those segments to be maintained, with a correspondingly better functional capacity. • If non-resectability is revealed during the operation, a catheter should immediately be implanted in the hepatic artery for regional chemotherapy. • For non-cirrhotic patients, **mortality** is 1–3%, for those with cirrhosis 7–25%. The **survival rate** is 25–60% after five years, depending on tumour size; this rate sinks to 25–35% when the capsule or the portal vein are infiltrated. Decisive factors are the radicalness of the intervention and the functional capacity of the residual liver parenchyma. Intraoperative blood loss should be kept as low as possible in order to limit morbidity. Patients in **Child-Pugh** stage A showed a five-year survival rate of 27–53% (cf. disease-

free survival rate of 20–33%), and in stage B of about 30%; stage C is usually non-resectable or has no surgical benefits. Preoperative staging using laparoscopy is absolutely necessary. It is decisive for choosing the correct management (the original procedure had to be changed in 20–30% of patients due to the laparoscopic findings). (7, 9, 17, 60, 77, 85, 94, 96, 116, 124, 140, 182) (s. p. 825)

The **radicalness of the intervention** is assessed by the pathologist based on the findings of the resected preparation and the surgical report. First, the pTNM stage is determined. (s. tab. 37.2) Then, the **R classification** is made to establish whether the resection was curative. *R0 resection* means that the tumour was fully removed, no tumourous residues were left behind, and the resection margin is tumour-free. *R1 resection* implies that there are still tumour cells at the resection margin. *R2 resection* signifies that macroscopically visible tumour tissue is left. When the tumour markers normalize within the first four postoperative months after R0 resection, this is defined as *R0a resection*, and without normalization as *R0b resection*. (7) • In cirrhosis patients with small HCC, **liver function** is the most important factor for long-term survival. In this context, the indocyanine green test, MEGX test and the Okuda stage system have proved useful. Under favourable conditions, *relapse resections* are also possible. (69) • Resection therapy can be used as “bridging” prior to a liver transplantation.

Recidivation is generally due to undetected small intrahepatic foci. Especially in cirrhosis, the recurrence rate is very high as a result of this factor. A further cause of recidivation after primary R0 resection is attributed to the multicentricity of the HCC, i. e. synchronic or metachronic development of additional tumours which are independent of the primary tumour. Therefore, the **secondary prophylaxis** takes on a special meaning (systemic or intra-arterial chemotherapy, interferon, retinoids, autologous lymphocyte transfusion, etc.). An increase in ornithine decarboxylase and spermidine is apparently a high risk factor for recurrence. • Even after recidivation, repeated resection or interventional procedures (e. g. RFTA) are sometimes successful.

Cryosurgery: Cryotherapy of tumours was introduced by I.S. COOPER in 1963. • Intraoperative insertion of a probe into the liver tumour is carried out directly. Necrosis is induced in the tumour tissue by the application of fluid nitrogen and the subsequent rethawing of the iced area (ca. -50°C). This procedure is usually repeated. It is indicated in cases of non-resectable liver tumours and for the freezing of margins following resection. (22, 174) (s. p. 826)

Liver transplantation

With insufficient functional reserve capacity of the liver and/or non-curative resectability of the tumour, liver transplantation is generally indicated. However, such a procedure does not yield better long-term results than

resection, particularly since the frequency of **relapse** (some 65% of cases) in the transplanted liver is higher due to the fact that *immunosuppression* is constantly required. A further problem is that the tumour-doubling time (102–195 days) is shortened to about 26 days. Relapses originate from preoperatively undetected metastases, which show strikingly rapid growth.

In order to limit these relapses, **neoadjuvant chemotherapy** has been recommended, e. g. intra-arterial or systemic administration of cisplatin and doxorubicin, possibly in combination with interferon. The survival rates after 1, 2 and 3 years were reported as 70%, 60%, and 59% respectively. Another form of neoadjuvant therapy was based on 5-FU (continuous infusion for 6 months), with intermittent administration of adriamycin and cisplatin prior to transplantation. This procedure had a survival rate after 1, 2 and 4 years of 73% vs 55%, 61% vs 40%, and 61% vs 22% respectively. The relapse rate was only 18%. *Indications for liver transplantation should always be considered with great caution.*

Careful preoperative examination regarding **HBV** or **HCV infection** (PCR, if necessary) is recommended, since there is a very high risk of the transplanted liver being infected by viruses from extrahepatic tissues under immunosuppression. • **Survival rates** in HCC cases without and with cirrhosis are almost equal at up to 85% after 1 year, 30% after 3 years, 20–45% after 5 years, and about 20% after 10 years. A long-term survival rate is only to be expected in patients with small solitary tumour nodes (<5 cm) or not more than 3 nodes of <3 cm in diameter and without signs of vascular invasion (so-called Milano or Mazzaferro criteria). (113) A hyperextended indication is only given in rare cases. These rates largely correspond to the results obtained in non-malignant liver diseases. Transplantation is regarded as being better than resection in cirrhosis patients with early detected HCC, since the precancerous potential of cirrhosis is totally eliminated at an early stage. In every case, preoperative and/or postoperative chemotherapy should be considered. The previous **operative mortality rate** of 15–20% has now been further reduced. (23, 53, 85, 116, 121, 151, 156)

3.9.2 Interventional therapy

After discussing the clinical and imaging findings as well as the result of exploratory laparoscopy, it is important to decide on the most promising management in the interdisciplinary conference. • Once resection techniques and liver transplantation have been ruled out, the next alternative are interventional procedures. (s. tab. 37.9)

Percutaneous injection therapy

Percutaneous injection therapy has meanwhile proved effective in a number of cases. Two principal methods are important in this respect.

1. **Percutaneous injection therapy**
 - ethanol
 - acetic acid
2. **Transcatheter arterial therapy**
 - transarterial chemotherapy
 - transarterial embolization
 - transarterial chemoembolization
 - transarterial radiation
 - ¹³¹I-lipiodol
 - ⁹⁰yttrium
3. **Percutaneous thermoablation therapy**
 - laser-induced thermotherapy
 - microwave coagulation
 - radiofrequency ablation

Tab. 37.9: Local-interventional procedures in HCC management

Fig. 37.11: Subcapsular HCC in liver cirrhosis: mostly necrotic following ethanol injection

► **Percutaneous ethanol injection (PEI):** This procedure was described by N. SUGIURA et al. in 1983. In solitary HCC with a size of <3 (–5) cm in diameter, alcohol (96 vol.%) is injected into the tumour using sonographic, laparoscopic (76) or CT monitoring. This technique (5–10 ml, about 3 times a week, regularly over a period of 3–4 months) is a relatively inexpensive procedure which is technically simple and well tolerated (albeit usually very painful!). Due to the fact that HCC has a soft consistency compared to the firmer liver tissue, it is possible to a large extent to infiltrate the tumour selectively and limit necrosis as desired. (s. fig. 37.11)

Imaging findings after PEI are: in US, alcohol distribution appears like an echogenic cloud and the tumour becomes relatively hyperechoic; in Doppler sonography, the colour signals disappear; in CT, gas formation is sometimes visible. More than 70% of the tumour mass may be necrotized. Under favourable conditions, a complete response can be achieved in 80% of cases. • Adverse events include acute cholecystitis, cholangitis, haemorrhages, liver abscess, pleural effusion, portal vein thrombosis, etc. • The PEI technique has no significant

effect on tumours with a size of >5 cm and multilobar tumours. Some cases of stitch-track metastases have been reported. The relapse rate is approx. 60%. The survival rate is 68–80% after 3 years and about 50% after 5 years. Long-term success depends upon the number and size of the tumours as well as on the respective liver function. PEI is contraindicated in Child-Pugh stage C. (18, 68, 76, 82, 86, 104, 114, 117, 132, 138, 175)

► **Percutaneous acetic acid injection (PAI):** Injection of acetic acid (40–50%, 2–5 ml, two to four sessions) into the tumour also resulted in necrotic destruction of the tumour tissue (M. IMAMURA et al., 1995). PAI is considered to be just as effective as PEI; the success was most evident when the intratumoural retention of acetic acid persisted for about three days after completion of the treatment. (63, 101, 130)

Transcatheter arterial therapy

As an alternative to percutaneous injection therapy, there is a possibility to develop new local-interventional treatment strategies by selectively exploring the tumour-feeding branch of the proper hepatic artery.

Transarterial chemotherapy (TAC): The systemic administration of cytostatics, both as monochemotherapy or polychemotherapy, led to unsatisfactory results with considerable side effects. By transporting cytostatics transarterially to the tumour itself, it was possible to build up a high concentration of these substances in the arteries supplying the HCC. Because there were far fewer side effects, the dosage of cytostatics could be optimized. A further advantage of this method is that the extratumoural parenchyma has a portal venous blood supply; thus the arterially transported cytostatics do not cause any significant peritumoural liver damage. This transarterial chemoperfusion could be improved even more by positioning the selective-arterial catheter exactly and by implanting a port system. (s. p. 827)

Lipiodol (= iodized ester of poppyseed oil) used as a contrast medium for lymphography accumulates selectively in the tumour over a longer period. As a result, local-interventional (oily) *lipiodol chemotherapy (TOCE)* was developed. Lipiodol acts as a carrier for the admixed cytostatic agents, so that the latter retain their effect in the tumour long-term in a high (systematically unacceptable) dose. Hereby, cisplatin or epidoxorubicin (99) is emulgated in lipiodol. It was possible to achieve 1-year survival rates of 36–55%. Other cytostatics did not prove to be any more effective.

Transarterial embolization (TAE): By occluding the smaller tumour-feeding arteries, it is possible to achieve a hypoxia-induced necrosis of the HCC. This is more successful if the tumour is encapsulated. Such embolization is effected using collagen particles, polyvinyl alcohol, gelfoam or galactose spheres. However, the HCC cannot be eliminated completely, because the malignant

cells in its periphery, which are supplied by the portal venous system, remain intact, so that recidivation often occurs (30–50%) at the same place. (108) With (repeat) embolization, 1-year and 2-year survival rates of 65% and 38% respectively were achieved. (s. p. 827)

Transarterial chemoembolization (TACE): The direct application of a cytostatic agent (using the DSA technique via the femoral artery) into the tumour-feeding artery, followed by temporary occlusion of the vessel, leads to (1.) high intratumoural concentration of the cytostatic agent, (2.) longer action time of this substance, and (3.) therapeutically important ischaemia of the HCC. As a rule, lipiodol is applied together with cisplatin (or mitomycin-C, epiduricin, doxorubicin); this is followed by embolization (see above). Evaluation of therapy success is best carried out using MRI, but coded phase-inversion harmonic sonography is likewise highly sensitive and accurate. TACE is also possible under outpatient conditions. *Repeated embolization* is recommended at intervals of about four weeks; this creates extensive tumour necroses. Remission was achieved in 30–60% of patients.

The following *side effects* have been observed: fever, nausea, vomiting, upper abdominal pain (= *post-embolization syndrome*), lipiodol embolisms, pancreatitis, gall-bladder infarction, tumour rupture and liver failure. (74) Chemoembolization is thus a very aggressive form of treatment and should only be considered in patients with a well-functioning liver. The administration of BCAA after TACE has proved beneficial (increase in serum albumin, reduction in mortality, improvement in quality of life). (142) • The 1-year and 2-year survival rates were given as 82% and 63% respectively.

A further improvement in the survival rate was observed following the oral administration of pravastatin (20–40 mg/day). (78) For HCC which is primarily supplied by venous blood, chemotherapy is contraindicated, as is also the case with portal vein thrombosis and renal insufficiency. • It is open to question whether it is possible (and whether it makes sense) to improve the results of a subsequent resection by primary reduction in the tumour mass through chemoembolization or even by treating resectable HCC with chemoembolization from the onset. (31, 48, 74, 130, 143, 180) (s. p. 827)

Combination therapy: The use of local-interventional procedures is restricted to a maximum tumour size of 5 cm in diameter. Therefore, a combination of two local techniques may be promising. • The joint application of PEI and TAE has proved efficacious. (175) Similarly, there have been reports about the successful use of TACE following laser thermal ablation. (134) Further encouraging options include a combination of TACE and RFTA, TACE with microwave coagulation (147) or TACE with cryotherapy. Using TACE, the size of the HCC can be reduced in some cases, making it possible to carry out subsequent ablation with better results.

Transarterial radiation (TAR): Intra-arterial radiation of ^{131}I lipiodol into the tumour tissue has shown good results with a six-month survival rate of 48–52%. This procedure has hardly any influence on hepatic arterial perfusion. For this reason, the technique can also be used in portal vein thrombosis. (27, 95, 142) • Transarterial injection of ^{90}Y particles did not lead to tumour regression in the first study carried out in 1992. (148) A new administration form consisting of 30 μm -sized particles of resin loaded with ^{90}Y was recently developed. The radiation dose amounts to approx. 2 gigabecquerel. The rays penetrate the tissue to a depth of about 2.4 mm. The results obtained so far have proved excellent (A. KENNEDY et al., 2004).

Percutaneous thermoablation therapy

Targeted, temperature-related tumour necrotization can be achieved either through extreme refrigeration (= *cryotherapy*) or overheating (= *thermotherapy*). In the latter case, microwaves, laser-induced radiation or high-frequency current are generally used. The energy is applied with the help of a specially developed probe.

Laser-induced thermotherapy (LITT): In 1983, S.G. BOWN applied this technique for the first time as minimally invasive percutaneous ablation therapy. By means of quartz fibres, Nd : YAG laser light (1,064 nm) is conducted directly into the tumour via a probe. The laser light is converted into heat, thus causing a coagulation necrosis of the tumour. Necroses of up to 4–5 cm in diameter may result. Probe application is carried out by MR-guiding; this technique is also used for monitoring success. The procedure is considered to be both safe and efficacious. (42, 127) (s. p. 826)

Microwave coagulation therapy (MCT): Necrotization of liver tumours by means of microwave coagulation (2,450 \pm 50 MHz) is another thermoablation technique (T. SEKI et al., 1994). The tumour is punctured using a 14 G needle, through which a special probe is inserted. Good results were obtained by using this US-guided procedure. The four-year survival rate of patients with superficial HCC was 64.2%; the local recurrence rate was 27.1%. In 12.8% of cases, no evidence of surviving tumour tissue was observed following treatment. (44, 71, 129) When MCT was compared with RFTA, the results, side effects and complications proved to be more or less equal. MCT is also recommended in metastases. (371)

Radiofrequency thermal ablation (RFTA): S. ROSSI et al. (1990, 1993) were the first to introduce this procedure. Under analgesedation and local anaesthesia, an expandable, cooled-tip needle electrode is inserted percutaneously into the tumour with the help of US, CT or MR guidance. There are various types of probes with some differences. Due to high-frequency alternating current (480–500 kHz), the tumour tissue is gradually heated (up to max. 105°C). A necrosis volume of 4–5 cm in diameter can be achieved. An indication is given

for one to three foci, each with a maximum size of 5 cm in diameter. This also applies to compromised liver function. One or more sessions are necessary for this treatment. Morbidity is <10%, lethality 1–2%. The 3-year survival rates were 80–85% in Child A and 30–35% in Child B. After ablation of the tumour, success is monitored using CT plus CM: in the case of complete ablation, there is no enhancement of CM. Local recidivation is observed in 10–15% of cases. Therefore, a regular monitoring (laboratory parameter together with US or MRI) is required. In the case of recidivation, subsequent therapy with the help of TACE is promising. The following adverse events have been observed: liver insufficiency, colon perforation, portal vein thrombosis, liver abscess, pleural effusion, pneumothorax, haematoma, haemoperitoneum, needle-tract seeding, etc. RFTA can also be carried out laparoscopically (145) or operatively. • Overall, the results of RFTA are better than those of PEI (2-year survival rate: 64% vs. 43%); this is especially true of the disease-free survival rate. It would appear that RFTA is just as effective as resection therapy. (22, 56, 57, 79, 105) (s. p. 826)

3.9.3 Medicinal therapy

Systemic chemotherapy: This kind of treatment yielded a response rate of 5–15% only, irrespective of whether monotherapy or polytherapy was used. (98) A major cause of the low efficacy is the considerable quantity of mixed-functional oxidases in the tumour cells together with an overexpression of the multidrug resistance gene localized on chromosome 7. This MDR can be compensated to a large extent by chemosensitizers (e. g. calcium antagonists). However, there was no clinical success and the side effects were stronger. • In a recent study, the combination of gemcitabine plus oxaliplatin seemed promising. (160) The application of 5′fluorouracil + cisplatin + IFN also proved well-tolerated and favourable. (89) With such chemotherapy, there are generally considerable side effects, particularly in the case of an underlying cirrhosis. • Overall, HCC shows hardly any response to systemic chemotherapy, so that this treatment does not really represent a therapeutic option.

Hormone receptor antagonist: The hepatocytes possess oestrogen receptors and react to oestrogen with proliferation. Therefore, it seemed advisable to apply anti-oestrogens as part of the therapy. However, the efficacy of these substances, e. g. tamoxifen at 10–20 mg twice daily, could not be confirmed. *Toremifen* appeared to be more successful. • *Cyproterone acetate* proved inefficacious as an anti-androgenic agent. *Flutamide* likewise showed no effect.

Immunotherapy: *Interferon-alpha* has an antiproliferative effect on tumour cells. Previous studies, however, have shown no success in HCC, not even when IFN was combined with cytostatics. • In order to improve the severely weakened immune system of tumour patients, *immunostimulants* (e. g. autologous lymphocyte infusion, thy-

mostimulin) were used. (135) The incorporation of liposomes loaded with monoclonal antibodies into tumour cells is a further therapeutic option. • In *gene therapy*, the application of so-called suicide genes by means of retroviruses (possibly even adenoviruses) has aroused particular interest. So far, however, the experimental gene transfer has not been sufficient to eliminate the respective tumour mass.

Somatostatin: Somatotropin release inhibiting factor (SRIF) displays antimitotic effects regarding various non-endocrine tumours. In animal experiments, *octreotide* retards tumour growth. The subcutaneous administration of octreotide (250 µg, 2x/day) led to a considerable improvement in survival time and quality of life. (90) This result could not, however, be confirmed. (19) There are still no clinical results available regarding the use of *lanreotide*, which has a longer action time.

3-bromopyruvate, a potent inhibitor of ATP, has proved efficacious as an intra-arterial injection. (55) Likewise, i.m. administration of **arginine deiminase** (160 IU/m²) was effective and well-tolerated. (40) • In recent studies, two further groups of substances have proved efficacious with good tolerance: *bevacizumab* for angiogenesis inhibition, and *sorafenib* as the dual inhibitor of Raf kinase and VEGF. They may well represent a new approach in the systemic chemotherapy of HCC.

3.9.4 Adjuvant measures

There are several adjuvant measures which are deemed unconventional, i.e. the purported therapeutic efficacy has not yet been confirmed in controlled clinical studies. In the field of oncology, many treatment approaches (cancer-related diets, medication, physical or instrumental therapy forms, psychological methods, etc.) have been propagated. • These should not be seen as alternative techniques, since they cannot replace the frequently tested and well-established methods used in surgery, radiology and chemotherapy. Thus they are known as “supplementary”, “additive”, “adjuvant”, and “complementary” measures or “best supportive care”. • It is understandable that many tumour patients or their relatives demand these treatment options besides the traditional mainstream medical care when the diagnosis of “cancer” has been made. Up to 70% of all tumour patients try out such unconventional methods in the course of their disease. • Numerous cancer-related diets have been extolled – none of which came up to previous expectations. Everybody is, however, at liberty to add various supplements (beetroot, probiotics, vitamins C and E, etc.) to their daily diet in line with the physiological principles of nutrition. • Moreover, special psychological treatment methods have been used, such as autosuggestion, crisis therapy, meditation and visualization. Psychotherapeutic and spiritual assistance can, without doubt, have positive effects on tumour symptomatology. A combination of *dietary recommendations*

+ *physiotherapy* + *psychotherapy* should indeed be included in the overall concept of cancer therapy.

► Both physician and patient are confronted with a wide range of *unconventional therapeutic measures*. It is logical that patients and their relatives resort, in their desperation, to any methods which may offer a therapeutic chance: “We have nothing to lose, but maybe we can defeat the cancer in the end; time and again, one hears of such healing or remission.” And which doctor would want to destroy hope even in the face of oncological reality? • The alternatives indeed cover a broad spectrum. (s. tab. 37.10)

Tab. 37.10: Some adjuvant or unconventional therapeutic methods used in malignant diseases

► Experiencing and coping with the diagnosis of carcinoma (and also “accepting” it) puts any patient under severe stress. As a consequence, the **immune system**, which is of essential significance in fighting the malignant disease, is usually weakened. • Subsequent *surgery* burdens the immune system even more. Unfortunately, *chemotherapy*, in addition to its cytostatic effectiveness, also results in massive long-term suppression of the immune system. This is equally true of *radiology*. • *The survival time varies considerably both in the natural course of disease and/or subsequent to invasive therapeutic measures mainly as a result of differences in individual defence systems*. • In comparative studies, the patients treated symptomatically (*how?* and *with what?*) often fare better in terms of survival time and the remaining quality of life – without painful therapeutic interventions, which often involve numerous side effects. The greatly varying efficiency of individual immune systems makes it difficult to compare the clinical and thus also

statistical data obtained from group studies, and this might also account for the divergent results. • The tested, carefully considered and (largely) well-established techniques of (1.) *surgery*, (2.) *radiology*, and (3.) *chemotherapy* continue to serve as unchallenged pillars in the treatment of malignant tumours. In future, (4.) *immunotherapy* will also play a more important (perhaps decisive) role – even though the patient’s “immune status” cannot (unfortunately) be measured adequately.

Nevertheless, all possibilities of activating the **immune system** should be made use of. These adjuvant measures can (and should) precede or simultaneously supplement any invasive treatment procedures.

Selenium: As a main constituent of glutathion peroxidase and thioredoxin reductase, selenium is a valuable antioxidant. The daily requirement of 75 µg is often not reached, especially by tumour patients, and substitution is necessary. In addition, malignant diseases generally show a reduction in the serum value of selenium. Moreover, it intensifies the cytotoxicity of T lymphocytes and natural killer cells, leading to a corresponding effect on tumour cells. This effect is enhanced through the stimulation of IFN-γ. The application of cytostatics thus becomes more favourable. A daily dose of 200 µg (–1,000 µg) selenium is recommended. (s. pp 55, 310, 388)

Zinc is of greatest importance for the normal functioning of the immune system. (s. pp 55, 635) In abdominal surgery, we usually detected pronounced *zincuria* (s. tab. 3.15), which, in our experience, could not be prevented by intravenous (even high-dosage) administration of zinc. Zinc deficiency, however, has negative effects on the immune system. • We found that postoperative zincuria could mostly be prevented in abdominal surgery by the peri- and postoperative administration of the aldosterone antagonist **potassium canrenoate**. *At the same time, major postoperative intestinal atonicity (probably due to potassium deficiency in the cells) was no longer observed in this condition!* • This was the rationale for administering zinc and potassium canrenoate intravenously in all cases involving abdominal surgery one day prior to and three or four days after the operation. *We wish to share these positive clinical experiences, which are free from side effects.*

At this point, it is worth mentioning several efforts aimed at preventing **metastasis formation** subsequent to surgical manipulation of the organ containing the primary tumour. • In 1984 **D-galactose-specific lectin** was discovered on hepatocytes. Lectins seem to play a major part in the “docking” of tumour cells on other organ cells. Apparently, the organ specificity of malignant cells is determined by the lectin pattern on the surface of their target cells, with which the corresponding sugars on the tumour cells link up. Animal experiments based on the **lectin-receptor theory** (G. UHLENBRUCK et al., 1986)

showed that the formation of liver metastases was almost completely prevented by administering D-galactose prior to tumour inoculation. In two pioneering clinical studies (compared to a control group), formation of liver metastases subsequent to colorectal tumour surgery was suppressed in 50% of patients within three years. A 5% D-galactose solution (1.6 g/kg BW) was infused 1 hour prior to surgery, and this was repeated until the third postoperative day. (365) • This use of galactose (or other carbohydrates?), which is free from side effects, should indeed be investigated. Such procedures can probably also be recommended in the puncture of tumours as a means of preventing tumour cell spread.

3.10 Fibrolamellar carcinoma

In 1956 this rare tumour was described by H. A. EDMONDSON in a 14-year-old girl as a “fibrosing variant of HCC in adolescents” (238); subsequent to tumour resection, the patient was without relapse for two years. J. R. CRAIG et al. (1980) outlined the specific clinical and histological criteria of fibrolamellar hepatocellular carcinoma (FHCC). Some 2–3% of HCC cases are assigned to FHCC; frequency is 20–60 cases/year in Germany. • FHCC shows the following features: (1.) it develops in a non-cirrhotic liver (cirrhosis frequency about 4%); (2.) it is found in younger people (between the ages of 5 and 35); (3.) men and women are affected with the same frequency; (4.) it is not associated with HBV or HCV infection (HBsAg is positive in 6–8% of cases); (5.) AFP values are not at all or only rarely increased (7–11%); (6.) FHCC is most often localized in the left liver lobe, generally as a grey, firm tumour. • With increasing growth, abdominal pain and weight loss occur. As the tumour grows in size, the transaminases, AP, γ -GT and copper values increase. (188, 194, 195) • With regard to **imaging procedures**, sonography yields a hyperechoic pattern, while CT and MRI show FHCC as a large, solitary and solid tumour. (184, 186, 187) The tumour resembles FNH by virtue of a generally recognizable central scar and multiple fibrous septa. FHCC was therefore suspected to be a malignant variant of FNH. In MRI, both the scar and the septa show hypodense signal intensity in T₁ and T₂ images. In contrast to FNH, haemorrhages, necroses or central fibrous scars and calcifications are occasionally observed in this hypervascularized tumour. Metastatic spread occurs late and initially into the abdominal lymph nodes.

The **diagnosis** is based on histology (because of hypervascularization using FNB or targeted biopsy under laparoscopy): large eosinophilic tumour cells with large nuclei and dense nucleoli are found. The polygonal tumour cells contain a copper protein as well as inclusion bodies (consisting of α_1 AT, α_1 FP, fibrinogen, ferritin, etc.). Granular eosinophilia is caused by a surplus of mitochondria. Lamellar connective tissue lies between the trabecular formations. (183, 185, 191, 193–195) (s. figs. 37.12, 37.13)

Fig. 37.12: Fibrolamellar hepatocellular carcinoma as is usually seen in a non-cirrhotic liver

Fig. 37.13: Fibrolamellar hepatocellular carcinoma: large, polygonal cells with granular-eosinophilic cytoplasm (based on a surplus of mitochondria) (HE)

A high vitamin B₁₂ value in the serum is typical, because the tumour cells trigger enhanced synthesis of transcobalamin I. Neurotensin and ceruloplasmin are also seen as tumour markers. • The **prognosis** of FHCC is generally more favourable than that of HCC and cholangiocarcinoma. Some 50–80% of patients are resectable. The survival rate after 5 years was 40–60% (the overall survival rate equals 3–16 years following surgery, but is no more than two years without surgery). After liver transplantation, the prognosis of FHCC is better than in HCC and CCC. (189, 190, 192, 195)

4 Cholangiocellular carcinoma

Intrahepatic localizations must be distinguished from extrahepatic CCC. They are subdivided into **three areas** of the large bile duct: (1.) the upper third from the liver hilum to the opening of the cystic duct (frequency about 49%); (2.) the medial third of the common bile duct (frequency about 25%); (3.) the lower third reaching to the opening into the duodenum (frequency about 19%). Diffuse involvement of the whole extrahepatic area was found in 7% of cases. • Tumours situated in the upper

third are designated proximal, central or hilar CCC and are also known as **Klatskin tumours**. (206) • Distal localizations of the extrahepatic CCC must be clearly differentiated from carcinomas of Vater's ampulla and pancreas head.

4.1 Definition

Cholangiocellular carcinoma (CCC) is a malignant tumour originating from the cholangiocytes of the intrahepatic small bile ducts (*peripheral CCC*) or the larger bile ducts (*hilar CCC*). Intrahepatic CCC is found with a frequency of 10%; this type is far more rare than hepatocellular carcinoma. More than 90% are adenocarcinomas. CCC occurs mainly between the ages of 60–70, with men and women being equally affected. Prognosis is poor; the survival time is one to two years.

4.2 Morphology

In more than 90% of cases, a (rather slow-growing) adenocarcinoma can be detected. Evidence of glandular and trabecular structures with substantial connective tissue-like stroma is typical. A reliable histologic diagnosis is only possible if carcinomatous changes in the bile ducts can be demonstrated, a process which is very rarely observed in a liver biopsy specimen. Usually, a highly differentiated tumour is present; lesser degrees of differentiation are only seldom found. Distinguishing between CCC and metastases or adenocarcinomas (e.g. of the gastrointestinal tract or pancreas) can prove extremely difficult. Evidence of keratin 7, 19 or 903 in the tumour cells is characteristic of CCC. Expression of lamina- γ -2 is believed to play an important role in growth-related morphology. (196, 197) (s. fig. 37.14)

Fig. 37.14: Cholangiocellular carcinoma with tubular glands (HE)

Morphological classification: Precise characterization of CCC in terms of growth pattern and staging is very important for optimal treatment planning and for determining a prognosis. (205, 208, 209, 211)

(1.) *Mass-forming type:* This form appears firm and coarse due to profusely developed stroma. The tumour is only slightly vascularized. It generally has a greyish-white, sometimes dark green colour and can reach a size of up to 15 cm in diameter; the margins are well circumscribed, but irregular. Central necrosis may be present. Satellite or daughter nodules are frequent and vary in size. Usually, this tumour type does not produce bile. Evidence of keratin 903 is considered to be typical. (196) In comparison to the other types of CCC, metastases are more frequently found in hilar and parapancreatic lymph nodes as well as in the peritoneum; the tumour itself often has a haematogenous spread. Vascular invasion is rare. (207, 215)

(2.) *Periductal-infiltrating type:* This form grows along the bile ducts; it is therefore elongated, spiculated or branch-like. The bile ducts proximal to this CCC may be dilated if the lumen is narrowed or even obstructed. The tumour remains unidentifiable for a long time.

(3.) *Intraductal-growing type:* This form is mostly a papillary adenocarcinoma. It comprises innumerable frond-like infoldings of proliferated columnar epithelial cells and a slender fibrovascular core. The tumour is generally small, but often spreads superficially along the mucosal surface, forming a kind of “papillomatosis”. Mostly, it produces a profuse amount of mucous, resulting in focal or segmental biliary obstruction with respective dilatations. Such a papillary adenocarcinoma has low-grade malignancy. • Some papillary tumours produce a large amount of mucin. This *mucinous tumour* is seen as a variant of the intraductal-growing type. (198)

Cholangiohepatocellular carcinoma arising from both cell types is a mixed form. (216) It sometimes appears as a subtype with two separate tumour forms or as a subtype with mixed HCC and CCC components. This type of carcinoma can develop in different parts of the liver; its subtypes may also be seen in close proximity to one another or even appear within the same tumour. It is rarely found in liver cirrhosis. Typically, there is extensive mucin production and evidence of glandular biliary epithelia. With the help of specific keratin patterns, these tumours can be identified immunohistochemically. Prognosis is poorer than in the case of the respective singular form.

Mucoepidermoid carcinoma was first described by L.E. PIANZOLA et al. in 1971. (225) It is a rare entity; this subtype constitutes only 2–3% of all CCC. Up to now, 41 cases have been reported. The tumour contains components of both adenocarcinoma and squamous cell carcinoma. It is discussed that this condition derives from a squamous metaplasia of the terminal ramifications of the bile canaliculi or from adenocarcinoma cells. A combination of HCC and mucoepidermoid carcinoma has been observed. (222) This tumour contains components of both cell types. A male predominance was found. The clinical findings and laboratory data are

similar to CCC. Pathogenesis is unknown; various congenital cysts of the biliary tract (221) and non-parasitic cysts (224, 226) as well as hepatic cholelithiasis (usually associated with infection) have been proposed as aetiological factors. (220) • Although its resectability was shown to be better than that of CCC, the prognosis is poor. (200, 223, 227) (s. tab. 37.1)

4.3 Epidemiology

CCC is rare, comprising about 7% of malignant liver tumours. The tumour is most commonly found between the ages of 60–70. Men and women are affected with the same frequency. Incidence is largely dependent upon regional risk factors; on average, it ranges from 1-8/100,000 inhabitants.

4.4 Pathogenic risk factors

The pathogenesis of CCC is associated with numerous risk factors. (1.) *Intrahepatic cholelithiasis* results in CCC in 5–10% of cases; chronic cholangitis is usually present. (219) (2.) *Parasitic infestation* of the bile ducts, e.g. *Clonorchis sinensis*, *Opisthorchis felinus* and *Opisthorchis viverrini* (204), may be associated with CCC in up to 60% of cases when it has been present for several years. (3.) *Congenital anomalies* of the bile ducts (biliary atresia, cysts, dilatations, Caroli's syndrome, Alagille's syndrome) (201) pose a much higher carcinoma risk. (4.) *Primary sclerosing cholangitis* increases the morbidity risk to 15–30%. (212, 213) Subsequent diagnosis of CCC was confirmed in 40% of a group of patients who had died from PSC and in 35% of liver transplant patients. The prevalence of CCC in patients suffering from chronic inflammatory intestinal diseases also rose by 0.2–1.4% with pathogenic association between PSC and ulcerative colitis, whereby CCC occurred earlier in these cases (i.e. from the age of 40). A higher frequency of mutations of the oncogenes (e.g. K-ras, c-myc, p16) and tumour suppressor gene p53 (213), with a strong expression of p53 in tumour tissue, was confirmed in patients with PSC-associated CCC. (5.) *Thorium dioxide*, which is stored lifelong in the RES, led to the development of CCC in many cases, with an average latency period of 35 years. (6.) *Chemical agents* such as dioxin, nitrosamine and aflatoxin are seen as risk factors for the development of CCC. (7.) *Medication* (isoniazid, anabolic steroids, methyl dopa, contraceptives) has often also been associated with an increase in CCC.

4.5 Clinical features and diagnosis

Symptoms: The clinical symptomatology principally depends on the localization of the tumour. Extrahepatic CCC manifests in most cases as obstructive jaundice. In intrahepatic localization of CCC, the developing clinical picture reveals abdominal pain, nausea, inappetence,

loss of weight and weakness; cholangitis is often observed. (199)

Biochemistry: Non-specific signs of inflammation, cholestasis parameters and increasing jaundice are found. The tumour markers AFP and CEA are normal, while the tumour markers CA 19–9 and CA 50 are usually elevated. There may also be mutations of the cyclin-dependent kinase inhibitor p16/MTS1. (s. tab. 37.11)

Tab. 37.11: Diagnostic parameters and examination techniques in cholangiocellular carcinoma

Sonography: In this biochemical constellation, sonography (also colour-encoded duplex sonography with visualization of the intrahepatic bile ducts) is the examination technique of choice, particularly when obstructive jaundice is suspected. There is evidence of prestenotically dilated bile ducts and, in some cases, accompanying strand-like, hyperechoic, infiltrating structures, which may be surrounded by a hypoechoic margin. The tumour itself can be identified in most cases, especially when it is localized in the liver hilum.

CT: This technique is useful for assessing intrahepatic carcinoma and detecting peripheral CCC. Occasionally, proximally dilated bile ducts can also be visualized. The gall bladder and the common bile duct are inconspicuous. Differential diagnosis of metastases or HCC can be extremely difficult. (217, 218) • **MR** cholangiography has become an important procedure due to more sophisticated technology. (s. fig. 37.15)

Fig. 37.15: Cholangiocellular carcinoma (↑) in CT with contrast medium

Cholangiography: If *ERCP* proves unsuccessful or if it is not possible to assess the bile ducts or the extent of tumour expansion, *PTC* is indicated. Nevertheless, *ERC* remains the method of choice, especially when combined with brush biopsy.

Scintigraphy: Hepatobiliary sequential scintigraphy imaging using ^{99m}T -etifenin can often provide additional information about tumour localization. Fluoro-2-deoxy-D glucose PET may be helpful in the diagnosis of perihilar CCC or metastatic spread.

Angiography: CT arteriography, CT arteriportography or MR angiography may help to detect vascular invasion and irregularities. Cholangiocellular carcinomas are poorly vascularized.

Laparoscopy: Laparoscopy should be used to confirm the diagnosis morphologically. This technique provides photodocumentary findings and also affords the possibility of targeted thick-needle, fine-needle or forceps biopsy. Tumour biopsy is only deemed necessary prior to palliative therapy. Moreover, *explorative laparoscopy* offers a much better overview of the whole abdominal area than does explorative laparotomy – and the risk involved is considerably lower. Carrying out laparotomy staging prior to liver transplantation is, in our opinion, also far less efficient and thus not indicated; instead, laparoscopy should be the technique of choice. (s. pp 158, 163, 169, 806)

4.6 Therapy

Resection or liver transplantation are considered to be the only curative forms of treatment for cholangiocellular carcinoma. • External or intracavitary radiation therapy is the method of choice when it comes to palliative measures. • The spectrum of adjuvant or alternative therapy procedures used in HCC is broad, as it is for all oncological conditions.

4.6.1 Invasive and surgical techniques

Classification of intrahepatic CCC is also made according to the TNM staging system. Due to the low frequency rate of CCC, experience of treating this tumour surgically by **resection** is limited. Patients with resectable tumours were reported to have a survival time of 12–24 months – which is not essentially longer than the normal course of disease. Survival times of more than 5 years have been reported in about 10% of cases. In 80–85% of patients, however, the tumour was not resectable at the time of diagnosis. (199, 203, 205, 210, 214)

Results to date concerning **liver transplantation** have been disappointing, so that this treatment is not considered to be indicated for CCC. Recurrence of CCC in a transplanted liver is most likely caused by immunosuppression. Attempts are hence being made to prevent such recurrence by combining liver transplantation with subsequent irradiation of the portal liver hilum and simultaneous administration of 5-FU.

Drainage therapy results in subjective improvement and decreases the risk of cholangitis. Techniques used include *biliodigestive anastomosis*, *percutaneous transhepatic drainage* or an *endoprosthesis* to bridge bile-duct stenosis.

4.6.2 Chemotherapy and radiotherapy

To date, **chemotherapy** for CCC has remained unsuccessful, no matter what kind of substance is used in monotherapy or polytherapy (e.g. 5-FU plus leucovorin). Local chemotherapy using arterial infusion of cytostatics may be indicated in individual cases. • **Radiotherapy** has no influence on survival time, but usually reduces pain.

4.6.3 Adjuvant measures

Even in cases of CCC which appear to be hopeless in terms of oncology, both the patient and the attending physician still have a broad spectrum of **adjuvant** and/or **unconventional therapeutic approaches** at their disposal. It is essential to provide sympathetic counselling and guidance for the desperate patient, who is prepared to seize any chance of preventing unnecessary suffering and harm. (s. p. 811) (s. tab. 37.10)

5 Cystadenocarcinoma

Primary biliary cystadenocarcinoma (CC) was first described by P. BASCHO in 1909. It is a rare tumour (about 120 cases have been reported) which occurs in malformations of the bile ducts. CC mainly affects women and is predominantly found in the right liver lobe. Cystadenomas or choledochal cysts are seen as a probable precursor. (229, 232, 233, 235) Diagnosis is reached using imaging techniques (228, 231) and histology (229, 235).

Sometimes, CC develops without ovarian-like stroma. (230) The marker CA 19-9 may be increased. The tumour is usually made up of plurilocular cysts with papillary folds lined with carcinomatous biliary epithelium and contains bile-stained mucinous material. It is surrounded by a fibrous capsule consisting of dense hyaline stroma. (229) CC with a “pseudosarcomatous growth pattern” has been described (P.D. UNGER et al., 1987). After resection, the survival rate can be as high as five years. (234) (s. tab. 37.1)

6 Hepatoblastoma

The most common liver tumour in children is malignant foetal hepatoblastoma. (238) (s. tab. 37.1) It constitutes 30–45% of all primary liver tumours and 50–60% of all malignant tumours occurring in childhood. (239, 240, 241, 243) Hepatoblastoma is often associated with a congenital anomaly, especially with familial adenomatous polyposis coli. (236) The tumour is partially lobulated by fibrous septae and well-vascularized. Arising in the endodermal liver epithelium, it usually becomes manifest prior to the third year of life, but rarely in older children or adults. (242, 245) Boys are affected twice as often as girls. • *Histologically*, there are *three types*: (1.) epithelial type with embryonal hepatocytes or foetal hepatocytes, (2.) mixed-cellular type containing epithelial and mesenchymal components, and (3.) anaplastic type with small, undifferentiated cells. • *Embryonic hepatocytes* are small, partially spindle cell-like, cuboidal or polygonal, and display uniform hyperchromic cell nuclei. The sparse cytoplasm is easy to stain. The cells have band-like or rosette-like structures. *Foetal hepatocytes* are larger and possess a marked cytoplasm; they contain abundant glycogen and form canaliculi as well as cellular trabeculae between the sinusoids. Epithelial cell nests of bright and dark cell elements alternate. Haematopoietic foci are detectable in the area of the foetal hepatocytes. (s. fig. 37.16)

Fig. 37.16: Hepatoblastoma (three-year-old boy) with mainly foetal differentiation (HE)

Macroscopically, there is usually a solitary medullar tumour, 5–15(–25) cm in size, which mostly develops in the right liver lobe. A tumour capsule is found in 50% of cases. It may contain necroses, haemorrhages and calcifications. This tumour grows relatively rapidly. Metastatic spread affects the infradiaphragmal lymph nodes, lungs and brain. Immunohistochemistry shows an expression of cytokeratin 7, 8, 18 and 19, or AFP as well as vimentin. • Hepatomegaly, fever, anaemia, growth retardation, sexual precocity (due to ectopic gonadotropin), abdominal pain and high or non-decreasing values of α_1 -foetoprotein (which normally decreases in the first years of life in healthy infants) are suggestive of the kind of tumour. Imaging techniques and biopsy facilitate the diagnosis. (237) Cystathionine is increased in the urine in most cases. Early detection allows curative resection in about 20% of children. Preoperative chemotherapy may help to reduce the tumour size, thus leading to better surgical results. (238, 239, 244) Liver transplantation is sometimes indicated. (240)

7 Mesenchymal liver tumours

7.1 Embryonal sarcoma

Undifferentiated embryonal sarcoma (UES) was first described by J.T. STOCKER et al. in 1978. (251) (s. tab. 37.1) This mesenchymal tumour is the third most frequent tumour in childhood and adolescence; occurrence in adults is a rare event. (248) There are no gender-related differences. It is predominantly localized in the right hepatic lobe. The tumour presents as a well-circumscribed node with a size up to 20 cm in diameter comprising cystic zones (of necrotic tissue and blood). An association with a mesenchymal hamartoma is discussed (249), especially since alterations in chromosome 19q have been detected in both conditions. • The polynuclear tumour cells are star-shaped or fusiform with numerous mitoses. In addition, there are large cells with PAS-positive, diastase-resistant globular inclusions. The tumour cells show no differentiation; they are surrounded by pronounced myxoid stroma. (12, 250, 252) • In a CT scan, the tumour appears hypodense with a peripheral capsule. (247) This malignancy is not (or only slightly) vascularized. It grows rapidly and can infiltrate the neighbouring organs or metastasize in the lung or abdomen. US shows a solid space-occupying lesion with an inhomogeneous reflex pattern and circumscribed cystic areas. • If feasible, resection is indicated, possibly in combination with chemotherapy. (246) A ligature of the hepatic artery may also be applied. Recidivation after resection therapy is frequent. The three-year survival rate is about 30%. (252, 253)

7.2 Epithelioid haemangioendothelioma

Epithelioid haemangioendothelioma is a malignant mesenchymal tumour, which was first described in the

liver by S.W. WEISS et al. in 1982. (s. tab. 37.1) It is probably a variant of haemangiosarcoma, but with a much better prognosis (approx. 50% of patients survive for more than 5 years). This multifocal, vascularized tumour with low-grade malignancy can affect the liver primarily or appear in the liver as a metastasis. Women are more affected than men. Usually, the liver is interspersed with multiple, firm and greyish-white lesions up to 3-11cm in diameter. (12) There are no differences in frequency with respect to age. The tumour cells grow along the vessels, whereby the portal fields and the acinar structure are unchanged. These cells are irregular-shaped, dendritic or spindle-like; they may display intracytoplasmic vacuoles and *Weibel-Palade bodies* (E.R. WEIBEL et al., 1964) as markers of arterial endothelia. The stroma contains collagenous fibres, mucopolysaccharides and, later on, calcifications as well. (255) Often, a Budd-Chiari syndrome is mimicked. (268) Immunohistochemical demonstration of factor VIII antigen is helpful in differential diagnosis. An association with vinyl chloride and contraceptives as well as with NRH has been postulated. (263) • Some laboratory parameters (AP, GPT, GOT, bilirubin) are increased. • Imaging procedures show a space-occupying lesion without characteristic findings. (261, 266, 267) Diagnosis can only be reached by means of histology (254, 256–258, 260, 262, 265), best guaranteed with (forceps) biopsy under laparoscopy. (257) • The tumour grows slowly, but may metastasize. (254, 258, 259) Resection mostly cannot be carried out. Liver transplantation is the therapy of choice, occasionally combined with IFN. The five-year survival rate is >75%. (259, 260, 264)

7.3 Angiosarcoma

Angiosarcoma is the most frequent mesenchymal tumour; it has a soft consistency. (12) *Macroscopically*, conglomerate sponge-like nodes are found, which are partially greyish-white and interspersed with haemorrhages or central necroses. They are highly vascularized and show blurred margins. Smaller satellite nodes may also form. • *Histologically*, this tumour consists of polymorphous, fusiform sinusoidal endothelial cells, which line blood spaces and grow in a confluent infiltrative manner. The rate of mitoses is high. There are peliosis-like dilated cavities. Polynuclear giant cells may be present. Infiltration of tumour cells in portal or central veins and extramedullary foci of haemopoiesis are usually demonstrable. Liver cell plates, provided they remain in position, are characteristically enwrapped by tumour cells. Immunohistochemically, factor VIII-associated antigen can be detected. (s. figs. 30.1; 37.17)

Angiosarcoma is closely associated with the effects of thorium dioxide (273) (s. p. 586!), chronic arsenic poisoning (278) (s. p. 586!) and exposure to vinyl chloride (276) (s. p. 584) or radium as well as with neurofibromatosis

Fig. 37.17: Hepatic haemangiosarcoma (s. fig. 30.1) (HE)

or haemochromatosis. Transition of infantile haemangioendothelioma and cavernous haemangioma into angiosarcoma has been reported. It has also been observed following the intake of phenylhydrazine and anabolic (271) or contraceptive steroids. Older people are mainly affected, men more than women (3–4:1). In childhood, girls are the main sufferers. (269) • The tumour progresses quickly, grows multicentrically (in the shape of a cavernoma or node) and is localized in both hepatic lobes. The survival time is less than one year. Metastatic spread occurs in the lungs and hilar lymph nodes as well as, occasionally, in the spleen and bones. (277) Diagnostic biopsy (even as FNB) is contraindicated in this highly vascularized tumour. (272) Diagnosis is made by CT angiography, FDG PET or MR angiography. (274) Vascular murmur “over” the liver may be audible. A sudden complication is a rupture with haemoperitoneum; DIC sometimes develops. The course is irrepressibly progressive; the prognosis is poor.

7.4 Leiomyosarcoma

Leiomyosarcoma originates from smooth-muscular elements of the liver, which are located in the walls of vessels and around bile ducts. (12) Men and women are affected with the same frequency, predominantly in middle age. It is a very rare mesenchymal tumour (only about 50 cases have been reported so far). This tumour grows slowly, the colour is greyish-white and the consistency is firm; it can reach up to 35 cm (!) in diameter. Occasionally, there are multiple nodes. (281) It not only occurs in the liver (mainly in the right liver lobe), but is also found in the round ligament, the hepatic or portal veins (280) and inferior vena cava (283) (possibly together with the Budd-Chiari syndrome). The tumour cells appear homogeneous and spindle-like with eosinophilic cytoplasm. Clinical findings or imaging results are non-specific; splenomegaly and ascites may occur. (279, 281, 282, 284) Therapy consists of tumour resection.

7.5 Rhabdomyosarcoma

Rhabdomyosarcoma is a mesenchymal tumour of grey colour with partially cystic growth. (12) It mainly occurs during childhood. (285) The tumour cells appear small, round or spindle-like, hyperchromatic, sometimes with eosinophilic cytoplasm. (287) They show various stages of differentiation of embryonal skeletal muscle cells. This tumour originates from peribiliary located muscular structures. (285) • An association with the long-term use of oral contraceptives has been reported. (286)

7.6 Fibrosarcoma

Fibrosarcoma is a mesenchymal tumour originating from fibroblasts; it can therefore occur ubiquitously in the whole body. (12) It was first described by R.H. JAFFE in 1924. About 35 cases have been reported so far. This type of tumour has a firm consistency and contains cystic structures with focal necroses and haemorrhages. It possesses a fibrous pseudocapsule and consists of fascicularly arranged, spindle-like or fusiform tumour cells embedded in parallel collagen fibres. The non-epithelial stroma marker vimentin is overexpressed. These cells may exhibit marked polymorphism. Fibrosarcoma mainly occurs in men of advanced age. Therapy consists of tumour resection and adjuvant chemotherapy. (288, 289)

7.7 Fibrous histiocytoma

Malignant fibrous histiocytoma (MFH) is a rare mesenchymal tumour of histiocytic origin. This tumour was first described by L. OZELLO et al. (1963) and J.E. O'BRIEN et al. (1964). It has not yet been clarified which cell type this tumour derives from and whether it is a single entity. The tumour tends to develop in the tissue of the extremities and in the retroperitoneum. MFH rarely occurs in the liver (so far, reports of 22 cases have been published). (12) The tumour cells contain a vacuolated cytoplasm with oval-polymorphic nuclei; giant cells may be present. (291, 292) MFH shows a firm consistency and greyish-yellow colour. There are no typical findings. (290, 293, 294) It appears mainly in patients of advanced age. Diagnosis is confirmed immunohistochemically. The prognosis for this extremely aggressive tumour is poor. Resection at an early stage with subsequent chemotherapy is the only possible therapeutic option.

7.8 Malignant schwannoma

Malignant schwannoma is a very rare mesenchymal tumour derived from the Schwann cells or nerve-sheath cells. It is also termed neurilemmoma or neurinoma. Only about ten cases involving the liver have been reported. This tumour is mostly associated with neurofibromatosis. Men are more frequently affected than women. Schwannoma usually occurs in the ages between 20–50 years. It shows a firm consistency and

has a greyish-white colour. Generally, there are multiple lesions. In the tumour itself, necroses and haemorrhages are found. Schwannoma consists of strands of spindle cells which interweave to form a herringbone pattern. The stroma contains strong bundles of collagen fibres. There are cell polymorphisms and mitoses as well as areas of densely grouped cells. Expression of S-100 antigen from the tumour cells is increased. A high level of alkaline phosphatase is a characteristic finding in spite of normal transaminases. Prognosis is relatively poor. (295, 296)

7.9 Hepatic liposarcoma

The first liposarcoma observed in the liver was reported by J.I. KIM et al. in 1987. (297) Up to now, about 10 cases have been published. Bright yellow tissue containing mature fat cells admixed with scattered immature lipoblasts were found in various stages of development. Moreover, hyperchromatic nuclei in pleomorphic tumour cells, eosinophilic cytoplasm and fusiform cells were evident. (298) On US, liposarcoma is generally inhomogeneous with hypoechoic or hyperechoic features. Also on CT, this myxoid tumour is inhomogeneous and has Hounsfield units ranging from near-water density to that of muscle and may exhibit contrast enhancement. In addition, cystic areas and septated areas may be seen in MRI.

7.10 Hepatic osteosarcoma

Primary hepatic osteosarcoma is a very rare mesenchymal tumour, which was first described by J.H. MAYNARD et al. in 1969. It is of greyish-white to pale yellow colour and shows a gritty consistency. It grows rapidly with an aggressive behaviour. The survival time is short. • Histologically, there are different components, such as osteoblastic, chondroblastic and fibroblastic cells. Numerous osteoblastic-like giant cells are present. Expression of vimentin is positive, whereas actin, desmin and cytokeratin are not detectable. The tumour cells produce lace-like osteoid. (299, 300)

8 Neuroendocrine tumours

These tumours generally grow slowly. They develop from the neuroendocrine system, which is considered to be part of the APUD system (= amine precursor uptake and decarboxylation) (A.G.E. PEARSE et al., 1978). However, due to the secretion of biologically active hormones, they give rise to manifold clinical symptoms. Such tumours very seldom develop primarily in the liver. They meanwhile present a real diagnostic challenge even for today's sophisticated imaging procedures. (305) (s. fig. 37.28)

8.1 Hepatic gastrinoma

This primary hepatic gastrinoma is a rare event, although the liver is a very common site for gastrinoma metastases. Hepatic gastrinoma is a subtype of the neuroendocrine tumour. It tends to occur in slightly younger patients or those with a Zollinger-Ellison syndrome. Males are more frequently affected than females. Gastrin levels in the serum are high. Imaging procedures for diagnosis include somatostatin-receptor scintigraphy with ^{111}In DTPA octreotide. Because of the slow growth and the feasibility of resection, the prognosis is relatively good. (301–304)

8.2 Primary hepatic carcinoid

The term “carcinoid” was coined by S. OBERNDORFER in 1907 as a result of observations involving tumours in the small intestine. H. HARTMANN first reported a primary hepatic carcinoid in 1920. To date, only few cases have been described in the literature. Its histology is similar to that of adenocarcinoma, but it is aggressive. • Hepatic carcinoids are mostly metastases arising from primary carcinoids in the area of the appendix, stomach or colon. Such carcinoids may infiltrate the liver diffusely or form nodes and cysts. Both primary and metastatic forms have a brownish colour and grow slowly. Endocrine tumour cells show ribbon-like or rosette-like patterns; they may develop along the intrahepatic bile ducts and lead to the formation of hepatic carcinoid tumour. The inclination to infiltrative growth and metastatic spread apparently depends on the localization and size of the tumour. (306, 309) Expression of neuroendocrine marker proteins (chromogranin A, synaptophysin, neuro-specific enolase, etc.), but also of CEA, is found. (308) A specific marker is the enhanced excretion of 5-hydroxyindolacetic acid in the urine (> 30 ng/24 hr).

Biochemical parameters are only slightly altered. Imaging techniques show space-occupying lesions. In sonography, this tumour is echogenic with many cystic areas. Lesions are markedly hypervascular on colour Doppler US and angiography. (307) The diagnosis, however, is only secured histologically or by scintigraphy with I^{131} -meta-iodobenzylguanidine or octreotide. The *carcinoid syndrome* is triggered by the release of serotonin from the tumour cells into the blood circulation. A larger amount of serotonin in the blood causes a “flush” (= pronounced redness of the face and upper body due to vascular dilatation, which may last several hours) as well as sweats, hypotension and bronchospasms. • Octreotide or ketanserin are useful medicinal agents. Surgery (resection or possibly transplantation) is indicated. Chemoembolization also shows good results.

9 Malignant lymphoma

Primary malignant lymphoma of the liver is rare (A.A. ATA et al., 1965); so far, about 100 cases have been described. It occurs both in children and adults; how-

ever, men older than 50 years are mainly affected. There is a close association to immunosuppressed patients, especially in HIV infection. (312) Single observations regarding a pathogenetic relationship with EBV infection, hepatitis B and C, PBC (319), coeliac disease and lupus erythematosus have not been confirmed. Lymphadenopathy is absent. • *Histology* shows lymphomatoid infiltrations in the portal fields; they can penetrate the neighbouring parenchyma. These lymphomas derive from the lymphocytes and Kupffer cells of the portal fields. About two-thirds of the hepatic lymphomas are B cell type and one-third are T cell type, the latter usually consisting of anaplastic large cells (H. STEIN et al., 1985). Malignant lymphomas generally develop as solitary nodes, less frequently in the form of multiple nodes, and, occasionally, as diffuse infiltrations throughout the entire liver. (316) Special forms include low-grade malignant B cell lymphoma of the *MALT type* and *$\gamma\delta$ -T cell lymphoma*. (314, 318) The latter affects mainly younger adults, and its course is more aggressive. In this subtype, the spleen and bone marrow are also involved. • Clinical and imaging findings are not characteristic (313); in most cases, fever, loss of weight and night sweats are found. The transaminases may be increased. Diagnosis is confirmed by histology and with the help of immunohistochemical examinations of epithelial and lymphatic antigens. Reactive lymphatic hyperplasia must be ruled out as a differential diagnosis. • The mean survival time is one to two years. Therapy consists of resection and chemotherapy. (310, 311, 315, 317, 320)

10 Liver metastases

10.1 Definition

Metastasis (“tumour spread”) is a secondary focus of disease caused by haematogenic, lymphogenic or ductal transport of living or dead matter from the primary focus of disease. • In the narrow sense of the term, **metastasis** is the secondary or “daughter” focus (“filia”) of a malignant primary tumour. It may manifest as *local metastasis* (with a local relationship to the primary tumour as a neighbouring metastasis due to continuous tumour growth, e.g. in gall-bladder carcinoma), *regional metastasis* (within the regional lymphatic system) or *distant metastasis*. Metastases occur spontaneously or due to mechanical transportation. • **Liver metastasis** develops via the portal vein (particularly in carcinomas of the gastrointestinal tract), via the hepatic artery (e.g. from the lung, breast, oesophagus, pancreas, and in melanomas) or via retrograde lymphatic permeation and extension along the vascular lumen. This occurs in 30–35% of all malignancies and in 45–50% of abdominal tumours. In 95–97% of cases, liver metastases cause malignant hepatic lesions.

10.2 Morphology

Liver metastases may occur as well-demarcated solitary or multiple nodes and can ultimately infiltrate almost the whole liver tissue. This metastasis itself results in extreme *hepatomegaly* (>5,000 g). In most cases, there are clearly limited nodes of a greyish-white colour and firm consistency. The consistency depends on the ratio of cancer cells to fibrous stroma. Metastases tend to bulge from the liver surface; localization is very rarely confined to the interior of the liver. A solitary node is found in some 10% of patients at the time of diagnosis; in 15–20% of cases, only one lobe is affected. • There is often a central depression due to tumour necrosis caused by insufficient blood supply within the tumour (= *cancer umbilicus*). (s. figs. 37.18, 37.19) Sometimes, the metastases are enclosed in a fibrous pseudocapsule. (362) The immediate surroundings of the metastases are occasionally characterized by a dark, bluish-red discoloration due to venous hyperaemia (= **Zahn's infarct**).

Fig. 37.18: Large metastasis in the right hepatic lobe with distinct “cancer umbilicus” subsequent to breast cancer (serosa, peritoneum and ligaments without pathological findings)

Fig. 37.19: Pronounced liver invasion by metastases of varying sizes partly with “cancer umbilicus” and neovascularization. Clinical diagnosis: bronchial carcinoma

Fig. 37.20: Liver metastases of G3 prostatic carcinoma

In rare cases (particularly in small-cellular bronchial carcinoma), diffuse metastasis develops (s. figs. 37.19, 37.21), which resembles liver cirrhosis and may cause acute liver failure. (324, 342) • *Histology* is often similar to that of a primary tumour. (s. figs. 37.22, 37.23) However, there may also be considerable deviation, which makes classification of the primary tumour difficult and uncertain, or indeed impossible. (326) • In *liver cirrhosis*, metastases are less frequent, whether due to the altered vascular structure of the cirrhotic liver, an enhanced content of metalloproteinases, decreased expression of adhesion molecules or the fact that the patients do not survive long enough for the formation of metastases to become evident – the short survival time is a result of the combination of cirrhosis and carcinoma. (363) Fatty liver or angiostatin suppresses angiogenesis in metastases. (348) By contrast, alcohol consumption enhances liver metastasis in colon carcinoma. (357) • *Spontaneous regression* has also been reported. (334, 346)

Adjacent tissue often shows local, *non-specific reactive hepatitis* (activation of Kupffer cells, small round-cellular infiltration of the sinusoids and portal fields, single-cell necroses, nodular infiltrations). (s. fig. 21.1)

Fig. 37.21: Sinusoidal infiltrates of a small-cell carcinoma of the lung (HE)

Fig. 37.22: Metastasis of a highly differentiated colonic adenocarcinoma (HE)

Fig. 37.23: Metastasis of a malignant granulosa cell tumour of the ovary (HE)

10.3 Symptomatology

The occurrence and growth of liver metastases are accompanied by increasing lassitude and malaise, a pervasive feeling of weakness, febrile attacks, upper abdominal pain, inappetence, night sweats and weight loss. Pronounced hepatomegaly is often found, together with

Fig. 37.24: Pronounced peritoneal metastasis (with simultaneous liver metastases) in ovarian carcinoma

a hardening of the liver and occasional palpability of the tumour nodes. The spleen may also be enlarged. Jaundice usually develops as the tumour continues to grow. Pleural effusion, oedema (reflecting obstruction of the inferior vena cava), ascites (reflecting peritoneal metastases) (s. figs. 37.24, 37.25), haemoperitoneum (368) and thrombosis of the portal vein may occur. Sometimes, there is a swelling of the lymph nodes, especially in the right supraclavicular region. • Tumour cells have a limited lifespan in the blood circulation (<24 hr) if the defence system of the body is intact. Even if a peritoneovenous shunt is carried out in malignant ascites, metastatic spread is rare.

Fig. 37.25: Chylous ascites, greenish-coloured due to bile, in colon carcinoma, with metastases in the liver and peritoneal cavity

10.4 Diagnosis

Biochemistry: Non-specific signs of inflammation become more pathological. A rise in γ -GT, initially as an isolated value, is characteristic; this is then accompanied by higher cholestasis-related parameters. (328) In addition, there is an increase in LDH, GPT, GOT and the DeRitis quotient. Gamma GT is also seen as a control parameter in chemotherapy. In colorectal liver metastases, the serum value of endothelin-1 is often elevated. (370) • While **tumour markers** can be helpful in establishing the diagnosis and for classifying metastases, they are of even greater importance in monitoring the course of disease. (s. tab. 37.12)

Sonography: Metastases can be detected from a size of >0.5 cm. Diffuse infiltration is not visible. Due to their high water content, metastases appear as hypoechoic lesions. (s. p. 144) (s. figs. 6.20; 37.26–37.28) With continued growth, central echo amplifications occur due to regressive tissue changes. In metastasis, a halo has a specificity of 86% and a sensitivity of 88% – a finding which, however, also applies to benign tumours. A bulging liver surface or displacement of the vessels and bile ducts may also point indirectly to metastases. Normal sonographic findings do not exclude metastasis of the

Tab. 37.12: Laboratory findings and tumour markers arousing suspicion in liver metastasis

Fig. 37.26: Early metastases (0.7–1.0 cm (↑) detected during aftercare following sigmoid carcinoma surgery

liver. Ascites or haemoperitoneum (368) can occasionally be found. • With a sensitivity of 96%, *endosonography* is the gold standard. (343, 352, 360, 364) • Detection of *calcified liver metastases* by sonography or CT is rare (340); we were able to observe this event subsequent to surgical removal of a colon carcinoma and a breast carcinoma. (s. figs. 37.29, 37.30)

CT: Most metastases are hypodense prior and subsequent to the application of contrast medium. Sensitivity

Fig. 37.27: Numerous centrally liquefied liver metastases (differential diagnosis: liver abscesses)

Fig. 37.28: Metastases of a neuroendocrine tumour (carcinoid): typically complex space-occupying structure with echo-free and echo-rich parts. Colour-coded duplex sonography shows intensive tumour vascularisation

Fig. 37.29: Calcified liver metastasis and other small hypoechoic tumours; condition after resection of a colon carcinoma

Fig. 37.30: Calcified metastasis after treatment of breast cancer: hyperechoic pattern and numerous white nodules representing microcalcifications (↑)

Fig. 37.33: Laparoscopic staging: peritoneal metastases in gastric carcinoma

Fig. 37.31: Liver metastases in colon carcinoma with fatty liver: foci in both liver lobes, hyperdense margin formation with central hypodensity

Fig. 37.34: Laparoscopic staging: metastases at the falciform ligament in oesophageal carcinoma

Fig. 37.32: Numerous cystoid liver metastases due to a central necrotizing process (differential diagnosis: liver abscesses)

is 92% in foci of > 15 mm, but only 55% in smaller ones. When there is concomitant fatty degeneration, CT is inferior to sonography for the detection of metastases. The best results were achieved by using spiral CT and CTAP with a sensitivity of 92–93%; all metastases larger than 6 mm could be identified. (335, 350, 360, 372) (s. p. 183) (s. figs. 37.31, 37.32)

MRI: Metastases usually show low signal intensity in T₁-weighted images and high signal intensity in T₂-weighted images. Necrotic metastases may show a signal intensity in T₂-weighted images similar to that of haemangioma. In contrast-amplified T₁-weighted images, perifocal oedemas can be distinguished from the tumour. Haemorrhages are signal-intense in T₁-weighted images. Sensitivity is 85–95% and can be further improved when superparamagnetic iron oxides are used. (335, 350, 373) (s. p. 186) (s. fig. 8.8)

Fig. 37.35: Laparoscopic staging: Melanotic and non-melanotic metastases of melanoma (right liver lobe with transition to right abdominal peritoneum; liver capsule/peritoneal adhesions)

Fig. 37.36: Liver metastasis of a malignant melanoma: dark-brown coarse-grained pigment in melanoma cells (HE)

Laparoscopy: If it has not been possible to make a clear diagnosis, explorative laparoscopy now becomes the method of choice. (s. figs. 37.18, 37.19, 37.35) This technique allows excellent *inspection* of the whole abdominal cavity, also for the purpose of **staging**, as well as facilitating targeted, low-risk biopsies, preferably using forceps. With the help of this method, we very often found small metastatic foci, for example on the peritoneum (s. fig. 37.33) or the falciform ligament (s. fig. 37.34), which could not be detected prior to surgery by any other technique (not even by explorative laparotomy).

All findings are documented using **photolaparoscopy** and, together with histology, they can facilitate a more reliable assessment both for the pathologist and for *interdisciplinary discussion* of any therapy concept which may be necessary – this applies to other diseases as well. (347, 359, 367) (s. p. 164) • **Fine-needle biopsy** allows cytological diagnosis in a high percentage of cases.

10.5 Metastases in children

In children, metastases are also found far more frequently than primary liver tumours. Generally, we may

expect metastases from the same tumour types in children as are observed in adults. However, two types of tumour are particularly important in this respect.

(1.) **Wilms' tumour:** This extremely malignant embryonic adenosarcoma of the kidney causes liver metastases in 20–25% of cases.

(2.) **Neuroblastoma:** Liver metastases develop with extreme rapidity within the first six to nine months of life. The general condition is not compromised until later. This metastatic spread is a result of a sympathogonioma which has its origin in the adrenal medulla or autonomic ganglia. Such a clinical picture is also termed *Pepper's syndrome* (W. PEPPER, 1901).

10.6 Therapy

The manifestation of liver metastases and their prognosis are largely determined by the localization and degree of malignancy of the primary tumour. The survival time subsequent to the detection of metastases is about one year. Patients with liver metastases from colon carcinoma have the most favourable prognosis.

As a general principle, treatment of liver metastases should be preceded by an **interdisciplinary consensus conference** – this also applies to primary liver tumour. (s. p. 807)

10.6.1 Resection therapy

The choice of resection procedure is based on the size, location and number of the metastases. (321, 330, 332, 361) (s. pp 807, 825, 900)

Metastasectomy: Using this method, small and superficial metastases can be removed without having to pay attention to vessels; a safety margin of 1 cm around the metastases should be adhered to. (374)

Segmental resection: In some cases only a monosegment is resected, in other cases bisegmental or polysegmental resections are carried out to remove adjacent segments. Under certain conditions, multi-segmental resection is used for removing several segments from different areas of the liver at the same time. Perisegmental resection is necessary when a metastasis is located on the boundary between two separate segments. • In all these resection procedures, it is also necessary to adhere to a safety margin of 1cm (although the technique of parenchymal dissection used today makes it possible to resect with a smaller safety margin). (322, 329, 330, 336, 337, 344, 355, 378)

Parenchymal dissection: Instead of the parenchymal-fracture technique used in the past, ultrasound dissection or aqua-jet dissection is now applied.

Parenchymal sealing is usually carried out by means of fibrin spray if the wound surface is “dry” or by means of argon beamer if the wound surface is still bleeding.

To date, resection of liver metastases of colorectal or neuroendocrine tumours is the only treatment option which may result in definitive removal of the cancerous disease. Resection is indicated in those cases in which the primary tumour can be removed completely and when no further metastases are detectable. Repeated resection is also possible. Extrahepatic metastases or involvement of neighbouring organs are generally no longer regarded as contraindications. (322, 323, 329, 330)

Morbidity should not exceed 30%. Lethality is between 0–3%. The 5-year survival rate following **R0 resection** in metastatic colorectal carcinoma is 20–40%, in neuroendocrine tumours 90–100%, in malignant melanoma 15–25%, and in breast cancer 10–30%. Prognosis is poor in metastasizing renal cell carcinoma and in gastric or pancreatic carcinoma. Both **R1** and **R2 resection** worsen the prognosis to the same extent.

The following factors are decisive for the success rate: (1.) age of the patient, (2.) distribution pattern and number of metastases, (3.) size of the largest metastasis, (4.) stage of primary tumour, (5.) extrahepatic metastases, (6.) lymph node involvement, (7.) respective value of the tumour marker, and (8.) intraoperative blood loss. (336)

For the follow-up after resection, sonography and determination of CEA and CA 19-9 (or other relevant markers) are necessary. In about 60% of cases, resected liver metastases recur; in about 30% of these patients, repeat resection is possible. (379)

In patients undergoing surgical resection of colorectal liver metastases, haematogenous tumour cell dissemination could be detected in preoperative blood samples in 30%, in intraoperative blood samples in 46% and in postoperative blood samples in 22% as well as in bone marrow samples in 16% of cases. • Thus, there are once again good reasons for using *neoadjuvant systemic chemotherapy* together with perioperative administration of *i.v. galactose infusions*. (351)

10.6.2 Cryotherapy

This technique, first described by J. ARNOTT in 1945, was applied by I.S. COOPER in 1963 for liver metastases. The treatment uses a probe, introduced (possibly by laparoscopy) into the tumour, which is subsequently frozen with liquid nitrogen at a temperature of -196°C . The result is necrotic degeneration of the tumorous tissue. Usually, two freezing procedures lasting 15 minutes each are carried out. The risk of damaging the large vessels is relatively low. The advantage of cryotherapy is that the tumour cells are kept in place mechanically with the help of the extracellular ice matrix, thus inhibiting dissemination of the tumour cells. The method is painless. However, there are some disadvantages, including the

high costs and the more pronounced parenchymal trauma. (339, 349, 358, 366, 369) (s. p. 808)

10.6.3 Liver transplantation

In the case of diffuse metastasizing in the liver due to a neuroendocrine tumour, transplantation may be indicated.

10.6.4 Local treatment

There are no clear recommendations concerning indications for percutaneous interventional procedures. It is uncertain whether the metastases have been completely removed when guiding is based on imaging techniques. Moreover, the extent of the placed necrosis can only be assessed in a limited way; however, evaluation is more exact if the resected tissue is analyzed histologically.

RFTA: The monopolar system which has been used up to now will probably be replaced in the near future by a bipolar system. Coagulation necrosis of up to 5 cm can be achieved. However, RFTA sometimes has a negative impact in areas near the large vessels, since the cooling effect may cause the tumour cells close to the vessel walls to survive, with a risk of recidivation. In special cases, RFTA can also be applied as an open (operative) technique. A combination of ablation therapy and resection is possible. RFTA has several advantages: it is relatively low in cost, there is less parenchymal loss, the procedure is safe and can be repeated. (353) (s. p. 811)

LITT: Even in the case of liver metastases, the laser applicator is positioned using a percutaneously or laparoscopically inserted puncture needle. The procedure lasts 15–20 minutes. Repeat treatment is possible. (331, 356, 376) (s. p. 810)

PEI: Percutaneous ethanol injection therapy with alcohol or acetic acid is not recommendable in liver metastases. (338)

10.6.5 Local chemotherapy

TAC: Application of cytostatics is generally carried out using a port-catheter system via the gastroduodenal artery and the proper hepatic artery (R.D. SULLIVAN et al., 1964). Foci in excess of 2 mm are supplied by this artery in 80–100% of cases. Moreover, the blood flow can be slowed down by administering starch microspheres or similar substances, so that a higher concentration of cytostatics is achieved in the tumours. In order to avoid toxic damage, the right gastric artery must be ligated and a cholecystectomy carried out; cholangitis may develop as a side effect. (327) In about 30% of patients, positioning of the catheter is not possible or must be modified due to vascular anomalies. Therefore, it is necessary to perform a coeliacography preoperatively to check the anatomy of the vessels. TAC has been applied

for the treatment of colorectal liver metastases using 5-FU/folinic acid, 5-FU/mitomycin or fluorodesoxyuridin as a continuous i.v. infusion based on (still) varying schemes. This therapy option is not regarded as effective for liver metastases. (325, 341, 344, 345, 354, 375) (s. p. 810)

TAE, TACE: Both transarterial embolization and chemoembolization with the help of a port-catheter system via the proper hepatic artery (analogous to TAC) might be a therapeutic option regarding non-resectable liver metastases. An indication is also given if there is a high surgical risk involved. Embolization can be repeated several times. In metastatic neuroendocrine tumours, preoperative treatment with somatostatin analogues is recommended. The response rate in colorectal liver metastases is usually low. In combination with lipiodol, however, a response rate of 45% can be achieved in solitary metastasis. It should be noted that lipiodol enrichment only occurs at the margins of metastases. More positive results have been obtained with a combination of collagen + cisplatin + doxorubicin + mitomycin, particularly when administered at intervals of six to eight weeks. (s. p. 810)

10.6.6 Systemic therapy

In special kinds of tumours, the application of a certain substance can be helpful as adjuvant therapy.

Anti-hormone therapy: Gastroenteropancreatic tumours show a good response to the systemic administration of anti-hormonal substances, especially those which are directed against the biological activity and peptide secretion of these tumours. • As a result, **octreotide** therapy can be applied as s.c. injection for a longer time. Follow-up is possible by determining serotonin and chromogranin A in the serum as well as 5-hydroxyindole acetic acid in the urine. • In metastasized insulinoma, **diazoxide**, a benzothiazide analogue, can block the release of insulin and increase glycogenolysis. However, this substance has considerable side effects.

Interferon therapy: The application of IFN is based on inhibiting protein synthesis and thus cell proliferation. Its indication is recommended in metastatic neuroendocrine tumours.

10.6.7 Systemic chemotherapy

Systemic chemotherapy is usually not indicated in non-colorectal liver metastases due to lack of response. The systemic administration of cytostatics (also in combination) possesses the status of palliative therapy. • However, in metastatic neuroendocrine tumours, a combination of octreotide + IFN had a positive effect on the survival time. Systemic chemotherapy produced remission rates of up to 60%. (333) • In metastatic breast cancer, systemic chemotherapy is indicated, usually in combination with hormonal and immune therapy. (329, 356)

• In metastatic gastric carcinoma, palliative chemotherapy can achieve a remission rate of up to 40%, with a slight extension of survival time.

As a rule, the suitability of a combination of cytostatics following operative or local interventional therapy should be discussed at an interdisciplinary conference.

5-FU monotherapy: In metastatic colorectal carcinoma, 5-FU/folinic acid has constituted the basis of systemic chemotherapy for more than 40 years: survival time is prolonged, tumour-related symptoms are diminished and quality of life improves. Folinic acid is seen as the main modulator of 5-FU efficacy. Various schemes are used in different dosages and forms: (1.) *O'Connell scheme*, (2.) *Ardalan scheme*, (3.) *Machover's scheme*, and (4.) *Rougier's scheme*. • In the meantime, the *De Gramont scheme* has been introduced in France (200 mg/m² folinic acid, 400 mg/m² 5-FU [bolus] and 600 mg/m² [22 hr i.v. infusion] on day 1 and 2, repeated on day 15), and the *AIO scheme* has been introduced in Germany (500 mg/m² folinic acid, 2.6 g/m² 5-FU [24 hr i.v. infusion] 6 x/week, 1-week interruption of therapy).

Fluoropyrimidine-based prodrugs: A new development are the oral prodrugs *ftorafur* and *capecitabin*. Both substances have already proved effective. Capecitabin should not be combined with folinic acid.

Irinotecan-based combination: Irinotecan is a camptothecin-derivative, which as a prodrug is converted into a cytotoxic agent by means of carboxylesterase. It is considered to be one of the most active cytostatics in advanced colon carcinoma. The combination with 5-FU as an i.v. continuous infusion is recommended as a preferential form of treatment.

Oxaliplatin-based combination: Oxaliplatin has likewise been used successfully in combination with 5-FU. The most important limiting side effects of a long-term therapy are cumulative neuropathic symptoms.

► In metastatic colorectal carcinoma, it is possible to achieve complete surgical removal (R0) of the metastases in initially incurable resected patients due to the relatively successful systemic chemotherapy schemes used today. In about 20% of the patients with oligotropic metastatic spread, this **therapy triad** consisting of resection + chemotherapy + resection can lead to a 5-year survival rate of 25% (cf. primary curative resection).

10.6.8 Adjuvant measures

The information presented in section 3.9.4 (s. p. 811) similarly provides a basis for adjuvant or unconventional treatment and for general care of tumour patients with metastases. (s. tab. 37.10) • In addition, the perioperative use of **galactose** may be worth considering in surgical (or invasive) treatment of metastases, especially

since it is without side effects and does not involve undue costs. • Furthermore, we would like to point out that the administration of **zinc** and **selenium** as well as **potassium canrenoate** is useful when planning a resection of metastases. (s. p. 813)

38 Systemic diseases and the liver

Systemic diseases originating in the *haemopoietic* or *lymphatic* systems and those belonging to the category of *rheumatic diseases* can affect the liver either directly or indirectly. (s. tab. 38.1)

Haematopoietic system

1. Direct effects on the liver

- = pathological extramedullary haemopoiesis in the liver
- = disturbed liver haemodynamics following haemolysis

2. Indirect effects on the liver

- = reduced defence against infections facilitates bacterial, viral or mycotic liver damage
- = toxic liver damage caused by drugs (e.g. cytostatics, immunosuppressants)
- = graft-versus-host reaction in bone-marrow transplants

Lymphatic system

1. Direct effects on the liver

- = pathological formation and deposition of lymphocytes or lymphoblasts with formation of infiltrates or focal lesions
- = cholestasis following mechanically mediated biliary dyskinesia

2. Indirect effects on the liver

- = reduced defence against infections facilitates bacterial, viral or mycotic liver damage
- = toxic liver damage caused by drugs (e.g. cytostatics, immunosuppressants)

Rheumatic diseases

1. Direct effects on the liver

- = rheumatism-related inflammatory or immunologically induced intrahepatic vasculitis with sequelae
- = non-specific reactive hepatitis

2. Indirect effects on the liver

- = toxic liver damage caused by drugs (e.g. antirheumatic agents, immunosuppressants)

Tab. 38.1: Relationship of the liver to the haematopoietic and lymphatic systems and to the category of rheumatic diseases

1 Systemic haematological diseases

1.1 Extramedullary haemopoiesis

Intrahepatic haemopoiesis is a **physiological process** in foetuses and neonates. From 6th to 24th week of pregnancy, haemopoiesis takes place in the liver (and spleen)

in a diffuse manner within the sinusoids. Thereafter, focal haemopoiesis may still continue in the liver up to about the second week of life.

Myeloid metaplasia beyond this physiological endpoint of intrahepatic haemopoiesis is regarded as a **pathological event**. Haemopoietic foci are seen in the sinusoids, in Disse's spaces and sometimes to a minor degree in the portal fields; they consist of erythropoietic and myeloproliferative precursors as well as polynuclear giant cells of the megakaryocyte type. This variety of cells provides important evidence in histological differential diagnosis for excluding leukaemic infiltrates and mononuclear hepatitis. Myeloid metaplasia accompanies displacement of the bone marrow, e.g. in osteomyelofibrosis, bone-marrow carcinomatosis and myeloproliferative diseases. Occasionally, megakaryocytes are also present in the liver. Naphtol-AS-D chloracetate esterase-positive cells of granulopoiesis are a striking feature in this context. Hepatomegaly is generally found. Ascites can develop due to portal hypertension. (s. fig. 38.1)

Fig. 38.1: Extramedullary haemopoiesis in the liver with erythropoiesis precursors and intrasinusoidal megakaryocyte (↑) due to the so-called marrow-replacement syndrome or chronic myeloproliferative disease (HE)

1.2 Acute leukaemia

In acute myeloid leukaemia or lymphatic leukaemia as well as in acute leukaemic episodes in non-Hodgkin lymphoma, involvement of the liver may only be detectable clinically by the presence of hepatomegaly and subicterus. • **Laboratory parameters** usually show slightly elevated transaminase as well as bilirubin values, and distinct cholestasis is occasionally observed. (7) Acute hepatic failure can occur during the course of acute leukaemia. (1, 8, 27, 65) • **Histologically**, there are massive, yet uniform blast-cell infiltrates; these are found mainly within the portal fields in acute lymphatic leukaemia

(about 95%) and within the sinusoids in acute myeloid leukaemia (about 75%). • Involvement of the liver is of no consequence with regard to the underlying disease and its therapy. Secondary infections require systemic treatment with antibiotics and/or antimycotics.

1.3 Myeloproliferative syndrome

The term myeloproliferative syndrome encompasses the following forms: (1.) chronic myeloid leukaemia, (2.) idiopathic osteomyelofibrosis and sclerosis, (3.) polycythaemia vera, and (4.) essential thrombocytosis. Intermediate forms of these manifestations are possible. The pathogenesis is based on the transformation of a stem cell and its clonal proliferation. • Chronic lymphatic leukaemia is classified as malignant non-Hodgkin lymphoma. Overlaps between the different forms of disease are frequent. There is a tendency for fibrosis to develop in all types of the myeloproliferative syndrome with subsequent sclerosis of bone marrow in later stages. Certain forms may progress to acute leukaemia, which is termed *blast crisis*.

1.3.1 Osteomyelofibrosis

Osteomyelofibrosis is a chronic, progressive, fibrous obliteration of the bone marrow. Greyish-white discoloration appears with an increase in collagenous fibrils and later also in reticular fibrils. Clinically, there is hepatomegaly (and generally also splenomegaly) correlating with the stage of disease. Arthralgia occurs occasionally. • *Laboratory parameters* may show a slight elevation of γ -GT, AP, transaminases and bilirubin. Leucocyte alkaline phosphatase is enhanced. • *Histologically*, extramedullary haemopoiesis, comprising erythrocyte and granulocyte precursors as well as dysplastic megakaryocytes, is found in the liver in >90% of cases. (14, 17) (s. fig. 38.1) Infiltrates appear in the sinusoids, which are partly dilated and display fibrosis and deposits of haemosiderin. This results in portal hypertension (6, 13); ascites (10) and oesophageal varices are rare (about 7% of cases). Further potential complications include cholelithiasis (its relationship has not been clarified so far), Budd-Chiari syndrome and portal vein thrombosis. (2) • Diagnosis is established by liver histology. Imaging procedures are of no significance here.

1.3.2 Chronic myeloid leukaemia

In CML, granulopoiesis is markedly accelerated, with increased formation of immature precursors. This occurs mainly in the bone marrow. Accordingly, there is only a rare and slight involvement of the *liver* in CML, with the exception of a terminal myeloblast crisis. (s. fig. 38.2) Hepatomegaly is pronounced in some cases. Massive splenomegaly is generally evident; it often presents as a sugar-icing spleen (= *perisplenitis cartilaginea*). (s. fig. 38.3) • Infiltrations of immature granulo-

cytes and erythrocytes as well as of megakaryocytes are identifiable above all in the (generally dilated) sinusoids. Biochemically, there is an elevation of alkaline phosphatase and LDH. Complications include portal hypertension following obstruction of the sinusoids and as a result of increased hepatic blood flow. (19) Acute liver failure has been observed. (16) In the final stage, metastasis-like structures can appear in the liver (= *chloroma*). Imaging procedures reveal no abnormalities in the area of the liver parenchyma. (5, 12) • *Therapy* with imatinib was recently reported as being successful.

Fig. 38.2: Terminal blast crisis of chronic myeloid leukaemia: numerous myeloid blasts in the sinusoids (HE)

Fig. 38.3: Splenomegaly with perisplenitis cartilaginea (sugar-icing spleen) in chronic myeloid leukaemia

1.3.3 Polycythaemia vera

Liver involvement in Osler-Vaquez disease is rare or not detectable at all. There is, however, evidence of *hepatosplenomegaly* due to extramedullary haemopoiesis. Of importance here is the association with the *Budd-Chiari*

syndrome and *veno-occlusive disease*. Polycythaemia vera should be considered in cases of aetiologically unclarified *portal vein thrombosis*. (s. fig. 39.11)

1.3.4 Essential thrombocytosis

With the exception of occasional hepatosplenomegaly, liver involvement is rare. There is again an association with the *Budd-Chiari syndrome* and *veno-occlusive disease*.

1.4 Haemolytic syndrome

► Numerous congenital or acquired diseases lead to *haemolysis*. (s. p. 226) (s. tab. 12.3) They are subsumed under the term haemolytic syndrome. Sick-cell anaemia, thalassaemia and paroxysmal nocturnal haemoglobinuria are worthy of mention in this context.

1.4.1 Sick-cell anaemia

This form of genetic *haemoglobinopathy* is characterized by chronic haemolysis and haemolytic crises. • **Acute haemolysis** is associated with acute right upper quadrant pain, leucocytosis, jaundice and elevated transaminases, AP and LDH. This hepatic crisis can mimic acute cholecystitis. It lasts two to three weeks. The condition is caused by a slowing down of the sinusoidal blood flow, which contains sickle cells, and, in addition, by a multiplication of the Kupffer cells. The liver is enlarged, rich in blood and violet-red. The sinusoids are dilated and contain agglutinates of sickle cells. The Kupffer cells contain ceroid, siderin and phagocytosed erythrocytes. Single-cell necroses of hepatocytes with Councilman bodies are detectable. Acute liver failure, usually with cholestasis and deep jaundice, is a rare event. (s. fig. 38.4)

Fig. 38.4: Erythrophagocytosis in Kupffer cells (arrows) in haemolytic anaemia (HE)

Chronic haemolysis can lead to mostly asymptomatic gallstones (approx. 25% in children, 50–70% in adults). Furthermore, portal hypertension and portal fibrosis may develop. There is a slight elevation of the transaminases in a steady state of the disease. Higher values of

AP may be due to associated veno-occlusive crises involving the bones. (3, 4, 9, 11, 15, 20) • **Therapy:** Exchange transfusion is indicated. Surgery must be avoided in cases where acute cholecystitis is only mimicked. Successful liver transplantation has been reported.

1.4.2 Thalassaemia

As a result of the crises entailing destruction of the red blood cells and the frequently required blood transfusions, liver siderosis develops. This may lead to fibrosis in some cases. Episodic cholestasis can be observed. In progressive siderosis, treatment with deferoxamine is indicated. *Pigment gallstones* (s. figs. 35.16, 35.17) can appear in the course of chronic haemolysis. (4)

1.4.3 Paroxysmal haemoglobinuria

Paroxysmal nocturnal haemoglobinuria may also give rise to chronic haemolysis. This membrane defect of the erythrocytes is due to mutation of the PIG-A gene on chromosome X resulting in deficient biosynthesis of the glycosylphosphatidylinositol anchor. The erythrocytes are sensitive to lysis when the pH of the blood becomes more acidic during sleep. This clinical picture can lead to hepatomegaly, a rise in the transaminases, iron deficiency, siderosis and centrilobular necrosis. *Thrombosis* of the portal and splenic veins as well as the *Budd-Chiari syndrome* are possible complications. Sclerosing cholangitis is likely to develop due to ischaemia. (18)

2 Systemic lymphatic diseases

Hodgkin's disease and non-Hodgkin's lymphomas belong to this group. Liver involvement due to these diseases consists of lymphocytic infiltrates or their precursors as well as the formation of lymphatic tissue nodes. The liver itself has no organ-specific lymphatic tissue.

2.1 Hodgkin lymphoma

► TH. HODGKIN first described this condition in 1832; in 1865 S. WILKS coined the term Hodgkin lymphoma. R. PALTauf reported on lymphosarcomatosis in 1897. • The aetiology of this malignant systemic disease is unknown. Hodgkin's lymphoma invariably begins in the lymphatic tissue (= *lymphogranulomatosis*), mainly in the neck and mediastinum. The lymph node swelling is not painful.

Typical **Hodgkin cells** derive from undifferentiated reticular cells. They have a slightly basophilic cytoplasm and one or two glowing red or violet nucleoli in a very light, almost unstained nucleus. These cells are the mononuclear precursors of the polynuclear **Paltauf-Sternberg giant cells** (R. PALTauf, 1897; C.V. STERNBERG, 1936). Such reticular giant cells are seen as a reliable symptom of Hodgkin lymphoma in the liver (stage IV) when they

are found in the typical cellular environment of a Hodgkin's granuloma. • **Five forms** of Hodgkin lymphoma are distinguishable histologically:

| | |
|--------------------------------|---------------|
| 1. nodular sclerosis | 40–80% |
| 2. mixed cellular form | 20–40% |
| 3. lymphocytotic type | 2–10% |
| 4. lymphocytopenic type | 2–5% |
| 5. unclassifiable form | 1–5% |

The **liver** is the most frequently affected non-lymphatic organ in Hodgkin lymphoma (30–50% of cases). Liver involvement is highest in the lymphocytopenic type (which also has a particularly unfavourable prognosis) and in nodular sclerosis. It is lowest in the lymphocytotic type. There is evidence of large, irregularly delineated tumour nodes and multiple, diffusely distributed nodules or even subcapsular miliary nodules. These macroscopic forms also occur in combination; their histological properties are largely identical. Acute liver failure can develop. (36, 39) *Hepatomegaly* is frequently observed. *Splenomegaly* is generally associated with liver involvement. Non-involvement of the spleen is rare (35); a normal-sized spleen mostly rules out liver involvement. • *Hodgkin infiltrates* originate in the portal fields; they are arranged irregularly. Numerous reticulin fibres and dilatations of the sinusoids are frequently found in zones 2 and 3. The infiltrates consist of focally arranged histiocytes, epithelioid cells, eosinophils and small lymphocytes as well as *Hodgkin cells* and *Sternberg cells*. Central venous obstruction and endophlebitis can appear as a consequence of Hodgkin lymphoma in the liver. (21, 28, 40, 51, 57) (s. figs. 38.5–38.9)

Fig. 38.5: Hodgkin lymphoma: portal granuloma with Paltauf-Sternberg giant cell (↑) (HE)

Clinically, there is *loss of weight* (>10% within 6 months), *fever* (= Pel-Ebstein type, i.e. periodic fever at short intervals), *night sweats*, weakness, pain in the lymph nodes (following intake of alcohol) and pruritus (particularly in the later stages). The so-called *B-symp-*

tomatology (= (1.) weight loss, (2.) fever, (3.) night sweats) is mostly given when the liver is involved. (34)

Laboratory investigation reveals highly pathological “inflammatory criteria”, which probably point to a con-

Fig. 38.6: Hodgkin lymphoma: relatively well-defined, large intra-lobular granuloma with numerous Hodgkin cells (HE)

Fig. 38.7: Late stage of lymphocyte depleted Hodgkin lymphoma (HE)

Fig. 38.8: Hodgkin lymphoma: node at the margin of the left liver lobe; clear, diffuse (reticular) fibrosis of the liver

Fig. 38.9: Hodgkin lymphoma: several foci up to the size of a lentil and a 1.5 cm tumour node in the greatly enlarged spleen

suming or malignant process. Alkaline phosphatase and bilirubin rise in the further course of disease (about 80% of cases). Lymphopenia and eosinophilia are often in evidence. (37, 39, 42) (s. tab. 38.2)

| Non-specific “inflammatory criteria” (or indicators of a consuming process) | | | |
|--|---|----------------|---|
| ESR | ↑ | α-globulins | ↑ |
| CRP | + | haptoglobin | ↓ |
| fibrinogen | ↑ | copper | ↑ |
| iron | ↓ | cholinesterase | ↓ |
| haemoglobin | ↓ | D-dimer | ↑ |

Tab. 38.2: Non-specific “inflammatory criteria” (or indicators of a consuming process) (s. tabs. 37.6, 37.11, 37.12)

Imaging procedures display focal lesions, which appear hypoechoic and generally without a halo in sonography; in the further course of disease, the centre can yield a more hyperechoic structure. MR-SPECT has proved especially reliable in this connection. (26, 58, 62) • The diagnosis is established morphologically. This can be achieved most reliably by **laparoscopy** and targeted biopsy. (23, 51) Percutaneous biopsy has low specificity; it must be carried out, if at all, under US or CT guidance (several samples should be obtained from both liver lobes). Liver involvement always corresponds to *Hodgkin stage IV* (= non-localized, diffuse or disseminated disease of one or more extralymphatic organs or tissues with or without involvement of the lymphatic system). (44) • **Therapy** consists of polychemotherapy and/or intercurrent small-field irradiation, if applicable. The recurrence rate can be significantly reduced by mild chemotherapy prior to irradiation. In the case of recidivation, however, high-dose chemotherapy clearly shows greater efficacy. (53)

2.2 Non-Hodgkin lymphoma

The term non-Hodgkin lymphoma (NHL) subsumes a large number of different malignant diseases of the lymphatic system. Taken together, they have more or less the same frequency as Hodgkin’s lymphoma itself. The annual incidence of the disease in Germany is about 15 per one million inhabitants.

► According to their clinical progression, they are classified into lymphomas of low and high malignancy. **Classification** was formerly based on the Kiel Classification (K. LENNERT, 1978), the USA Classification (H. RAPPAPORT et al., 1978) or the New Working Formulation (1980). This whole system has now been replaced by the WHO classification (2001). Staging corresponds to that of Hodgkin’s lymphoma, i.e. liver involvement represents the prognostically critical stage IV. (s. tab. 38.3)

1. Diffuse large B-cell lymphoma (DLBCL)
2. T-cell rich B-cell lymphoma (TCRBCL)
3. B-cell chronic lymphocytic leukaemia (B-CLL)
4. Classical Hodgkin lymphoma (cHL)
5. Follicular lymphoma (FL)
6. Marginal zone lymphoma (MZL)
7. Leukemic plasmacytoma (PL)
8. Burkitt lymphoma (BL)
9. Mantic cell lymphoma (MCL)
10. B-lymphoblastic leukaemia (B-ALL)
11. Hairy cell leukaemia (HCL)
12. Peripheral T-cell lymphoma, unspecified (pTCL)
13. Anaplastic large cell lymphoma (ALCL)
14. Hepatosplenic T-cell lymphoma (HSTCL)

Tab. 38.3: Entities of lymphomas based on the WHO classification

| NHL occurs in three macroscopic forms |
|---|
| 1. disseminated micronodular infiltrates (s. fig. 38.10) |
| 2. multiple macronodular nodes (s. fig. 38.11) |
| 3. solitary tumour masses (s. fig. 38.12) |

Liver: There is (primary or secondary) involvement of the liver in about 50% of NHL patients (initially in approx. 20%, postmortem in >60%). The liver is seldom affected without simultaneous involvement of the spleen. However, liver involvement in NHL is less important than in Hodgkin’s lymphoma. Lymphocytic lymphomas mostly result in miliary foci, whereas histiocytic lymphomas mainly develop into tumour nodes. Macronodular, greyish-white (or yellowish-white) nodes and solitary, greyish-white tumour masses are rare. Micronodular, disseminated infiltrates are produced by involvement of the portal fields, especially in low-grade malignant forms of NHL. They appear as barely recognizable, fine-grained, white foci on the cut surface of the liver. • **Diagnosis** is confirmed morphologically using laparoscopy and targeted biopsy or forceps biopsy (23, 51), or by percutaneous biopsy under US or CT guidance. Immunohistochemical methods allow further differentiation and a more reliable diagnosis. (21, 22, 38, 52) (s. figs. 38.10, 38.11, 38.12)

Fig. 38.10: Micronodular infiltration of the liver by disseminated non-Hodgkin lymphoma

Fig. 38.11: Nodular involvement of the liver by a highly malignant B-cell non-Hodgkin lymphoma. Laparoscopy shows macronodular nodes of yellowish-white colour and different sizes; whitish fibrin deposits; furrowing of the liver

Fig. 38.12: Large tumour masses formed by a highly malignant B-cell non-Hodgkin lymphoma

Clinically, general symptoms of illness, such as fatigue, weakness, lack of appetite, loss of weight and fever are in evidence. A tentative diagnosis is based on hepato-(spleno)megaly and peripheral lymphadenopathy. • **Laboratory investigations** reveal “inflammatory criteria” in relation to the severity and form of NHL, as in Hodgkin lymphoma. (s. tab. 38.2) LDH and alkaline phosphatase are generally elevated; a slight rise in transaminase values is sometimes evident. There is a strikingly frequent association with HCV infection (29, 30, 33, 45, 55, 60), AIDS, and possibly also azathioprine. • **Imaging procedures** can provide diagnostic evidence by displaying local lesions, usually as a singular space-occupying process of varying echogenicity and density. (43, 54, 58, 62) • The majority of cases are not diagnosed until they have reached an advanced stage. The symptomatology, course and prognosis depend on the type of NHL. Fulminant liver failure is relatively frequent – sometimes as the initial manifestation. (25, 31, 32, 41, 46, 50, 63) • New methods of **treatment** – in addition to or instead of interferon – are continuously being sought in the therapy of NHL. This includes transplantation of blood stem cells following whole-body irradiation combined with chemotherapy, chemoembolization or possibly tumour resection. Moreover, *rituximab* is available as an antibody against lymphoma cells.

2.2.1 Low-grade malignant NHL

The incidence of low-grade malignant lymphoma shows an increasing tendency. There are signs of a causal relationship with environmental factors (e.g. pesticides). Low-grade malignant NHL leads more often to liver involvement than do the other forms.

Chronic lymphatic leukaemia: CLL occurs as B-cell and T-cell types. B-CLL is the most common form (approx. 95%); it is based on the malignant transformation of B-lymphocytes and occurs mainly in older people. The surface of B-cells is coated with immunoglobulins of the heavy chain type. T-CLL results from malignant transformation of T-lymphocytes; it is comparatively rare (5%). All in all, CLL is the most common form of both leukaemia (approx. 30%) and NHL. The liver is involved in >40% of cases. (s. figs. 38.13)

Histologically, there are dense, uniform portal field infiltrates of small lymphoid tumour cells, whereas lymphoblasts are generally not detectable. The portal fields are extended, but the limiting plates usually remain intact and are only penetrated by the lymphocytic tumour cells in the later course of disease. (s. figs. 38.14, 38.15) Bridge-like infiltrates can then develop between the portal fields. Small infiltrates also occur in the liver lobule. The sinusoids show a cumulation of round cells. Jaundice and cholestasis develop following obstruction of

the portal bile ducts. These findings can also be caused by compression of enlarged lymph nodes. (59) • **Complications** include portal hypertension (following fibrosis) (47), nodular regenerative hyperplasia and cholelithiasis (due to chronic haemolysis). Micronodular cirrhosis may also develop. • **Therapy** is carried out in accordance

Fig. 38.13: Chronic lymphatic leukaemia: smooth liver surface, greyish-red colour with slight cholestasis; reticular fibrosis. (Three different patients in 38.13–38.15)

Fig. 38.14: Chronic lymphatic leukaemia: dense portal lymphoid cell infiltration (HE)

Fig. 38.15: Chronic lymphatic leukaemia: dense portal lymphocytic infiltration extending into the liver parenchyma (HE)

with haemato-oncological guidelines, especially with *alemtuzumal* (= antibody campath-1 H).

Hairy cell leukaemia: This designation is based on the microvillar “hairy” surface of the tumour cells. It is considered to be a special form of B-CLL. The disease begins insidiously, mainly at an advanced age, and has a chronic progressive course. (24) Men are affected four times more often than women. Massive splenomegaly and pancytopenia are already detectable at an early stage. • In the **liver**, there is characteristic infiltration of the sinusoids with intralobular angiomatous changes, simulating the clinical picture of peliosis hepatis. (66) The associated angiomatous lesions are covered by hairy cells. (49, 64) A special feature of the hairy cell infiltrates is the presence of tartrate-resistant acid phosphatase, which is a reaction product of the tumour cells. Hepatomegaly is often present (in 40% of cases), whereas lymphadenopathy is very rare. In severe forms of infiltration, the picture of a nutmeg liver can develop. Collimation of liver parenchyma with formation of lacunas can be detected as focal lesions by means of sonography and CT. Ascites can occur. • **Therapy** (with a generally favourable prognosis) consists of interferon- α or deoxycoformycin. Hairy cell leukaemia is resistant to radiation treatment and chemotherapy.

Mycosis fungoides: This malignant T-cell lymphoma begins in the skin, but may also affect internal organs. The liver is rarely involved; this is more frequently the case with a leukaemic variant, the so-called **Sezary syndrome**. In the final stage of mycosis, however, portal field infiltrations are frequently detectable. They consist of atypical polymorphic lymphoid *Lutzner cells* (M.A. LUTZNER et al., 1971) and of larger cells containing hyperchromatic and highly polymorphic nuclei (= *mycosis cells*). The disease is apparently caused by retroviruses. The prognosis is unfavourable; radiation therapy and cytostatic agents are ineffective.

Immunocytoma: This tumour originates in three types of immunoglobulin-secreting cells: (1.) lymphoplasmocytic, (2.) lymphoplasmocytoid, and (3.) polymorphic. In isolated cases, patients with Waldenström’s macroglobulinaemia can also be assigned to this category. • **Clinical** symptoms include lymphadenopathy, splenomegaly, infiltration of the skin, fever, night sweats and pruritus. Immunoglobulins M and G are elevated. • The **liver** is involved in >90% of cases. The portal fields are only focally affected. The infiltrates are loosely and diffusely arranged. They frequently contain (50–80% of cases) PAS-positive, globular, nuclear and cytoplasmic inclusions, which represent retained immunoglobulins. The infiltrates also comprise a scattering of mast cells and eosinophils. The limiting plates remain intact. Increased flooding of the sinusoids is regarded as a sign of a leukaemic course.

Plasmocytoma: Extramedullary plasmocytic lymphoma likewise has its origin in immunoglobulin-secreting B-

lymphocytes. It is also termed *multiple myeloma*. The condition occurs most frequently in the 7th decade of life and ends fatally after 1–2 (–3) years. • In the *liver*, there are sometimes sinusoidal and portal infiltrations of B-lymphocytes and plasmocytic tumour cells; nodular formation can also occur. Generally, however, liver involvement is found in 40% of cases. (48, 61) (s. fig. 38.16) • Recently, patients with non-response or relapse after high-dose chemotherapy were treated successfully with *thalidomide* (starting with 200 mg daily, the dose was increased by 200 mg every two weeks until it reached 800 mg per day). (56) • **Plasma cell leukaemia** is a rare complicative variant which tends to have its own individual course.

Fig. 38.16: Intrasinusoidal accumulation of atypical plasma cells in plasmocytoma (HE)

Centrocytic lymphomas: These have their origin in lymphatic germ centre cells. *Liver involvement* occurs in about 50% of patients. The portal infiltrates consist of small cells with bright, irregularly shaped, indented nuclei. The portal fields are globularly distended as a result of the infiltration; the limiting plates remain intact, however, and the portal bile ducts are also undamaged.

Centroblastic-centrocytic lymphomas: This tumour type also develops from lymphatic germ centre cells. *Liver involvement* occurs in about 30% of cases. The portal fields are rounded due to infiltration; the limiting plates are penetrated in places. Follicular structures can occasionally be recognized.

2.2.2 High-grade malignant NHL

High-grade malignant lymphomas in the *liver* bring about destruction of the periportal limiting plates and fragmentation or neogenesis of the portal reticular fibres. All of these extremely malignant forms of NHL were classified as reticulosarcomas in the past, but only immunoplastic lymphoma can strictly be assigned to this category. High-grade malignant NHL is usually characterized by irregular portal infiltrates, which penetrate the limiting plates and show (rapid) destructive growth. (29, 38) Fulminant liver failure has also been observed. There is usually far less liver involvement in

high-grade malignant NHL than in low-grade forms. • Good results (complete remission in up to 75% of cases) could be achieved by shortened CHOP 14 therapy (cyclophosphamide + hydroxydaunorubicin + vincristine + prednisolone) in six cycles every two weeks.

3 Systemic rheumatic diseases

Rheumatic diseases can also cause direct or indirect liver damage (s. tab. 38.4). A common denominator is the occurrence of HLA type B8. There is often a close association between rheumatic diseases or collagenoses and chronic viral hepatitis (B, C), autoimmune hepatitis, primary biliary cholangitis as well as cirrhosis.

| 4. Sjögren's syndrome | 10. Wegener's granulomatosis |
| 5. Felty's syndrome | 11. Churg-Strauss vasculitis |
| 6. Polymyalgia rheumatica | |

Tab. 38.4: Rheumatic diseases causing direct or indirect liver damage

3.1 Rheumatoid arthritis

The cause of this systemic disease, which has a chronic course, is unknown. Generally, several small and large peripheral joints are affected, usually symmetrically. Women suffer far more frequently than men. **Clinically**, there is arthralgia of varying intensity and symptoms of chronic proliferative inflammation of the synovial fluid in the diseased joints. Systemic manifestations can be recognized on the basis of haematological, neurological, pulmonary, renal, cardiovascular and hepatic symptoms. **Laboratory parameters** show marked "inflammatory criteria" (s. tab. 38.2) as well as a rise in γ -globulins and immunoglobulins M and G. The *rheumatoid factor* is often detectable. (s. p. 124) Alkaline phosphatase may be elevated. (100)

Liver involvement occurs in 10–20% of cases. There is hepatomegaly and a slight elevation of the transaminases. Histologically, inflammatory infiltrates and fatty changes in the liver cells may be present together with *non-specific reactive hepatitis*. (s. figs. 21.1; 38.17) Slight fibrosis or rheumatic nodules also occur in some cases after a lengthy period of disease. (67, 76, 79, 85, 91, 94, 101, 107)

3.2 Still's disease

Juvenile rheumatoid arthritis is termed Still's disease (G.F. STILL, 1897). The disease begins in the finger joints and attacks the large joints and the cervical vertebral

Fig. 38.17: Acute exacerbation of chronic rheumatoid arthritis. Laparoscopy shows light red liver with slightly uneven surface (see scattered light reflex); fine reticular and perivascular fibrosis; isolated red (= inflammatory) foci. Histology shows slight steatosis and non-specific reactive hepatitis

column in progressive steps. Lymphadenopathy is also present. • The *liver* and spleen may be considerably enlarged. Despite this, there are few histological findings, such as periportal lymphocytic infiltrates and Kupffer cell proliferations. (103)

3.3 Adult Still's disease

Adult Still's disease presents with seronegative polyarthritis, febrile attacks, lymphadenopathy, skin symptoms, hepatosplenomegaly, jaundice and involvement of the pleura and pericardium. • The *liver* is enlarged in about 30% of patients; the transaminases may be slightly elevated. Periportal lymphocytic infiltrates and Kupffer cell proliferation can be demonstrated histologically. (68, 69)

3.4 Sjögren's syndrome

Sjögren's syndrome (H. S. C. SJÖGREN, 1933) is characterized by reduced secretion from the salivary and lacrimal glands with parotid enlargement (and occasional formation of calculi) together with chronic polyarthritis. Women in the menopause are mainly affected. Hyperfibrinogenaemia is common. The cause of the syndrome is unknown. • The *liver* is involved in 5–20% of patients with "sicca" syndrome. (88) Hepatomegaly and elevated alkaline phosphatase (25–40%) are detectable. Liver involvement can be ascertained on the basis of the findings of non-specific reactive hepatitis. (96, 99, 106, 107) An association with the Budd-Chiari syndrome has also been reported. (89)

3.5 Felty's syndrome

Felty's syndrome (A. R. FELTY, 1924) is a special form of seropositive polyarthritis. It leads to considerable

changes in the articular structures. Characteristic findings include splenomegaly, leucopenia, lymphadenopathy and skin pigmentation. Men are mainly affected. • The *liver* is involved in about 70% of patients. The transaminases and γ -GT values are moderately elevated, and there is an occasional rise in alkaline phosphatase. Lymphocytic infiltrates of the sinusoids, proliferation of Kupffer cells and periportal fibrosis are detectable histologically. Nodular regenerative hyperplasia can develop, which may subsequently cause portal hypertension and macronodular cirrhosis. (71, 95, 104)

3.6 Polymyalgia rheumatica

Clinically, this pathological picture is characterized by severe pain in the area of the shoulder/upper arm, pelvic girdle and femoral musculature. Symptoms include fatigue, weakness, fever and loss of appetite. Women are affected far more frequently than men – generally after the age of 50. • *Laboratory parameters* show highly pathological "inflammatory criteria" (s. tab. 38.2) and greatly elevated AP, but no antibodies or rheumatoid serological findings. • *Temporal arteritis*, which is a special form of polymyalgia rheumatica, is frequently found. • If larger arteries emanating from the aortic arch are likewise affected, this condition is known as **giant-cell arteritis**. (78, 81, 86, 87, 92) The thickened intima and the media contain histiocytic, lymphocytic and epithelioid cell infiltrates with polynuclear giant cells and plasma cells. Thrombosis often occurs in the affected arteries – also in the liver.

Liver involvement is common. Granulomatous arteritis of the hepatic artery and its intrahepatic branches gives rise to the clinical picture of granulomatous hepatitis. There are lymphocytic infiltrates in the portal fields together with liver cell necroses, so that chronic persistent hepatitis is in evidence. Fatty changes in the liver cells together with hypertrophy of the perisinusoidal lipocytes can also be observed. • *Therapy* is with glucocorticosteroids. (83, 86)

3.7 Polymyositis

Polymyositis can occur as a primary disease or a paraneoplastic syndrome. *Clinically*, there is weakness and pain in the shoulder and hip musculature, with muscular atrophy. *Laboratory parameters* show greatly elevated "inflammatory criteria" (s. tab. 38.2) and a rise in myosin AB. • *Liver involvement* is characterized by hepatomegaly, inflammatory infiltration of the portal fields, fatty changes in the liver cells and single-cell necrosis as well as necrotic foci.

3.8 Periarteritis nodosa

Necrotizing inflammation of small and medium-sized arteries as well as of the perivascular tissue (= periarter-

itis) with inclusion of adjacent veins leads to nodular-aneurysmal changes in the diseased arteries. The arterial capillaries remain unaffected. The vessel walls are permeated by polymorphonuclear leucocytes and monocytes; the inflammatory infiltration does not always involve the entire circumference of the vessel. Vascular branches are particularly affected. The aneurysmal distensions of the vessels show a tendency to rupture. • *Clinically*, there is evidence of fatigue, weakness, fever, lack of appetite, myalgia and arthralgia, together with abdominal pain. *Laboratory parameters* show highly pathological “inflammatory criteria” (s. tab. 38.2), e.g. greatly elevated ESR and alkaline phosphatase.

If the *liver* is involved, the respective enzymes (GPT, GOT, γ -GT, GDH) are increased. There is frequently an association with HBV or HCV infection (50–75% of cases). Together with the skin and the kidneys, the liver is one of the most affected organs. There are cell necroses. Vascular involvement can lead to infarction, intrahepatic bleeding (98), acute cholecystitis (leading to perforation) (72) and thrombosis. Nodular regenerative hyperplasia can develop. • Aneurysms in the area of the medium arteries are detectable by arteriography. Percutaneous liver biopsy is not recommended because of the bleeding risk and the low success rate. • *Therapy* is with glucocorticosteroids in combination with azathioprine or cyclophosphamide. (70, 75)

3.9 Lupus erythematosus

Lupus erythematosus (LE) is a systemic autoimmune disease, occurring mainly in young women. Its aetiology is unknown. The *clinical* symptoms are chronic recurrent arthralgia with febrile attacks, lack of appetite, fatigue, decreased performance, skin changes on areas of the body exposed to light, lymphadenopathy and renal findings following localized vasculitis. Its *biochemistry* is characterized by highly pathological “inflammatory criteria” (s. tab. 38.2) as well as by the detection of anti-nuclear antibodies, DNA-AB and the LE factor. Anaemia, leucopenia and thrombopenia are also frequently in evidence. In rare cases, jaundice due to haemolysis occurs. LE cells may be present in the blood or bone marrow (M. M. HARGRAVES et al., 1948).

The *liver* is involved in 40–60% of cases, but with greatly varying intensity. Hepatomegaly is frequently present. Even acute liver failure has been observed. Discrete laboratory or histological findings relating to the liver can precede the diagnosis of LE by several years in some cases. The clinical picture of acute hepatitis with cholestasis has also been observed. Histologically, there is a broad spectrum of changes comprising fatty degeneration in the liver cells, chronic persistent hepatitis, giant cell hepatitis (73, 77), hepatic infarction (82), cholestasis, veno-occlusive disease (93), nodular regenerative hyperplasia, and cirrhosis with portal and

pulmonary hypertension. (108) Lupus anticoagulans (antiphospholipid antibody) can lead to hepatic vein thrombosis. The activity of LE correlates well with the activity of the liver changes. It is a striking feature that patients with liver involvement complain less frequently of arthralgia, but more frequently have gastric, thyroid and haematological complications. It should be noted that there is hepatic idiosyncrasy towards nonsteroidal antirheumatics. (90, 97, 102, 105)

3.10 Wegener's granulomatosis

Wegener's granulomatosis (F. WEGENER, 1936, 1939) is a necrotizing form of granulomatous vasculitis originating in the upper respiratory tract and lungs (rhinitis and sinusitis with sanguineous secretion, repeated nosebleeds, ulcers, encrustations and pulmonary infiltrations). Glomerulonephritis subsequently develops. Finally, generalized vasculitis can be detected. (80)

The *liver* shows vasculitis with necrotizing epithelioid cell granulomas. Non-specific reactive hepatitis is also present. *Therapy* is with cyclophosphamide (1–2 mg/kg BW/day). • We have given an extensive description of this clinical picture based on 132 cases in the literature as well as on our own experience. (84)

3.11 Eosinophilic granulomatous vasculitis

Churg-Strauss vasculitis (J. CHURG et al., 1951) is characterized by angitis with extravascular granulomas, eosinophilia and bronchial asthma. Allergic factors are held to be responsible for this disease. Reports on about 200 cases have been published so far; men are affected twice as often as women. • Histologically, there is necrotizing inflammation of the small arteries and accompanying veins with paravascularly arranged granulomas deriving from macrophages and giant cells as well as leucocytes and lymphocytes; the centre of a granuloma is strikingly rich in eosinophils. • Such changes also occur in the *liver*. Concurrent involvement of the liver and the omentum can result in a palpable tumour. *Therapy* is with glucocorticosteroids. (74)

4 Mastocytosis

Mast cell hyperplasia can affect several organ systems. Regarding the liver, 50% of cases present as hepatomegaly. Mast cell infiltrates are found in the portal fields. They can lead to occlusion of the small vessels with subsequent fibrosis or cirrhosis. (112) Moreover, there is evidence of marked lymphadenopathy and skin lesions. Polygonal cells with eosinophilic granules are present in the portal fields. On staining with Giemsa and toluidine blue, the typical metachromatic cytoplasmic granules are sometimes identified. NRH, VOD

and marked fibrosis have been reported and may be the cause of portal hypertension and ascites. (114, 116) Cirrhosis occurs in 5% of cases. (112)

5 Histiocytosis X

In 1938 A.H.T. ROBB-SMITH mentioned this condition for the first time. One year later, he and R.B. SCOTT together described a disease characterized by “fever, wasting, generalized lymphadenopathy and hepatosplenomegaly, which in the final stages was associated with jaundice, purpura, anaemia and leucopenia”. This disease almost always resulted in death after an average duration of 15 weeks. The authors termed the condition “histiocytic medullary reticulosis”. (117) • The term “histiocytosis X” was introduced by L. LICHTENSTEIN in 1953 (115), summarizing (1.) Letterer-Siwe disease (reticulosis in infancy), (2.) Hand-Schüller-Christian disease (lipogranulomatosis), and (3.) eosinophilic granuloma of bone. Overlapping syndromes and mixed forms of these three diseases exist. The first two disease forms are mainly disseminated, while eosinophilic granulomas mostly appear as solitary bone lesions (with a better prognosis). • The term “malignant histiocytosis” was introduced by H. RAPPAPORT in 1966. These disseminated forms were distinguished as being benign or malignant and acute or chronic by W.A. NEWTON et al. in 1973.

Histiocytosis X is considered to be a form of reticulosis because of the proliferation and aggregation of Langerhans' cells in the RES. These cells contain so-called *Birbeck granules* and the neural-specific protein S-100. The involvement of the liver and spleen (which is not evident in every case) becomes visible as hepatosplenomegaly. In most cases, there are diffuse, sinusoidal infiltrations consisting of large, mostly multinucleated, atypical histiocytes (usually with hyperchromatic nuclei) and widespread phagocytosis of erythrocytes. (s. fig. 38.4) The Kupffer cells show hyperplasia. Periportal infiltration and cell necrosis are sometimes found. (s. fig. 38.18)

Fig. 38.18: Histiocytosis X: distinct portal inflammation and periportal infiltration by Langerhans cells simulating cholangitis (↑) (HE)

Gross tumour-nodule formation in the liver and spleen is rare. (122) Mild portal fibrosis may be present. (111, 113, 118, 121) In some two-thirds of cases, periportal cholestasis with portal-duct proliferation can be demonstrated. The clinical picture of primary sclerosing cholangitis may appear. (119) Occasionally, pronounced fibrosis with portal hypertension and oesophageal varices develops. (110) Transition into cirrhosis is possible. A suitable form of chemotherapy resulted in a 30–40% decrease in lethality. In portal hypertension, shunt surgery has been applied. Liver transplantation was successfully carried out without evidence of recurrent disease during a seven-year follow-up. (123)

39 Cardiovascular diseases and the liver

Due to its twofold vascular supply (portal vein, hepatic artery), the liver is closely integrated into the systemic circulation. The total blood flow through the liver is $1,500 \pm 300$ ml/min. Oxygen consumption amounts to 6 ml/min/100g LWW. (s. pp 21, 252) The portal vein supplies about two-thirds of the hepatic flow volume and is thus responsible for 50% of the oxygen requirement of the liver. The ratio between portal and arterial perfusion is about 2:1; this may, however, be reversed by compensatory autoregulation in cirrhosis patients. Blood from the portal and arterial systems reaches the sinusoids, where both mixing and pressure compensation occur. The hepatic blood flow is mainly regulated by inflow from the hepatic artery, which can be doubled when more oxygen is required. With continued demand for oxygen, the high capacity of the liver cell to extract oxygen (up to 95%) compensates for a limited blood flow. The hepatic flow volume is about 20–25% of the cardiac output (CO). • In addition, the pressure in the lesser circulation is transferred directly to the pressure in the hepatic vein, so that the latter is almost equal to the pressure in the right atrium. The oxygen saturation of the arteriportal mixed blood in the sinusoids decreases continually with the flow of blood from the periportal zone to the central vein. The venous blood is then carried from the central veins and the venous branches into the inferior vena cava, usually through three (valveless) hepatic veins. • This anatomical proximity explains disturbances of the liver function as well as morphological damage resulting from shock situations, acute flow block in the hepatic veins and global heart failure. • **Cardiovascular diseases** may thus affect the heart or each of the three vascular systems:

1. Diseases of the hepatic vein
2. Diseases of the portal vein
3. Diseases of the hepatic artery
4. Hereditary haemorrhagic telangiectasia
5. Impaired cardiac function

1 Cardiocirculatory disorders of the liver

Historical review

► The functional relationship between the heart and the liver has been known since ancient times. In animal experiments conducted in 1914, C. BOLTON examined the effects of a ligation of the inferior vena cava on liver histology for the first time. • N. JOLLIFFE (1929) detected clinically measurable changes of the hepatic function in congestive heart failure. (11) • Systematic investigations by S. SHERLOCK (1951) showed the consequences

of passive liver congestion on hepatic morphology: complete cirrhosis was observed in 25.5% and an increase in reticular fibres in 27.5% of cases; the liver was without pathological findings in 47% of cases. • Autopsies carried out by P. KOTIN (1951) showed “cardiac cirrhosis” in 10% of patients suffering from right heart insufficiency. (14) • Subsequently, the effects of cardiocirculatory disturbances on various partial functions and on the morphology of the liver, including the effects of drug metabolism, were presented in numerous publications.

Pathophysiology

► The close functional relationship between the heart and the liver is based upon **two physiologic facts**:

- (1.) The *hepatic flow volume* is 20–25% of the CO and is thus directly dependent on the cardiac ejection volume.
- (2.) The *pressure* in the lesser circulation is transferred directly to the valveless hepatic veins and may thus also reach the central veins.

► Even though the pathophysiology of hepatic changes during circulatory shock and in chronic liver congestion is very complex, **two single mechanisms** may be held jointly responsible for the impairment of metabolic and excretory liver functions:

- (1.) Reduction in blood flow through the liver with hypoxia.
- (2.) Increase in hepatic vein pressure with centrilobular hyperaemia.

► Circulatory disturbances within the hepatic lobules are of central pathophysiological importance; **three forms** can be differentiated:

- (1.) *Disturbed outflow*: the microscopic correlate is centrilobular hyperaemia; macroscopically, the liver is enlarged and has a dark red colour.
- (2.) *Disturbed inflow*: hypoperfusion due to arterial, portovenous or combined oligoemia results in centrilobular necrosis or even anaemic liver infarction.
- (3.) *Disturbed flow*: primarily, this occurs intralobularly due to various disorders (e.g. DIC, intrasinusoidal fibrin precipitation, centrilobular increase in fibres).

The liver may be involved in numerous ways due to acute, short-term disturbances of the cardiocirculatory function or due to chronic, long-term heart failure:

| Acute heart insufficiency | Chronic heart insufficiency |
|---|---|
| <ol style="list-style-type: none"> 1. Shock liver 2. Acute liver congestion | <ol style="list-style-type: none"> 1. Chronic liver congestion 2. Congestive fibrosis 3. Cardiac cirrhosis |

Tab. 39.1: Pathophysiology of cardiocirculatory changes in the liver

1.1 Acute heart insufficiency

Shock liver and acute liver congestion often display very similar histological changes, while the pathophysiologic features, such as laboratory findings, functional tests and drug metabolism, vary considerably. • Cardiogenic shock resulting from myocardial infarction is considered to be both a typical and frequent cause of shock liver, while acute liver congestion (acute right heart insufficiency) is in most cases the consequence of pulmonary embolism. • During shock, the liver is involved in two ways: (1.) it is an important regulatory organ (= *liver in shock*), and (2.) its function and morphology are compromised by shock mechanisms (= *shock liver*).

1.1.1 Shock liver

This condition is characterized by a reduced hepatic blood flow (CO ↓) and hepatocellular hypoxia, resulting in a loss of glycogen, the formation of hypoxic vacuoles in the hepatocytes and membrane blebbing; there are also coagulation necroses in acinar zone 3. Strikingly, the function of the liver is only mildly compromised and recovers quickly once the circulation is stabilized. Since the lattice fibre framework is generally intact, the centrilobular necroses do not leave behind any scars. During this phase, we only detected slightly delayed indocyanine green (ICG) elimination, while galactose elimination capacity and theophylline clearance were slightly inhibited. (19) This means that essential partial functions of the liver are relatively independent of the blood flow and that short-term hypoxia can be compensated by increased extraction of oxygen. By contrast, we also found greatly increased GOT and GPT values similar to those present in “hepatitis”, with low-grade

cholestasis and jaundice. The terms ischaemic hepatitis, hypoxic hepatitis or acute hepatic infarction are alternative definitions. (4, 6, 7, 12, 26, 30) In shock liver, there is therefore a marked discrepancy between a relatively slight reduction in excretory and metabolic functions and considerable liver cell damage detectable by enzyme analysis. • The hepatic blood flow is decreased due to shock-induced hyperperfusion of the heart and brain with simultaneous vasoconstriction in the splanchnic nerve area (= *centralization of circulation*). However, liver cell damage often develops or intensifies as a result of subsequent reperfusion, whereby the substances that are introduced in increased amounts at this point (endotoxins, cytokines, biogenic amines, degradation products, etc.) are probably the main cause of such liver cell damage. (27) A diffuse hepatic microcalcification as a sequela to shock liver can sometimes be found. (28) The damage occurring in shock liver and acute liver congestion may thus be due to ischaemia and/or ischaemic-toxic factors. (2, 3, 5, 29) (s. fig. 39.1)

1.1.2 Acute liver congestion

In our investigations, patients suffering from acute right heart insufficiency showed considerable delays in ICG half-times. In an earlier study, we were able to demonstrate a close correlation with right-sided atrial pressure. Theophylline clearance was likewise delayed. Standard enzymes revealed only slightly increased or even normal values; hyperbilirubinuria, which is seen as the most sensitive laboratory value in liver congestion, was generally present. Thus there is also a discrepancy between “liver function” and “cell damage” in this context – albeit exactly the reverse of that found in shock liver. (17, 19) Patients with acute liver congestion have greatly impaired metabolic and excretory functions, even after clinical recompensation. Perisinusoidal oedema due to elevated hepatic vein pressure is of utmost pathogenetic significance in acute liver congestion, because it lengthens the transit route. In acute congestion, the liver is capable of taking up blood equivalent to 70% of its own weight (1.0–1.5 l), so that both circulatory overload and tachycardia are reduced.

Morphology: Within the first day following the onset of acute liver congestion, massive sinusoidal hyperaemia and perivenous cell necroses occur due to the fact that centrilobular oxygen saturation is lower than that of the lobular periphery. The reticular fibre framework usually remains intact. Venous stasis may also occur, especially in acute congestion, including dilatation of the central veins and sinusoids with blood pooling, resulting in hepatomegaly. Macroscopically, the liver appears heavy and dark red. Microthrombi may be present due to disseminated intravascular coagulation. They can form the basis of later diffuse calcification. This might be related to the disturbance of intracellular calcium homeostasis

Fig. 39.1: Centroacinar shock necrosis and acute haemostasis in the liver (HE)

Fig. 39.2: Acute blood stasis with centrilobular congestion and centricentral congestion paths

due to ischaemia. (28) After recompensation, numerous granulocytes and pigment-loaded macrophages appear, followed by proliferating epithelial cells. The necrotized cells and erythrocytes are phagocytized by the Kupffer cells. Morphological repair starts after about five days and is completed within three to four weeks. (1, 17, 20) (s. tab. 39.1) (s. figs. 39.1, 39.2)

Drug metabolism: According to present knowledge, there is a delay in the elimination of certain drugs in patients with acute heart insufficiency. Thus, a *dose reduction* may have to be considered in some cases. In particular, these drugs include quinidine, cumarin/warfarin, digoxin, hydrochlorothiazide, lidocaine, mexiletine, procainamide and theophylline. (17, 19) • Our studies demonstrated a 30% reduction in the elimination rate of flow-limited (= ICG) and capacity-limited (= galactose, theophylline) substances. • We found a normal glucuronidation capacity for **4-methylumbelliferone**, but a significant delay in the biliary excretion of *4-MU-monoglucuronide*. (16) These findings are considered to be the cause of conjugated hyperbilirubinaemia, which is common in patients suffering from a congested liver.

Clinical features: Acute liver congestion results in upper abdominal pain due to stretching of the capsule caused by liver enlargement; this might even mimic an acute abdomen. There have also been courses with fulminant liver failure, particularly with existing chronic heart insufficiency. (9, 21, 25, 27) In addition to the laboratory findings given above, it is worth mentioning the increase in GDH, mainly localized in the centrilobular cells. The ratio (GOT + GPT) : GDH is < 10 . (s. tab. 5.6) In general, LDH is markedly elevated. Mild jaundice is often in evidence; hyperglycaemia and renal impairment sometimes occur. A decrease in Quick's value may point to DIC. An increase in the transaminases due to ischaemia (with bioptic detection of centrilobular cell necroses) was observed even in cases of severe hypoxaemia caused by sleep apnoea in patients with considerable obesity (without cardiac or respiratory dysfunction!). (6) Imaging procedures show hepatomegaly and dilated hepatic veins. (s. fig. 39.3) • *Treatment* consists of stabilizing the circulation and eliminating the causes.

Fig. 39.3: Massive cardiac congestion of the hepatic veins with distinct dilatation up to 14.6 mm (++) (normally up to 10 mm)

1.2 Chronic heart insufficiency

The hepatic blood flow is decreased in chronic heart insufficiency, and there is disturbed venous outflow, i.e. cardiac output is diminished. There is also a pressure increase in the splanchnic nerve area with subsequent blood pooling as a result of the rise in CVP. The markedly reduced hepatic blood flow at first evokes an increase in oxygen extraction, but after its elimination, hypoxia with centrilobular cell necroses follows. The elevated CVP extends as far as the central veins, so that dilatation and hyperaemia of the sinusoids occur. Pericentral atrophy in the liver cell trabeculae develops at a later stage. (s. tab. 39.1) (s. fig. 39.4)

Fig. 39.4: Chronic passive congestion with centroacinar parenchymal atrophy and fibrosis (HE)

Chronic congestion leads to an enlarged and plump liver with a dark red (purplish) colour. The central veins are dilated. In continued congestion, stasis paths develop between the central veins, resulting in the formation of confluent stasis areas. Various degrees of fatty changes in the liver cells as well as pigment deposits (lipofuscin, ceroid) appear. In the course of time, fibrosis of sinusoidal reticular fibres takes place; fibroses can also be observed along the stasis paths. In about 15% of cases, periodic acid-Schiff positive and diastase-resistant hyaline globules can be found. They are typically located directly around the zones of centrilobular congestion in hepatocytes. These globules range in size from 3 to 20 μm ; they occur either as one or two large globules or as clusters of smaller inclusion bodies. (13) The extent of the **congestive fibrosis** depends largely upon the degree of cardiac congestion. (s. fig. 39.4) In 147 patients with chronic pulmonary heart disease, it was possible to demonstrate congestive fibrosis by autopsy in 14–42% of cases (depending on the degree of severity and duration of disease). (8) • Chronically indurated **nutmeg liver** (F. KIERNAN, 1833) develops gradually; the cut surface of such a diseased liver shows sunken, dark red centrilobular zones and slightly raised bulging, yellowish to pale brown (depending on the degree of fatty changes) peripheral areas of the lobules. • **Cardiac cirrhosis** was mentioned in older studies in up to 10% of cases. (14) Our own studies did not yield a single case of cardiac cirrhosis. (8) This clinical picture must be considered rare and is most likely in cases of constrictive pericarditis or in long-standing tricuspid valve insufficiency. It is assumed that the development of cardiac cirrhosis originates in sinusoidal thrombosing processes which extend to the vascular bed of the hepatic veins. (24, 31) Distinct regenerative nodes are not found in cardiac cirrhosis; this condition generally does not lead to extrahepatic cirrhosis-related complications.

Clinical features: With regard to the main findings of chronic heart insufficiency, the liver is symptom-free, apart from tenderness upon pressure in the right upper abdomen corresponding to *hepatomegaly*. On palpation,

Fig. 39.5: Sonographic image of chronic liver congestion with dilated hepatic veins and inferior vena cava

the liver is hard and has a smooth surface. *Splenomegaly* is detected in about 20% of patients.

In this condition, **hepato-jugular reflux** is *positive* if the venous channels between the hepatic and jugular veins are patent (i.e. long-standing pressure below the right costal arch accelerates the filling of the jugular veins, since the insufficient right ventricle is incapable of transporting the rising amount of blood supplied by the liver). • When the result is *negative*, the free passage between the hepatic veins and the jugular vein is interrupted. This sign is useful for diagnosing tricuspid regurgitation.

According to our own investigations, **P-III-P concentration** is the most important laboratory parameter (18): it is significantly higher in patients suffering from chronic liver congestion (due to the activity of fibrogenesis). There was also a correlation with the pressure in the right atrium. Moreover, the P-III-P value allowed a follow-up of chronic liver congestion or chronic congestive fibrosis. No correlation with hepatic biochemical standard values was found – these were normal or just marginally elevated. (15, 17, 18) Only the serum bilirubin was slightly increased in most cases. ICG elimination and the galactose elimination capacity were significantly reduced. Severe jaundice may occur in heart failure (23), in some cases with massive liver cell necroses.

Hepato(spleno)megaly is detected by **sonography**. The liver margin is rounded, the reflex pattern is dense and inhomogeneous. The hepatic veins are enlarged (at the confluence >10 mm) and show a systolic – diastolic pendular blood flow with predominant hepatopetal flow. (s. figs. 39.5, 39.6) The inferior vena cava presents a rigid wall without respiratory-dependent lumen fluctuations. Smaller amounts of ascites are frequently detectable. *Echocardiography* and *colour-encoded Doppler sonography* are the most important diagnostic and monitoring methods. (10) *CT* may yield additional findings of chronic liver congestion. (22)

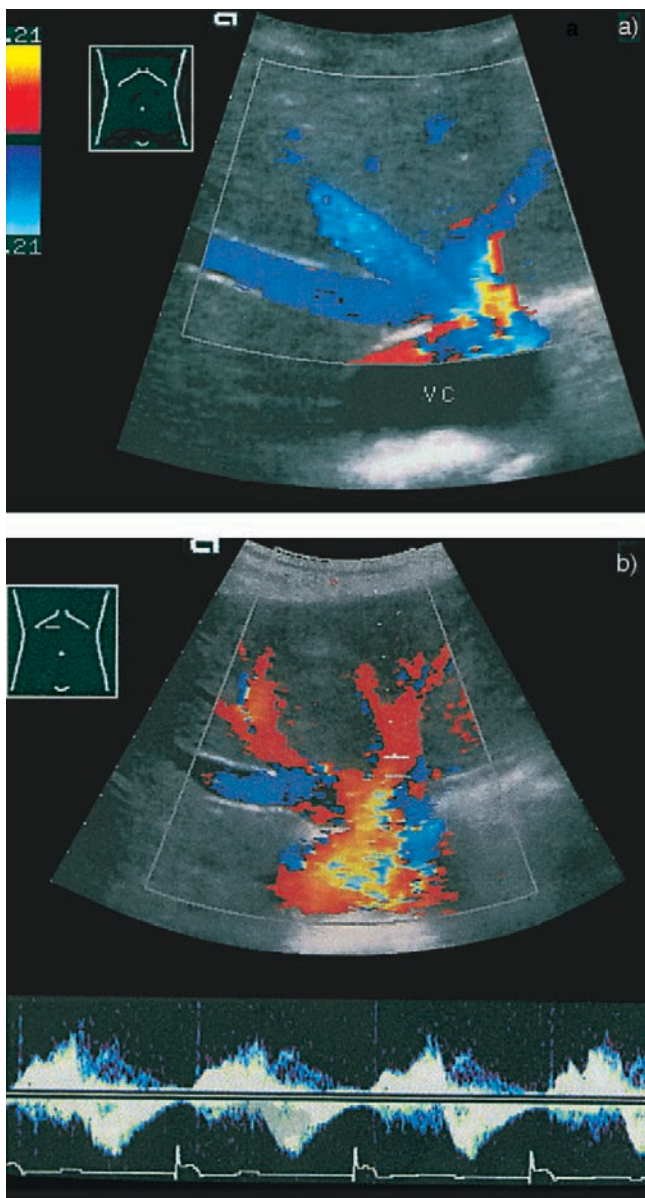

Fig. 39.6: “Hepatic vein star” • a) Normal finding: blue-coded right, medial and left hepatic veins indicate the hepatofugal flow. (VC = vena cava) • b) Right heart insufficiency: systolic-diastolic pendular blood flow with predominant hepatopetal flow

2 Disorders of the hepatic veins

The hepatic venous blood flow begins in the **central vein** of the lobules (= terminal hepatic vein), drains into the *sublobular veins* (= intercalated veins), from there into the *collecting veins* and then into the *truncal veins*. Perivenous connective tissue increases with the diameter of the vein. Venous blood reaches the *inferior vena cava* via three (valveless) **hepatic veins**; the confluence is below or within the diaphragm. From the **caudate lobe**, one to two small veins open directly into the inferior vena cava, as do a few small veins from the posterior segment of the right lobe of liver. (s. p. 21) • There are generally no **anastomoses** between the hepatic veins and the portal

vein, except in liver cirrhosis. Similarly, no anastomoses are present between the hepatic veins and arteries either in a healthy liver or in a cirrhotic liver. • Normal **hepatic vein pressure** is about 6 mm Hg. **Oxygen saturation** of the hepatic veins amounts to approx. 67%.

With regard to the main diseases of the hepatic venous system, there are **three types** worthy of mention:

1. Budd-Chiari syndrome
2. Veno-occlusive disease
3. Endophlebitis obliterans hepatica

2.1 Budd-Chiari syndrome

2.1.1 Historical review

► REYNAUD (1829) was the first to report thrombosis in the vena cava with involvement of hepatic veins and the development of collateral circulation. In 1842 E. LAMBRON described inflammation of the hepatic veins concomitant with a liver abscess. • In 1845 the English internist G. BUDD reported three further cases: in two of them, hepatic vein thrombosis was likewise caused by liver abscesses, whereas no cause was evident in the third case although membranes were detected in the hepatic veins. • In 1899 the German pathologist H. CHIARI, who was working in Prague at that time, gave an account of two of his own patients and assessed the 8 cases which were known to him from the literature. However, more than 25 cases of veno-occlusive disease had already been reported prior to Chiari’s publication. • The above-mentioned clinical picture with unclarified aetiology was defined by H. CHIARI (1899) as primary phlebitis of the large hepatic veins with secondary thrombosis, which he regarded as a separate entity. This gave rise to the term *endophlebitis obliterans hepatica*, also called Chiari’s disease.

2.1.2 Definition

The Budd-Chiari syndrome (BCS) is defined as partial or complete obstruction of the hepatic veins due to thrombosis. This may affect the whole hepatic venous system from the central vein to the large hepatic veins, even as far as the opening of the inferior vena cava into the right atrium. However, the obstruction can simply occur in individual branches of the hepatic veins and thus affect only certain areas of the liver. The syndrome may have an acute onset or begin insidiously and take a chronic course. The clinical picture is usually characterized by the *Chiari triad*: (1.) hepatomegaly, (2.) abdominal pain, and (3.) ascites.

2.1.3 Aetiology

Aetiologically, BCS is characterized by an extremely heterogeneous clinical picture, even though it is initially possible to categorize the majority of causes into four groups: (1.) hypercoagulopathies, (2.) infections, (3.) malignant diseases, and (4.) endotheliotoxic substances. In 80–90% of patients, BCS can be attributed to a specific cause. The disease has often been detected during

pregnancy as well. The observation that women contract the disease twice as often as men following the introduction of oral contraceptives supports the aetiological theory that it is linked to an increase in the oestrogen/progesterone level. The discovery of new genetic defects causing hypercoagulability can also explain some cases of BCS. (60) • A membranous obstruction, especially close to the opening of the middle and left hepatic veins into the inferior vena cava, is considered to be an aetiological peculiarity. Such a “web” varies from a thin membrane to a thick fibrous band. This unusual phenomenon is often encountered in India, Japan and South Africa (congenital?, phytotoxins?). A chronic course develops. (s. tabs. 14.5; 39.2) (s. pp 257, 562)

2.1.4 Morphology

Laparoscopy: The liver is enlarged and displays a dark reddish cyanotic surface with a rounded margin. Congested veins and collaterals in the abdominal region suggest portal hypertension. Transformational processes may occur in a chronic course (in 30–40% of cases) or when the liver is only partially affected, so that even the picture of a cirrhosis has been observed. Ascites, occasionally also in its sanguinolent form, is detected in most patients.

Liver biopsy: Histology reveals pronounced centrilobular congestion as well as sinus ectasia, necroses and thrombi in the central veins, which are either fresh or already organized. Parenchymal atrophies and nodal transformational processes can be observed after a longer period of time. (s. figs. 29.9; 39.7)

Fig. 39.7: Budd-Chiari syndrome due to essential thrombocythaemia. Long-standing thrombotic occlusion of a liver vein (Sirius red) (s. fig. 29.9!)

2.1.5 Clinical features

BCS is a rare disease and responsible for about 5% of all cases of portal hypertension. The highest incidence is observed in the third and fourth decades. Frequency varies considerably in different countries and regions depending on its aetiology. • The clinical picture is determined by the course of disease and therefore there

1. **Hypercoagulopathies**
 - Antiphospholipid syndrome (63)
 - Antithrombin III deficiency
 - Essential thrombocytosis
 - Factor V mutation (42)
 - Hyperhomocysteinaemia
 - Lupus anticoagulant
 - Myeloproliferative disease (32)
 - Paroxysmal nocturnal haemoglobinuria
 - Polycythaemia vera
 - Protein C deficiency (71)
 - Protein S deficiency
 - Sickle-cell anaemia
2. **Infections**
 - Amoebic liver abscess
 - Aspergillosis
 - Crohn's disease
 - Echinococcosis
 - Hepatic abscess
 - Pyogenic abscess (49)
 - Schistosomiasis
 - Syphilis
 - Tuberculosis
3. **Malignant diseases**
 - Adrenal carcinoma
 - Bronchogenic carcinoma
 - Fibrolamellar carcinoma
 - Hepatocellular carcinoma
 - Leiomyosarcoma
 - Leukaemia
 - Renal cell carcinoma
 - Rhabdomyosarcoma
4. **Endotheliotoxic substances**
 - Cytostatics (66)
 - Azathioprine
 - Phytotoxins
5. **Hormonal factors**
 - Oral contraceptives (60)
 - Pregnancy (50)
6. **Immunological factors**
 - Behçet's disease (36)
 - Hypereosinophilia
 - Sarcoidosis (67)
 - Sjögren's syndrome (57)
7. **Other aetiological observations**
 - Abdominal trauma (56)
 - Laparoscopic cholecystectomy
 - Membranous obstruction
 - Polycystic liver disease (37)
 - Retroperitoneal neurilemmoma (68)
 - Tumour in the right atrium (45)

8. Cryptogenic

Tab. 39.2: Possible causes of the Budd-Chiari syndrome (including some references) (s. figs. 29.9; 39.7)

is great variability in findings. In **chronic BCS**, abdominal pain is mild, and hepatomegaly develops only gradually. Splenomegaly, diarrhoea and ascites, including oedema in the legs, are occasionally in evidence. Oesophageal varices may develop as a result of postsinusoidal portal hypertension. Non-characteristic symptoms (fatigue, inappetence, weakness, meteorism) are present in most cases. All laboratory parameters may remain in the normal range for a long time. • A far

smaller percentage of patients suffer from **acute BCS** with severe pain in the upper abdomen, nausea, vomiting and malaise. Jaundice is often present. Hepatomegaly develops rapidly. Acute BCS can present clinically as acute liver failure. (64) The *caudate lobe* is enlarged as it has efferent hepatic veins of its own, which circumvent the main branches of the hepatic vein and lead directly to the inferior vena cava. (35) As a rule, in an enlarged caudate lobe, which may also compress the inferior vena cava, it is technically impossible to apply a portacaval shunt. In cases of severe parenchymal deterioration, there is a risk of hepatic encephalopathy and hepatorenal syndrome. The prognosis of acute BCS is very poor; the dramatic course of the disease rapidly leads to liver failure. (40, 43, 54, 55, 58, 64, 72, 76, 77)

2.1.6 Diagnostics

Laboratory parameters are irrelevant for diagnosis! Transaminases, LDH, GDG and alkaline phosphatase are in general moderately increased, and hyperbilirubinaemia can be detected in 20–25% of cases. The albumin level is usually reduced; hypoproteinaemia may be caused by protein-losing enteropathy. Evidence of disturbances in *blood coagulation*, with regard to both hypercoagulopathic status and haemorrhagic diathesis, is of significance. *P-III-P* serum values rise in chronic courses with increasing fibrosis. Liver function tests, however, generally show normal results.

Sonography shows hepatomegaly and inhomogeneous, hypoechoic zones. The hepatic veins are invisible or present as narrow structures. The caudate lobe is enlarged and often causes an hourglass-like constriction of the inferior vena cava. Ascites is confirmed. Colour-encoded duplex (or Doppler) sonography provides extra information, e.g. high flow velocities in areas of stenosis in the IVC or hepatic veins. Diagnosis proves to be correct in 85–90% of cases; the results are further improved by CT angiography or MR angiography. (38, 41, 58, 72, 77)

Computer tomography, especially when coupled with a contrast medium and in the form of CTAP, is an excellent tool for analyzing the venous blood flow and detecting any disturbances in inflow or outflow. Thrombosed hepatic veins are not visible, whereas intrahepatic collateral vessels are detectable. The parenchyma is characterized by an inhomogeneous, patch-like enhancement. (39, 44) (s. fig. 39.8) • **MRI** provides reliable evaluation by means of multiphase, contrast-enhanced, three-dimensional MR angiography. (76, 77)

Angiography, coupled with cavography and venography of the liver, is the most reliable examination method: venous obstructions can easily be localized, and the residual venous blood circulation always displays a spider web-like picture. • In some 20% of cases, the portal vein is also thrombosed, indicating arteriography in

the form of indirect splenoportography. In addition, angiography also offers the therapeutic possibilities of interventional radiology. (47, 50)

Histology: In cases where histological evidence is required, samples should be taken from both liver lobes, since the expressivity of the histological picture can vary greatly in different sections of the liver in BCS. The best technique in this connection is **laparoscopy** (possibly combined with *targeted biopsy*). Although the risk of haemorrhage is generally high in biopsy, intense bleeding or delayed coagulation can be effectively reduced and more easily controlled under laparoscopy. As a rule, however, the laparoscopic image of BCS is impressive enough per se – especially if supported by imaging procedures – so that biopsy and the accompanying risks can indeed be avoided altogether.

2.1.7 Treatment

There are very few reports of **spontaneous remission** even in partial BCS. • The *therapeutic principle* in all cases is to remove liver congestion, limit and lyse any thromboses as well as eliminate ascites. (43, 55, 72) • Medication includes immediate **lysis treatment** followed by heparinization. Despite initial success, frequent complications have been reported (e.g. pulmonary embolism, re-occlusion, intraperitoneal bleeding). (69) • **Percutaneous balloon angioplasty** was first used by S. EGUCHI et al. in 1974 in membranous obstruction of the inferior vena cava and was subsequently applied in BCS. (s. fig. 39.8)

In some cases, a *stent implantation* proved to be successful. (53, 73–75) The significance of *percutaneous transluminal angioplasty* is not only based on its long-term therapeutic effect, but also on its combination with operative shunts or other surgical techniques. (47) This method was improved by laser assistance (S. FURUI et al., 1988) • To date, a total of 23 different **surgical techniques** have been reported (33, 51, 54, 58, 62, 72, 76), consisting mainly of shunt placements, preferably the mesocaval shunt, bypass operations, resections, thrombectomies and liver transplantation. Even though it is technically difficult, dorsocranial liver resection with direct hepatoatrial anastomosis successfully corrects the venous perfusions of the liver physiologically. Meanwhile, urgent covered (polytetrafluoroethylene) TIPS and portal vein thrombectomy have proved effective. (46, 48, 59, 61, 65) It is relatively quick and easy to apply, has proved to be a low-risk procedure and can be carried out before resorting to other invasive or surgical techniques. Thus it is possible to bridge the time required for planning any surgical intervention or **liver transplantation**. The latter is urgently indicated in an acute course. Continuous long-term anticoagulation is necessary even after transplantation, as is invariably the case with all of the above-mentioned treatment measures. (48, 52, 70)

Fig. 39.8: Budd-Chiari syndrome • a) Pronounced collateral circulation resulting from thrombotic occlusion of the right hepatic vein. • b) Re-opening of the vessel and rapid reduction of the collateral vessels following successful balloon dilatation

Constrictive pericarditis

The clinical picture and hepatic changes are like those of the Budd-Chiari syndrome. Considerable thickening of the liver capsule resembles *sugar icing*. The liver is enlarged and firm. Tense ascites is present. Histologically, the changes are similar to those of cardiac cirrhosis.

2.2 Veno-occlusive disease

2.2.1 Definition

Veno-occlusive disease (VOD) is characterized by thrombosis of the central and small (sublobular) hepatic veins. It is also known as the *radicular form* of the Budd-Chiari syndrome or as the *Stuart-Bras syndrome*. (s. tab. 14.5) (79, 96–98)

2.2.2 Aetiology

Toxic substances or physical impact cause direct damage to the centrilobular veins and the small branches of the hepatic veins, resulting in thrombosis. • The first reports

were published simultaneously in South Africa (G. SELZER et al.) and Jamaica (K.R. HILL) in 1951. This disease is due to chronic intoxication with pyrrolizidine alkaloids, which are found in plants like *Senecio*, *Crotalaria*, *Heliotropium* and *Cynoglossum*. Intake occurs by drinking medicinal tea or through consuming contaminated pulses and cereals. In 1974 and 1978, epidemic-like outbreaks of VOD were observed in Afghanistan and India after local inhabitants had eaten cereals contaminated with pyrrolizidine alkaloids. The real toxicity of these alkaloids is based upon their transformation into alkylating pyrrole derivatives, which are toxic to endothelial cells and hepatocytes. • Other causes of VOD include cytostatics, immunosuppressives, radiotherapy (> 30 Gy), immunological reactions and alcoholic hepatitis. (s. tab. 39.3) (s. pp 562, 587)

- | |

|--|

Tab. 39.3: Possible causes of veno-occlusive disease (VOD) (including some references) (s. fig. 29.10)

2.2.3 Morphology

Histology provides useful diagnostic evidence. Sinusoidal endothelial damage can be found, including extravascular accumulation of erythrocytes in Disse's spaces as well as subendothelial oedema and cellulation. After two to three days, delicate fibres appear within the central and sublobular veins, occasionally also in the medium-sized hepatic veins, ultimately resulting in occlusion of the lumen. Fibrotic thickening of the vessel walls occurs. Stenosis and thrombosis of the small hepatic veins cause extensive sinusoidal congestion. The liver cells become necrotic or atrophic. • Micronodular cirrhosis develops in a chronic course. (s. fig. 29.10)

2.2.4 Clinical features

The clinical symptomatology is similar to that of chronic Budd-Chiari syndrome. About 10% of cases display an asymptomatic clinical picture over an extended period of time. • Spontaneous reversibility of VOD has been observed following administration of pyrrolizidine. (95) However, the disease may also progress rapidly to liver failure. A chronic course generally leads to liver cirrhosis with postsinusoidal portal hypertension. • *Laboratory values* reveal a slight increase in the transaminases and occasionally in alkaline phosphatase as well as thrombocytopenia with a rapid decrease in haemo-

globin. A rise in P-III-P is also significant in VOD, both for early diagnosis and monitoring purposes. (84) • The *wedged hepatic vein pressure* is increased. Due to its localization in the small hepatic veins, VOD cannot be diagnosed by means of *imaging techniques*. However, these techniques, particularly CEDS and CTAP, provide reliable evidence of gradually developing portal hypertension as well as the reduction or reversal of the portal blood flow during normal flow in the hepatic veins and the inferior vena cava. (85, 86, 98) • *Histology* makes it possible to achieve a reliable diagnosis. (s. fig. 29.10)

2.2.5 Treatment

Once the cause of VOD has been found, it must be eliminated (if possible). Treatment is symptom-oriented and directed towards the sequelae of portal hypertension. In order to reduce portal hypertension, medication (spironolactone, molsidomin, beta blockers, etc.) and TIPS are recommended. (81) Ultimately, indications for liver transplantation have to be considered. (91)

2.3 Inferior vena cava syndrome

An obstruction of the IVC above the influx of the hepatic veins can be caused by a congenital anomaly or the presence of “webs”. The latter may also be acquired in the case of membranous obstruction. Sometimes, a hepatopulmonary syndrome develops; in this case, balloon cavoplasty is a possible indication for treatment. • Such an obstruction passes over into HCC in 30–40% of cases. This is probably caused by the ongoing liver cell necrosis and regeneration processes. An important diagnostic hint is the formation of whorls in the obstructed area of the IVC, as shown by colour-encoded Doppler sonography. This finding points to an infiltrating, usually malignant process in the caudate lobe. (s. fig. 39.9)

Fig. 39.9: Inferior vena cava syndrome with infiltration and stenosis: blue-red-yellow colour changes as a sign of whorl formation due to an infiltrating malignant process in the caudate lobe

3 Disorders of the portal vein

► The **portal vein** is formed by the retropancreatic union of the right and left gastric veins, the pyloric vein, the superior and inferior mesenteric veins and the splenic vein. Its trunk runs inside the **hepatoduodenal ligament** to the liver. Within the porta hepatis, the portal vein divides into a **right branch** (which also receives the cystic vein) and a **left branch** (into which the paraumbilical veins contained in the round ligament and the ventroflexus ramus from the left sagittal fossa open). • The rami of the portal vein branch out and reach the portal fields where they become **interlobular veins**, which generally fork into **two interlobular venules** (= leading veins). The latter transport the blood into distributory veins which continue in Y-form into the **afferent venules** (final ramifications) and transport portal blood into the **sinusoids**. • The portal vein is 5–8 cm in *length* and has a *diameter* of 1.2 ± 0.2 cm. The normal *portal pressure* is 3–6 (–8) mmHg. (s. fig. 2.6) The portal blood flow amounts to 1150–1300 ml/min. (s. pp 21, 252)

Portal vein diseases may be *congenital* or *acquired*, or arise as a sequela of portal hypertension: (1.) portal vein anomalies, (2.) pylephlebitis, (3.) portal vein thrombosis, and (4.) portal venous gas.

3.1 Anomalies of the portal vein

Congenital anomalies of the portal vein are very rare. This also applies to accessory portal veins with their individually varying patterns.

Accessory portal veins are small veins at the surface of the hepatic serosa and in the surrounding peritoneal folds which normally originate in the diaphragm and the stomach. They can either open into the portal vein or enter the liver parenchyma independently. • **Anomalous accessory portal veins** may sometimes originate in the area of the portal veins around the gall bladder, the porta hepatis, the omentum, the interior surface of the abdominal wall or the hepatorenal ligament, etc.

Anomalies include missing portal vein and intrahepatic branches with simultaneous hyperplasia of the hepatic artery. • *Abernethy malformation*: The congenital aplasia of the portal vein was first described more than 200 years ago (J. ABERNETHY, 1793). In this condition, the portal vein connects with the inferior vena cava, generally at the same point as the renal veins. (99) • The portal vein and its branches may also be located in front of the duodenum and the pancreatic head. Sometimes, a multitude of small vessels are found instead of a single portal vein. Another anomaly is a faulty opening of the portal vein into the renal vein, with the enlarged hepatic artery taking over the entire blood supply to the liver. • Moreover, there may be anomalous anastomoses between the portal vein and the branches of the greater

circulation. (100) • Besides aplasia or obliteration of the portal vein, congenital arterioportal fistulas (s. tab. 14.2) (s. p. 253) or portal vein stenoses also cause portal hypertension with subsequent *phlebosclerosis*.

In addition to the congenital anomalies, various other clinical features are considered to be responsible for disorders affecting the portal vein system. (s. tab. 39.4)

1. Anomalous accessory portal veins
2. Aplasia
3. Arterioportal fistula
4. Cavernous transformation
5. Cruveilhier-Baumgarten syndrome
6. Faulty openings of the portal vein
7. Displacement
8. Obliteration
9. Portal vein stenosis

Tab. 39.4: Clinical features responsible for disorders of the portal vein system

3.1.1 Cavernous transformation

This condition is primary angiomas of the portal vein: a spongy convolution of venous vessels branching in a tendril-like manner has formed instead of a trunk – predominantly in the area of the hepatoduodenal ligament. (101, 102) • Prehepatic portal hypertension develops as a result of the disturbed outflow from the splanchnic nerve area. However, both liver function and histology are normal. Occasionally, considerable mechanical jaundice has been observed. Clinical symptoms include abdominal pain, splenomegaly, haematemesis and oesophageal varices. (103) The internal pressure in the spleen is increased, while the wedged hepatic vein pressure remains in the normal range. Successful diagnosis is based upon imaging techniques and colour-encoded duplex Doppler sonography. (105) There is often an atrophy of the left lateral segment and right liver lobe as well as a hypertrophy of the caudate lobe and segment IV can be found. (104) (s. tab. 14.2) (s. p. 253)

3.1.2 Cruveilhier-Baumgarten disease

In the absence of physiological postnatal closure of the umbilical vein, an anastomosis will form between the portal vein and the abdominal wall. Hypoplasia of the portal system and liver can also be observed. Prehepatic portal hypertension develops with visible and palpable venectasia in the abdominal skin (= *Medusa's head*) (M.A. SEVERINO, 1632). (s. p. 91) (s. fig. 14.13) A venous murmur (= *venous hum*) is often heard periumbilically, generally in the centre of the Medusa's head. Splenomegaly causes splenogenous maturation arrest. Diagnosis is confirmed by imaging techniques. (s. p. 254!)

Cruveilhier-Baumgarten syndrome: This is a secondary syndrome observed in liver cirrhosis with pronounced portal hypertension. Recanalization of the umbilical

vein and of the paraumbilical veins develops. (s. fig. 39.10) • Clinical symptoms include splenomegaly, Medusa's head, periumbilical vascular murmur and ascites.

Fig. 39.10: a) Re-opened umbilical vein (VU) due to pronounced portal hypertension in haemochromatotic cirrhosis. (VP = umbilical branch of the left portal vein) • b) Hepatofugal blood flow in the umbilical vein (VU) depicted by colour-encoded duplex sonography

Acquired causes may also be responsible for some of the congenital anomalies described above. Mention should be made of (1.) arterioportal fistulas, (2.) cavernous transformation of the portal vein (in portal vein thrombosis), (3.) fibrous obliteration of the portal vein, and (4.) cicatricial portal vein stenosis. These may also cause prehepatic hypertension. (s. tab. 14.2) (s. p. 254!)

3.1.3 Arterioportal venous fistula

Arterioportal venous fistulas (R. SACHS, 1892) between the arterial and portal system may occur following puncture,

trauma, HCC, HHT, invasive surgery and tumour growth. Congenital arterioportal fistula is rare. About 12 cases have been reported. (106) Clinical symptoms include prehepatic portal hypertension (111, 113), vascular murmur in the right hypochondrium, abdominal pain (113) and signs of hyperdynamic circulation. Sonography shows dilation of both the hepatic artery and the intrahepatic portal vein branches, often with hepatofugal flow. (110) Calcification of a liver biopsy-related fistula may occur. (109) Diagnosis is made by duplex Doppler sonography and confirmed by angiography, with the possibility of simultaneous embolization of the fistula. Diffuse forms are usually congenital, whereas solitary fistulas are typically acquired. The latter are more frequent. (108, 112) If treatment fails, selective resection of the fistula is indicated. (107) There is normally no change in portal hypertension after the development of *hepatoportal sclerosis*. (s. p. 254)

3.2 Pylephlebitis

Purulent inflammation of the branches of the portal vein is usually accompanied by subsequent portal vein thrombosis. Aetiologically, intrahepatic and extrahepatic purulent pylephlebitis share certain similarities. • Portal vein infections have their *origin* in inflammatory processes of neighbouring structures such as appendicitis, cholecystitis, liver abscesses (as was already postulated by H. CHIARI in the first cases published) (s. p. 856), suppurative hydatid cysts, colitis, diverticulitis, infected haemorrhoids, covered perforations (gall bladder, gastric ulcer) and malignant tumours (gall bladder, pancreas). • *Clinical symptoms* include fever, chills, abdominal pain, meteorism, enlarged and tender liver as well as splenomegaly. In most cases, inflammation parameters are clearly pathological. (s. tab. 37.6) Bacteriological haemocultures only yield positive results when the defence mechanisms of the liver RES have been overwhelmed. The clinical picture of septic portal vein thrombosis can often be observed. • *Treatment* with local fibrinolysis and TIPS has proved successful.

3.3 Portal vein thrombosis

Thromboses in the vessels of the portal system are the most common cause of prehepatic portal hypertension. • Even in the **postpartal** phase, portal vein thrombosis may occur due to the obliteration of the umbilical vein spreading to the portal vein or due to an infection of the umbilical vein with subsequent pylephlebitis. • In the **adult**, this clinical picture is often observed in liver diseases that cause the portal blood flow to slow down (or even reverse). All diseases accompanied by hypercoagulopathies also have a strong tendency to cause portal vein thrombosis. (117, 118, 120, 122, 124, 129, 132, 133, 136) Patients with HCC due to cirrhosis frequently develop thrombosis. Septic processes (e.g. appendicitis, diverticulitis, colitis) are a further cause, particularly in

immunocompromised patients. In addition, inflammatory tissue, tumours, lymphomas or fibrosis may narrow the lumen of the portal vein and trigger thrombosis. Thrombosis of the portal vein can also result from progressive thrombosis of the splenic vein. (s. tab. 14.2) Portal vein thrombosis is hence caused by many factors. (119, 133, 136–138) (s. tab. 39.5)

Tab. 39.5: Possible causes of portal vein thrombosis

The severity of the clinical picture depends upon how rapidly and to what extent the portal vein obstruction develops. • Haemorrhagic infarction of the intestine, due to sudden thrombotic occlusion, causes severe abdominal pain, haematemesis and melaena, circulatory shock and, ultimately, the death of the patient. • In gradual obstruction, splenomegaly and hypersplenism develop, accompanied by collateral vessels in the form of a sponge-like venous network (= *cavernous transformation*), which makes partial compensation possible. Gall-bladder varices, even with rupture and bleeding, have also been observed. (115, 121) Pronounced gastric varices can sometimes be found. (s. fig. 39.11). The size of the liver is normal, as are the wedged hepatic vein pressure (with increased intrasplenic pressure) and histology.

Fig. 39.11: Pronounced gastric varices (arrows) in portal vein thrombosis (= prehepatic block) caused by polycythaemia vera

Impairment of liver function only occurs at a later stage (131), and *hepatoportal sclerosis* develops. • Diagnosis is made by colour Doppler sonography (sensitivity >90%) (126), CT (s. fig. 39.12) and angiography (e.g. CTAP). Angiographic findings are also useful for deciding on the respective *therapy*: thrombolysis with subsequent anticoagulant treatment (if possible!) (116, 125, 128), percutaneous transhepatic angioplasty and thrombectomy (both procedures can only be applied in the early stages

of disease), TIPS (possibly with local thrombolysis) or a shunt operation. Prognosis is poor.

Fig. 39.12: Thrombosis of the portal vein (⇔) and splenic vein (→): contrast medium-free, hypodense structure; evidence of ascites

3.4 Portal vein aneurysm

Aneurysms of the portal vein are very rare. However, since the introduction of imaging procedures, this generally asymptomatic finding has been detected more frequently, in most cases by chance. In **intrahepatic localization** (first reported by H.S. VINE et al., 1979), the aneurysms are mainly situated in the right lobe and reach a size of up to 4 cm in diameter. The cause is not clear. Congenital malformation with subsequent portal hypertension has been postulated, as has acquired vessel wall weakness (e.g. in pancreatitis). The diagnosis is made by sonography and MRI. (139, 140) Caroli's syndrome has to be ruled out by differential diagnosis. Spontaneous rupture of such an aneurysm has been reported. (142) Treatment is not primarily required, but regular monitoring is necessary. In portal hypertension, however, the application of a shunt (surgically, transjugal-portacavally) may be indicated. (141)

3.5 Zahn's pseudoinfarct

This well-demarcated hyperaemic area in the liver was first described by F.W. ZAHN in 1897. He called the phenomenon "atrophic red liver infarction", but without necrosis. Such a form of infarct is an oddity. (123, 130) Sudden intrahepatic occlusion of the portal vein branches with simultaneous reduction of the arterial blood flow results in a narrowing and atrophy of the liver cell trabeculae and consecutive dilation of the associated sinusoids. A wedge-shaped, dark bluish-red area of the liver appears, which is most clearly visible when the liver is simultaneously congested. The thin end of the wedge points to the occluded branch of the portal vein. Despite the term "infarct", no necrosis can be

observed! • Zahn’s infarct may also be found in the area surrounding liver metastases due to compression of the portal vein branches by tumourous tissue.

3.6 Hepatic portal venous gas

This rare condition, which has a high mortality rate (up to 80%), was first described by J.N. WOLF et al. in 1955. (146) • In cases of diverticulitis, bowel-wall fistulas, necrotizing enterocolitis, intraperitoneal abscesses, etc., gas-forming pathogens may pass into the portal vein system. These gas bubbles are visible using US and CT. (s. fig. 39.13) At the same time, thrombosing processes may develop in the portal veins. • Therapy depends on the underlying disease and is based on antibiotics. In isolated cases, it is also necessary to administer anticoagulants and apply interventional methods. (143–145)

Fig. 39.13: Pylephlebitis with gas bubbles (arrows) in the portal vein system in intestinal gangrene

4 Disorders of the hepatic arteries

► The **common hepatic artery**, a branch of the coeliac artery, runs in a retroperitoneal direction above the pancreas into the hepatoduodenal ligament. It continues as the **proper hepatic artery**, which branches into the **right hepatic artery** (with the cystic artery) and the **left hepatic artery** to supply the two liver lobes. Ramification of the hepatic artery varies greatly. • The branches of the hepatic artery accompany the bile ducts and the portal vein as far as the portal fields. Radicular branches subsequently fork off forming the **peribiliary plexus** within the connective tissue of the portal paths. The peripheral, medial and central areas of the hepatic lobules are supplied by **intra-lobular arterioles**. • A small percentage of the arterial blood supply is also guaranteed by influx from the superior mesenteric, inferior pancreatic-duodenal and supraduodenal arteries. • Only 40–50% of the oxygen requirement and 35% of the blood volume of the liver (350–500 ml/min.) are supplied by the hepatic artery. Hence, the clinical picture of diseased liver arter-

ies is usually relatively mild, apart from bleeding caused by ruptures. (s. p. 20) • The most important clinical disorders of the hepatic artery are:

- | | |
|--------------|--------------------------|
| 1. Aneurysm | 3. Nodular periarteritis |
| 2. Occlusion | 4. Arteriosclerosis |

4.1 Aneurysm

4.1.1 Definition

While aneurysms of the hepatic arteries are in themselves rare, they nevertheless constitute 20% of all aneurysms of the splanchnic arteries. They are located extrahepatically in 80% and intrahepatically in 20% of cases. At 60%, the common hepatic artery is most frequently involved, followed by the right hepatic artery, which is affected in 30% of cases. A rupture (up to 80% of cases) constitutes a great risk to the afflicted, but often symptom-free patients. After confirmation of the diagnosis, treatment should begin immediately.

4.1.2 Aetiology

Congenital anomalies and aneurysms in the hepatic arteries are very rare. (148) **Acquired** aneurysms are the result of vessel wall damage, injuries or inflammatory processes. (150, 152, 156) • **Pseudoaneurysms** may occur after acute pancreatitis and the formation of pseudocysts. (155) (s. tab. 39.6)

Tab. 39.6: Possible causes of hepatic artery aneurysm

4.1.3 Clinical features

Symptomatology depends on the extent and localization of the aneurysm, which can vary greatly in size, ranging from the diameter of a millet seed to that of a walnut (there have been cases with aneurysms as big as a grapefruit). Small aneurysms do not cause any symptoms and are only discovered incidentally during imaging procedures or surgery. Patients mostly complain of uncharacteristic abdominal pain, which may precede a rupture by several months. Large aneurysms are characterized by a continuous murmur. (151)

After **perforation** (60–80% of patients), an aneurysm becomes manifest in the form of abdominal pain, which

can be very severe. (148) When an intrahepatic haematoma reaches the bile ducts, haemobilia may result (about 40% of cases) (152), just as compression of the excretory bile ducts may lead to the development of jaundice (in some 50% of cases). (154, 158) Heavy bleeding into the free abdominal cavity constitutes an acute abdomen with signs of circulatory shock. Bleeding into the intestinal tract or into the portal vein is less frequent. Lethality due to rupture is 30–50%; the prognosis for massive bleeding with haemoperitoneum is even poorer.

4.1.4 Diagnosis

Laboratory findings are normal. However, alkaline phosphatase (and LAP) and possibly also bilirubin may be increased in biliary stasis.

With unclarified abdominal pain, **sonography** is usually the diagnostic procedure of choice. An aneurysm appears as a round or oval focus either intrahepatically or extrahepatically between the portal hilum and the pancreas. The hypoechoic, cystic focus may contain hyperechoic, thrombotic material. Occasionally, there is a connection to an afferent vessel. (147) A suspected aneurysm can be confirmed by **colour Doppler sonography**, with the possibility of distinguishing blood flow and arterial blood. An echo-free aneurysm provides a typical arterial sphymogram.

CT scanning reveals a hypodense to hyperdense focal space-occupying lesion, with the hyperdense parts corresponding to the thrombotic structures within the aneurysm. Diagnostic accuracy is considerably improved by using contrast-medium CT.

Angiographic scanning of the hepatic artery confirms the diagnosis as well as giving an indication of the most appropriate therapeutic measures. • Due to the development of modern MRI techniques, invasive angiography is no longer necessary in most cases.

4.1.5 Treatment

Once detected, an aneurysm of the hepatic artery requires immediate treatment. Up to a certain size, intrahepatic aneurysms are treated by angiographic embolization. Coagulation by means of direct thrombin injection has also been described. (149) Larger aneurysms are treated by vascular surgery (ligation, vascular reconstruction, resection). (151, 153, 157)

4.2 Arterial occlusion

Occlusion of the hepatic artery is responsible for a 50% reduction in oxygen supply. Even if an unimpaired oxygen supply via the portal vein is guaranteed, arterial occlusion usually causes ischaemic infarction. The clinical and morphological pictures are characterized (1.) by the speed with which an occlusion develops, and (2.) by the presence of variants that can be used as a bypass

or of collaterals that have already been established in gradual vascular occlusion. This results in a broad clinical spectrum, which may range from a symptom-free condition to liver hypoxia, including infarction up to hepatic coma.

4.2.1 Aetiology

Causes of occlusion are as follows: (1.) primary vascular diseases (nodular periarteritis, giant-cell arteritis, etc.), (2.) iatrogenic measures (intra-arterial catheterization, i.v. cytostatic infusions, surgical interventions, etc.), (3.) traumas (dissections), (4.) embolisms (bacterial endocarditis, severe arteriosclerosis, mitral valve defect), and (5.) fibromuscular hyperplasia.

4.2.2 Clinical features

In acute occlusion with infarction, there is dull upper abdominal pain, often coupled with shock symptoms; the liver is tender upon pressure. Fever, jaundice and leucocytosis rapidly develop; Quick's value decreases, and haemorrhages develop. Transaminase and alkaline phosphatase levels rise. Liver failure is imminent. Apart from possibly detecting hypoechoic foci, sonography provides no diagnostic information. Contrast-medium CT reveals hypodense regions with mostly blurred boundaries. In MRI, the infarct is low T₁-weighted, with a high signal intensity in the T₂ image. The diagnosis is confirmed by arteriography, which should be carried out without delay if there is suspicion of acute occlusion. • *Treatment* is symptomatic and aimed at stabilizing the liver function in order to allow time for the formation of collaterals (within a few days). A lethal course must be anticipated if the openings of the gastric and gastroduodenal arteries are involved in the occlusion. The prognosis for distal occlusions in the area of the right or left hepatic artery is more favourable.

Ischaemic infarction: Ischaemic infarction with haemorrhagic marginal zones not only occurs after occlusion (159–161), but also *without* vascular obstruction, e.g. in shock, diabetic ketoacidosis, pre-eclampsia or lupus erythematosus. Small infarctions have also been described as complications following liver biopsy. • Morphologically, fresh anaemic infarctions appear as coagulation necroses. Large infarctions may cause “bile lakes” with evidence of air. From the second day, a wall of leucocytes forms at the infarction margins, and pigment-loaded macrophages can be observed. The reticular fibre structures collapse, and the granulation tissue is vascularized. Ultimately, indrawn scars develop.

4.3 Nodular periarteritis

This *primary vascular disease* is a febrile systemic autoimmune reaction, presumably caused by excessive immune activities. In this process, immune complexes are deposited in the walls of vascular arterioles as well

as in the larger arteries, giving rise to a progressive inflammatory reaction with round-cell infiltrates, pearl string-like thickening and proliferations of the intima. The narrowing of the lumen results in ischaemic necroses, which are also present in the liver in up to 65% of patients. Non-specific reactive inflammation in the portal fields may also be observed. As a rule, the gall bladder is involved just as frequently. Nodular periarteritis often leads to the development of aneurysms. • *Clinically*, there are highly pathological inflammation parameters. (s. tab. 39.2) Marked increases in BSR and alkaline phosphatase are characteristic. Various pains generally develop in the abdomen, joints and renal areas; weight loss adds to a distinct feeling of being ill. If the liver is affected, transaminase values may be slightly increased. • *Treatment* consists of prednisolone and azathioprine, unless active viral hepatitis is present.

4.4 Arteriosclerosis

Arteriosclerosis affects the extrahepatic liver arteries with the same frequency as the mesenteric arteries, but less frequently than the splenic artery. • The intrahepatic branches of the hepatic artery are usually only involved in cases of pronounced arterial hypertension. In these patients, thickening of the media can be found in the small arteries of the portal fields.

5 Hereditary haemorrhagic telangiectasia

This *dysvascular state*, also known as *Osler's disease* or *Rendu-Osler-Weber disease*, was first observed by the Canadian internist W. OSLER in 1901. (173) It is a rare autosomal dominant hereditary disease (1:100,000) with high penetrance (almost 100%). The homozygous presence of the affected allele is a lethal factor. All types of vessels are affected by these vascular malformations. Thus, for example, arteriovenous fistulas, aneurysms and telangiectasias of the arterial and venous terminal vessels as well as phlebectasias are found. The liver is involved in 40–70% of cases. Star-shaped vascular ectasias appear on the liver surface. Polymorphism of these angiodysplasias is caused by genetically determined damage to fibroelastic fibres within the vascular walls and the perivascular tissue. There is no evidence of any mesenchymal reaction or inflammatory activity. (162, 163, 166, 168, 175, 176, 179) • Osler's disease usually progresses through three phases: the asymptomatic *latent period* extends from childhood into puberty; the subsequent *haemorrhagic phase* is generally characterized by recurrent nasal bleeding; *manifest angiomatosis* has its onset in the third or fourth decade. Various clinical features can be observed, including posthaemorrhagic anaemia, hyperdynamic circulatory problems due to arteriovenous fistulas with cardiac insufficiency, signs of

portal hypertension with hepatomegaly (157), phases of hepatic encephalopathy and, in some cases, gastrointestinal bleeding. Dense vascular networks with vascular anomalies are found especially in the region of the mesenteric arteries. Diagnosis is based on colour-encoded Doppler sonography (163, 164, 165, 169, 172, 177), CTAP, MRF and arteriography. (167, 179) The common artery is dilated (180); a giant aneurysm can develop. (171) The CO level is high, so that right-sided cardiac catheterization is indicated in these patients. Following a protracted course, which requires frequent blood transfusions, secondary biliary cirrhosis may appear. (170) • Embolization or surgical interventions (ligation of afferent vessels, partial liver resection) and even liver transplantation (166, 174, 178) are indicated, provided such procedures are technically possible.

1 From mythology to provable treatment

1.1 In global medicine

► Recommendations and discussions on the treatment of diseases and injuries are as old as medicine itself. According to our knowledge of earlier times, medicine has its origins in **mythological therapy**. This also applies to the treatment of liver diseases. • Understandably, “*surgical medicine*”, especially traumatology, enjoyed the highest scientific status in antiquity, since the actual “cause” and medical “effect” were most obvious in this field. • Mythological ideas and rituals were therefore of minor significance to the barber surgeon: in general, practical experience, manual skill and (mostly self-developed) appropriate instruments produced the desired result. By contrast, “*conservative medicine*” was characterized by mythology, steeped in ritual as well as (mantic) divination and, for many epochs, mostly left in the hands of the “priest doctor”. In spite of sometimes astonishingly good diagnostic capabilities and prognostic accuracy, medicine on the whole – especially treatment of the individual patient – was subject to the prevailing mythology of the respective epoch. (s. tab. 40.1)

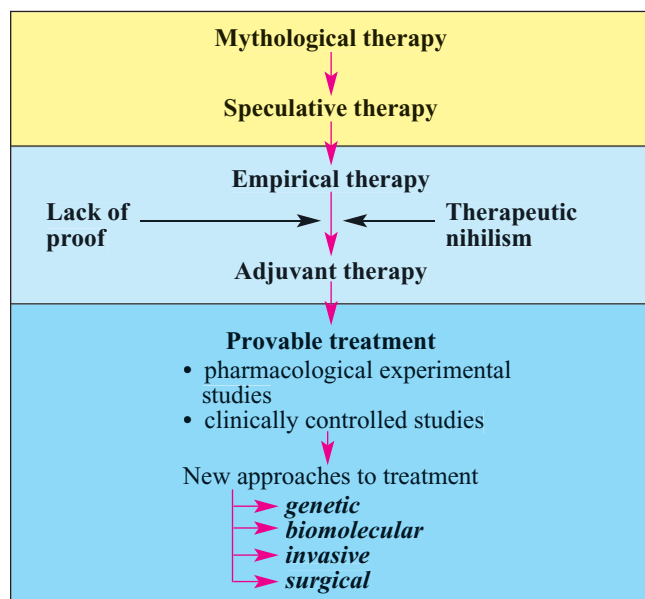

With the gradual rejection of “mythos” and a stronger tendency to “logos”, therapeutic measures of a mythological and ritual nature were increasingly abandoned. At the same time, however, the absurd ideas of **speculative therapy** reached an unimaginable level of odiousness. Obscure mixtures, fantastic preparations as well as nauseating and even cruel treatment methods were more and more propagated and applied. An insight into these abnormalities of speculative medicine is given by K.F. PAULLINI (1699) in his book: „*Neu-vermehrte, heilsame Dreck-Apotheke*“ (“Revised and Enlarged Curative Dirty Pharmacy”).

With the coming of the Age of Enlightenment in the middle of the 18th century, accompanied by a rapid increase in medical knowledge, the calls for confirmed results became more and more urgent. This led to the advent of **empirical therapy**, which required subtle observation, critical analysis, careful examination and, above all, a written record of case histories. In this connection, surgical empiricism was more strongly based on morphological facts and objective methodological experience than the therapeutic empiricism of conservative medicine.

► Preventive therapeutic empiricism was applied for the first time around 1600, when it was discovered by “therapy comparison” that those seamen of the East India Company who drank lemon juice as a supplementary beverage did not contract scurvy. *This was the basis of (probably) the first “statistical” therapeutic study, which J. LIND carried out in 1747 in order to confirm the theory of a lemon-juice therapy in several groups of people by administering various substances, including a “placebo”.* This theory was also confirmed by J. COOK in 1776, using a similar study design. • Further therapeutic milestones of medical history include the comparative studies with *digitalis* (W. WITHERING, 1785), *smallpox vaccine* (E. JENNER, 1798) and *mercury treatment* of syphilis (J. PEARSON, 1800). • Such comparative studies, which were based on individual observations, aimed at proving the effectiveness of treatments; this development ended the epoch of empirical therapy. (2) (tab. 40.1)

1.2 In hepatology

► During a period of about 3,000 years, hepatology also experienced these **historical medical epochs** of therapy, (1.) mythological, (2.) speculative, (3.) empirical, and (4.) provable. (s. tab. 40.1) • In addition to cataplasms – consisting of various herbs, oils or products derived from animals, mostly prepared and used according to mythologically related ideas – cupping, scarification, enemas, blood-letting and sternutators, the following materials were also used: dried wolf liver with honey, donkey liver with parsley, raw ox liver dipped in honey, ox blood, etc. Some highly complex and fantastic mythological diets were applied as well. Therapeutic measures were often based on certain mythological numbers or ritual-dependent points in time and performed before statues of gods or in connection with animal sacrifice. (see chapter 1.) • From the mediaeval “dirty pharmacy” came numerous, disgusting therapeutic recommendations for patients with liver disease, e.g. consumption of the excrement of certain animals, ear wax, dirt scraped off sheep udders, earthworms, polypods dissolved in wine, or a certain number of live sheep’s lice. (s. p. 446) • Empirical treatment increasingly made use of substrates of plant origin or extracts of Hyoscamus, Chelidonium, dandelion or milk thistle, etc. To my knowledge, *comparative therapeutic investigations* such as those mentioned above were not performed in hepatology. Until modern times, treatment of liver diseases remained almost exclusively empirical – and thus scientifically unproven.

Tab. 40.1: Epochs of medicine: (1.) mythological, (2.) speculative, and (3.) empirical therapy, through to (4.) provable treatment

The occasionally pronounced “polypragmatism” was confronted by the opposite extreme of “therapeutic nihilism” in the sense of treatment based on expectation. This inevitably led to frustration on the part of the physician and to resignation on the part of the patient suffering from a liver disease. • Thus, the realization of provable treatment also became an urgent challenge in hepatology.

2 Clinical studies

► The first ethical principles of biomedical research had already been developed in Germany prior to World War I: relevant instructions were issued by the Prussian Education Office in 1900. • At the proposal of the German National Health Board, guidelines for modern curative treatment and for the performance of scientific studies in humans were issued in 1931 by the Ministry of Internal Affairs in Germany.

This measure was indeed the beginning of *scientifically based therapy*. • In 1932 P. MARTINI published his methodology of therapeutic research (8), and in 1937 A. B. HILL established the principles of medical statistics. (6)

2.1 Types of clinical studies

Significant contributions have since been made concerning the importance, performance and evaluation of **clinical studies**. (5, 7) In recent years, statistical and legal issues in particular have been discussed. (3, 10, 11, 12) • Controlled clinical studies are rightly called for and they

are indispensable for avoiding therapeutic misjudgement deriving from “trial and error” and for creating an objective basis for official decisions. They may be carried out, as far as possible comparatively, as a retrospective or prospective investigation. • A **retrospective study** is a backward-looking review of facts and effects, i.e. against a time axis, to identify preceding causes. The data can be collected according to a fixed plan (= **pro-lective**) or generated before the study begins (= **retrolective**). Furthermore, a distinction is made between following the individual course from the time the causative factor appears through to the onset of effect (= **cohort**) and following the individual course from the onset of effect back to the earliest possible point in time when the causative factor appeared (= **trohoc**) (A.R. FEINSTEIN, 1977). Thus, a retrospective study is deemed scientifically correct if its execution is justified and the methodology is clearly defined. • A **prospective study** starts from causative factors, observing the effect over the course of time. (7, 10, 12)

Special cases are the *open (non-blind) study* on the one hand and the *crossover study* on the other hand. • This means that the controlled clinical study is “fundamentally” (i.e. with some exceptions) the sole and most essential tool for obtaining proof of the efficacy of a given substance. If the conditions for a controlled clinical study cannot be met, then it must be dispensed with.

The **typology** of clinical studies differentiates four types according to their aims: (1.) pharmacological studies, (2.) therapeutic explorative studies, (3.) therapeutic confirmative studies, and (4.) drug-monitoring studies. The purpose of the last-mentioned group is to define the cost/benefit ratio more precisely, identify rare side effects and provide better dosage recommendations.

2.2 Problems of clinical studies

There is a vast array of literature dealing with still controversial aspects of controlled clinical studies. • *We should be aware that on the one hand, medicine is not an exact science and on the other hand, humans do not represent a quantifiable model with data on call as needed.* Problems in clinical studies often arise in **different fields**:

- | | |
|-------------------|------------------|
| 1. ethical | 4. psychological |
| 2. methodological | 5. heuristic |
| 3. legal | 6. economic |

Proof in the strict sense cannot be delivered by a controlled clinical study, which has been called the “sacred cow”. (5) However, the probability of statistical error in terms of the chosen target criteria can be fixed in advance. In clinical studies, different interpretations of results are still possible, since “*intuitive medical observation and judgement remain indispensable in the individual*

case" (E. BUCHBORN, 1982). • The **triad** of *empiricism*, *intuition* and *logic* is necessary in both diagnosis and treatment (R. GROSS, 1988).

2.3 Placebo

A placebo (Latin, "I shall please") or ADT (= any what you **desire thing**) is a "dummy" without any active substance, identical in appearance to the respective active drug and not designed to be effective. This term has been known since the 14th century. (4) • In medicine, a placebo assumes **two roles**: (1.) as a therapeutic agent in the practical treatment of patients, intended to have an "effect" on a disease or a symptom, or exerting such effects without the physician's knowledge, and (2.) as a control substance in clinical studies with drugs. • In individual cases, even **objective** changes in physiological functions and **specific** effects may be demonstrable. The form of administration and the dosage of a placebo, the physician's personality (and that of the patient) and the intensity of the disease situation may lead to a weakening or potentiation of the placebo effect. The important (individual and social) ethical issues associated with placebo administration concern both the patient and the physician, who have to be informed in general about such procedures. These issues have been clarified by law after being discussed in detail and assessed on the basis of experimental findings.

► The placebo effect in controlled clinical studies should never be regarded as "zero", even though this is, of course, desired (or even imputed) from the statistical viewpoint.

Within the scope of clinical studies, valuable economic information on medical procedures can (and should) be obtained. Today, **economic assessment** assumes a special role in clinical studies, and because of its complex stratification and the general need for rationalization, e.g. in terms of the cost/benefit analysis, it is likely to become more and more important. The quality-adjusted life year (G.W. TORRANCE, 1987) should be included in the assessment. (s. p. 878)

2.4 Difficulty of evaluation

Proving the efficacy of a (surgical or medicinal) therapeutic measure – *and this also applies in hepatology* – is very difficult, as it mainly depends on **two factors**:

1. non-comparability of individual humans
2. non-comparability of individual diseases

Statistical methods cannot render either **non-comparability** of individual humans or that of diseases comparable – at best, they may compensate it by means of large patient numbers or are able to assess sameness

under certain circumstances. (1, 5) • Statistical **comparability** of different patient groups can only be achieved if **three requirements** are met:

1. equality of structure
2. equality of observation
3. equality of representation

Even with great diagnostic effort, no convincing *structural equality* is obtainable. Consequently, randomization alone does not guarantee a valuable clinical study. Despite these problems, **three study types** should (and must) be used:

1. **Examination of effect**
= change in any one parameter
2. **Examination of efficacy**
= cure or improvement of disease
3. **Examination of superiority**
= improvement of parameters, or cure, or improvement of disease by conventional therapy vs. new therapy

2.5 Provability of treatment

In clinical studies involving drugs – *this also applies to hepatology* – the terms "effect" and "efficacy" have not always been appropriately distinguished, but were often (erroneously) considered identical. • The **effect** of a specific drug (or "liver therapeutic") showing changes in any measured parameters or reactions is easier to prove than its efficacy in the sense of cure or improvement of disease. Therapeutic **efficacy** (or efficacy of "liver therapy") is defined by the difference between the uninfluenced disease course (i.e. possible or usual course) and the disease course changed by therapeutic measures (i.e. actual course). *There is, however, no chance of ever observing and assessing the "possible" and the "actual" disease course simultaneously.*

(1.) The **marketability** of a pharmaceutical preparation is controlled by an act of administration. In this context, **three criteria** must be satisfied for the licensing of medications, including "liver therapeutics":

1. *quality*
2. *safety*
3. **efficacy**

(2.) The term "**quality**" is defined by various criteria: purity, identity, content, galenic properties and temperature stability of a substance. • The term "**safety**" is defined in relation to acute and chronic toxicity, foetal toxicity and fertility, mutagenic and carcinogenic potential.

(3.) As regards the term "**efficacy**", no legal definition exists. As a rule, efficacy is defined by the sum of desired

effects with regard to a certain therapeutic aim. Thus, in terms of the licensing regulations, the efficacy of a drug, including “liver therapeutics”, may be defined as “*the abstract quality of medicine to achieve therapeutic success with proper use, accidental and placebo success having been excluded*” (K. J. HENNING, 1978). The US Food, Drug and Cosmetic Act defines the term “efficacy” in a similar manner. • Mere proof of quality and safety is sufficient for medicine that does not have to be licensed, but only registered; no proof of efficacy is required. This applies to homoeopathic remedies, for example.

(4.) The efficacy of medicinal remedies, including “liver therapeutics”, may be regarded as a **continuum**, i. e. from “*very weak*” to “*highly potent*”. Thus, efficacy is also proven when the substance is shown to be only slightly effective or is only effective in some patients (individual cases). Principally (= exceptions are possible), proof of efficacy is to be provided by controlled clinical studies. No proof of superiority of the drug under investigation over the standard preparation is required by law. Nor does the licensing procedure check whether there is a potential need for the drug in question.

Thus the aim of clinical studies is to provide proof of safety and appropriate efficacy. • However, it is essential to ensure the quality of the randomized, controlled trials in every respect! (9)

3 Principles of liver therapy

3.1 Basic considerations

First of all, two terms need rectifying, since the superficial yet incorrect use of the designations “*liver therapy*” and “*protective therapy of the liver*” have rendered it fundamentally more difficult to make accurate statements. These terms are relics from the epochs of speculative or empirical therapy and constitute the origin of the catchword “*therapeutic nihilism*”. (s. tab. 40.1)

3.1.1 Liver therapy

There has never been and there still is not any “liver therapy” in the true sense – and no such therapy will exist in future either. The liver as the largest biochemical performance centre of the body is constantly active in some 11 major metabolic areas with 60–70 integrated partial functions. In order to accomplish the many tasks, about 300 billion liver cells undertake approx. 500 biomolecular reactions daily – indeed an unbelievable feat. Consequently, it is not possible for drugs to have an effect on the liver as a whole. **However, therapies for liver diseases or therapies for hepatological symptoms are available.** With this linguistic correctness, our therapeu-

tic efforts in hepatology become *realistic* and *objectifiable*. There are far more than 100 liver diseases plus variants and diverse complications. A large number of them can be treated successfully with pharmacological regimens – sometimes with strikingly good results – as well as, of course, by invasive and surgical therapy.

3.1.2 Liver therapeutic agents

In the strict linguistic and hepatological sense, there is no such thing as liver therapeutic agents. However, this *unfortunate term* is frequently – and indeed deliberately – used rhetorically in publications or for administrative reasons. Here, the expression “**hepatic agents**” (analogous to cardiac, otologic and diuretic agents, etc.) would be more correct and not so promising in the popular sense as the designation “liver therapeutic agents”. • *In any case, one ought to be aware of the possible psychological effect of such a term, especially with regard to a “placebo”.* (s. p. 874)

3.1.3 Protective therapy of the liver

Similarly, there is no generally protective therapy of the liver. Liver “protection” as such may include active vaccination against viral hepatitis A or B, for example, and, in a wider sense, also passive immunization after exposure or general avoidance of typical liver noxae. This can “protect” the liver from diseases. (16)

In **in-vitro** and **in-vivo experiments**, certain substances can be studied for their protective effect on the hepatocytes or endothelial cells (including biomembranes and organelles) under the influence of various noxae or toxins. *Many substances have been shown to display distinct protective properties experimentally under various investigative conditions.* Such studies are not, however, admissible in humans. • These experimental protective properties may also be of therapeutic value in individual cases (e. g. application of *silibinin* in *Amanita* poisoning).

A “liver-protective preparation” must therefore be capable of protecting the hepatocytes (as well as the sinus endothelium) from a particular liver toxin, or from two to three clearly defined (or, in the optimal case, all oblige) liver toxins, *by administration before or, at the latest, when the damage occurs.* The use of a substance in existing cellular damage would be classified as “therapy” and no longer “protection”. The term protective liver therapy clearly implies prophylaxis – which, apart from the above exceptions (e. g. vaccination), is usually not feasible under the provisions of the respective health insurance system. (16)

3.2 Preconditions

The question of provability of a certain therapy is also dependent on various **factors** in hepatology: (1.) knowledge of the spontaneous course of a liver disease (not

known in individual cases, but only globally assessable), (2.) endogenous factors (gender, age, genetics), and (3.) exogenous influence (e.g. lifestyle, noxae, patient compliance). These imponderables can scarcely (if at all) be integratively assessed or excluded even using subtle statistical methods. Randomization and double-blind clinical trials can do no more than balance out these differences. In order to obtain usable data, certain **statistical conditions** should be fulfilled as far as possible:

- homogeneous findings
in
- homogeneous patients
with
- homogeneous disease

These requirements are difficult to meet even in controlled clinical studies in hepatology. Moreover, the use of medication in liver disease is based on further essential **clinical conditions**:

1. Detailed hepatic diagnosis with exact classification of the liver disease
2. Identification and elimination of the causative noxa(e)
3. Elimination of concomitant negative factors or additional noxae

Therapeutic uncertainties or differing conclusions regarding drug effects or efficacy may thus be attributed to varying degrees of methodological **inaccuracy**:

- different disease courses
with
- different pathogenesis
in
- different patients
and an
- insufficient detailed diagnosis were submitted
to
- joint statistical evaluation

3.3 Forms of “liver therapy”

Causal treatment of liver diseases, which is rarely (if ever) feasible, should achieve the complete elimination of the actual cause(s) (e.g. elimination of the causative noxa, antiviral treatment, gene therapy in hereditary liver diseases). • **Treatment of pathogenetic primary reactions** (e.g. with interferon, immunosuppressants or penicillamine) is aimed at interrupting the “postcausal” pathogenesis. • **Treatment of disease progression** intervenes in the pathological process in a lasting and efficient manner and thus prevents or slows down the generally dangerous consequences (e.g. inhibition of cholestasis, fibrogenesis and portal hypertension). •

Almost all substances used in hepatology are classed as **symptomatic treatment**. These substances help (1.) to combat malaise and disturbances secondary to the liver disease (e.g. antipruritics), and (2.) to influence the structures and functions of the hepatocytes and endothelial cells as well as the bile capillaries (e.g. antioxidants, essential phospholipids, UDCA, silymarin). (16)

3.4 Aims of treatment

Drug therapy of a particular liver disease or complicative development must have basic **treatment aims**. The primary therapeutic aim is to eliminate the existing causative factors and pathogenetic mechanisms. The final goal is always the *rehabilitation* of the liver patient. (s. tab. 40.2) (s. p. 912)

- | |
|--|
| 1. Eliminating or definitively overcoming the cause of disease (as far as possible) as well as promoting and speeding up its cure |
| 2. Inhibition of inflammatory reactions 3. Curbing of mesenchymal reactions 4. Modulation of immunological reactions 5. Support/normalization of liver cell functions 6. Stimulation of hepatic regeneration |
| ↓ Rehabilitation |

Tab. 40.2: Treatment aims in liver diseases

3.5 Categories of “liver therapeutics”

A number of substances and preparations are available for the treatment of liver diseases. They can be categorized in various ways. (s. tab. 40.3)

1. **Prophylactics**: e.g. immunoglobulins or vaccines against hepatotropic virus infections
2. **Antidotes**: e.g. silibinin against Amanita poisoning or N-acetylcysteine in paracetamol intoxication, haemarginate in acute porphyria
3. **Primary liver therapeutics**: e.g. penicillamine, glucocorticoids, azathioprine, interferon- α , aimed at primary intervention in the aetiology or pathomechanism of liver disease.
4. **Secondary liver therapeutics**: e.g. fat-soluble vitamins in impending deficiency states, drugs to reduce portal hypertension, substances to relieve hyperammoniaemia, aimed at secondary prevention of the various sequelae of liver disease.

Tab. 40.3: Categories of liver therapeutic agents

3.6 Active substances

For several years, (negative) claims appeared in the press stating that the pharmaceutical market was over-

saturated with more than 600 liver preparations. Although the originator of this claim was not identified, this utopian number made the rounds. • In fact, there are merely **25 substances** or **groups of substances** (of chemical or plant origin) listed in the pharmacopoeia. Here, the various preparations containing the same substance are numbered separately, which gives a total of **90–100 listed preparations**. • It is irresponsible that some “liver therapeutics” still have an **alcohol content** of 25–66 vol.% (particularly homoeopathic and phytotherapeutic remedies). (s. p. 64) Although the often quantitatively low intake of alcohol in a preparation may be “harmless” (even “3 times daily”), it will usually cause a relapse in an abstinent alcoholic. *In principle, there is no justifiable argument for keeping the alcohol content in a hepatological preparation!*

Some drugs with **special indications** are used in liver diseases or in certain complications. They are not found in the special category of liver therapeutics (pharmacopoeia), but are listed according to their main indication. Treatment with some of these active substances may be accompanied by side effects. (s. tab. 40.4)

| Chemical substances (or groups) |
|-------------------------------------|
| 1. AA of the urea cycle |
| 2. Beta blockers |
| 3. Bile acids |
| 4. BCAA |
| 5. Deferoxamine |
| 6. D-penicillamine |
| 7. Diuretics |
| 8. Glucocorticoids |
| 9. Haemarginate |
| 10. Immunosuppressants |
| 11. Immunostimulants |
| 12. Lactulose |
| 13. Nucleoside analogues |
| 14. S-adenosyl-L-methionine |
| 15. Somatostatin |
| 16. Spironolactone |
| 17. Virustatics |
| 18. Vitamins (A–K) |
| 19. Zinc |
| Phytotherapeutic agents (or groups) |
| 1. Colchicine |
| 2. Essential phospholipids |
| 3. Glycyrrhizin |
| 4. Silymarin |
| 5. Various herbal preparations |

Tab. 40.4: Active chemical substances (or groups) and phytotherapeutic agents used in some liver diseases or their complications

Active substances with proven efficacy in hepatology are only administered as “treatment” and not as “liver protec-

tion” (apart from the prophylactics mentioned above). These active substances are used in patients when, according to the diagnosed disease and the clinical and pharmacological results, they are actually indicated. • *Thus, it is the existing liver disease and/or complication and not the medication budget or the patient’s wishes which decides the therapeutic indication.* • Anything else would go against the principles of a physician or be uneconomical, and legally problematic in individual cases.

The second dimension of controlled studies, “time”, is frequently given insufficient consideration in evaluating therapeutic results. In fact, it is only possible to assess whether the substances used in chronic liver disease have the required efficacy after an adequate treatment period. In the drug therapy of patients with chronic liver disease as carried out by the clinician and general practitioner, evaluation periods invariably extend over several years. In such cases, positive or negative results can be obtained “empirically”, but because they are not “statistically” confirmed, they are not “provable”. In this context as well,

- *empiricism*
- *intuition*
- *logic*

may diverge (s. p. 873), so that statistics, which as such are indispensable, may indeed prove to be an obstacle.

Perhaps the expectations or requirements of “liver therapy” are too high. With regard to other organs and their respective diseases, established medication often does not really achieve a “cure”, but merely “functional improvements” (e.g. recompensation, inhibition of progression, stabilization in everyday life, improvement in quality of life, rehabilitation). In principle, these fully acceptable therapy aims apply to the treatment of liver diseases as well.

3.7 Dose adjustment of medicaments

Liver and medicaments are interrelated in **three ways**:

1. Medication **inducing** liver diseases
2. Medication **for** liver diseases
3. Medication **changed by** liver diseases

Apart from the kidneys, the liver is the most important excretory organ for drugs. In contrast to other mechanisms of drug elimination, which are relatively well understood, **liver metabolism** of drugs has proved extremely complicated. (s. pp 56–60) *Biotransformation* is influenced by variable and non-variable factors under physiological and pathological conditions. (s. tab. 3.18) • **Changes in pharmaceutical preparations** are alterations in the respective properties which occur due to the disturbed metabolization function of the liver cells and/or hepatic blood flow secondary to liver disease. Additionally, drug metabolism may be drastically modified by

coexisting hypoalbuminaemia or cholestasis. Liver diseases do not only affect the elimination parameters (e.g. half-life, clearance), but also absorption (e.g. bioavailability) and distribution of the drug in the body. A further factor are the interactions of certain drugs with receptors at the site of action (e.g. increased sensitivity of the brain to diazepam in cirrhosis patients). Biotoxometabolites and lipid peroxidation, which are not normally typical of a certain medicament, must also be anticipated. • In principle, a **dose reduction** should be considered in severe and chronic liver disease, especially when the medicament is used regularly. On the other hand, a **dose increase** may be required in i.v. administration owing to reduced hepatic blood flow and using medication with a high elimination rate. • Disturbed drug metabolism may be further aggravated by alcohol consumption with its multiple biochemical effects. (s. p. 65) (s. tabs. 28.2, 28.3)

Despite great efforts, it has not been possible so far to make single **dose calculations** (1.) for a *certain* medicament, (2.) in a *certain* liver disease, and (3.) in a *certain* patient. Some drugs have been classified into three groups on the basis of their hepatic extraction rate and route as well as their form of administration: drugs with a high, with a moderate and with a low risk of overdose – however, such information is given with reservations. The difficulties regarding the correct dose adjustment of a medicinal remedy in therapeutic use require careful **monitoring** of the individual patient, sometimes also determination of the blood values, or consultation with a pharmacologist. (16)

► **Clinical studies:** In view of the above-mentioned difficulties, it may be problematic to administer the **same** dose to **all** volunteers and to obtain pharmacologically **equivalent** results in clinical studies. • This might also explain the occasionally great variation in study results (despite a carefully chosen trial design) and any potential “inefficacy” or undesired effect of the drug. (s. pp 60, 873, 878)

3.8 Significance of quality of life

Of the two dimensions of life, quantity and quality, clinical studies have inevitably paid far more attention to the former (i.e. length of life). The **quantity of life** (judged by survival probability, mortality rate or survival curves) seems to be the most important parameter for assessing treatment efficacy. A review of 99 publications which appeared in leading surgical journals from 1981–1986 revealed that in 97% of the papers, no mention was made of quality of life after surgical procedures – in 341 publications on cardiac surgery, this was mentioned in only 8% of cases (J. O'YOUNG et al., 1985, 1987). Obviously, the prolongation of life was paramount in fixing therapeutic aims. (1, 13, 14, 18, 19)

Defining and measuring the **quality of life** has become important in recent years. This also applies to the conservative or invasive treatment of liver disease, and, in future, more attention will have to be paid to criteria for assessing the changed quality of life under certain therapies as well as the choice of certain treatment strategies (M. LUDWIG, 1988). • The *definition* of good life quality implies that (1.) a person experiences the least possible impairment and handicap under a given therapy (= *clinical norm*), (2.) this person functions in accordance with existing social roles and derives satisfaction from this (= *social norm*), and (3.) the hopes and expectations of this person are fulfilled (= *individual norm*) (M. BULLINGER, 1988). • In one comprehensive survey of the literature, not one single study focusing on the quality of life in liver disease is cited. • Remarkably, a later study mentioned a significant reduction in the quality of life in *patients with chronic hepatitis C*. (14) In a further study, interferon treatment was not only shown to improve the disease, but also to enable the patients to resume their normal daily routine.

3.9 Assessment of survival rate

In the treatment of liver diseases which have a fulminant course or which are chronically progressive (and the respective complications), the question of survival arises. In this context, the classification according to *Child-Turcotte* (1964) and *Pugh* (1973) has proved its worth worldwide. (s. fig. 35.7) • We have used this classification on a regular basis.

In 2000 a score was published giving a prediction of the survival chances in patients with TIPS. (16) Subsequently, this score was validated in several cohorts of patients suffering from different forms of liver disease with varying degrees of severity. The studies included inpatients and outpatients in many different geographical regions. The new model was initially termed “Mayo end-stage liver disease” (MELD). This name was later changed into “Model for end-stage liver disease” (*MELD*), although the acronym MELD remained unaltered. (18) MELD is based on values relating to creatinine, bilirubin and INR (international normalized ratio). These values are included in the original mathematical formula for MELD:

$$9.57 \times \log_c(\text{creatinine}) + 3.78 \times \log_c(\text{bilirubin}) + 11.2 \times \log_c(\text{INR}) + 6.43 = \dots$$

4 Nutritional therapy of liver diseases

The Hippocratic idea that “*dyscrasia*” was the cause of nearly all diseases meant that **dietetics** (= *diaita*) was necessary for the “*restoration to normal of the life order*”.

(s. p. 6) Even in antiquity, special forms of nutrition were of great importance in the treatment of liver diseases. In addition to those dietary prescriptions which were within the reach of everyone (e.g. donkey liver with parsley and honey) (s. pp 7, 872), there were also extremely complicated diets for the treatment of jaundice which only “kings” could afford (Celsus called jaundice the *morbus regius*). (s. p. 7) • During all historical epochs of medicine, dietetic measures have played an essential role in the treatment of liver diseases – even in the so-called “dirty pharmacy” of mediaeval times. (s. p. 872) Because dietetics assumed such an important role in hepatology, nutrition, i.e. enteral intake of special beverages and food, was mainly based on mythological and, at a later date, also on speculative ideas.

From the beginning of the 20th century, a **mild liver diet** was propagated, which in some cases was pursued with scientific meticulousness. The purists issued strict nutritional rules for patients concerning liver diets. In those days, we young clinicians often had great difficulty in implementing such guidelines in practical terms. • This one extreme was set against the other extreme of therapeutic nihilism, i.e. a **free choice of food** by the patient (“eat what you like”). (s. tab. 40.1)

► *Neither extreme is acceptable – in fact, certain liver diseases or complicative developments require special forms of nutrition.*

4.1 Artificial feeding

Artificial feeding is indicated when the liver patient (1.) is no longer *able* to, (2.) does not *want* to, or (3.) is not *allowed* to eat anything because of certain complications. It may also be necessary to prevent malnutrition as well as to eliminate manifest dietary deficits rapidly and successfully. • Artificial feeding can be performed **enterally** by nasogastric tubes, percutaneous-endoscopic gastrotomy (PEG) or jejunostomy (PEJ), and **parenterally** by central-venous catheter systems. This measure is carried out **short term** during inpatient treatment or **long term** on an outpatient basis at home.

4.1.1 Enteral feeding

Should artificial feeding be necessary, the enteral route of application should be given preference. This is feasible in 90% of hepatological problem cases. Nutrition consists of high or low molecular weight formula diets. Feeding may be continuous or in four to five phases. Nasogastric tubes (i.e. 7–8 Ch) are harmless even when oesophageal varices exist. The correct position has to be checked and documented, preferably using radiology! • Artificial enteral feeding must correspond with the principles of energy and metabolism as well as containing vitamins, electrolytes and trace elements in optimum

amounts. It must be appropriate with regard to the underlying liver disease. • Enteral feeding has significant trophic effects on the intestinal mucosa in terms of stimulating local IgA production, improving its integrity as a barrier against bacterial translocation, regulating the physiologically adapted intake of nutritional components (which are subsequently made available to the liver in a physiological first pass effect) as well as steering secretion and hormone production. Serious metabolic disturbances must be avoided; other complications occur only rarely. (22, 29, 31)

4.1.2 Parenteral feeding

Indications for artificial feeding via a central-venous catheter must be considered carefully. As a rule, it is possible only for a brief time, since the application period is limited by several **complications**: (1.) venous thrombosis, (2.) local infection, and (3.) systemic infection (in the usually immunocompromised liver patient). With prolonged parenteral alimentation, (4.) complications in the form of various liver damage must be anticipated. (28, 42) • The reported frequency of **liver damage** is 15–100%. This generally depends on the duration of parenteral feeding, but occasionally the composition of the infusion solution proves to be inappropriate. Laboratory parameters show increases in GPT, GOT and γ -GT as well as in alkaline phosphatase and bilirubin. As a rule, these changes are reversible; however, excessive elevations, especially catheter-associated infections, may necessitate the discontinuation of parenteral feeding. Deaths have occurred in up to 3% of cases. (20, 21, 23, 27) • Various forms of *morphological liver damage* may develop, possibly in combination:

- | | |
|------------------------|------------------------|
| 1. Cholangitis | 6. Fibrosis |
| 2. Cholelithiasis | 7. Hepato/splénomegaly |
| 3. Cholestasis | 8. Jaundice |
| 4. Chronic hepatitis | 9. Liver cirrhosis |
| 5. Fatty liver disease | 10. Steatohepatitis |

The **pathogenetic mechanisms** of liver disease caused by artificial feeding are not fully understood. Various **theories** have been postulated: (1.) deficiency of essential fatty acids or essential phospholipids, (2.) exceeding the maximum glucose oxidation rate, (3.) lack of important substances (e.g. choline, taurine, glutamine, inositol, carnitine), (4.) in individual cases, the presence of toxic metabolic components (e.g. methionine, plant sterols) or newly formed biotoxometabolites. • It must be borne in mind that cirrhosis patients usually show *endogenous hyperinsulinaemia*. A high intake of glucose should thus be avoided, as should the additional administration of insulin. • *The so-called sugar substitutes (e.g. sorbitol, mannitol, xylit, maltit) are not to be recommended.* (26) (s. p. 387)

The calculated glucose requirement of the brain is 1.5 mg/kg BW per minute (i.e. 140–160 g carbohydrates, 560–700 kcal). Blood glucose and lactate levels must be monitored. Fats are the most important energy carriers; 20–50% of the total calorie requirement should be provided in the form of lipids, preferably as MCT/LCT emulsion (1 g fat/kg BW). The latter are also readily metabolized by cirrhosis patients. (25–27) In acute liver failure, disturbances in amino-acid metabolism often occur. Amino-acid infusions should be avoided in this phase – coma-adapted or liver-adapted amino-acid infusions may be indicated (0.4 g AA/kg BW/day with a possible dose increase up to 1.0 (–1.5) g/kg BW/day). Vitamins, electrolytes and trace elements must be sufficiently substituted. The adjuvant use of essential phospholipids and ornithine aspartate is pharmacologically plausible. The regimen of parenteral nutrition must be monitored daily. (23, 26)

The daily requirement of energy, substrate and electrolytes is based on fixed values. (s. tab. 40.5)

| | |
|---------------------|-------------------------|
| Water | 25–45 ml/kg BW |
| Energie | 25–30 kcal/kg BW |
| • Carbohydrate | 50–55% |
| • Lipids | 30–35% |
| • Protein | 15–20% |
| • Standard | 0.8–1.5 kcal/kg BW |
| Electrolytes | |
| – Natrium | 550 mg |
| – Chloride | 830 mg |
| – Potassium | 2,000 mg |
| – Calcium | 1,000 mg |
| – Phosphorus | 700 mg |
| – Magnesium | 400 mg |

Tab. 40.5: Daily requirement of water, energy and electrolytes under normal conditions

4.2 Diet in malnutrition

Chronic liver diseases, especially cirrhosis and alcohol-induced conditions, are accompanied by (protein-caloric) malnutrition in 65–90% of cases. The prognosis of the liver disease largely depends on the nutritional state – there is also a direct relationship between the degree of malnutrition and the progression of the disease and/or complications as well as the probability of survival after liver transplantation. (22, 23, 25, 26, 31–34, 36, 39) • *A BMI of less than 20.5 denotes malnutrition.*

Causes of malnutrition include: (1.) reduced quantity and quality of nutrition, (2.) maldigestion and malabsorption, (3.) accelerated protein breakdown and protein loss as well as *reduced protein synthesis*, (4.) increased energy requirement, especially in the case of complications, and (5.) metabolic disturbances (e.g.

insulin resistance, sympathicotonia, loss of metabolic efficiency). (s. p. 765)

The **resting energy expenditure** (REE) (in kcal) in chronic liver disease can be calculated according to the *Harris-Benedict equation* (1918), considering the patient's body weight, kg (W), height, cm (H) and age, years (A). • Multiplying the REE (kcal) by **activity factor** 1.2–1.4 gives the energy requirement under normal daily conditions (in e.g. trauma, sport up to factor 6.0 or even more).

| | |
|--------------|---|
| Men | = 66.47 + (13.7 × W) + (5.0 × H) – (6.8 × A) |
| Women | = 655.1 + (9.6 × W) + (1.8 × H) – (4.7 × A) |

The **proportions** of carbohydrates (4.0–5.0), fats (1.0–2.0) and proteins (0.8–1.5) (each in g/kg BW/day) in patients with chronic liver disease correspond to those of an ordinary diet; the basic calorie requirement is 25–30 kcal/kg BW/day. • From the metabolic viewpoint, and in the case of diabetes, daily **food intake** should be divided into three main meals and two snacks. As a prophylactic measure, it is advisable to restrict the use of common salt to 7–8 g (because of the very high NaCl content in the usual diet). Moreover, a preponderance of lactovegetarian proteins over proteins derived from meat and fish (with their higher production of ammonia) is recommended. A sufficient intake of vitamins, electrolytes, trace elements and roughage should be guaranteed. (29, 35, 37, 40, 41) (s. p. 765)

Principles of lifestyle

1. Alcohol abstinence
2. Avoidance of noxae and toxins
3. Reaching and maintaining a normal BMT
4. Paying attention to the sensitive water-electrolyte balance (s. figs. 16.1, 16.3) (s. pp 294, 311, 765)
5. Avoidance of malnutrition and undernourishment (s. pp 604, 751)

List of instructions: These “principles of lifestyle” should be closely observed by the patient; they apply to every liver disease. We have always included these principles on a *list of instructions* given to our patients together with the *documentation sheet*. (s. fig. 15.3)

4.3 Special diets

Special dietary measures are of major, often even of decisive importance for several types of liver disease or associated complications. • Here, too, the false, universal claim that “there is no liver diet” is invalid. In the same way that treatment of a liver condition is indeed possible, there are also dietary measures for certain forms or complications of liver disease. • After an exact diag-

nosis has been made, there is often a necessity for dietary therapy based on the respective situation.

At this point, we would like to emphasize once again that a strict lactovegetarian protein supply must be adhered to not only in latent encephalopathy, but also in (acute or chronic) liver diseases in which insufficient detoxification of ammonia is anticipated. When assessing the so-called protein tolerance threshold (s. p. 286), the *documentation sheet* (s. fig. 15.3) as well as a *psychomotoric test programme* (s. p. 211) can be of great help.

Metabolic diseases: A *fatty liver* does not require a low-fat diet, but standard nutrition based on general reference values for usual daily routine. With a normal body weight and an increased energy requirement (work, sports), the calorie intake has to be adjusted accordingly. • In *overweight patients*, a slow, continuous, yet systematic weight reduction should be striven for. Coexistent *hyperlipoproteinaemia* may require supportive treatment. *Diabetes mellitus* must be properly controlled. This also applies to concomitant *gout*.

Cirrhosis: In compensated liver cirrhosis without obvious malnutrition or undernourishment, no special diet is necessary, and normal balanced nutrition is adequate. In liver cirrhosis, a lactovegetarian protein supply always has to be given preference; ammonia-forming animal proteins should only be present in the food in low quantities and consumed every few days. *Malnutrition* has to be eliminated by corresponding dietetic measures. In severe cases of disease, artificial feeding (enteral, or for a short time parenteral) may be recommended. (24, 30, 33, 37–39) (s. pp 765, 879)

Haemochromatosis: Iron is ubiquitous in food. A *low-iron* diet must be observed (using available food tables). Although a lactovegetarian diet is desirable, attention should be paid to the high iron content of pulses, green vegetables and dried fruit. • *Black tea* (2–3 cups per day) should be drunk regularly. (s. p. 644)

Wilson's disease: With a normal diet, the daily copper supply amounts to 3–6 mg. In Wilson's disease, however, the copper content should be reduced to <1 mg/day (using the available food tables). As in haemochromatosis, a lactovegetarian diet is important, but attention should be paid to the high copper content of coarse-grained wholemeal products, nuts, cheese (Emmental, Edam) and cocoa. The intestinal absorption of copper can be reduced further by potassium sulphide (3×20 mg). (s. p. 635)

Encephalopathy: The diagnosis of HE, even in the stage of latency (s. p. 280) (s. fig. 15.3), requires an adjustment of protein intake. This applies to both the daily amount (= cutting down) and the type of protein (= only lactovegetarian proteins). No reduction in fats is necessary. (34) Carbohydrates should be restricted to 2.5–3.5 g/kg BW. The return to standard nutrition should correspond to the gradually improving quantitative and later also qualitative protein tolerance threshold, varying from

case to case. Should no nitrogen balance and no improvement in the HE symptoms be achieved with lactovegetarian protein intake, supplementation with *branched-chain amino acids* is indicated. The latter also stimulate muscular protein synthesis and promote the formation of glutamine in the brain. However, they are not equivalent to substitution by balanced amino-acid solutions. Commercially available protein preparations should be low in common salt. (s. pp 285, 754)

Ascites: The occurrence of a disturbed water-electrolyte balance in the late stage of latent oedema (s. fig. 15.3) requires immediate restriction of the salt intake (<3–6 g/day) – depending on the level of natriuresis: the intake of fluid is limited to 1.0 (–1.5) l/day, especially in hyponatraemia. An intermittent *fruit and rice diet* (generally for 1–2 days) is recommended because it is extremely low in sodium, but rich in potassium. Marked *NaCl restriction* simultaneously leads to a reduction in protein intake. The use of commercially available low-salt protein preparations is therefore advisable (e.g. 60 g protein/100 g + 5 mval sodium/100 g, or 48 g protein/100 g + 13 g, or 15 g sodium/100 g). NaCl restriction is contraindicated in natriuresis of <25 mmol/day. (s. p. 314)

Storage diseases: Some genetic metabolic diseases require special dietary measures: e.g. (1.) *disorders of the urea cycle* are treated with a diet similar to that used in encephalopathy (s. p. 611), (2.) *Gierke's disease* needs a high-carbohydrate diet (s. p. 612), (3.) *Cori's disease* is treated with formula diets and a starch diet (s. p. 613), (4.) *galactosaemia* wants a galactose- and lactose-free diet (s. p. 614), and (5.) in *fructose intolerance*, a fructose- and saccharose-free diet must be given. (s. p. 615)

5 Drug therapy of liver diseases

Many different **active substances** have been discussed in connection with the treatment of the various liver diseases or their complications in the respective chapters. The effectiveness of these substances has either been *statistically confirmed* in controlled trials, or they have been *tested empirically*, or they seem to be *pharmacologically plausible* for a specific application. • Some of these therapeutic substances and their uses are presented in the following.

5.1 Virustatics

Viruses have no metabolism of their own; and they just contain DNA or RNA and envelope proteins. They are only able to replicate in living host cells, whereby they need to make use of the enzymes, synthesis mechanisms, amino acids and nucleic acids of the host cell. Replication can be inhibited by virustatics. Generally, however, viruses cannot be completely inactivated; as a rule, this is only possible by means of the body's own defences. •

The viruses attach themselves to the cell membranes via specific receptors (= **adsorption**). Viruses enter the cells by means of **endocytosis**. The virus coat opens, with the result that viral nucleic acid and enzymes are liberated (= **uncoating**). This is followed by **transcription** of viral nucleic acid to mRNA, the formation of enzymes (= early-phase proteins) and structural proteins (= late-phase proteins) as well as nucleic acids for virus multiplication (= **replication**). After maturation, the viruses are released from the host cells by exosomes.

Virustatics are substances which inhibit viral replication without inactivating the viruses themselves (i.e. they are not virucidal). Chemically speaking, they are either derivatives of nucleic acids or glycoproteins (e.g. interferon). Virustatics have no effect until the virus has been taken up in the host cell. They can therefore have the following *points of attack*: (1.) prevention of viral attachment to the host cells, (2.) inhibition of penetration, (3.) inhibition of uncoating, (4.) inhibition of nucleic acid synthesis, (5.) inhibition of protein synthesis, and (6.) prevention of virus liberation. • *Any therapeutic impact on viruses is also an attack on the metabolism of the host cell.* (s. tab. 40.6)

Due to their various modes of action and viral targets, some first and second generation virustatics have also been employed for treating hepatitis viruses. Thus, various virustatics are indicated in infections with **secondary hepatotropic viruses** (s. pp 118, 474):

| | |
|-------------|---------------------|
| Aciclovir | HSV, VZV (EBV) |
| Amantadine | Influenza A, B |
| Didanosine | HIV |
| Famciclovir | HSV |
| Foscarnet | HSV, CMV, HIV |
| Ganciclovir | CMV, HSV, VZV (EBV) |
| Vidarabine | HSV, VZV (EBV) |
| Zidovudine | HIV |

Virustatics are indicated in *acute* viral hepatitis C, with interferon being the therapy of first choice in this connection. They are used as early as possible. Their application is also recommended in *chronic* hepatitis B, C and B/D. • In infections with hepatotropic viruses, the following virustatics have already been introduced or are under discussion:

| | | |
|------------------|----------------------------------|---------------------|
| 1. Aciclovir | 6. Famciclovir | 11. Lobucavir |
| 2. Adefovir | 7. Foscarnet | 12. Ribavirin |
| 3. Amantadine | 8. Ganciclovir | 13. Tenofovir |
| 4. Emtricitabine | 9. Interferon α , β | 14. Vidarabine etc. |
| 5. Entecavir | 10. Lamivudine | |

5.1.1 Interferon

Interferons (IFN) were discovered in England by A. ISAACS et al. in 1957. (46) They are low molecular weight glycoproteins acting as cytokines (so-called intercellular mediators) with clear species-specific effects.

| | | DNA-dependent polymerase | Reverse transcriptase | Chain break |
|-------------|-----------------------------|----------------------------------|-----------------------|-------------|
| Amantadin | Uncoating | | | |
| Aciclovir | Replication | + | | + |
| Adefovir | " | + | | + |
| Famciclovir | " | | | + |
| Foscarnet | " | + | | |
| Ganciclovir | " | + | | + |
| Interferon | " | + | | |
| Lamivudine | " | + | + | |
| Lobucavir | " | + | | + |
| Vidarabine | " | + | | |
| Didanosine | Transcription of RNA to DNA | | + | + |
| Foscarnet | | | + | |
| Zalcitabine | | | + | + |
| Zidovudine | | | + | + |
| Interferon | Maturation | | | |
| Ribavirin | Replication | Inosinmonophosphat-Dehydrogenase | | |

Tab. 40.6: Some modes of action and points of attack of virustatics

Interferon type I includes the subtypes IFN- α and IFN- β . They are formed by nearly all cells, whereby IFN- α is mainly produced by monocytes and B-lymphocytes, and IFN- β mainly by fibroblasts. Both subtypes bind to the same receptor at the target cells and are taken up in the hepatocytes by endocytosis. Prior to degradation, IFN activates many genes, thus causing a broad spectrum of proteins to be synthesized. This explains its multiple biological effects. The antiviral effect of IFN- α is evident in all the important steps of virus replication. However, the various cell types form different IFN- α subtypes; so far, more than 30 subtypes are known. IFN- α and IFN- β have a half-life of three to four hours.

Interferon type II includes IFN- γ , which is probably only produced by T lymphocytes and natural killer cells. IFN- γ is of no importance for the therapy of viral hepatitis. (44) (s. p. 723!) • Recently, IFN- ω was isolated, but its biological role is not yet understood.

Recombinant IFN is produced from a clone of E. coli, which carries a plasmide that possesses a gene for IFN- α_{2b} . The molecular weight amounts to 19,200 daltons. It has a high level of purity (>99%). If antibodies against recombinant IFN occur, natural IFN may prove useful. Recombinant interferons differ in only one single amino-acid position:

| | Position 23 | Position 34 |
|--------------------|-------------|-------------|
| IFN- α_{2a} | lysine | histidine |
| IFN- α_{2b} | arginine | histidine |
| IFN- α_{2c} | histidine | arginine |

Lymphoblastoid IFN- α is a mixture of natural IFN- α subtypes with different structures of the carbohydrate chains. • A **consensus IFN- α** has also been developed; this is a genetically modified IFN- α , which has the properties of various IFN- α subtypes. Thus its biological activity is increased (by ca. 30% in chronic hepatitis C, probably due to better receptor affinity).

Pegylated IFN optimizes the biological effects of IFN. The term “pegylation” denotes covalent linkage of polyethylglycol (PEG) to IFN. Thus IFN is protected from proteolysis, and its half-life is extended approx. tenfold (to about 40 hours). This “depot interferon” therefore has improved efficacy due to prolonged persistence in the body. (43, 45, 51) (s. pp 723, 728)

| | Peginterferon alpha-2a (40 kDa) | Peginterferon alpha-2b (12 kDa) |
|---|---------------------------------------|---------------------------------------|
| Volume of distribution (units) | 8–12 l | 0.99 l |
| Clearance (units) | 94 ml/h | 22.0 ml/h |
| Absorption half-life | 50 h | 4.6 h |
| Elimination half-life | 80 h | ~40 h |
| Peak-to-trough ratio | 1.5 | >10 |
| Time to maximum concentration (T_{max}) | 72–96 h | 15–44 h |

1. Antiviral effects

- Reduction in cellular uptake of viruses
- Inhibition of intracellular processing of viruses
- Reduction in viral mRNA synthesis
- Reduction in protein synthesis
- Induction of ribonuclease

2. Immunostimulation

- Induction of substances inhibiting cell division and reducing oncogene expression
 - cytokines
 - complement factors (B, C_2)
 - nuclear proteins
- Increase in the activity of
 - macrophages and natural killer cells
 - cytotoxic T lymphocytes
- Hypothalamus-mediated fever

3. Increased expression of membrane proteins

- HLA classes I, II – antigens
- β_2 -microglobulin
- Fc-receptor

4. Antineoplastic effect

- Inhibition of cell division
- Decrease in oncogene expression
- Direct cytotoxicity

5. Inhibition of fibrosis

Tab. 40.7: Biological modes of action of interferons

► The interferons display multiple **biological modes of action**. Each of these effects (or their sum) contributes

to therapeutic efficacy. It is still unclear which actions or mechanisms assume a central role in the treatment of chronic viral hepatitis. (47–45) (s. tab. 40.7)

5.1.2 Nucleoside analogues

Nucleosides (e. g. adenosine, cytidine, guanosine, pyrimidine, thymidine, uridine) consist of a nitrogenous purine or pyrimidine base linked to a 5-carbon sugar (ribose or deoxyribose). **Nucleotides** (adenine, cytosine, guanine, thymine, uracil), the phosphate esters of nucleotides, form the basis of RNA and DNA. As infectious viral nucleic acids, they are capable of penetrating the cells and using available enzyme systems for replication.

As modified nucleoside components, the **nucleoside analogues** inhibit the replication of viral nucleic acids. Therefore, they belong to the group of virustatics. They are phosphorylated by means of cellular or viral kinases, thus becoming biologically active. As regards their clinical application as virustatics, it must be ensured that endogenous DNA synthesis is not inhibited along with viral nucleic acid synthesis. Otherwise, severe mitochondrial lesions with lactic acidoses and irreversible liver damage may occur, possibly with a fatal outcome, as was the case with fialuridine used in chronic hepatitis B (R. MCKENZIE et al., 1995).

Many of these nucleoside analogues have already been used clinically as **virustatics** against secondary hepatotropic viruses, influenza A or HIV infection. (s. p. 882). The development of nucleoside analogues is of great importance for the treatment of chronic hepatitis B and C or D. Their virustatic efficacy can be studied in chronic hepatitis B using standardized in-vitro systems and animal experiments. (56) In hepatitis C, no such models exist, so that efficacy studies are only possible in infected patients. Several new developments have already been incorporated into clinical studies in hepatology. They are generally used in combination with interferon; in some cases, two nucleoside analogues may be used together. (51, 56, 58, 61)

(1.) **Famciclovir:** After absorption, this guanine derivative is converted to its active form *penciclovir*. The biologically active metabolite penciclovir triphosphate, which effects the inhibition of viral DNA polymerase, is only formed in the infected liver cell. The dosage is 3×500 mg/day. • After discontinuation of this substance, the previous findings usually reappear, i.e. it is only effective as an ongoing treatment. It is used therapeutically in combination with IFN. (53) (s. p. 725)

(2.) **Lamivudine:** This is a cytosine(cytidine)-nucleoside analogue. Its effect is based on the inhibition of reverse transcriptase in HIV and of DNA polymerase in HBV. The daily oral dosage is $1 (-3) \times 100$ mg/day. After discontinuation of lamivudine, the previous findings recur; here, too, efficacy only exists with continued therapy. A combination with famciclovir seems promising.

Its clinical application is mainly in combination with IFN. Long-term monotherapy over several years may be necessary. (54, 60) (s. p. 725)

(3.) **Lobucavir:** This guanosine derivative has proved very effective against HBV. The dosage is $1-4 \times 200$ mg/day. After discontinuation of the one-month therapy, values returned to their initial levels. A combination with IFN is also recommended for this substance, and indeed has a very good action profile.

(4.) **Aciclovir:** After oral application, only about 20% of the applied dose of this guanosine derivative is absorbed. Aciclovir is mainly eliminated via the kidneys (ca. 85% of the dose within 48 hours). Its half-life, which is approximately three hours, depends on renal function. The substance is employed especially in HSV and VZV infections. This agent inhibits DNA polymerase (i.e. replication) and effects a chain break. As a monotherapy in HBV infection, aciclovir only shows moderate efficacy. Side effects are rare.

(5.) **Ganciclovir:** This is a guanosine derivative with a good action profile in HBV, EBV, CMV and VZV infection. Ganciclovir triphosphate inhibits virus replication. Half-life is about four hours. Elimination is via the kidneys. Only a fraction of this substance is absorbed after oral administration; application (e.g. in CMV infection) is intravenous (10 mg/kg BW/day). It has severe toxic side effects. Ganciclovir was given successfully as early as 1989 in chronic hepatitis B. Subsequently, good results were achieved in combination with IFN.

(6.) **Ribavirin:** This guanosine analogue was first used experimentally by O. REICHARD et al. (1991) and in chronic hepatitis C by J. ANDERSSON et al. (1991). It is rapidly absorbed and distributed in the body, but excreted slowly (half-life is 79 hours). Bioavailability is 45–65%. As a monotherapy, it only leads to a decrease in the transaminases and a slight improvement in histological activity. Ribavirin may not exhibit a direct antiviral effect, but can trigger a favourable response to interferon. When combined with IFN, ribavirin proved far more efficacious in chronic hepatitis C (immunomodulation?) without any increase in the typical side effects of IFN. (55, 57, 59) (s. p. 729)

(7.) **Amantadine:** The antiviral efficacy of amantadine (1-adamantanamine) was reported for the first time by W.L. DAVIES et al. in 1964. The mode of action consists in preventing uncoating and viral maturation (i.e. inhibiting the release of the nucleic acids that have already penetrated the host cell). The active substance is almost completely absorbed following oral administration. It is eliminated unchanged via the kidney. The half-life is about 15 hours. So far, it has only been indicated to combat influenza virus type A. (s. p. 730)

5.2 Immunosuppressants

Immunosuppressants are substances that suppress the immune response. Inhibition or neutralization of the

major part of the body's defence system is essential in (1.) organ transplantation, and (2.) autoimmune diseases. The following are considered to be some of the most important immunosuppressants:

- | | |
|-----------------------------|--------------------|
| 1. Antilymphocytic globulin | 6. Glucocorticoids |
| 2. Anti-CD 3 antibodies | 7. Methotrexate |
| 3. Azathioprine | 8. Sirolimus |
| 4. Cyclophosphamide | 9. Tacrolimus |
| 5. Cyclosporine A | |

5.2.1 Glucocorticoids

The immunosuppressive effect of glucocorticoids is based on the reduced formation of interleukins 2 and 6 with inhibition of T lymphocyte proliferation and on a decrease in IL-2 release. The glucocorticoids are therefore effective at a very early phase of the immune response. • At the same time, phospholipase A₂, and thus prostaglandin synthesis, is inhibited, and leucocyte migration is reduced (= anti-inflammatory effect). The clinical use of glucocorticoids is indicated in (1.) autoimmune hepatitis, (2.) immunocholangitis, (3.) PBC with a progressive course, (4.) florid alcohol-induced hepatitis or progressive alcoholic liver disease with evidence of antihistone B2, and (5.) drug-induced idiosyncrasy of the immunological type. In the diseases mentioned under points (4.) and (5.), the use of glucocorticoids should be reviewed critically.

5.2.2 Azathioprine

The effect of azathioprine is based on inhibition of T lymphocyte proliferation and differentiation of activated B and T cells. This results in a change in interleukin expression. Azathioprine suppressed CD 28-dependent Rac-1 activation, resulting in suppression of bcl-x expression and a consecutive induction of T cell apoptosis. These results have important implications for the development of novel substances showing higher affinity to Rac-1 with more specific therapy in autoimmune diseases and organ transplantation. Azathioprine is converted in the hepatocytes to 6-mercaptopurine, the actual active agent. Half-life is five hours. It can take several weeks until a steady state is reached in the blood, which explains the delayed effect of azathioprine (3–6 months). It is assumed that (due to genetic determination?) the imidazole residue of azathioprine is capable of binding sulphhydryl groups, resulting in an additional antimetabolic effect. (62) Pharmacological differences are further suggested by a report stating that treatment failure with azathioprine in autoimmune hepatitis was successfully overcome by subsequent treatment with 6-mercaptopurine. (68) A short time after the introduction of azathioprine, results of comparative studies with azathioprine and 6-mercaptopurine in CAH (probably autoimmune hepatitis) were reported. (66) • Azathioprine is used clinically in autoimmune hepatitis, immu-

nocholangitis and progressive PBC. Combined use with prednisolone yields even better results. (68) These two substances administered at a low maintenance dosage can ensure remission for many years. Maintenance of remission achieved with azathioprine following discontinuation of prednisolone has likewise been reported. Hepatological side effects include bone-marrow depression, allergic reactions, greater susceptibility to infection, cholestasis, destructive cholangitis, VOD and nodular regenerative hyperplasia. (s. pp 664, 683)

5.2.3 Cyclosporine A

This active substance suppresses the release of interleukin 1 from monocytes and the synthesis of interleukins 2, 3 and 4 as well as of TNF- α from T helper cells; T cell proliferation, macrophage stimulation and B cell activation are inhibited. Even at an early stage of the immune reaction, this leads to the suppression of both humoral and cellular immune responses. The body's bacterial defence is still not significantly influenced, as the phagocytic activity of the RES is barely inhibited by cyclosporine. Bioavailability is about 35% following oral application; it is almost completely metabolized in the body and eliminated predominantly via the bile. Clinically, its main indication is the prevention of transplant rejection. (63, 67, 69) Occasionally, it has also been used in liver diseases, particularly in autoimmune hepatitis and PBC. (70) As in the case of azathioprine, cholestasis also constitutes a major hepatological side effect when using cyclosporine. Canalicular damage demonstrated in animal experiments could be prevented by S-adenosyl-L-methionine. Cyclosporine may cause elevated as well as reduced blood values in combination with many other medicaments. (72) (s. pp 665, 684)

5.2.4 Tacrolimus

Tacrolimus was introduced for clinical use in 1989 as a new, well-tolerated immunosuppressive substance that can be administered orally or intravenously. Its immunosuppressive effect is based on the inhibition of the lymphokinin synthesis of interleukins 2 and 3, interferon- γ and TNF- α as well as a reduction in interleukin-2 receptor expression. Tacrolimus leads to inhibition of T cell activation, the formation of cytotoxic T lymphocytes, the induction of specific T helper cells and T helper cell-dependent B cell proliferation. Its bioavailability is about 20%. A number of studies have meanwhile been published reporting the superiority of tacrolimus over cyclosporine. (64, 67) Experimentally, tacrolimus has been found to effect a decrease in free radicals, cytokines, tumour necrosis factor and neutrophilic infiltration in liver tissue. A possible increase in blood values (hitherto) occurring with about 20 drugs and a fall in blood values with numerous other drugs must be considered. Tacrolimus may cause manifestation of diabetes, or even trigger it. Initially only intended as an immunosuppressant against graft rejection (65),

tacrolimus has meanwhile also been used successfully in PSC and autoimmune hepatitis. (71) (s. p. 684)

5.2.5 Cyclophosphamide

Cyclophosphamide is a prodrug which is converted into active metabolites in the liver. Urotoxic side effects must be anticipated; they can be suppressed by the additional administration of sodium-2 mercaptoethanesulphonate. • This alkylating substance has a strong immunosuppressive effect; therefore, it is occasionally used to prevent graft rejection or (at a low dosage) in autoimmune hepatitis. (s. p. 684)

5.2.6 Methotrexate

This folic acid antagonist belongs to the group of anti-metabolites which suppress endogenous substances (metabolites) and trigger the formation of functionally incompetent macromolecules. Because of their largely non-specific effect, all rapidly dividing cells are adversely affected and toxically damaged. At a low dosage, methotrexate has been used in autoimmune diseases. (s. pp 665, 684, 692)

5.3 Immunostimulants

Immunostimulants are defined as substances which stimulate immunological responses and improve a weakened immune system. They include interferon, thymus factor, interleukins, extracts of microorganisms, chemically defined substances (e.g. levamisole, selenium, zinc) and plant-derived substances (extracts from Phyllanthus, Bupleurum, Glycyrrhiza, Schizandra, etc.). (s. pp 726, 898)

5.3.1 Selenium

Discovered by J.J. BERZELIUS as early as 1817, selenium was only recognized as being an essential trace element for humans in 1957. So far, glutathione peroxidase (G.C. MILLS, 1957) and 5-deiodase (D. BEHNE et al., 1990) have been defined as selenium-containing enzymes. The daily requirement ranges from 20 to 100 μg , which is met mainly by animal protein; in the case of a lactovegetarian diet and a simultaneously increased need (e.g. due to liver cirrhosis or malabsorption), cellular selenium deficiency may occur. (77) Of the thirteen selenium proteins known so far, only two glutathione peroxidases have been closely defined: one membrane-bound and one cytosol-bound enzyme. They are components of an antioxidative system in that they catalyze the reduction in hydrogen peroxide, organic hydroperoxides and fatty acid hydroperoxides. Further biochemical effects include stimulation of the immune system (increased activity of the natural killer cells, stimulation of IFN- γ synthesis, enhanced capability to phagocytize) (76), hepatoprotection, detoxication of heavy metals, regulation of lipid peroxidation (scavenger of free radicals), inhibition

of carcinogenesis and tumour growth, etc. (76, 77, 79) (s. pp 55, 812) • *Sodium selenite* seems to be most appropriate for infections. (s. p. 310)

5.3.2 Zinc

Zinc is an essential trace element, 98% of which is deposited in the intracellular space. The various organs differ significantly in their zinc concentration. The total body content amounts to 1.5–4.0 g. The daily zinc requirement ranges between 10 and 15 mg. A high content of certain amino acids (alanine, cysteine, glycine, histidine) greatly facilitates the intestinal absorption of zinc, whereas phytate-containing pulses and cereals as well as chronic alcohol abuse impair its absorption to a considerable extent. Zinc is readily excreted and hardly accumulates in the body. All in all, there are many factors leading to relative or absolute zinc deficiency. (s. p. 55) (s. tab. 3.15) • Zinc is an essential component of about 200 enzymes. It plays a major role in the metabolism of carbohydrates, proteins, lipids, vitamin A and alcohol as well as influencing DNA and RNA synthesis and stimulating the immune system. It activates ornithine carbamoyltransferase, alkaline phosphatase, δ -ALA synthetase and carboanhydrase, and especially superoxide dismutase. Zinc metabolism primarily occurs in the liver. It is largely governed by hormones (e.g. glucagon, insulin, glucocorticoids, ACTH, STH, sex hormones) and regulated by interleukins 1 and 4 as well as TNF. Its close relationship with the immune system thus becomes evident. Among other things, zinc influences thymulin, DNA and RNA polymerase (= gene expression in cell differentiation and proliferation) and the mediator functions in the immune response. (79) Understandably, zinc deficiency in liver cirrhosis or alcoholic liver diseases may well contribute to the patient's susceptibility to infections or febrile conditions (e.g. spontaneous bacterial peritonitis) and possibly even the induction of carcinogenesis. • The multiple biochemical roles of over 200 zinc-containing enzymes explain the wide spectrum of manifestations associated with zinc deficiency in hepatology. This is of great importance for the pathogenesis of hepatic encephalopathy and the therapeutic use of zinc. (73, 74, 80, 82) (s. pp 105, 277, 286, 812)

5.3.3 Thymosin

Of the group of thymosins, a mixture of various thymus hormones (or factors), fraction 5 has been well defined. It is already used, for example, for the synthetic manufacture of **thymosin- α** . Further thymus factors include *thymulin* and *thymostimulin* (G.M. MUTCHNICK et al., 1991). • Thymus factors effect the maturation of thymus T cells, which migrate to the lymphatic system as immune cells. The clinical use of thymosin- α is indicated in impaired immune defence with a decreased count or

reduced function of T lymphocytes. (78) Clear effects on HBV DNA and on the transaminases were demonstrated in chronic hepatitis B. (75) • In combination with IFN, good results were also obtained in chronic hepatitis C. (83) In a recent study, the use of thymosin as monotherapy in chronic hepatitis C did not prove to have any beneficial effect. Generally, good tolerance was recorded for this drug. (81) (s. p. 726)

5.4 Ursodeoxycholic acid

The secondary bile acid *7-keto-lithocholic acid* is transported from the intestinal tract via the portal vein to the liver, where it is converted to **ursodeoxycholic acid** (UDCA) by bacterial enzyme action. (s. pp 40, 684) (s. fig. 3.3!) • The *molecular formula* of UDCA is identical to that of CDCA (= $C_{24}H_{40}O_4$); however, it has the hydroxyl group at the C_7 atom in the β -position and not in the α -position like chenodeoxycholic acid. The tertiary bile acid UDCA thus constitutes the 7β -epimer of the secondary bile acid CDCA. This changes the steric arrangement: the molecule possesses a *higher polarity* and is thus less able to form micelles. UDCA is hydrophilic and only slightly lipophilic, and therefore practically non-toxic to the organism. With its *molecular weight* of 392.6, it constitutes 0.5–1.0 (–5.0)% of human bile. Following oral administration, UDCA is passively absorbed in the jejunum and in the proximal portion of the ileum and, through active transport, in the distal ileum; in addition, approx. 20% of the UDCA can be absorbed in the colon. In portal blood, UDCA is transported bound to protein and conjugated in the liver with taurine (to a small extent also with glycine). These conjugates reach the bile. The *half-life* is 3.5–5.8 days. Like its breakdown product isoursodeoxycholic acid, UDCA is excreted predominantly in faeces and to a lesser degree in urine. (90, 92, 93, 100, 111, 117)

Functioning as detergents, **hydrophobic (lipophilic) bile acids** (cholic acid, chenodeoxycholic acid, deoxycholic acid, lithocholic acid) exert toxic effects on the biomembranes of liver cells and mitochondria. At the same time, these bile acids display an immunosuppressive effect and influence the humoral and cell-mediated defence (e.g. inhibition of monocytes). As in the case of PBC, hydrophobic bile acids also induce an excessive expression of MHC-I and MHC-II molecules from hepatocytes and biliary cells.

Modes of action: The mechanisms of UDCA and its effects in cholestatic liver diseases are not yet fully understood – even though a number of different effects have been demonstrated. (87, 101) These include (1.) hepatoprotective (99, 109, 110), (2.) cytoprotective (96, 114), and (3.) biliary-metabolic effects (88, 102, 120, 121), as well as (4.) an influence on the immune system. (119) In ligature of the bile duct in rats, UDCA was found to reduce the occurrence of histological changes and biliary cirrhosis as well as of portal hypertension. (s. tab. 40.8)

1. Inhibition of the enteral absorption of hydrophobic bile acids
2. Induction of bicarbonate hypercholeresis
 - increase in bile flow (hypercholeresis)
 - increase in the cholehepatic circulation of UDC (= cholehepatic shunt) (s. p. 40)
3. Incorporation into the lipid membranes of liver cells and mitochondria, preventing loss of phospholipids and cholesterol
 - stabilization of membranes
 - improvement of bile acid transport
 - amelioration of immunological membrane functions
4. Influence on calcium-mediated intracellular signal transfer
5. Interaction with the glucocorticoid receptor
6. Influence on protein kinase C
7. Reduction in MHC-I and MHC-II molecule overproduction (= decrease in T lymphocyte toxicity)
8. Inhibition of interleukins 1, 2, 4 and 6, TNF- α and immunoglobulin formation
9. Synergistic effect with IFN- α

Tab. 40.8: Biochemical and pharmacological modes of action of ursodeoxycholic acid

Contraindications: The following contraindications should be observed: acute cholecystitis, acute cholangitis, obstruction of the cystic duct and common bile duct as well as frequent biliary colic.

Indications: The indications for the clinical use of UDCA are either already well-documented, empirically proven or pharmacologically justified. (98, 103, 105, 108, 113–115, 117) • Practically *no side effects* are to be expected. From the therapeutic viewpoint, it is possible to achieve an improvement in the clinical symptoms (fatigue, pruritus, gastrointestinal symptoms, steatorrhoea), especially in cholestasis with decreased values of AP, LAP, γ -GT and bilirubin. (104–106) • There is a similar improvement in further laboratory parameters (transaminases, GDH, IgM, cholesterol, etc.) together with an amelioration of histological alterations. (86) Special attention should be paid when administering UDCA in cirrhosis with ascites. (s. pp 664, 684, 692) (s. tabs. 13.10; 40.9)

Viral hepatitis

Acute viral hepatitis (94)
Chronic hepatitis (86, 106, 115)

Autoimmune diseases

1. Autoimmune cholangitis
2. Autoimmune hepatitis
3. Overlap syndrome (s. p. 709)
4. Primary biliary cholangitis (89, 103, 113) (s. p. 705)
5. Primary sclerosing cholangitis (97, 118) (s. p. 707)

Cholestatic liver diseases

1. Alcoholic liver disease with cholestasis
2. Chemically induced cholestasis
3. Cholestasis with complete enteral feeding (84)
4. Drug-induced cholestasis
5. Secondary sclerosing cholangitis

Genetically determined cholestasis

1. Alagille's syndrome
2. Byler's syndrome
3. Cholestasis of pregnancy (95)
4. Disturbances of the steroid ring
 - 7 α -hydroxylase deficiency
 - 4 δ -3-oxosteroid-5 β -reductase deficiency
 - 3 β -hydroxysteroid-5 δ -dehydrogenase
5. Mucoviscidosis (91)
6. Recurrent benign cholestasis

Organ transplantation

1. After liver transplantation (85, 89)
2. Refractory graft vs. host reaction (116)

Prevention of carcinoma

1. Colorectal carcinoma (107, 118)
2. Cholangiocarcinoma (112)

Tab. 40.9: Demonstrated, empirically confirmed or pharmacologically justified indications for the therapeutic use of ursodeoxycholic acid (with some references)

5.5 Lactulose

Chemistry: Lactulose does not occur in nature, nor is it present in breast milk or fresh cow's milk. Small amounts of lactulose are, however, found in heated dairy products, especially in condensed milk (an average of 660 mg, up to a maximum of 940 mg, per 100 ml). • The initial substance for the synthetic manufacture of lactulose is **lactose**. This disaccharide consists of D-glucose and D-galactose. • **Lactulose** was originally manufactured as a keto-analogue of lactose (E. MONTGOMERY et al., 1929). As a disaccharide, it is composed of D-galactose and D-fructose. The **molecular formula** is C₁₂H₂₂O₁₁, with a **molecular weight** of 342.3. Lactulose has a high **degree of sweetness** (0.48–0.62, compared with 1.0 for sucrose). The **pH value** ranges between 3.4 and 4.0. (122)

Pharmacokinetics: Lactulose can be neither absorbed nor broken down by enzymatic or bacterial action in the small intestine; after one to two hours, it reaches the colon unchanged. There is no influence on the lactase activity in the intestinal mucosa. Following oral intake of lactulose, 0.5–1.0% is taken up by the intestinal mucosa through **passive diffusion** and completely excreted unaltered in the urine. However, its absorption is increased by intestinal disease or damage to the intestinal mucosa due to cytotoxic chemotherapy. With simultaneous oral ingestion of hyperosmotic solutions, elevated lactulose levels are likewise detectable in the urine. The amount of lactulose thus excreted provides clues to the degree of damage caused to the intestinal mucosa. After oral administration of 20–25 ml lactulose, there is only a slight rise in the **blood sugar level** of 1–12 mg%; therefore, no clinically relevant aggravation of diabetes need be feared with lactulose therapy, nor are any systemic effects evident. • Lactulose is not demonstrable in the stool; this suggests that a complete **breakdown** takes place in the colon owing to saccharolytic bacteria. The following bacteria have proved effective for lactulose catabolism: Lactobacillus species, Bifidobacterium, Clostridium perfringens and the Bacteroides species. Up to 80 ml lactulose can be broken down per day

by bacterial enzyme action under physiological conditions. Long-term treatment with lactulose stimulates the formation of bacterial β -galactosidase, whereby higher bacterial metabolization rates of lactulose are achieved. (122) The main metabolites include **lactic acid**, resulting from anaerobic fermentation, and **pyruvic acid**, resulting from aerobic metabolism. This leads to a **fall in the pH value** in the colon (dose-dependent) to 5–6. The pH value is not in the desired therapeutic acid range until an **increase in osmotic pressure** with an evacuation frequency of two to three times/day has been achieved at the respective lactulose dosage. • Degradation of lactulose in the colon with enhanced formation of organic acids results in an **inhibition of growth** of gram-negative proteolytic microorganisms responsible for the formation of endotoxins. There is also promoted growth of saccharolytic bacteria, creating bifidus flora typical of breast-fed babies. (126)

“Wrong idea, good results (the lactulose story)” (U.P. HAEMMERLI et al., 1969); “Lactulose works, but why?” (K.A. HUBEL, 1973); “In several aspects lactulose is an unusual drug”; “Lactulose is a fascinating hybrid of a nutrient and a drug” (J. BIRCHER et al., 1988); “Lactulose is a many splendored thing ... with many other beneficial actions in its bag of tricks” (H.O. CONN, 1992). (s. fig. 40.1)

Pharmacology: Unchanged lactulose is pharmacologically inert. Its multiple effects are only evident after breakdown by bacterial enzymes in the colon. (122) • The ability to **break down** lactulose varies greatly from one bacterial species to another, and even from strain to strain, depending on their enzyme endowment. Therefore, the quantity and the predominant type of organic acids formed on breakdown depend on the lactulose dose and the enzyme endowment of the saccharolytic bacteria. The total acid content of the colon is also influenced by individual factors, such as the absorption rate into the colon mucosa or the buffering caused by secreted bicarbonates, and possibly also by retroactive effects of the lactulose metabolites on the intestinal bacteria with potential changes in their metabolism. • The organic acids and the bacterial formation of gas as well as the increase in osmotic pressure account for the **laxative effect** (F. MAYERHOFER et al., 1959). This action occurs within 8 hours of lactulose administration. With a rise in the bacterial count of more than 50%, there is also (1–2 days after lactulose application) a rise in the stool mass and thus an additional acceleration of defaecation. • The **formation of ammonia** in the intestine is due to

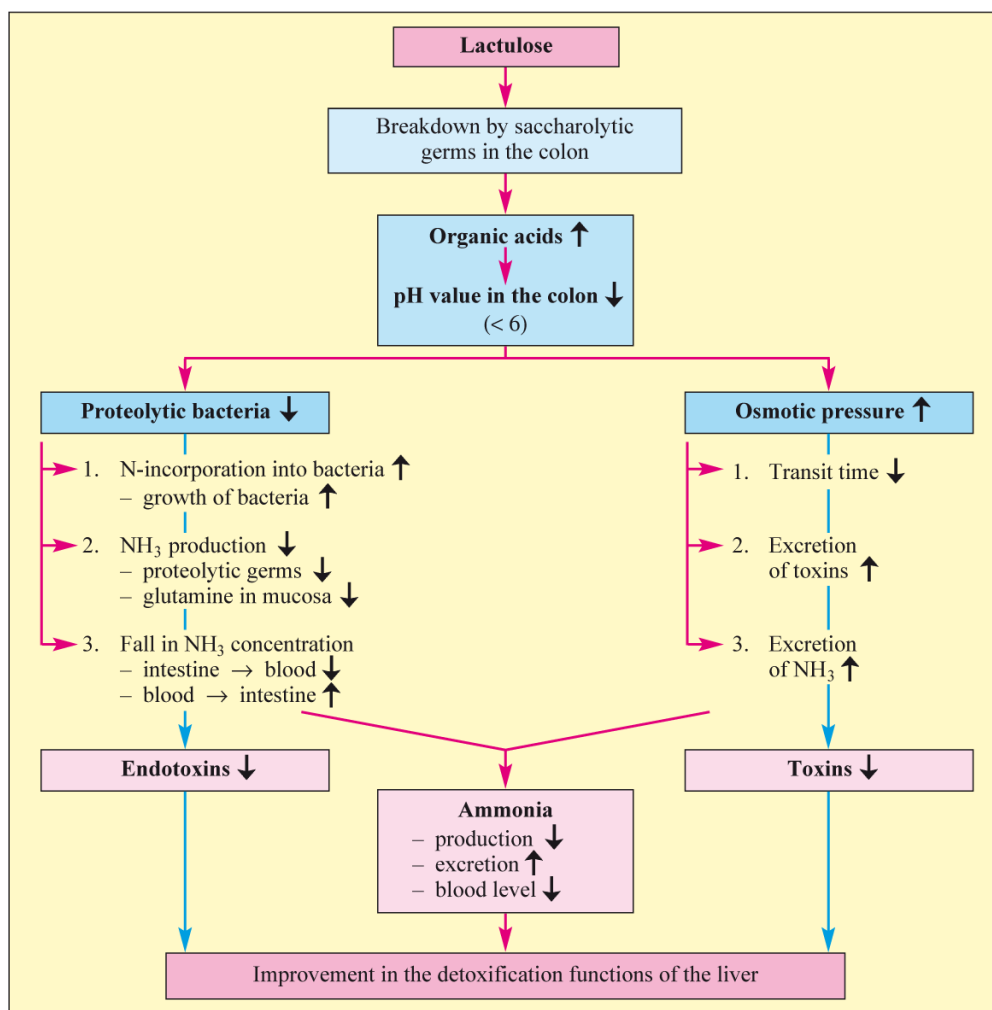

Fig. 40.1: Reduction in the blood ammonia levels with a corresponding improvement in the detoxification functions of the liver as a result of multifactorial influence exerted by lactulose on ammonia metabolism

the breakdown of proteins or amino acids, nucleic acids and biogenic amines. The intestinal formation of ammonia is inhibited by intraluminal acidosis and promoted by alkalosis. Independently of the intestinal flora, ammonia is also formed in the intestinal mucosa through glutamine uptake and the release of ammonia, alanine and glutamic acid. This metabolic NH_3 production with hyperammonaemia was also demonstrable in microbe-free and hepatectomized experimental animals. With an intestinal pH value of <6 , non-ionized ammonia (NH_3) diffuses from the blood to the intestine, while the diffusion of non-ionized ammonia from the intestine into the bloodstream is simultaneously decreased. This results in an elevated excretion of ammonium cations (NH_4^+) in faeces and a **reduction in hyperammonaemia**. The rapid onset of effect on hyperammonaemia following lactulose enemas can also be explained by the influence on non-ionic diffusion. A further mechanism underlying the lactulose-induced decrease in hyperammonaemia may be based on the fact that lactulose constitutes a valuable carbon and energy source for intestinal bacteria. Bacterial growth is thereby promoted and a substantial quantity of nitrogen is included in the protein synthesis of bacteria, which leads to a measurable consumption of ammonia. A fall in the colonic ammonia level may also be the result of a marked reduction in proteolytic intestinal bacteria by lactulose. (123, 125, 129)

The therapeutic efficacy of lactulose in the treatment of **hepatic encephalopathy** was demonstrated by J. BIRCHER et al. in 1966. Numerous publications dealing with this indication have appeared. (s. p. 287) Such favourable experience has been further supported by recent studies. (123, 124, 127, 128) • The efficacy of lactulose in **endotoxaemia** shown by D. SCEVOLA et al. (1979) was later confirmed in various publications, and recently demonstrated anew. Different explanations for this anti-endotoxin effect of lactulose have been put forward: (1.) increased removal of endotoxins due to higher evacuation frequency, (2.) blocking of endotoxin receptors by lactulose, and (3.) influence on the number and metabolic performance of gram-negative intestinal bacteria. (s. fig. 40.1)

► A therapeutic drop in the pH value to <6 is generally achieved when *evacuation occurs two or three times per day*. In order to guarantee this condition, respective quantities of lactulose should be administered in two to three daily doses. • In principle, evacuation frequency should be **“no less than two and no more than four times per day”**. With this regimen, no major side effects need to be feared.

A **reduction in the cholesterol level** due to lactulose was observed by N. EBNER in 1973 and confirmed by D. CONTE et al. in 1977. Lactulose can also be used in hepatogenic disturbances of lipid metabolism. • **Translocation** of gram-negative bacteria to the mesenteric lymph nodes

was significantly suppressed in experimental obstructive jaundice under lactulose treatment compared to the reference group without lactulose. Furthermore, galactosaemia-induced liver damage and bacterial conveyance could be prevented by lactulose therapy. (129)

Indications: The multiple modes of action of lactulose, which are based on an interplay of several effects, require a sufficiently acidic pH value in the colon.

Lactulose is administered as long-term therapy. The indications are derived from its modes of action. (s. tab. 40.10)

1. Reducing or normalizing hyperammonaemia in hepatic encephalopathy
2. Eliminating endotoxaemia
3. Prophylactic use in cirrhosis (and other chronic liver diseases)
4. Decreasing susceptibility to infections in cirrhosis by inhibiting the translocation of intestinal bacteria
5. Reducing the cholesterol level and influencing lipid metabolic disturbances in primary biliary cholangitis (and other liver diseases accompanied by hyperlipidaemia)
6. Improving the absorption of calcium in malabsorption

Tab. 40.10: Indications for the therapeutic use of lactulose

5.6 Branched-chain amino acids

The cirrhosis patient is in a **vicious circle** regarding protein metabolism: *cirrhosis* → *hepatic encephalopathy* → *protein restriction* → *malnutrition* → *catabolism* →. Thus, prolonged protein restriction and catabolism may considerably worsen the prognosis of cirrhosis. • *In this hazardous situation, the dietary and therapeutic use of branched-chain amino acids (BCAA), i. e. valine, leucine and isoleucine, is a logical therapeutic intervention.*

The **urea cycle** is the most important process in biological ammonia detoxication. (s. pp 61, 274) (s. figs. 3.12, 3.13) • It is directly linked with **amino-acid metabolism** and thus also with NH_2 donors and precursors through specific amino acids and transamination processes. Here, the major transamination processes are those involving glutamate and oxalacetate as well as α -ketoglutarate and aspartate.

The **ammonia hypothesis** postulates that a high ammonia concentration in the tissue inevitably leads to a clear increase in glutamine. This results in a marked intracellular **decrease in glutamate** (and α -ketoglutarate). This glutamate pool can be refilled by a more intensive **degradation of BCAA** as NH_2 donors. At the same time, transamination effects the **formation of branched-chain**

keto-analogues of the respective amino acids. • Succinyl CoA is also facultatively involved, providing **α -ketoglutarate** via the citric acid cycle; this is the starting substrate of glutamate prior to transamination. These reactions occur mainly in the muscles. (135, 142) (s. fig. 40.2)

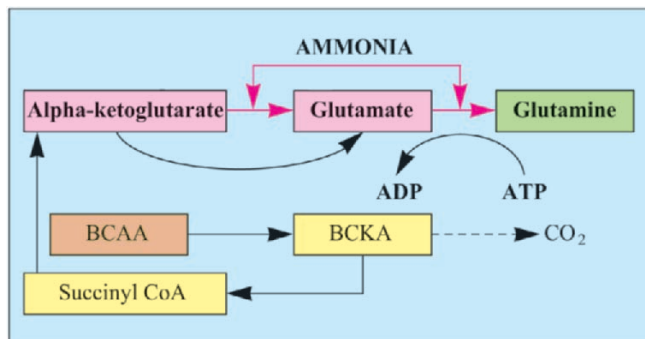

Fig. 40.2: Indirect influence of ammonia on the metabolism of branched-chain amino acids (so-called *ammonia hypothesis*) (BCAA = branched-chain amino acids, BCKA = branched-chain keto acids)

Branched-chain amino acids apparently stimulate the urea cycle. Carbamoylphosphate synthetase, which channels ammonia into the urea cycle, is induced by ornithine and N-acetylglutamate as a cofactor of urea synthesis. Here, BCAA follow **two modes of action:** (1.) they stimulate the synthesis of N-acetylglutamate via synthetase formed from glutamate and acetyl CoA, and (2.) they inhibit ornithine-keto acid transferase, which is the enzyme responsible for ornithine degradation, leading to an increase in ornithine concentration. • **Ammonia detoxication is thus stimulated by two regulatory mechanisms.** (s. fig. 40.2)

As a rule, cirrhosis patients show reduced plasma BCAA levels and unchanged BCAA concentrations in the brain, whereas methionine and aromatic amino acids (AAA) (phenylalanine, tyrosine, tryptophan) are elevated in the plasma and brain. (s. p. 288) • The **fall in BCAA levels** is attributable to its increased degradation, which, in turn, is caused or aggravated by hyperinsulinaemia. Methionine and AAA compete with BCAA for the same transport system at the **blood-brain barrier**. Lowered BCAA levels in the blood therefore favour the passage of elevated methionine and AAA concentrations. The influx of these amino acids is increased by concomitant hyperammonaemia. Ammonia crosses the blood-brain barrier freely. In the astrocytes of the brain, BCAA effect an increase in glutamate by transamination with α -ketoglutarate. Glutamine formation rises, permitting the removal of ammonia from the brain. Glial swelling could be reduced in animal experiments. • **Anabolic protein metabolism** in the muscles is responsible for (1.) reduction in muscle protein breakdown products which contribute to the formation of ammonia, and (2.) higher amounts of ammonia being taken up by the musculature and converted via glutamate to glutamine, which is harmless. • Hyperammonaemia in liver

cirrhosis cannot be influenced by **keto-analogue amino acids**, which are N-free precursors of protein synthesis. However, the keto-analogue of leucine can inhibit the breakdown of muscle protein, which means that favourable effects might still be achieved by using BCKA in decompensated cirrhosis – without any discernible impact on the ammonia level itself. (130, 131, 134, 135, 147)

The use of branched-chain amino acids is based on different **modes of action.** (s. tab. 40.11)

1. Compensation of the amino-acid imbalance
2. Restoration of the competitive transport mechanisms at the blood-brain barrier
3. Stimulation of glutamine synthesis in the brain, muscle and liver (= transitory ammonia detoxication)
4. Inhibition of ornithine breakdown in the liver with a favourable effect on urea synthesis (= definitive ammonia detoxication)
5. Anabolic and anticatabolic effects, especially in muscles
6. Stimulation of the HGF, favouring liver regeneration

Tab. 40.11: Modes of action of branched-chain amino acids

The **indication** for administering BCAA in patients with hepatic encephalopathy to compensate amino-acid imbalance was proposed by J.E. FISCHER et al. in 1974, and implemented parenterally. However, oral application of BCAA for an adequate treatment period also has *beneficial effects* on cirrhosis and HE: (1.) improvement in protein tolerance and the nutritional condition (140), (2.) improvement in cerebral functions (132, 136, 138), probably due to an amelioration of liver function, (3.) stimulation of ammonia detoxification with a positive nitrogen balance (132, 136), (4.) reduction in or normalization of AAA levels, and (5.) promotion of glutamine synthesis with a favourable effect on the cells of the immune system and on renal function. • Using BCAA, it was possible to prolong survival time and delay liver failure in rats with CCl₄-induced cirrhosis. (139, 144) • However, there are diverging results, which need further clarification. Nocturnal administration of BCAA is primarily used for protein synthesis (and therefore advisable), whereas intake during the day is preferentially used for physical exercise. In principle, the use of BCAA is seen as a necessary form of supplementary treatment for catabolic metabolism in cirrhosis (142, 143, 145, 146, 148–151), in (also latent) HE and after curative resection of hepatocellular carcinoma. (137, 141) (s. p. 288)

5.7 Amino acids of the urea cycle

As early as 1932, H. A. KREBS and K. HENSELEIT discovered in their investigation of the amino acids that *ornithine*, even in small amounts, was capable of increasing urea synthesis from (toxic) ammonia. Otherwise, only *argi-*

nine had a slight effect in this respect. (157) The following table shows which of the **amino acids involved in the urea cycle** are available for therapeutic purposes:

| | |
|---|--|
| Arginine Ornithine aspartate (OA) = available | Arginine aspartate Arginine malate Aspartic acid Citrulline |
| Arginine + citrulline + ornithine = available | Ornithine Ornithine α -ketoglutarate = not available at present |

► The ammonia-reducing effect of the amino acids involved in the urea cycle has been strikingly well demonstrated in a variety of **experimental studies** by several research groups. In most of these studies, ornithine aspartate was used, although arginine, ornithine and ornithine α -ketoglutarate have also been investigated. (153, 156, 160, quot. 158) • The greatest effect on ammonia reduction was achieved with **ornithine aspartate**, the combination of these two amino acids being more effective than the administration of either substance alone. The above results were confirmed in experimental studies by K. ZICHA et al. (1968) and G. HERMANN (1972). In healthy dogs, the increased ammonia levels due to ammonia overload were lowered to normal by ornithine aspartate; in dogs with Eck's fistula, the occurrence of toxic ammonia levels could be prevented (C.E. GROSSI et al., 1967). • Further experimental studies revealed that the liver content of ornithine, citrulline, arginine, glutamate and urea rose following exposure to ammonium chloride in rats. The urea synthesis rate exceeded the norm by 50%, while glutamate concentration doubled as a result of α -ketoglutaric acid, which increased to the highest possible limit. With simultaneous administration of *arginine* or *ornithine*, hepatic ornithine concentration increased considerably, and urea synthesis rose by 80–85%. • In healthy volunteers, administration of *ornithine α -ketoglutarate* led to elevated renal excretion of urea and ornithine α -ketoglutarate, i.e. a clear stimulation of urea synthesis was attained.

Since the **clinical studies** of L. ZIEVE et al. in 1960, the use of these amino acids or their salts has been indicated in hyperammonaemia. (165) Thus, following protein overload in alcoholic cirrhosis patients, a reduction in ammonia levels was achieved by administering 60 g ornithine α -ketoglutarate. (154, 159) • *Since the first clinical use of ornithine aspartate more than 30 years ago (1968), a series of studies has been published.* (155, 161–164) This ammonia-reducing substance is the stable salt of L-ornithine and L-aspartic acid with the *empirical formula* $C_9H_{19}N_3O_6$ and a *molecular weight* of 265.3. *Bioavailability* is $82.2 \pm 28.0\%$. The substance is rapidly absorbed, with subsequent splitting into its two component amino acids. Its *half-life* is 40 minutes.

The **biomolecular modes of action** of ornithine have been the subject of several experimental investigations.

Ornithine activates the enzymes carbamylphosphate synthetase and ornithine carbamyltransferase, which are necessary for the liver-specific process of **urea synthesis** (153, 158); this occurs mostly in the *periportal hepatocytes* (= definitive ammonia detoxification). Glutamine synthesis (binding of ammonia to glutamate) takes place mainly in the *perivenous hepatocytes* (= transitory ammonia detoxification). Large amounts of glutamate are needed for this. Aspartate, ornithine (via α -ketoglutarate), glutamate and other dicarboxylates are taken up almost exclusively by the perivenous hepatocytes responsible for glutamine synthesis. In addition, aspartate and dicarboxylates are seen as activators of glutamine synthesis, a process which is disturbed in cirrhosis patients. (s. pp 62, 274) (s. figs. 3.12, 3.13)

Aspartic acid is not only involved in the urea cycle, but following oxidative deamination to α -ketoglutarate, it is also a component of the citric acid cycle. More energy is thus made available in the form of ATP for the energy-consuming urea cycle. More the energy cycle is additionally stimulated by transamination of aspartic acid to oxalacetate. The increased channelling of aspartic acid into the urea cycle facilitates the release of fumaric acid, which is also a substrate of the citric acid cycle, and thus further enhances the formation of ATP. Moreover, aspartic acid binds the ammonia which is present in the musculature; as a result, asparagine is formed, and free toxic ammonia is bound. • Aspartic acid is a glucoplastic amino acid and an important initial substrate for pyrimidine synthesis in liver cell regeneration. Following condensation with carbamylphosphate and the formation of the intermediate product L-dihydroorotic acid, orotic acid, the central product in the biosynthesis of pyrimidine nucleotides, is formed by oxidation. (s. tab. 40.12)

There are several biochemical and clinical **modes of action** associated with ornithine aspartate. (s. tab. 40.12)

1. Increase in urea synthesis by ornithine
 - substrate of the urea cycle
 - activator of carbamylphosphate synthetase
 - activator of ornithine carbamyltransferase
 - activator of glutamine synthesis
2. Increase in glutamine synthesis by aspartate
 - substrate of glutamine synthesis
 - activator of glutamine synthetase
3. Increase in the energy balance by aspartate
 - substrate of the citric acid cycle
 - formation of oxalacetate
 - channelling of fumaric acid into the citric acid cycle
4. Increase in NH_3 detoxification in the musculature
5. As a component of pyrimidine nucleotide synthesis leading to liver cell regeneration

Tab. 40.12: Modes of action of ornithine aspartate

The various modes of action provide the basis for the following **therapeutic indications** of ornithine aspartate:

1. Hepatic encephalopathy
 - with improvement in the mental condition and psychometric test results
2. Relief of NH_3 intoxication symptoms
 - e.g. fatigue, weakness

5.8 D-penicillamine

D-penicillamine is a **non-physiological amino acid**. It is a dimethyl derivative of cysteine, which is a structural component of many proteins. Metabolically, penicillamine is relatively stable. In addition to the amino group ($-\text{NH}_2$) and the carboxyl group ($-\text{COOH}$), it contains a sulphhydryl group ($-\text{SH}$) as a further reactive centre. The underlying biochemical **modes of action** are:

1. Chelate formation with heavy metals
2. Exchange reactions with disulphides
 - with low molecular weight substances
 - with proteins
3. Binding with aldehyde to form
 - pyridoxal phosphate
 - aldehyde groups in collagen and other proteins

Penicillamine may effect **chelate formation** with the heavy metals copper, lead, zinc, gold and mercury. This complex formation is accompanied by simultaneous reduction processes, e.g. copper is reduced to copper-1-ion. From the biochemical viewpoint, an influence on **collagen synthesis** is also conceivable, as the amino-oxidase involved in the formation of collagen contains copper, so that this enzyme is inactivated through the binding of copper to penicillamine. To my knowledge, this process has not yet been confirmed in vivo. • The **mesenchyma suppression effect** of penicillamine with a decrease in the formation of connective tissue is based on the inhibition of the cross-linkage between fibre protein precursors and hydroxyproline synthesis. However, it appears that the process of hepatic fibrosis is not influenced. • Of relevance is the reaction with macroglobulins, which is accompanied by the breaking of the disulphide (S-S) bridges through exchange reactions; this leads to depolymerization. An example of the binding of penicillamine to an aldehyde group is its binding to pyridoxal phosphate – a coenzyme which is formed in the body from vitamin B_6 . Equally important is the reaction of penicillamine with the aldehyde groups of tropocollagen, which causes the formation of thiazolidine, thus preventing synthesis of insoluble collagen. (168) • Intestinal **absorption** is rapid and relatively high. The *half-life* is three to four hours. The greater part of the orally applied substance is eliminated within 24 hours. In

particular, diseases with high hepatic copper concentrations are an indication for penicillamine. • *Side effects* occur frequently; the use of vitamin B_6 may be necessary.

The principal **indications** for penicillamine are:

1. Wilson's disease (s. p. 634)
2. Indian childhood cirrhosis (166) (s. p. 635)
3. Primary biliary cholangitis (167) (s. p. 683)
4. Heavy metal poisoning

5.9 Somatostatin

► Somatostatin was first isolated from the *hypothalamus* of sheep for use as a growth hormone-inhibiting factor in 1973 (P. BRAZEAU et al.). In the same year, its synthetic production was also reported (H. D. CROY et al., 1973). The *molecular weight* is 1,638. The *empirical formula* of this substance, which is composed of 14 amino acids, is $\text{C}_{76}\text{H}_{106}\text{N}_{18}\text{O}_{19}\text{S}_2$. To my knowledge, somatostatin was used *clinically* for the first time in 1974 in a patient with acromegaly (S. S. C. YEN et al.). • Since 1979, somatostatin has been recommended for **oesophageal variceal bleeding** (L. THULIN et al.). Its plasma half-life is one to two minutes; the substance is broken down by endopeptidases and aminopeptidases, with a renal excretion rate of about 80%. • The following **organ-specific effects** are worth mentioning: (1.) inhibition of endocrine and exocrine functions (in the area of the pancreas, stomach and small intestine – especially inhibition of insulin and glucagon release), and (2.) inhibition of the blood supply to the gastric mucosa and splanchnic vessels.

In **oesophageal variceal bleeding**, somatostatin is recommended immediately after emergency admission to hospital at the following dosage: an i.v. bolus injection of 250 (–500) μg and subsequently 250 μg per hour (possibly with two-minute bolus injections). In this way, sclerotherapy or ligation is technically facilitated and the effectiveness of the therapy improved; fewer blood products are needed. No major side effects have occurred at this dosage. (170, 171) The bolus injection rapidly effects a reduction in portal venous and intravaricose pressure as well as a decrease in the blood flow in the azygous vein. (169) It is worth noting that intestinal blood is eliminated more slowly and virtually unchanged, since somatostatin inhibits the release of digestive enzymes and prolongs the intestinal transit time. Continued passage of tarry stool may at first be erroneously interpreted as an effect of somatostatin – unless systemic problems or a fall in Hb actually suggest further bleeding. (s. p. 366)

5.10 Terlipressin

► Terlipressin, chemical name N- α -triglycyl-8-lysine-vasopressin, consists of 12 amino acids. The *molecular weight* is 1,377.5, and the *empirical formula* is $\text{C}_{52}\text{H}_{74}\text{N}_{16}\text{O}_{15}\text{S}_2 \cdot \text{C}_2\text{H}_4\text{O}_2 \cdot 5\text{H}_2\text{O}$. Through hydrolytic removal of the glycyl residues, the vasoconstrictor hormone *lysine-vasopressin* is slowly released as an active substance. Peak concentrations are obtained after 120 minutes. The breakdown of lysine-vasopressin into inactive metabolites, effected by hepatic and renal endopeptidases and exopeptidases, is almost total, so that only about 1% is excreted in the urine. • The *plasma half-life* is 12 minutes, the elimination time is 40–180 minutes. The

effect persists for four to five hours. The *vasoconstriction* is particularly intensive in the splanchnic system; as a result, arterial blood flow is reduced, and portal hypertension is lowered (by up to 35% with 1 mg terlipressin). (172, 174) The smooth muscles of the oesophageal sphincter are contracted with consecutive compression of the existing varices. At the same time, increased peristalsis occurs, leading to a more rapid evacuation of intestinal blood and of ammonia formed by intestinal bacteria. • The *renal blood flow* is elevated in hypovolaemia. The elevated WHVP and HVPG become reduced and hepatic arterial blood flow increases.

The following dosage is recommended for acute **oesophageal variceal bleeding**: 1–2 mg terlipressin as an i.v. bolus (if possible in the ambulance or upon emergency admission) followed by 1 mg as an i.v. bolus every four to six hours for a total period of two to three days. Terlipressin reduces the elevated blood levels of renin and aldosterone and increases the GFR. The combined use of vasoconstrictor therapy with local mechanical haemostasis gives the best results – and a higher chance of survival. The side effects are slight. (175, 176) (s. p. 366) • Application is recommended in the case of the *hepatorenal syndrome*. (173)

5.11 S-adenosyl-L-methionine

S-adenosyl-L-methionine (SAME) is present in nearly all **body cells**. About 30% of hepatic SAME is localized in the mitochondria. It is formed from methionine and ATP by SAME synthetase (G.L. CANTONI, 1952). Transport from the cytosol to the mitochondria takes place via a specific phospholipid carrier system in the biomembranes. (178, 184) • Metabolically, S-adenosyl-L-methionine is an important initial substrate for numerous **synthesis pathways** (178):

1. **Transmethylation**: The transfer of methyl groups is of great relevance for phospholipid synthesis in the biomembranes and for the synthesis of hormones, nucleic acids, proteins, porphyrins, etc.
2. **Transsulphuration**: The involvement of SAME leads to the formation of glutathione, cysteine, etc. These substances play an important metabolic role in detoxification processes and in the elimination of reactive oxygen intermediates.
3. **Aminopropylation**: The transfer of decarboxylated SAME is crucial to the synthesis of polyamines (spermine, spermidine, putrescine). Together with ornithine decarboxylase, SAME determines the synthesis rate of polyamines, which are essential for cell regeneration. At 30–60 minutes, the half-life of SAME decarboxylase is very short and thus readily adaptable to various metabolic situations.

In **experiments**, SAME was found to prevent lipid peroxidation and to normalize the reduced glycogen content of hepatocytes in liver damage. In further studies, its cytoprotective effect was also confirmed. (177, 180, 182, 183, 185, 189–192) This protective effect likewise applied to preneoplastic cell damage. The results concerning the prevention of cholestasis were impressive. • In cirrhosis or severe liver disease, there is a reduction in SAME synthetase, glutathione, cysteine and phospholipid methyltransferase (together with a simultaneous defi-

ciency in phosphatidylcholine formation, accompanied by disturbed membrane fluidity and decreased activity of Na^+/K^+ -ATPase and Ca^{2+} -ATPase).

The pharmacological effects and therapeutic uses of SAME in hepatology are discussed in a detailed review. (181) The impressive outcome of various experiments led to numerous **clinical studies**, which, however, had some negative results. (179, 181, 186–188) On the whole, there was a significant decrease in bilirubin, bile acids, alkaline phosphatase and transaminases. Pruritus, a frequent symptom in cholestasis, also showed regression.

S-adenosyl-L-methionine is an interesting substance which deserves further clinical investigation. The recommended *dosage* is 800 mg/day with intravenous administration or 1,200 mg/day orally. No major *side effects* have been noted. The studies available so far suggest the following *indications*:

1. Alcoholic liver disease, especially in cholestasis (s. p. 552)
2. Drug-induced cholestasis (s. p. 569)
3. Chemically induced cholestasis (s. p. 589)
4. Recurrent intrahepatic cholestasis (s. p. 241)
5. Recurrent intrahepatic cholestasis of pregnancy (s. p. 241)
6. Gilbert-Meulengracht syndrome (s. p. 229)
7. Compensated liver cirrhosis (s. p. 765)

5.12 Haemarginate

The requirements for successfully treating clinically manifest acute porphyria are: (1.) elimination of the causative factor(s), (2.) use of supportive therapeutic measures (fluid and electrolyte balance, analgesics, anti-convulsants, antihypertensive agents, antiemetics, anti-arrhythmics), (3.) i.v. glucose infusion (approx. 400 g/day), and (4.) haemarginate. (s. p. 625)

Haemarginate is produced from erythrocyte concentrate. It compensates the loss of the intracellular haem balance, which regulates haem synthesis. In this way, the overproduction of porphyrin precursors is reduced. Haemarginate is relatively stable; following i.v. administration, it is bound to haemopexin and albumin, and thus made available to the liver cells. (195) • *Dosage* is 3 mg/kg BW/day, administered per daily i.v. infusion (for about 15 minutes) exclusively in 0.9% NaCl solution (100 ml). Haemarginate is stabilized by arginine and contains 96 vol.% ethanol (1,000 mg/ ampoule) as well as propyleneglycol (4,000 mg/ampoule). It is degraded into bilirubin and excreted via the bile. The application period depends on the degree of severity of acute porphyria; as a rule, it extends over three to five days. With successful use of haemarginate, the excessive elimination of PBG and ALA is restored to normal, as is the excretion of uroporphyrinogen and coproporphyrin. These

values should be monitored in the urine under haemarginate therapy. (193, 194) • *Side effects* may appear in the form of phlebitis. This is, however, rare when haemarginate is administered intravenously into large veins. Minor, clinically insignificant effects on blood coagulation have only seldom been observed.

Important: Haemarginate treatment should be initiated as early as possible before any neuronal damage, which may be irreversible, occurs.

5.13 Phytotherapeutics

Plant extracts have been used in the treatment of liver diseases for over 2,000 years. • So far, more than 170 plant-derived substances from some 55 plant families have been well documented regarding their **hepato-protective efficacy**. (197) Recently, the *Rosmarinus* species (196) and *Salvia miltiorrhiza* (199) were added to this list as antifibrinogenetic agents. • In controlled **clinical studies**, many of these active substances proved effective in various liver diseases. Some of them are already listed in the pharmacopoeia. • *Two points* should be made here: (1.) in the plant kingdom, there are no doubt other substances with specific agents which would act on liver structures or against liver diseases, but have not yet been recognized as such; (2.) more sophisticated biochemical/biomolecular procedures now allow more exact characterization and a more precise description of known and previously unknown active substances, so that their targeted therapeutic use may be made possible. (198)

Phytotherapeutics are defined by law as substances derived from plants, plant parts or plant components in a processed or unprocessed form and used medicinally. As substances, phytogenic preparations are treated in the same way as synthetic chemical compounds or substances of other origin. Phytopharmaceuticals must likewise comply with the usual safety standards, such as quality, harmlessness and efficacy. (s. p. 567)

Phytotherapeutic agents are used as *primary preparations* (e.g. tinctures) or as a concentration of various *active substance fractions* and as *pure substances*. Monoextracts are complicated mixtures of chemical substances. They contain primary active agents, secondary active agents and inert accompanying substances. The **main active agents** wholly or predominantly determine the therapeutic properties of phytopharmaceuticals. **Secondary active agents** present in addition to the main active agent(s) may attenuate, potentiate or modify the effects of the main active agent. The overall therapeutic effect generally results from the synergy of several constituents. **Accompanying substances** include cellulose, lignin and starch as well as various forms of sugar, protein and fat. • The active constituents of plants essen-

tially depend on climate, location and other exogenous factors. Therefore, isolating the main active agent is a prerequisite for clarifying its composition, synthesis and pharmacosynthetic modification. Should an active substance be unknown or not well-documented, a quantitatively predominant substance (or several substances) amenable to analysis is then defined as the **key substance**. This is to ensure that a certain phytopharmaceutical preparation is offered at a standardized quality. According to the legal requirements, the key substances may also be defined as so-called “*other scientifically proven material*”.

► Pharmaceuticals of plant origin also form part of rational drug therapy in science-oriented medicine. They are used in the treatment of certain defined diseases and complaints. The more carefully the various pharmacological characteristics of phytogenic remedies are elucidated, the more reliably their clinical effects can be evaluated (e.g. *digitalis*, *rauwolfia*, *hyoscyamine*, *senna*). • *This is also true of the phytotherapeutic preparations used in hepatology.*

5.13.1 Essential phospholipids

► Essential phospholipids (EPL) are isolated from the **soya bean**. This plant was mentioned in the books of Pen Ts'ao Kong Mu (during the reign of Emperor Sheng Nung, 2838 BC). It was one of the five “*holy cereals*” considered essential for human life. • Today, about 800 soya bean species are known. Depending on the species, location and extraction method, the seeds contain 35–40% proteins, 20–30% carbohydrates, 5–10% accompanying substances (amines, vitamins, triterpene saponins, glycopeptides, lectin, flavonoids, xanthines, etc.) and 12–18% crude fats. The crude oil contains 90–95% fatty acid glycerides, predominantly unsaturated fatty acids (oleic acid, linoleic acid). Refining crude oil yields 30–45% phosphatides (soya lecithin). The phosphatides contain 15–20% phosphatidylcholine (“*lecithin*”), which represents an important constituent of cell membranes and is also involved in lipid metabolism in the liver (H. EIKERMANN, 1939). (*Detailed account: 200*)

Essential phospholipids are a highly purified phosphatidylcholine fraction from soybean containing essential (unsaturated) fatty acids, especially linoleic acid (about 70%), in the C₁ and C₂ positions. The main active ingredient in EPL is 1,2 dilinoleoylphosphatidylcholine (DLPC) (40–52% of the phosphatidylcholine molecules). Standardization is performed with reference to 3-sn-phosphatidylcholine (73–79% or 92–96%). In the literature, the designation PPC (polyenylphosphatidylcholine) is also used; this is intended to emphasize the special fatty acid composition. DLPC has a high bio-

availability and an affinity for cell membranes. The phosphatidylcholines constitute a typical lipid bilayer and are thus the main structural component of cellular and subcellular membranes. • Moreover, the proportion of phosphatidylcholines with highly unsaturated (essential) fatty acids is a decisive factor in determining membrane fluidity/flexibility and thus also the biological membrane functions (see figure 40.3 regarding the multiple functions of essential phospholipids). Endogenous phospholipids are substituted by EPL, which may be

administered by the oral route or, in a highly purified form, by the intravenous route. (222, 223, 241) (s. fig. 2.19)

EPL administration has protective, curative and/or regenerative effects on the biomembranes of hepatocytes and sinus endothelia following damage to the cell membrane through toxic, inflammatory, allergic, metabolic or immunological reactions. The cytoprotective effect of EPL has been demonstrated in 19 in-vitro and 121 in-vivo experiments including 33 different models and 8

| Intoxications due to chemical substances | | | Intoxication due to drugs | | |

Tab. 40.13: Cytoprotective effects of EPL in in-vivo investigations (121 experiments, 33 different models, 8 different animal species) (status 1988: E. Kuntz; status 2008: K.-J. Gundermann)

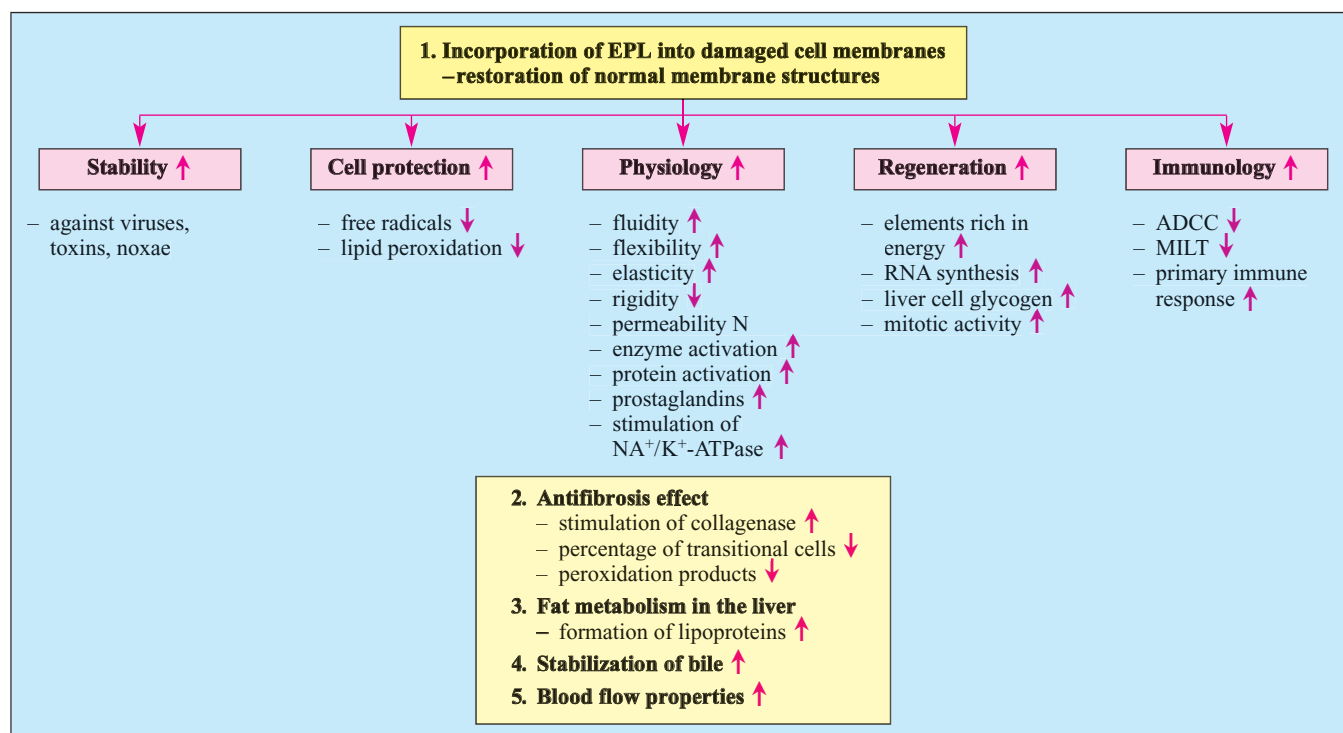

Fig. 40.3: Putative and demonstrated hepatic modes of action of EPL in vitro and in vivo. (ADCC = antibody-dependent cell-mediated cytotoxicity, MILT = mitogen-induced lymphocytotoxicity, N = normal)

different animal species. They were conducted using EPL together with various chemicals (201, 233, 244), alcohol (204, 208, 225, 227, 228, 230, 236–238), narcotic drugs, cytostatics, ionizing rays, etc. (s. tab. 40.13) These experiments clearly demonstrated the notable **hepato-protective** and **curative effects** of EPL in vivo. Remarkably good results were also obtained with EPL as an antifibrogenic agent. (209, 224–226, 229, 232) The earlier EPL was given, the more pronounced the effects were. Inhibition of lipid peroxidation in the liver membranes was likewise verified. In animal experiments, it could be demonstrated that PPC increases SAME and GSH levels in alcohol-induced hepatic oxidative stress. (203) Similarly, it was possible to diminish the antiapoptotic action against ethanol-induced hepatocyte apoptosis. (234) In a further study, the alcohol-induced increase in peroxynitrite hepatotoxicity and the concomitant production of oxide and superoxide could be prevented by PPC. (204) Furthermore, it has been shown that PPC activates enzymes such as hepatic triglyceride lipase, which is responsible for triglyceride degradation in the liver. (210) Dilinoleoylphosphatidylcholine, which is the main active ingredient in PPC, diminishes the activity of acylcoenzyme A: cholesterol acyltransferase, an enzyme that leads to the storage of cholesterol in the liver. (235) • Based on these pharmacological and clinical data, PPC would appear to be the drug of choice for significantly reducing or abolishing fatty liver of different origin, e.g. due to alcohol or obesity, even if the causing noxa cannot be eliminated, as is the case with diabetes-associated steatosis. (214, 216, 220) Interestingly, it could be observed that administration of betaine attenuates alcoholic steatosis by restoring the phosphatidylcholine generation via the phosphatidylethanolamine methyltransferase pathway. (219) • The **regenerative effect** of EPL on experimentally induced liver cell damage was confirmed by biochemical and histological findings. (215) (for further details, see 200, 209, 223) (s. tab. 40.13) (s. fig. 40.3)

These results were confirmed in further studies. (206, 240, 242, 243, 245, 246) It was also discovered that EPL can have an inhibitory effect on alcoholic fibrogenesis in baboons. (226, 230) The **clinical studies** which were available up to 1988 (200) have meanwhile been supplemented by other investigations. (207, 213, 218, 231, 239)

In **severe liver insufficiency**, we were able to achieve a life-saving reversal in 7 out of 10 seemingly hopeless cases by the first ever intravenous application of PPC (3,000 mg/day). (221) • A European multicentre double-blind study showed that EPL significantly increased the rate of IFN- α responders among patients with **chronic hepatitis C** as well as reducing the relapse rate. (239)

The modes of action of EPL suggest the following **indications**: curative, protective/curative and curative/regenerative therapy (1.) in toxic liver damage and fatty liver, and (2.) in acute viral hepatitis, acute intoxication, liver insufficiency, as well as (3.) as a supportive flanking therapy in chronic viral hepatitis and cirrhosis.

5.13.2 Silymarin

The name “sillybon” was given by ancient Greek writers – and later by THEOPHRASTUS (372–287 BC) – to a thistle species, without its being defined more closely. In “De Materia Medica” by DIOSCORIDES (about 50 AD), the plant later called milk thistle is described as a medical remedy for the bites of poisonous snakes. In his book “Historia Naturalis”, PLINIUS THE ELDER (23–79 AD) was the first to mention the choleric effect of milk thistle. The extract was recommended as a liver remedy by H. BRUNFELS (1434) and P.A. MATHIOLUS (1590), and also in the herbals of H. BOCK (1560) and A. LONICERUS (1564). • As a result of the investigations of F. MAYER et al. (1949) and O. EICHLER et al. (1949), the year 1949 can be regarded as the “hour of birth” of silymarin concerning liver treatment. (*Detailed account: 247*)

Silymarin is a mixture of three chemically related *flavanolignoids*; it is extracted from the seeds of the milk thistle (*Silybum marianum* Gaertn. or *Carduus marianus* [L]). These flavanolignoids include: (1.) *silibinin*, (2.) *silidianin*, and (3.) *silicristin*. **Silibinin** is the main active constituent. Its molecular weight is 482.5, the empirical formula is $C_{25}H_{22}O_{10}$. • The *major pharmacokinetic characteristics* are rapid absorption and a calculated absorbed fraction of 23–47%. Peak plasma concentrations are achieved after one to two hours. In plasma, 90–95% of silymarin is bound to protein. Half-life is 6.3 hours. Due to its relatively high molecular weight, >90% is excreted via the bile. About 10% of the given dose enters the enterohepatic circulation. With repeated administration, steady state elimination is achieved from the second day; thus there is no accumulation of silibinin. • *Silicristin* has pharmacokinetic properties similar to those of silibinin, yet with a lower biliary excretion rate (4–10%). No information is available on the second minor component *silidianin* (and *isosilibinin*). (248, 250, 261–263, 267, 280, 282, 285) (*Detailed account: 247*)

In addition to an array of general **pharmacological findings** in vivo or in isolated organs, specific hepatology-related results have been obtained. A number of studies provided evidence of different membrane effects; experimental cholestasis was prevented or reduced, and the release of histamine or serotonin from mast cells was diminished. Silymarin inhibits the different cytochrome P-450 enzymes to a varying extent. (248, 250, 262, 263, 270, 280, 282, 285) Evidence of **membranotropia** and **hepatoprotection** is of major relevance: respective positive effects have been shown in more than 30 different model studies in over 120 investigations. (252–256, 258–260, 266, 269, 274–276, 278, 279, 281, 286, 288) • The efficacy of silymarin as an **antioxidant** (= *radical scavenger*) was confirmed in recent studies. (249, 257, 271, 273, 275, 277, 287) Furthermore, an **antifibrosis effect** (251, 264, 268, 272) and

the inhibition of β -glucuronidase (256) have been demonstrated. The modes of action of silymarin are based on several cellular targets. (s. tab. 40.14)

The **clinical studies** (approximately 120) available up to 1988 (247) have meanwhile been supplemented by further investigations. (256, 262, 266, 283, 284) Silymarin did not prove beneficial to patients with PBC.

► The **combination** of *essential phospholipids* and *silymarin* is of special clinical interest because of the cellular targets and modes of action of these two drugs. (289, 291, 292, 294, 295) (s. fig. 40.3) (s. tab. 40.14) In patients with chronic hepatitis, this combination was applied with success. (290) Thus, the available results of clinical studies suggest a number of **indications**.

Tab. 40.14: Cellular tackling points and modes of action of silymarin

5.13.3 Glycyrrhiza glabra

Glycyrrhizin was first used in hepatology in 1977 by H. SUZUKI et al., who achieved good results in patients with chronic hepatitis. The main constituents isolated from the roots of *Glycyrrhiza glabra* are triterpene saponins, including glycyrrhizin (5–20%), and triterpene sapogenins. Glycyrrhizin is a conjugate of 1 molecule of glycyrrhetic acid with 2 molecules of glucuronic acid. It is metabolized by β -glucuronidase, predominantly in the

intestine (by bacteria) and to a lesser extent in the liver (by lysosomes). Half-life is three to five hours, in chronic liver disease four to ten hours. The following modes of action are postulated: (1.) it acts as a radical scavenger, (2.) it decreases cell-membrane permeability, and (3.) it prevents membrane penetration by viral particles. (297) The antiviral cytoprotective and immunomodulatory effects are based on these modes of action. Although its previously known pharmacological effects were not considered to be of any consequence for hepatology, glycyrrhizin has meanwhile surprisingly proved its worth as a hepatoprotective compound. The agent induces interferon formation and, in this way, also has an antiviral effect. Good therapeutic results were recorded in several clinical studies on chronic hepatitis B, NANB and C and for prophylactic use in transfusion hepatitis (with administration both before and after blood transfusions) as well as in subacute viral liver failure (200–600 mg/day). Glycyrrhizin inhibited HAV replication and improved the immunological identification of HBsAg; HBeAg-positive patients showed more rapid seroconversion. A mixture of glycyrrhizin (40 mg) + cysteine (20 mg) + glycine (400 mg) has also been used as therapy. • With long-term administration, **pseudoadosteronism** may appear, which can be eliminated by spironolactone (e. g. 50 mg/day). (296, 298, 299)

5.13.4 Colchicine

► Colchicine is an alkaloid obtained from the *autumn crocus* (*Colchicum autumnale*). It is a nitrogen-containing, tricyclic compound with a tropolone structure. The results of the pharmacokinetic studies available so far are summarized in a review. (310) Colchicine inhibits the function of the microtubuli (301) and acts as a toxin on cells, mitoses and capillaries. (300, 304, 308, 311) Albumin synthesis is apparently only slightly affected. In existing iron overload, further iron uptake is greatly increased by colchicine. Trimethylcolchicinic acid proved less toxic. The antifibrotic effect of colchicine is probably based on a reduction in collagen secretion and an increase in collagenase activity with elevated collagen breakdown. (307) In existing liver disease, the pharmacokinetics of colchicine is influenced. (309, 310) A potential antilipid peroxidative effect was observed in experimentally induced acetaminophen liver damage. (304)

The results obtained from the *clinical use* of colchicine are controversial. Good results in preventing cirrhosis in chronic hepatitis B and, when combined with UDCA, in primary biliary cholangitis are counterbalanced by unfavourable results in chronic hepatitis (303, 312), primary biliary cirrhosis (302), primary sclerosing cholangitis (306) and alcoholic hepatitis. • A beneficial effect of colchicine on hepatic fibrogenesis should be the subject of further debate. (305) (s. pp 683, 692, 766)

5.13.5 Betaine

Betaine is a quarternary ammonium compound. This substance is widely found in nature; it was first isolated from *sugar beet* (*Beta vulgaris*). • Like choline and methionine, betaine belongs to the group of *lipotropic substances*. Choline plays a major role in the mobiliza-

tion of neutral fats in the liver, using them to form transportable phospholipids with neutral fats. In order to give up its methyl group, choline requires betaine. Thus it assumes an important function in the transmethylation cycle of lipid metabolism. It could be demonstrated that betaine attenuates alcoholic steatosis by restoring the phosphatidylcholine generation (219), particularly since it is also essential for the resynthesis of methionine. Within the therapeutic dosage range, betaine is in no way toxic.

5.13.6 *Cynara scolymus*

Cynarine is the main active agent of artichoke extract. It is a cinnamic acid derivative; the substitution pattern of its aromatic rings is similar to that of dopamine. Caffeic acid is also regarded as a major active substance. It has not yet been clarified to which constituents the known *modes of action* are attributable: (1.) increase in choleresis, (2.) inhibition of cholesterol biosynthesis, (3.) hepatoprotection due to antioxidative effects, and (4.) activation of the urea cycle.

5.13.7 *Bupleurum falcatum*

An extract of *Bupleurum falcatum* with the active agent saiko has for a long time been used in hepatobiliary diseases in Eastern Asia. The substance is commercially available in China under the name Sho-Saiko-To. The active components are attributed to the saiko-saponins (M. YAMAMOTO et al., 1981, 1985). Inhibition of fibrogenesis was demonstrated in animal experiments. (313–315) A good effect was achieved in chronic hepatitis in several clinical studies. Significantly more rapid HBeAg elimination was attained in children with chronic hepatitis B. (316) (s. pp 567, 726)

5.13.8 *Phyllanthus amarus*

Extracts from *Phyllanthus amarus* and *Phyllanthus niruri* have been used in India for more than 20 years in acute viral hepatitis, apparently with success. Compared with essential phospholipids, Ph. niruri was equally effective in improving laboratory values, while Ph. amarus proved to be even more efficacious. *Phyllanthus* extracts inhibit HBV reduplication (319, 320) and DNA polymerase in HBV and WHV infection (321), whereas this effect was not verified in DHV hepatitis. (318) HBsAg carriers also exhibited a loss of HBsAg in 50% of cases and a significant rise in anti-HBs titres. (317) These good results contrast with a number of unfavourable experiences, which may be attributable to the fact that the *Phyllanthus* species contain varying amounts of active substances in different countries. This was also believed to explain the better efficacy of *Phyllanthus urinaria* compared to Ph. amarus and Ph. niruri.

5.13.9 *Schizandra chinensis*

The hepatoprotective efficacy of *Schizandra chinensis* is based on its lignoids Gomisines A, C, N, Wuweizisu C and Schisanthesin D. (323) A rapid decrease in the transaminases was verified in chronic viral hepatitis. (329) Hepatoprotective and anticarcinogenic effects were demonstrated in experimental studies. (322, 324–328)

5.13.10 Catechin

The active substance (+)-catechin is the main component of the plant *Uncaria gambir*. In the systematic chemical nomenclature, this natural substance is called (+)-cyanidanol-3. Pure (+)-catechin is considered completely non-toxic. Catechin is readily absorbed and rapidly degraded in the liver. So far, 11 metabolites have been identified. Because of its low molecular weight, catechin is mainly eliminated via the kidney. • The following *modes of action* have been demonstrated: (1.) increase in ATP concentration in the liver, and (2.) inhibition of lipid peroxidation. This is the basis of the marked hepatoprotective effect. It was used clinically as an adjuvant in acute viral hepatitis, chronic hepatitis and toxic (also alcohol toxic) liver damage. The results reported seemed promising. • Although catechin was regarded as totally non-toxic on the basis of experimental studies, major (unexplained) **side effects** including haemolytic anaemia, idiosyncratic reactions and even deaths occurred (K. A. NEFTEL et al., 1980; N. BRATTIG et al., 1981). The preparation, which had already been introduced in many countries, was thereupon **withdrawn from the market**.

6 Surgical therapy of liver diseases

► Even in antiquity, liver injuries were considered to be fatal due to the uncontrollable bleeding. Proof of an enemy's death was not furnished until his liver could be presented. (s. p. 5) As far as we know, CELSUS (30 BC–50 AD) gave the first, remarkable description of *liver surgery*, which, due to the high volume of blood, was carried out using a cautery knife. • Surgical treatment techniques for liver diseases were not included in textbooks on hepatology until 1965. The two-volume book by F. TH. FRERICHS (1861) (s. fig. 1.19), the textbook by H. EPPINGER (1937) (s. fig. 5.1) and the two-volume textbook by I. MAGYAR (1961) *contained no descriptions of liver surgery* – apart from the treatment of echinococcus cysts – although extensive liver or portal vein system surgery had been carried out since the second half of the 19th century.

► Since the first surgical treatment of refractory ascites by **hepatopexy** (C. T. BILLROTH, 1894) and, in the same year, of bleeding oesophageal varices using **resection of the short gastric veins** (G. BANTI, 1894), vast numbers of surgical techniques have been developed in order to manage both of these emergency situations.

The attempt to compile a systematic list of all procedures is bound to be incomplete despite thorough investigations. However, it is worth the effort to include the ingenious –

and seemingly logical – surgical methods of our worthy predecessors, so that their approaches to the operative management of ascites or bleeding oesophageal varices are not forgotten. (s. tabs. 16.19 and 19.7!)

An important prerequisite for liver surgery was knowledge of the **vascular system**, which was first described by F. GLISSON in 1654 (s. fig. 1.16) and again by R. REX in 1888, and which is known in detail today. • For the **segmental classification** of the liver, the system according to C. COUINAUD (1954) and A. PRIESCHING (1986), using the branches of the portal vein as orientation, gained prevalence. The caudate lobe is designated as segment I. Segment IV is situated on the right side of the falciform ligament (it is exclusively oriented to venous drainage via the intermediate hepatic vein). This sets limits for surgical techniques, and the haematogenous route of liver metastases is also taken into account. • Hjortsjö's concept (C.H. HJORTSÖ, 1948) referring to the division of the anterior segment into two vertical subsegments could be confirmed by recent investigations. (356) (s. figs. 2.5, 40.4) (s. p. 19)

During the past 30 years, surgical treatment of liver diseases or injuries has made enormous **progress** due to the introduction of more sophisticated techniques, newly developed instruments and anaesthetic procedures as well as better management of intraoperative haemodynamics. These options regarding superior liver surgery have only been made possible by modern imaging procedures, endoscopic techniques and angiography. As with the use of laparoscopy, such examination methods guarantee far more exact presurgical staging than was conceivable in the past. • It should be noted that an appropriate **shunt operation** creates a more stable situation than TIPS, especially in the long term. Indeed, shunt surgery, rehabilitated by C.E. ZÖCKLER et al. (1985), is experiencing a revival in many places.

6.1 TIPS

The most common **indication** for the placement of TIPS is as a prophylaxis for or therapy of oesophagogastric bleeding, ascites, Budd-Chiari syndrome, HRS, hepatic hydrothorax and complications associated with portal vein thrombosis. (331, 333, 336, 337) • **Contraindications** include a bilirubin value of > 3 mg/dl, HE (in secondary symptomatic HE, TIPS placement is possible), cardiac insufficiency (due to the shunt-related blood overload) and a MELD score of > 24 . The frequency of **complications** is 2–5%, the mortality rate is $< 1\%$. A common occurrence is HE; about 90% appear in the first seven days after the placement of a shunt. They generally respond well to conservative treatment. In 10% of cases, a chronic progressive course of HE develops. If uncovered stents are used, stenosis occurs in 5% of patients within one year. Stenosis can mostly be avoided by using covered (albeit expensive) shunts – the rate of stenosis

is merely 10% after one year. (332) Follow-up is performed by means of sonography. (s. figs. 16.15, 16.16) (s. pp 267, 320, 336, 343, 368)

Ascites in portal hypertension: Even though conservative therapy proves efficacious in 85–90% of ascites cases, 5–15% are unresponsive to such treatment. • These patients can be treated successfully using invasive or surgical measures, since the prognosis for ascites which is really refractory is poor. However, in each case, surgical options have to be carefully considered, taking into account all individual facts and deciding about indications with respect to (1.) peritoneovenous shunt, (2.) TIPS, or (3.) liver transplantation. • The first two methods contribute to recompensation and help to bridge the time gap until liver transplantation can be carried out, whereby the liver function should be maintained as effectively as possible. • After **peritoneovenous shunt** (s. p. 317) (s. figs. 16.12–16.14) (s. tabs. 16.14–16.18) or **TIPS** (320, 331, 335) (s. fig. 16.15, 16.16), a subsequent transplantation no longer poses a problem.

Bleeding in portal hypertension: The causal spectrum of upper or lower gastrointestinal bleeding is extremely broad. (s. tab. 19.4) (s. pp 354, 372) The most common sources of bleeding in portal hypertension are varices of the oesophagus and stomach (s. pp 262, 358), portal hypertensive gastropathy or intestinal vasculopathy (s. p. 265), and intestinal varices. (s. p. 264) It is particularly the unexpected and massive variceal bleeding which is life-threatening and requires intensive care, i.e. a combination of medication and mechanical measures. Of greatest importance are drugs to reduce portal vein pressure, sclerotherapy or variceal ligation, and (if necessary) balloon tamponade. (s. p. 365) • Whether or not surgical techniques are indicated is determined after definitive haemostasis and should be based on a critical evaluation of individual risk factors and the respective liver status. However, surgical treatment is needed for variceal bleeding which lasts longer than two days (requiring a daily supply of more than four units of blood) and which could not be stopped despite all conservative measures; this also applies to early relapse bleeding. • From a haemodynamic point of view, TIPS, which is a non-surgical connection between the hepatic and portal vein, represents a *portacaval side-to-side shunt*. This results in a sustained decrease in portal vein pressure. Relapse bleeding is reduced to 10–20%. Such an approach does not complicate subsequent liver transplantation. TIPS is thought to be the ideal technique for bridging the time gap before liver transplantation can be carried out. (331, 333)

6.2 Shunt operation

The importance of surgical treatment for oesophageal or gastric variceal bleeding is still controversial. Nevertheless, according to the findings to date, shunt surgery

with a relapse bleeding risk of 5 (–10)% is deemed to be the best **prophylaxis against bleeding**, so that >50% of Child A and B patients reach their fifth postoperative year. In the only comparative prospective study carried out so far, the small-calibre, portacaval H-graft prosthetic shunt proved superior to TIPS in all relevant aspects. • **Good selection criteria** are: (1.) Child A and B patients, (2.) liver volume between 1,000–2,500 ml (as a close correlation to the O₂ consumption of the liver), (3.) portal vein perfusion of 10–30% of the total hepatic blood flow (for a distal splenorenal shunt of >30%) in sequential scintigraphy or duplex Doppler sonography, (4.) selective panangiography to check if the arteries and veins have a sufficient length and lumen, and (5.) use of a shunt technique which does not harm liver function and at the same time facilitates subsequent liver transplantation. • The most efficient techniques are the **distal splenorenal shunt** (particularly in high portal vein residual perfusion), using the same procedure as with spleno-pancreatic disconnection and gastric transection (343), and the small-calibre **mesocaval interpositional prosthetic shunt** (especially in cases of decreased portal vein blood flow). Chylous ascites was observed as a rare complication of a distal splenorenal shunt. If, for surgical reasons, these methods cannot be applied, the portacaval side-to-side shunt using a small-calibre stent is now recommended when there is no possibility of liver transplantation. (340) The partial portacaval shunt is preferred to the direct shunt. (339) The **survival rate** after 5 and 10 years is reported to be 75–80% and 65–70% respectively. • The outcome of shunt surgery is determined by the **preoperative liver function** and the arterial compensation capacity (which still cannot be measured exactly). The preoperative portal vein pressure is obviously not a risk factor during surgery or postoperatively. (338, 341, 342, 344) • Treatment of multiple arteriportal fistulas by shunt surgery should be mentioned as a **rarity** here. (s. p. 370!) (s. tab. 19.7)

6.3 Block surgery

Block surgery prevents the portal blood from flowing to the oesophagus and thus intervenes directly at the site of bleeding. However, it does not reduce portal hypertension and portal vein residual perfusion is not decreased. • The numerous methods or modifications may be put into **three groups**: (1.) simple block operations, in which the oesophagus is divided close to the cardia and re-anastomosed, (2.) extended block operations, which comprise additional skeletization of the stomach in order to avoid fundus variceal bleeding, and (3.) the Sugiura method, which also includes splenectomy in addition to gastric devascularization and oesophageal section. (338) • Block operations are only indicated when TIPS or shunt surgery could not be carried out or were unsuccessful. Devascularization procedures are worth considering as emergency interventions. (s. p. 370)

6.4 Liver resection

► The first liver resection in the form of a lobectomy was carried out on a dog by G. ZAMBECCARI as early as 1680. The first resection in humans (removal of an adenoma) was also performed in Italy, but the outcome was fatal (A. LIUS, 1886). The first successful resection of a large, benign, pedicled lobular constriction was carried out by C. v. LANGENBUCH (Germany) in 1888, while successful resections were performed in the USA by W. W. KEEN as from 1892.

6.4.1 Basic principles

Definition

A liver resection is defined as the surgical removal of tissue components of the liver in order to eliminate a localized disease process. • The left hepatic lobe (segments I–IV) contains 40% and the right lobe (segments V–VIII) contains 60% of the total liver mass. (s. fig. 40.4) Removal of >80% of a healthy liver is (in principle) fatal. • Hyperplasia of the remaining liver can be expected, while regeneration of the resected portion of the liver is also possible.

Functional reserve: The method of choice and the extent of the resection depend upon the residual function of the remaining liver tissue. As a rule, it is relatively easy to determine the loss of tissue caused by surgical intervention, but this is not equivalent to the functional loss: on the one hand, the tumourous or diseased tissue which has been removed had no function and therefore cannot be evaluated as a functional loss; on the other hand, the neighbouring tissue, which was displaced by the growth process, might indeed experience functional recovery after tumour resection. It should be noted that healthy liver tissue usually has to be removed due to the necessity of allowing a safety margin. This is especially true when keeping to the respective segmental boundaries. Evaluation of the remaining functional reserve is extremely difficult in a diffusely diseased liver. This is above all true in cirrhosis; here, it is first of all necessary to determine the *Child Pugh stage*. (s. tab. 35.6) Several *laboratory parameters* (e.g. ChE, GEC, ICG, aminopyrin ¹⁴C test) (363, 364) as well as CT volumetry or ^{99m}Tc GSA (363) – and, in the future, *virtual liver surgery* (360) – are suitable for assessing preoperative liver function and its postoperative functional reserve (even though functional values cannot be directly related to the functional hepatocyte mass). (345, 357, 358, 365)

Parenchyma setting: When incisions are made in the parenchyma, all structures within the tissue (arteries, portal veins, hepatic veins, bile ducts) must remain intact. Apart from the well-established method called “finger fracture” (W. ANSCHÜTZ, 1903), ultrasonic cutters, water beam dissectors or laser scalpels are used nowadays in order to distinguish between hepatic parenchyma and vascular structures. • **Haemostasis** can be

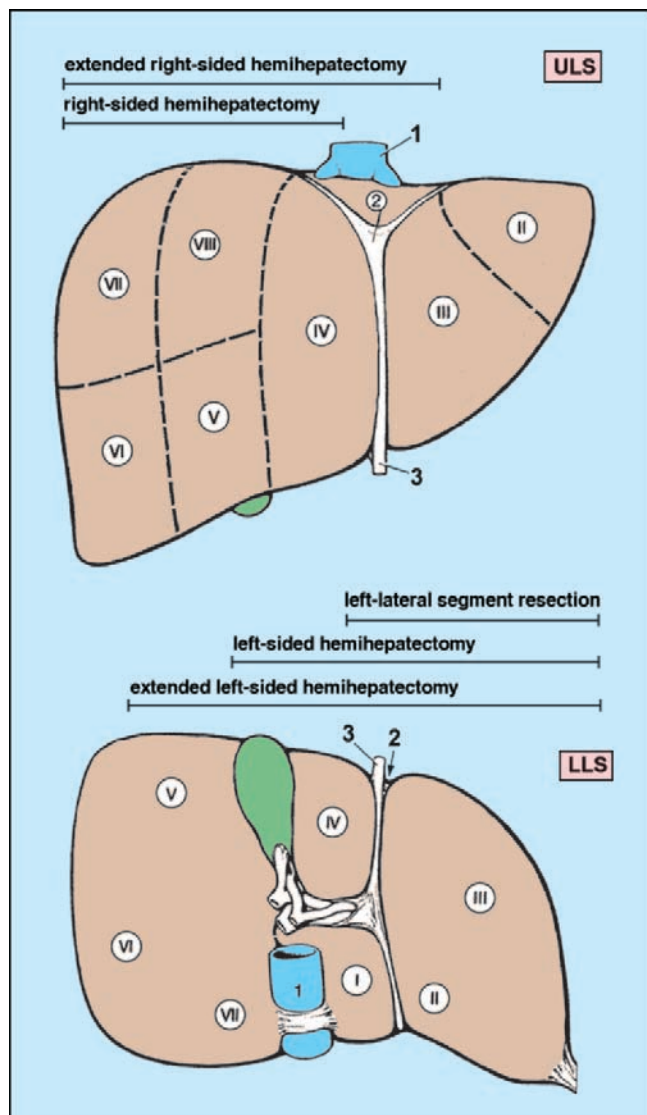

Fig. 40.4: Representation of the liver segments (according to C. COUINAUD, 1954) (ULS = upper liver surface, LLS = lower liver surface). (351) Left liver lobe: I–IV (segment I corresponds to the caudate lobe and can only be delimited at the LLS; segment IV is actually located to the right of the falciform ligament). Segment IV is subdivided into an apical part (IVa) and a caudal part (quadrate lobe) (IVb). Right hepatic lobe: segments V–VIII. (1 = inferior vena cava; 2, 3 = falciform ligament) (s. figs. 2.1, 2.5)

achieved by surgical techniques and electrocoagulation, infrared coagulation, argon beamer or fibrin glue. • The insertion of **drainage tubes** allows the removal of post-operative lymph, gall, residual haematomas and (possibly) oozing blood. Even if these surgical methods are carefully managed, it is not possible to avoid such fluid discharge completely. • The post-resection **methylene blue test** helps to reduce the postoperative biliary leakage rate. (359) (s. pp 807, 825!)

6.4.2 Classification and indications

Left hemihepatectomy: This procedure includes segments II, III and IV, i.e. left liver lobe is removed. • In

extended left hemihepatectomy, segment V or VIII is also resected. (s. fig. 40.4)

Right hemihepatectomy: This procedure was successfully carried out for the first time by W. WENDEL (Germany) in 1911 in order to remove a large adenoma. • The technique involves the resection of segments V, VI, VII and VIII, i.e. right liver lobe is removed. • *Extended right hemihepatectomy* also includes segment IV (left middle segment). (s. fig. 40.4)

Lobectomy: In left lobectomy, segments II and III are removed, while in right lobectomy, segments IV–VIII are resected (whereby the right and left halves of the liver are incorrectly called “lobes”). (s. fig. 40.4)

Segmentectomy: This surgical technique involves the removal of a single liver segment or a combination of segments. Both marginal and central segments may be involved. Another surgical option includes going beyond the boundaries of the segments, such as removal of segment V and the lower half of segment IV. • Resection of segment VIII is the most difficult procedure; usually, segment VII is removed at the same time, since the venous blood flow is interrupted in any case. • Segmentectomy IV divides the liver into two parts as far as the vena cava. The cava/gall-bladder line serves as orientation. • **Left lateral segment resection** involves segments II and III (also known as left lobectomy, see above). • **Segment I** cannot be assigned to either of the two halves of the liver. Its boundaries are difficult to determine; in general, the anterior boundary is defined by the hilar ramification of the portal vein structures, while the posterior boundary line is deemed to be the vena cava. Segment I varies in size, and sometimes it is nothing more than a thin layer of tissue. (368) • As a rule, it is possible to define the segmental boundaries by targeted puncture of the portal vein branches to show colour contrast in the respective segment and also by intrasurgical sonography. (350) (s. fig. 40.4)

Dorsocranial resection, a special technique with simultaneous hepato-atrial anastomosis, may be indicated in the Budd-Chiari syndrome (G. BANSKY et al., 1986; S. MEYER et al., 1988). (s. p. 856)

A wide spectrum of *focal lesions* of varying sizes provides the **indication** for liver resection (347, 349, 352, 354, 355, 357, 361):

1. Benign liver tumour (s. fig. 40.5)
2. Congenital malformations
3. Focal bile-duct processes

6.4.3 Regeneration

In 1879 H. TILLMANN'S first reported the phenomenon of liver regeneration following a large resection in an animal experiment. This observation was confirmed in 1931 by animal experiments, in which restoration of the liver was demonstrated following two-thirds resection in the rat. (353) • It has meanwhile been shown that liver

regeneration begins directly after resection with a cascade of biochemical and molecular mechanisms. It becomes measurable three to four weeks later. Numerous examinations revealed that the remaining liver reaches its initial, normal size again within three to six months. (348) Even in chronic hepatitis or cirrhosis, the liver demonstrates its regenerative capacity after extensive resection, albeit more slowly and to a lesser extent than a liver with healthy parenchyma. • Regeneration appears to depend on (1.) regeneration-stimulating factors in the portal blood after resection (e.g. endotoxin), and (2.) the quantity (and quality or special characteristics?) of the portal blood flow. • Regulatory factors of growth can be divided into: (1.) *mitogens* (which stimulate synthesis of DNA and mitosis of hepatocytes), such as EGF, TGF α , HGF and FGF; (2.) *inhibitors*, such as TGF β , HPI and some interleukins; (3.) *co-mitogens* (which enhance the effect of mitogens and reduce the effect of inhibitors), such as insulin and glucagon (“goodies of the liver”), TNF α , IL 1, IL 6 and hormones. The genetically steered interplay of numerous factors in separate phases of development leads to a closely controlled regeneration process. What is important for the result is the relationship between liver mass and body mass. (346, 362, 366) (s. p. 408!) • Regeneration did not occur in a portacaval end-to-side shunt under experimental conditions. Liver cirrhosis induced in animal experiments proved to have regenerative capacity, an observation which was confirmed by clinical findings. It is assumed that in resection-related regeneration, “other” mechanisms (apart from age) are set in motion than in cirrhosis-related regenerative processes. (367) The type and extent of the cirrhosis also seem to be important factors with regard to resection-stimulated regeneration in residual cirrhosis.

Complete regeneration of the right liver lobe occurred in two women following right lobectomy; surprisingly, the regenerated right lobe showed exactly the same external shape as the original one. This led to the well-founded assumption that there is both (1.) resection-stimulated hyperplasia of the remaining liver, and (2.) regeneration of its resected part. The causes of these two developments are still unclear, as is the varying capacity of a cirrhotic liver to regenerate. Several different methods of elucidating the regenerative processes have been suggested. (346) (s. pp 5!, 408)

6.5 Liver injuries

► Liver injuries, particularly caused by weapons and accidents, have been known ever since the dawn of mankind. There are numerous reports dating from antiquity and later centuries of liver injuries and surgical attempts to heal them. • About 1600, F. HILDANUS reported an excision of a prolapsed part of the liver after trauma – the patient survived. In 1716 G. BERTA succeeded in treating a prolapsed and severely injured liver in a madman who had cut open his belly with a knife. • Laparotomy has been used since 1886 to manage liver injuries; mortality rates were 60% (L. EDLER, 1887), 81% (F. TERRIER, 1896) and 44% (B. T. TILTUN, 1905).

The following **classification** is used to assess liver injury (H. BOCKHORN et al., 1982):

| | |
|-----------|--|
| Type Ia: | Superficial parenchymal lesions |
| Type Ib: | Deep liver ruptures |
| Type Ic: | Visible parenchymal destruction, with or without bile-duct injury |
| Type II: | Additional injuries of the porta hepatis (bile ducts, portal vein, hepatic artery) |
| Type III: | Injuries of the portal vein hilum |
| Type IV: | Liver injuries combined with lesions of the vena cava |

Whereas penetrating injuries are less common today, the number of blunt injuries has increased, frequently accompanied by liver rupture. A liver injury is involved in up to 40% of patients with blunt abdominal trauma. Conservative treatment is recommended as far as possible in order to avoid unnecessary laparotomy. (379) The overall mortality rates were 11.8% and 16.8% respectively. (371, 373) In many cases, the urgency of the situation does not allow the requisite examinations to be made (e.g. US, CT (376, 378), angiography, laparoscopy). An emergency operation has to be performed. Such an operation must even be done under shock if the patient does not respond directly to conservative methods.

The **surgical treatment** chosen depends on the type of injury, but also on the patient's condition at the time. Some 40–65% of all deaths are due to exsanguination, while 35–60% are caused by postoperative organ failure. Intra-abdominal formation of abscesses is deemed to be the most common complication. (370, 375) Based on the findings available, the following **surgical methods** are used: (1.) drainage, (2.) superficial suture with drainage, (3.) haemostasis by means of transcatheter arterial embolization (372, 374), fibrin glue, infrared coagulator or electrocoagulation, (4.) anastomosis techniques (e.g. intracaval shunt), (5.) hepatorrhaphy, (6.) resection techniques (e.g. debridement, segmentectomy), etc. (369, 370, 375, 377) An overall mortality rate of 10.5% was reported in 1,000 consecutive liver injuries.

7 Liver transplantation

► The first liver transplantation was carried out on a dog by C.S. WELCH et al. in 1955. (443) • After a five-year period of experimental preparations, T.E. STARZL et al. were able to carry out the first orthotopic liver transplantation for extrahepatic biliary atresia on a three-year-old boy in Denver (USA) on **1st March 1963**; however, the boy bled to death during the operation. Another four transplant recipients lived 6–23 days. (434) • In 1968 R. Y. CALNE et al. began carrying out liver transplantations in Cambridge (England). In Germany, A. GÜTGEMANN et al. started performing liver transplanta-

tions in 1968, followed by R. PICHLMAYR et al. in 1979. • While surgical techniques were constantly undergoing improvement, the problem of organ rejection could not be solved in a satisfactory way by the substances used at that time.

It was not until the introduction of cyclosporine A (R. Y. CALNE et al., 1979) and the combination of cyclosporine A + prednisolone (T.E. STARZL et al., 1980) that the ultimate breakthrough was achieved. In 1983, liver transplantation (LTX, LT) was recognized as an important option for patients in the final stage of chronic liver disease. • By 1993, a total of 26,500 liver transplantations had been carried out worldwide (R. BELLE et al., 1993). Due to the rapidly rising number of centres (about 300 worldwide), the *total number of liver transplantations was thought to have reached about 80,000 worldwide by the end of 2000*. • In Germany, the number of liver transplantations rose from 502 in 1992 to 779 in 2004. Currently, the number of LTX performed every year is 4,000 in Europe and 6,000 in the USA. • The 1-, 5- and 10-year survival rates amount to >90%, >80% and >75% respectively. However, the demand for liver transplantation is far greater than the supply of donor organs. This lack has **practical consequences**: (1.) on the indication for LT, (2.) on the development of more sophisticated liver-support devices for bridging a life-threatening situation and for avoiding LT should the diseased liver meanwhile become restored (s. p. 389), (3.) on the search for alternative transplantation techniques (e.g. split-liver, APOLT, LDLT) for optimizing the use of cadaveric livers, and (4.) on the mortality rate among patients waiting for a suitable organ. • The waiting period is currently 6–12 or even 12–18 months. (*see chapter 20. 5.4*)

Potential indications for liver transplantation are given in almost any kind of life-threatening liver disease (1.) which has taken a progressive and irreversible course (e.g. chronic liver disease in the end stage, acute liver failure, hepatic neoplasias) or (2.) in which a period of time has to be bridged between the patient's irresponsiveness to treatment and the probable reversibility of the diseased liver. • The motivation and compliance of the patient are prerequisites for LT.

7.1 Indications

If the indication for LT is given, the case should be registered with a liver transplantation centre. The patient is then checked regarding the indication, and all contraindications should be excluded. Subsequent to phase-1 and phase-2 evaluation, the patient is added to the waiting list. Principally, only those patients will be selected for LT (1.) who have a realistic chance of surviving the perioperative phase and (2.) whose chances of survival are much better following LT. Children under one year of age can also be successfully transplanted. (384, 397, 435)

Tab. 40.15: Indications for liver transplantation: *safe*, *putative* and *limited* indications (as have been published) (with some references)

The spectrum of **indications** for liver transplantation has widened enormously due to more sophisticated presurgical diagnosis, more exact evaluation of risk factors, better management of intraoperative techniques and supplementary measures, improvement in immunosuppressive agents and more qualified aftercare. The indications may be grouped into **eight main categories**, subdivided into *frequent* and *rare*. In addition, differentiation is made between *safe*, *possible* and *limited* indications for liver transplantation. (s. tab. 40.14)

The indication for LT depends on (1.) **type of liver disease**, and (2.) **stage of disease**, i.e. at what point LT is carried out during the course of disease. It should be noted that the preparations necessary for LT should commence as from stage Child B. • Eurotransplant assigns the status “**high urgent**” only to patients suffering from acute liver failure or acute transplant failure following LT. Patients suffering from acute deterioration of an existing liver disease are not included in this category. High urgent registrations undergo meticulous examination by Eurotransplant. In such cases, the waiting period is 6–30 hours. Important parameters regarding an indication for LT in acute liver failure include (1.) advancing encephalopathy, (2.) atrophy of the liver (daily US!), (3.) development of an ascites, (4.) decrease in the transaminases and Quick's value, and (5.) progressive renal insufficiency. In order to bridge the time until a transplant is available, the use of a liver-support device can be most helpful. (s. p. 389)

Three indication categories are differentiated according to the overall condition of the patient, respective liver

function, the effects of the liver disease on other organs, and existing risk factors:

(1.) **Elective indication:** The general condition is stable and the nutritional state is still good or can be improved; liver function is decreasing, but still sufficient; bilirubin is constantly rising; there are as yet no severe extrahepatic complications (e.g. encephalopathy, ascites, hepatorenal or hepatopulmonary syndrome).

(2.) **Late indication:** The general condition is poor and the nutritional state is considerably reduced; liver function is severely compromised and shows increasing deterioration; there are complications and additional risk factors.

(3.) **Emergency indication:** Failure of vital functions; severe complications are observed (HE stages II–IV, kidney insufficiency, respiratory insufficiency). • This situation may develop either (1.) as the final phase of a long-standing, preexisting liver disease or in an abrupt manner, or (2.) as an urgent indication in acute liver failure (386, 387, 392, 428) or acute liver transplant failure.

Time of indication: Determining the best time for LT is very important, but it is also difficult. Although Child-Pugh classification is used as a standard in liver cirrhosis, it has not turned out to be a valuable tool regarding the timing of LT. • Important **criteria** for determining the best time of indication are (1.) *type of liver disease*, including its natural course and risks due to complications, (2.) *subjective drop in performance of the patient*, and (3.) *progressive deterioration of certain laboratory parameters*. In this context, a slow but steady decrease

| | |
|--|-------------|
| I. Liver disease | |
| 1. Type: primary hepatocellular primary biliary | |
| 2. Natural course | |
| II. Subjective deterioration in condition | |
| III. Changes in laboratory values | |
| 1. Enzymatic activity | |
| • GPT, GOT | < 10 U/l |
| 2. Endogenous function values | |
| • Albumins | < 3 g/dl |
| • Quick's value | < 40% |
| • Cholinesterase | < 1,000 U/l |
| • Bilirubin | > 5 mg/dl |
| 3. Exogenous function values | |
| • Indocyanine green | > 5 min. |
| • Galactose elimination capacity | < 5 mg |
| • MEGX | |
| • Aminopyrine ¹⁴ C | |
| 4. Biliary function | |
| • Alkaline phosphatase | > 1,500 U/l |

Tab. 40.16: Important criteria in timing liver transplantation

in GPT and GOT to subnormal values points to severe and irreparable loss of parenchyma. Deterioration of endogenous functional values also suggests that the final phase is imminent. This is likewise confirmed by the fact that the results of exogenous function tests worsen. Such tests are easy to carry out, do not entail side effects, cause little inconvenience and are highly reliable, particularly in combination. (s. tab. 40.15) The ICG and the aminopyrine ¹⁴C breath test have proved to be valuable transplant control measures. (391)

It is important not to miss the right moment for LT. A long waiting period with conservative therapy generally leads to an increase in intraoperative risks as well as a decrease in postoperative survival time. Any complications further worsen the prognosis and put LT into the "late indication" category. (380) • In addition to rising bilirubin and AP values, the consequences of impaired bile flow (e.g. undernourishment and malnutrition, catabolism, osteoporosis, malabsorption, hypercholesterolaemia and pruritus) are prognostically relevant in primary biliary diseases – while liver function tests still show good values in most cases.

Liver transplantation has the following aims: (1.) improvement in life expectancy, and (2.) improvement in the quality of life.

7.2 Contraindications

As the management of liver transplantation has improved, absolute and relative contraindications have been established. Relative contraindications may question the success of LT in some cases. Obesity leads to an increased rate of postoperative complications, but it

does not influence the survival rate. (417, 424) (s. tab. 40.16) • Contraindications should also be considered in urgent LT due to acute liver failure – possibly accompanied by necrotizing pancreatitis, septic shock and problems with assisted respiration. • Visceral inversion is not deemed to be a contraindication: a successful LT was indeed carried out under such conditions by G.B. KLINTMALM et al. in 1993.

Absolute contraindications

1. Severe cardiac disease
2. Severe pulmonary disease
3. Extrahepatic metastases
4. Malignant secondary disease
5. Florid sepsis
6. AIDS
7. Severe irreversible brain damage
8. Active alcohol or drug abuse
9. Anatomical or postoperative anomalies
10. Portal vein plus superior mesenteric vein thromboses
11. Severe osteopenia
12. Poor nutritional state

Relative contraindications

1. Portacaval shunts
2. Portal vein thrombosis (with open superior mesenteric vein)
3. Age > 65–70 years (biological age is more important!)
4. Condition after complex hepatobiliary surgery
5. Chronic renal insufficiency
6. Muscular atrophy
7. Unstable personality structure
8. Unstable psychosocial environment
9. Obesity (> 100 kg BW)
10. Retransplantation

Tab. 40.17: Absolute and relative contraindications for liver transplantation. (The relative contraindications should be determined for each individual case)

7.3 Preoperative diagnostics

Clinical examination prior to LT comprises (1.) meticulous anamnesis including all previous findings, (2.) thorough internal examination, (3.) psychosocial and psychiatric assessment, and (4.) broad spectrum of laboratory parameters. *The medical "work-up" prior to LT takes about 10–12 days.*

Specific laboratory parameters comprise (1.) blood group and antibodies, (2.) HLA typing, (3.) hepatitis serology, including HCV RNA (by PCR) and HBV DNA, (4.) serology, including HSV I and II, EBV, CMV, HIV and varicella, (5.) coagulation status, (6.) thyroid function, (7.) renal function, and (8.) immunology, including ANA, AMA, SMA, anti-LKM and anti-SLA.

Technical examinations comprise (1.) thoracic X-ray, (2.) ECG, (3.) echocardiography, (4.) pulmonary function, (5.) gastroscopy, (6.) EEG, (7.) US and colour-encoded duplex sonography of the abdomen, (8.) radiology (including CT and angiography of the coeliac trunk) and right renal arteriography (to exclude high right kidney) as well as MRI cholangiography. With regard to post-operative osteoporosis, bone densitometry is recommended prior to LT. (390)

This **extensive programme** is, on the one hand, essential for preoperative diagnostics and the documentation of initial findings, while on the other hand, postoperative changes in the findings can be evaluated more easily. • The **indication** for LT is determined by an interdisciplinary team. If possible, both assessment and registration of cirrhosis patients should be carried out during Child B as soon as progressive deterioration is observed. • When preoperative diagnostics have been completed, patients grouped in the elective category may spend the **waiting period** at home. However, even if the findings are constant, there is always a risk of acute and unforeseeable complications.

Previous **shunt operations** and **TIPS** need to be removed in order to guarantee that the transplanted liver is sufficiently supplied with portovenous blood. In these cases, the portal system is checked preoperatively for thromboses by means of colour-encoded duplex sonography and X-ray techniques. In any case, the confluence of superior mesenteric vein and splenic vein must be free. (411) • The main advantage of portacaval end-to-side anastomosis is its low thrombosis rate of <5%; in addition, there is no need for a distal shunt ligature. In shunts distal to the hilus (mesocaval, distal splenorenal), no preparation of the liver hilus is required; however, in 10% of cases, these shunts show portal vein thrombosis (in TIPS, up to 15%). • Usually, all surgical shunts are disconnected or ligated before the liver transplantation is completed in order to avoid a steal effect. • Although portal vein thrombosis, previous operations in the liver hilus and portosystemic shunt surgery are (sometimes considerable) obstacles to liver transplantation, they are not regarded as contraindications. When there is isolated or partial portal vein thrombosis, a connection to the portal vein can often be restored by thrombectomy or bypass techniques; the survival rate is similar to that in patients with a primary open portal vein. Nevertheless, the conditions for a successful LT are more favourable if there is no portal vein thrombosis and the liver hilus does not require special preparatory measures.

7.4 Preparation of patients

(1.) During the waiting period, it is important to maintain or even improve the patient's **nutritional status**. Protein tolerance can be monitored by using simple *psychometric tests*. A protein intake of 1.0–1.5 g/kg BW/day would be ideal. Supplementation by *branched-chain*

amino acids may be helpful. The *calorie supply* has to be adjusted to the optimal requirement of the patient. (s. pp 765, 878, 888)

(2.) The daily food intake should be spread over **five meals**. However, it is almost impossible to achieve an optimum supply of water-soluble and fat-soluble **vitamins**. Administration of multivitamin preparations is therefore recommended. **Sodium chloride** intake should not exceed 7–8 g/day. (s. pp 286, 753, 765)

(3.) Depending on the patient's condition, regular **muscle training** should be carried out daily if possible in order to improve anabolism as well as urea and glutamine metabolism in the muscles. (s. pp 683, 755)

(4.) The administration of **lactulose** over an extended period of time (dosage aim = 2–3 stools per day) is recommended. (858) • It is advisable to use a combination with *metronidazole* or with *non-absorbable antibiotics* (e.g. paramomycine) preoperatively in order to suppress the gram-negative intestinal flora and thus also the formation of endotoxins. If necessary, **antimycotics** may be administered in addition.

(5.) *Latent encephalopathy*, detectable by psychometric tests (s. p. 211), is frequent; experience has shown that it can rapidly become manifest. Of the urea-cycle amino acids suitable for therapy, **ornithine aspartate** has proved the most successful – also as an i.v. infusion in the post-operative phase. (s. pp 287, 756)

(6.) The relevant literature additionally recommends **vaccination** against pneumococcus and influenza as well as hepatitis B (unless there is already immunity).

7.5 Surgical aspects

Compatibility of blood groups

Interestingly, compatibility within the **blood group system** has proved to be the decisive factor in liver transplantation to date. • Although the *HLA system* is usually determined (for retrospective evaluation), it seems to be of minor importance. This is also true of so-called “*cross-matching*” between patient serum and donor lymphocytes. No other compatibilities between recipient and donor (apart from body weight, height and thorax size) are known to be required.

Quality of a donor liver

The quality of the donor liver is of crucial importance for successful LT. First of all, careful and proper organ retrieval by a qualified team is an important prerequisite. Most centres now have such a designated multi-organ retrieval team. • Any information pertaining to the donor (e.g. clinical results, anamnesis, laboratory values, current medication, further findings) is listed in the **donor protocol**. Of equal importance in the evaluation of a donor liver are the circumstances leading to the

donor's death (cause of death, intensive care measures, etc.). • Using more suitable **preservation solutions** (Ringer's lactate, University of Wisconsin solution), the conservation time of donor livers could be prolonged to 15–20 hours. Great emphasis is being placed on achieving further improvements in this area. • During removal by the surgeon, the **donor liver** is assessed macroscopically and by palpation. This requires considerable experience, particularly since no other criteria for assessing the quality of the donor organ are available. (442) The **transplant** should be almost identical to the recipient's organ in terms of size, weight and vascular diameter (portal vein, superior/inferior vena cava). • The use of *size-reduced transplants* is being further developed as a possible method for the future.

Zero biopsy: Immediately after reperfusion of the donor liver, a biopsy is taken. This is seen as a starting point and reference value for the detection of pre-existing liver disease and assessment of organ quality (damage during preservation and respective reperfusion).

Types of transplantation

(1.) Normally, **orthotopic liver transplantation (OLT)** is used; in this technique, the donor liver is implanted at the site where the recipient's organ has been removed. The average survival rate is >90% after 1 year and >80% after 5 years. (s. p. 391)

(2.) A modified procedure, so-called **orthotopic segment liver transplantation (OSLT)**, has proved successful (H. BISMUTH et al., 1984); this involves implanting parts of an adult liver, i.e. segments II and III or I–IV depending on the size of the recipient's organ, into a young recipient ("reduced size").

(3.) In **split liver transplantation (SLT)** (R. PICHLMAYR et al., 1989), it is possible to transplant segments V–VIII, which are left over in OSLT, into an adult. This means that two recipients can be supplied with one donor organ. The surgical splitting of the donor liver subjects the organ to considerable stress, and therefore its quality has to meet particularly high standards. (389, 444)

(4.) In **living donation (LDLT)** (R. W. STRONG et al., 1990), segments II and III are taken from a parent and transplanted into the child. The surgical risk for the living donor, which was quite high at the beginning, has been reduced considerably in the meantime to about 0.24%. The survival chance of the recipient is 27–92%. To date, more than 3000 transplantations of this kind have been carried out worldwide. The technique has now been generally established for children. About 5% of all LT patients are also suitable for an LDLT. Therefore, the possibility of such an LDLT should be discussed in all those cases where the waiting time for a regular LT would prove to be a problem. More than 75% of the donors are free from complications. In LDLT involving adults, the volume of the donor organ should be equiva-

lent to approx. 1% of the body weight of the recipient. The respective size of the transplant, which is usually taken from the right lobe, is determined by means of CT volumetry. • After LDLT, bile leaks (7–10%) and biliary strictures (16–20%) frequently appear. In such suspected complications, ERC is recommended. (387, 403, 412, 413, 416, 430, 433, 445)

(5.) In **heterotopic liver transplantation (HLT)**, the donor liver is transplanted as an auxiliary (additional) organ into the right upper abdomen, but the recipient retains the diseased liver (K. ABSOLON et al., 1965; J. G. FORTNER et al., 1970). This technique is not easy to carry out in terms of surgical requirements; it involves the so-called *piggy-back method* and is used particularly for young patients suffering from acute liver failure. (s. p. 391)

(6.) **Auxiliary partial orthotopic liver transplantation (APOLT)** was introduced by G. GUBERNATIS et al. in 1991. In this procedure, segments II and III of the diseased liver are removed, while segments II–IV (or sometimes only segments II and III) of the donor organ are transplanted. The bile duct is reconstructed as a biliodigestive anastomosis. Full reversibility of the existing liver disease is a precondition for the surgical concept of APOLT. (428) (s. p. 391)

► The importance of an adequate supply of **zinc** is now accepted. In most cases, however, there is already a deficiency of this important trace element (unless previous medication has remedied the situation). Due to the scale of the operation, there is a considerable loss of zinc, which usually cannot be balanced even by intravenous substitution. Experience has shown that pronounced and extremely detrimental *zincuria* may be kept in check by i.v. application of **potassium canrenoate**. (s. p. 812!)

Venous bypass: Insertion of a combined venovenous and portovenous bypass reduces the negative effects of the anhepatic operative phase (lasting 30–120 minutes) by interrupting the blood flow in the portal vein and inferior vena cava. This measure allows greater haemodynamic stability during the anhepatic phase.

Biliary anastomosis: Reconstruction of the biliary flow is achieved by side-to-side anastomosis of the two choledochal stumps or, when primary bile-duct disease is present in the recipient, by anastomosis using a jejunum sling in the Roux-en-Y technique.

Duration of the operation: The duration of the operation varies greatly owing to the widely differing conditions during surgery. On average, it takes 5–10 hours. • The blood loss also differs considerably: 6–15 units of blood are normally substituted, but this quantity may be much higher in some cases. The number of units of blood can be reduced by administering *aprotinin*, which inhibits fibrinolysis after reperfusion.

Nitric oxide: Ischemia is the main cause of dysfunction in the transplanted liver. Inhalation of NO during the

operation helps to reduce the frequency of dysfunction in the initial phase, since the transplanted liver produces insufficient NO at this time.

Fig. 40.8: End-stage liver cirrhosis with a small hepatocellular carcinoma in a non-cirrhotic explanted liver

7.6 Postoperative features

The postoperative phase has **three main objectives:** (1.) monitoring the functional condition of the transplanted liver, (2.) adjustment of immunosuppression, and (3.) early detection and treatment of complications.

Early postoperative phase: Extubation is carried out as soon as possible with subsequent regular breathing exercises and optimal infusion therapy. This takes into account all problems arising from such extensive surgery, e.g. lactate-free volume replacement, stability of circulation and coagulation, pain therapy, electrolytes, zinc, vitamins, acid-base balance, energy carriers. Loss of protein is substituted by fresh-frozen plasma and albumin. The onset of bile production and a decrease in lactate values are initial signs that the transplant is functioning well. In addition, factor V and thromboplastin time generally increase. Occasionally, ascites can occur. (388) From the seventh day, the transaminases fall steadily. Antibiotic prophylaxis, which began during surgery, is usually discontinued on the second or third day. Oral and bodily hygiene as well as monitoring of infection are also part of the intensive-care programme. Special surveillance protocols have been carefully designed for this purpose.

Immunosuppression

Induction and adjustment of immunosuppression follow established protocols, which can, however, be executed in various ways. New immunosuppressants are meanwhile in use (tacrolimus, sirolimus, mycophenolate mofetile, brequinar, leflunomide, etc.). Cyclosporine and tacrolimus include a calcineurine inhibitor. Initially, the patients receive *triple therapy*: tacrolimus (or cyclo-

sporine) + prednisolone + mycophenolate, occasionally with interleukin-2 receptor antagonist (e.g. basiliximab, daclizumab). • After three months, the patient is given *dual therapy*, generally with tacrolimus (or cyclosporine) + prednisolone or with tacrolimus + mycophenolate; after a further six months, the patient is put on *monotherapy* with tacrolimus (or cyclosporine). During dual therapy, the dosage of prednisolone is reduced slowly until the drug is ultimately discontinued (except in cases with AIH as an underlying disease). (426) • In patients with HCC, immunosuppression based on rapamycin has often proved more efficacious, and appears to have an antitumorigenic effect. • The monitoring of tacrolimus (or cyclosporine) is carried out at regular intervals using the respective values in the blood. • Long-term follow-up is performed by the family doctor or internal specialist and, at certain intervals, by the outpatient department of the transplantation centre. (394) • The **toxicity** of immunosuppressive agents is the main cause of complications (e.g. hypertension, kidney damage and even kidney failure, severe headaches, altered blood values, nervousness, trembling, peripheral paraesthesia, increase in liver enzymes). Such toxicity-related complications may also be due to **interactions** between cyclosporine and other drugs. Differential diagnosis of transplant rejection may prove difficult.

Tolerance: Donor cells have sometimes been detected in the blood of liver transplant recipients. This chimerism may influence the immune system of the host with development of tolerance to donor tissue. (440) That would mean that a donor liver might, in some cases, be spontaneously accepted. As a result, it is possible to stop the administration of immunosuppressants. • Usually, after five-year survival of a primary graft, one third of all patients are able to cease immunotherapy.

Complications

Major complications after LT include (1.) non-function of primary graft (1st–2nd day), (2.) infection (3rd–14th day, and longer), and (3.) rejection (5th–10th day). The clinical features of these complications are similar:

| | |
|----------------------|----------------|
| ▶ liver | • fever |
| – large | • leucocytosis |
| – firm | • jaundice |
| – tender on pressure | |

Such findings require immediate and extensive examination: US, Doppler sonography, CT, HIDA scintigraphy, and cholangiography. • Further complications are (1.) afterbleeding (10–15%), (2.) portal vein thrombosis (up to 2.2%) or hepatic vein occlusion, (3.) hepatic artery thrombosis or stenosis, (4.) pleural effusion, and (5.) subcapsular necrosis (due to the disproportionate size of donor and recipient liver). Stenosing of the suprahepatic vena cava is a particularly dangerous condition, which can lead to ALF. • The most frequent

complication affects the **biliary system** in the form of leaks or strictures (5–25% of cases). They can be diagnosed with the help of T-drain radiology or ERC. (409)

Infection

One of the major problems following LT and immunosuppression are infections. During the early postoperative phase, the danger of **bacterial** or **fungal infection** is particularly great due to high-dosage immunosuppression and intensive medical care at a time when the patient's physical condition is considerably impaired. Monitoring of infection, accompanied by optimal hygiene and prophylactic measures, is required as well as (possibly) immediate treatment with antibiotics. In order to avoid translocation of gram-negative microorganisms, decontamination of the intestinal tract, already initiated in the preoperative phase, is often continued; in addition, the use of an antimycotic agent is recommended (e.g. against candidiasis or coccidioidomycosis). (399, 401, 425, 438) • **Viral infections** are most frequent two to four months after LT. A particular danger, both in adults and children, may come from new infection with or reactivation of CMV (431, 439), EBV, herpes-6 virus, varicella-zoster or *Listeria monocytogenes*. (406) CMV infection is associated with a higher rate of rejection. Early diagnosis (by PCR) and early treatment (e.g. intravenous ganciclovir) are required. Of the various viral infections, especially condylomas caused by papilloma viruses are to be feared in the long term, since a high percentage of them can develop into squamous-cell carcinoma. A new form of treatment with *imiqumod* may prove effective.

Transplant rejection

Hyperacute form: Transplant rejection may occur as an antibody-related complication within a short period of time after LT (= humoral rejection). This rare event is caused by donor antigens coming into contact with preformed antibodies in the recipient, which results in damage to the endothelial cells of the arteries with vascular occlusion. The outcome is necrosis of the transplant.

Acute form: This condition appears in the first three postoperative weeks. Some 40–60% of patients have one or even several rejection reactions of varying intensity, accompanied by discomfort, fever, exhaustion and, occasionally, mild jaundice. Early diagnosis is only possible by detecting an increase in liver enzymes, particularly GDH; the diagnosis is confirmed histologically. Percutaneous biopsy should be carried out with antibiotic protection. (405) Histology reveals the presence of large lymphocytes, plasma cells, macrophages and granulocytes in the portal fields in this type of cellular reaction. The interlobular bile ducts are damaged, and there is subsequent cholestasis. It is possible to observe adherence of lymphocytes to the venous and arterial endothelium, resulting in subendothelial inflammation (= **endo-**

thelialitis). (s. fig. 40.9) • *Therapy* is based on prednisolone (500 mg i.v. for 3 days). In cases showing no reaction, the dosage of tacrolimus should be increased, and, occasionally, mycophenolate (2 x 1g/day) or rapamycin can be added. In non-responders, therapy with OKT3 is recommended (after histology has shown persistent rejection). Thus, an acute rejection does not pose a risk for long-term prognosis. In most cases, drug therapy is successful and without morphological residues. (383) • *Retransplantation* is seldom necessary.

Fig. 40.9: Acute rejection: portal/periportal inflammation and portovenous endothelialitis (↓) (HE)

Chronic form: This condition is no longer observed very often (2–3%). It usually sets in one to nine months after LT and is characterized by progressive cholestasis. This form may develop after repeated acute attacks or develop insidiously from the beginning. There is a ductopenic reaction, whereby the interlobular bile ducts are infiltrated and destroyed by mononuclear cells; ultimately, the bile ducts disappear. Duct loss can be calculated from the ratio of the number of hepatic arteries to the number of bile ducts within a portal field (normal = >0.7), whereby 20 portal fields should be examined. At the same time, obliterating arteritis develops, with fibrinoid wall necrosis and deposition of foam cells within the intima. (414) The result is portal and periportal fibrosis. (s. fig. 40.10) Differential diagnosis is difficult

Fig. 40.10: Chronic rejection: stenosing foamy cell arteriopathy (HE)

and may require repeated biopsies. Chronic rejection can be graded histologically in a mild, moderate or severe form. (418) • **Therapy** with tacrolimus halted progression in some cases. Tacrolimus and mycophenolate may generally bring about a reduction in the chronic rejection response. Should the treatment fail, the only alternative is *retransplantation*. In this case, an elective indication for retransplantation is given, since liver functions remain intact for a relatively long time. • In acute and chronic rejection accompanied by an increase in alkaline phosphatase, *ursodeoxycholic acid* should be used as supportive therapy. • With regard to unclarified **complicative situations**, it is essential to determine the level of immunosuppressants in the blood (underdosage? toxicity?). Subsequently, US, colour-encoded duplex sonography, CT and MRI are indicated. Radiology-dependent interventions may be required.

Retransplantation is required in 5–10% of patients. The main indications are primary graft failure, hepatic arterial thrombosis and chronic rejection. • Results of retransplantation are not so satisfactory as with the first LT: the survival rate is shorter and mortality (usually due to sepsis) is mostly within six months. Nevertheless, the prognosis is improving steadily. (427)

Relapse of the underlying disease

Some 25% of hepatocellular and up to 70% of cholangiocellular **carcinomas** are subject to relapse within 12 months. Tumour relapse is caused by the presence of undetected extrahepatic metastases, which find their way back into the transplanted liver, and on the suppressed state of the immune system. According to some observations, the probability of relapse depends on the stage of the primary tumour. For this reason, only (selected) early tumour stages are a possible indication for LT. (s. fig. 40.10) • Reinfection of the transplant occurs in 80–100% of cases due to **hepatitis B** from extrahepatic reservoirs, most likely in the early postoperative (low-defence) stage. Of these cases, about 15% follow a fulminant course, about 15% show persistent hepatitis, 5% reach chronic carrier stage, and 20–25% develop fibrosing cholestatic hepatitis with a high rate of viral replication and an unfavourable course. (385) In some patients with severe reinfection, cirrhosis can develop within a few years. **HDV infection** may lead to a similar outcome. With such a negative outlook, it is important to consider every possibility of avoiding reinfection. The prophylaxis is based on HBIG (10,000 IU intraoperatively and then daily) + lamivudine until HBsAg has disappeared from the serum. In this way, the risk of reinfection can be reduced to 10–20%. (s. p. 725) Should reinfection nevertheless occur (renewed evidence of HBsAg), new nucleoside analogues (e.g. adefovir, entecavir, tenofir) are available under certain conditions. (381) • In **hepatitis C**, the transplant is reinfected in 90–100% of cases, although only about half the patients display HCV antibodies when immunosuppressives are administered. HCV replication occurs

1. Step-by-step reorientation of the individual patient from the clinical atmosphere to the more “normal” daily routine in a rehabilitation centre. Medical follow-ups, including monitoring of the immunosuppressive adjustment.
2. Gradual social and cultural reintegration within the rehabilitation community.
3. Detailed information for the patient regarding personal hygiene, nutrition, lifestyle, significance of after-care, recognizing complaints or abnormalities, etc.
4. Improvement in the patient’s nutritional state.
5. General physiotherapeutic measures; targeted training of the muscle groups atrophied to a varying extent in the individual patient.
6. Psychotherapeutic support (particularly in how to handle the fear of complications), opportunities for psychosocial care, discussion of questions relating to the patient’s occupation, etc.

Tab. 40.18: Tasks and objectives of aftercare and rehabilitation in specialized clinics

already in the first week after LT. The infection follows a mild course both in terms of clinical findings and morphology; fulminant or cholestatic courses are rare. In 10–30% of patients, chronic hepatitis, or even cirrhosis, appears. Nevertheless, in view of the great effort involved in performing an LT, the use of peg IFN- α with ribavirin, and occasionally in combination with amantadine, must be considered. (s. p. 723) (395, 399, 410, 419, 427, 439) • **HGV infection** (generally a result of numerous blood transfusions!) is of no clinical significance. (400) • **Alcoholic liver disease** is followed by relapse within two years in about 20% of cases. (421) • Relapses have been observed following **primary biliary cholangitis** (404, 437) or **primary sclerosing cholangitis** (<5%) (396, 407), **autoimmune hepatitis** (despite immunosuppression in 10–30%) (382, 413), **BCS** (without anticoagulant in 100%) and **non-alcoholic steatohepatitis**. (415)

7.7 Aftercare and rehabilitation

LT patients need seven to ten days in an intensive care unit and about three weeks in a normal ward of the hospital. The patient is usually fully rehabilitated after six months. Subsequent to inpatient treatment, *follow-up therapy* is carried out at a **rehabilitation clinic** which is specialized in hepatology. Generally, this stationary rehabilitation phase lasts four to six weeks and includes various **tasks** and **objectives**. (s. tab. 40.17)

Risk of infection: Patients are subject to a high risk of infection at public events, when using public transport, and particularly during waves of influenza. Interdigital mycosis also presents an infection risk. A further problem can derive from indoor plants (beware of fungal spores in potting compost!). Domestic animals similarly constitute a risk factor; it is of great importance that no

new pets are introduced. Towels and bed linen must be changed regularly. Shower water, which is usually heated to 60°C in the boiler, should be run for an extended period two to three times a week in order to prevent legionellosis. Vaccinations with live vaccines should be avoided. Intake of tap water and non-pasteurized milk is forbidden as these liquids have a high bacteria count. Lettuce and vegetables need to be washed several times and with particular care. Fruit that is difficult to clean (raspberries, etc.) should not be eaten; preference is to be given to fruit which can be peeled. Raw steak tartare must not be consumed. • These numerous recommendations and warnings are not designed to create hysteria, but to help minimize the risk of infection at a realistic and, for the patient, comprehensible level.

Nutrition: The patient's diet should comply with the basic principles of physiological nutrition. (429) It is recommended to take three main and two minor meals per day. Foodstuffs causing flatulence and containing poorly digestible fats (e.g. lard) must be avoided. It is important to consider the influence of glucocorticoids on appetite as well as their metabolic side effects (e.g. restriction of sodium chloride, loss of potassium).

Medical aftercare: This comprises adjusting and monitoring *immunosuppressants*, providing the patient with all necessary information as well as recognizing and controlling side effects. • Occasionally, *pleural effusion* has to be monitored and, if necessary, aspirated. *Ascites*, often evident as a local accumulation of fluid in the abdomen, may still be present. • Sometimes, *wound care*, treatment of postoperative wound complications or removal of a T-drainage, generally after six weeks, may still be required. • The *renal function* needs to be monitored carefully, even if there is no obvious progressive renal damage. • The *vascular system* (portal vein, inferior vena cava, hepatic artery) has to be checked by colour-encoded duplex sonography for the occurrence of thromboses, stenoses or aneurysms. Bile leakage or stenoses may appear in the *bile ducts*. • In 60–80% of patients, *hypertension* can be anticipated due to treatment with cyclosporin. In 20–30% of cases (more often with tacrolimus than with cyclosporine), *diabetes mellitus* or *hypercholesterolaemia* develops. • *Fatigue* is indeed a major and often difficult treatable problem. (441)

If this wide spectrum of sophisticated rehabilitation measures is carried out with great care – and with success – fewer problems will arise in the aftercare of outpatients when they return to their normal daily routine. The *length of stay* at a specialized clinic should be tailored to the patient's individual needs; on average, this lasts four to six weeks. In view of the high costs involved in LT and the great inconvenience to which the patient is subjected, the rehabilitation phase assumes an essential role; follow-up therapy is thus both necessary and recommended for achieving long-term survival and improved quality of life with reintegration into the work process.

Inpatient monitoring is succeeded by **outpatient control protocols**. The check-ups are carried out by the family doctor or internist in close cooperation with the transplantation centre. • The one-year survival rate after liver transplantation is 80–95%. The five-year survival rate varies depending on the underlying disease, e.g. 70–80% in cirrhotic patients, 45–50% in acute liver failure, and 35% in malignancies. (408) About two-thirds of the patients begin working again despite a long phase of being unable to work due to chronic liver disease. Most liver transplant recipients are very satisfied with their newly acquired quality of life. (420, 421)

8 Sociomedical aspects

Health awareness on the part of the individual as well as *preventive* and *rehabilitative medicine* in general are exerting more and more influence on developments in the medical world – and thus also on hepatology. These changes in medical practice are an inevitable and characteristic feature of a modern society. • Consequently, physicians will need to devote more attention to “*prevention*” in the healthy person in order to keep the curative phase of an illness as short as possible. And to an increasing degree, they will also have to undertake “*rehabilitation*” in order to reduce to a tolerable minimum any periods in which the individual cannot perform efficiently and is also unfit for work. (s. fig. 40.11)

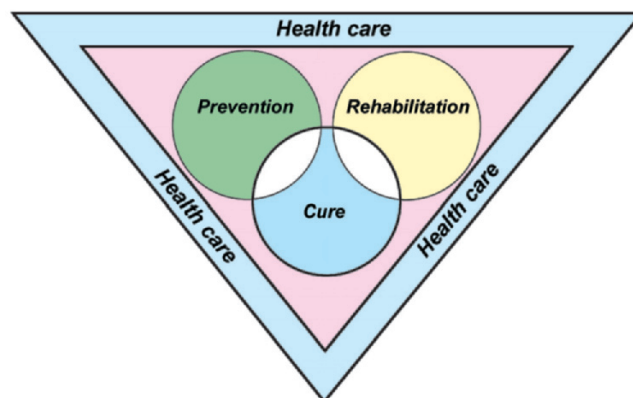

Fig. 40.11: Combination of prevention and rehabilitation in health awareness

8.1 Health awareness

► This term subsumes all factors which reduce potential damage to health. These include protective measures promoted by the state, various authorized institutions and associations as well as by industry, science and the medical professions. Above all, however, every individual should assume personal responsibility for maintaining his or her state of health through appropriate behaviour. • *The media must also accept a vital role in this context!*

Health awareness with regard to hepatology

- Healthy diet and normal body weight
- Hygiene concerning drinking water and food
- Physical/muscular fitness
- No alcohol abuse
- No medication abuse
- No drugs
- Avoidance of occupation-related damage
- Prevention of infections by observing basic hygiene

8.2 Preventive medicine

These are health measures which are carried out by individuals of their own accord, sponsored by the state, accepted by medical insurance companies, and basically feasible; they enable monitoring and preservation of health as well as early recognition of diseases.

Prevention with regard to hepatology

- Prophylactic vaccinations
- Safe blood transfusions
- Safe blood products
- Prevention of infections (antibacterial and antiparasitic measures)
- Occupation-related measures
- Regular medical check-ups

8.3 Rehabilitation

Rehabilitation is designed to reintegrate people with physical or mental impairment into both their professional and personal environment. It comprises aftercare with a social component in the sense that society is called upon to help, and thus it is a communal undertaking. Rehabilitative measures should start as early as possible during the curative phase. Once the disease has consolidated and as soon as the prognosis offers a realistic perspective, the physician should address the question of rehabilitation. The necessity for rehabilitation depends on the severity of the symptoms and/or the psychosocial problems involved.

The indications for **medical rehabilitation** are subject to strict legal stipulations. First of all, an expertise including a detailed medical evaluation is required from a physician. In rehabilitation centres specialized in hepatology, all necessary interdisciplinary diagnostic and therapeutic measures are applied. It is important that the rehabilitee cooperates actively.

Measures necessary for **occupational rehabilitation** are initiated at the same time. These include options for vocational retraining and additional qualifications,

redesigning the workplace to fit the needs of the handicapped person, reintegration into the work process, personal support, etc. Occupational rehabilitation also depends on the rehabilitee being adequately motivated. Furthermore, it is important to evaluate individual vocational preferences and prospects of success. Job-related psychological and aptitude tests together with measures aimed at finding a suitable job must be carried out before a final decision can be made.

Rehabilitation with regard to hepatology

- Adjustment to disease-dependent changes in life-style
 - special diets (e.g. low iron, low copper, MCT)
 - administration of medication (e.g. interferon, immunosuppressants, penicillamine, UDCA)
- Introduction of secondary prevention
 - elimination of risk factors (alcohol abuse, overweight, faulty nutrition, etc.)
 - vaccination prophylaxis
- Information about particular risks
 - hepatic encephalopathy, water retention, variceal bleeding, side effects of medication, etc.
- Muscular/physical exercise
- Psychological guidance for liver transplantees
- Assessment of the individual's remaining capacity for everyday life
- Introduction of occupational rehabilitation measures

► Altogether, the measures and objectives of our time do justice to the demands made by RITTER VON BUSS (a German specialist in constitutional law) who coined the term **rehabilitation** in 1844 with the words:

“The diseased who can be cured shall be completely rehabilitated, he shall rise again to the position from which he has descended, he shall regain the feeling of personal dignity and thus a new life.”

8.4 Capacity for work

A positive and negative profile of a patient's capacity for performing certain tasks should be compiled on the basis of the respective disease phase. For the rehabilitation process, it is important to assess the remaining capacity of the individual in combination with any personal strengths. In addition, liver function and potential health risks have to be considered. The medical evaluation of the patient's capacity for work forms the basis for the respective sociolegal decision. It should be

noted, however, that the medical expertise and the legal decision are independent of each other – such legal terms as “*incapacity for work*” or “*inability to practise the learned profession*” must be avoided in the medical report. • Capacity for work also includes *fitness to drive a vehicle* (e.g. in encephalopathy) or *fitness for public service* (e.g. in the educational or judicial sector). In severe cases of advanced liver disease, evaluation is not difficult. However, this is not so easy in less severe cases (e.g. diffuse fibrosis, no complications) or low-grade to moderate inflammatory processes. Objectivation of the findings is only possible by extensive diagnostic clarification of the function and morphology of the liver – as well as of other affected organs.

The physician’s assessment of a patient’s capacity for work considers individual factors in a certain type of liver disease and thus forms the basis for determining (1.) **unfitness for work**, (2.) **inability to practise the learned profession**, and (3.) **inability to earn** within the sociolegal framework of the country concerned. This involves reviewing the overall situation in a concrete manner, i.e. if there is a workplace available that is appropriate to the patient’s capacity for work. Pension allowances paid due to inability to practise the learned profession are generally lower than those paid due to unfitness for work. Assessment of the inability to earn does not depend on whether the person has recently worked or on current job prospects. It should be noted that clearly defined standards of assessment are required under pension law. For accident insurance, severe disability and social compensation, the principle of abstract damage assessment applies. Inability to practise the learned profession and inability to earn must be permanent. All indications for rehabilitation have to be checked carefully and with regard to the relevant conditions. **Unfitness for public service** is a term generally used for civil servants, but it also applies to soldiers and persons doing community work.

The hepatological diagnosis should be as accurate as possible, so that the physician is able to assess the (positive and negative) capacity profile. In this connection, the insured person is not obliged to tolerate **invasive examinations** (e.g. laparoscopy, percutaneous liver biopsy). However, the risk of underestimating the reduction in earning capacity can be detrimental for the individual. Moreover, the possibility of *further deterioration of a disease* is not included in an assessment; thus a follow-up report may be required after a certain time.

The original International Classification of Impairment, Disability and Handicap (ICIDH) has been revised as the International Classification of Functioning (ICF). This new classification requires a precise description of the disease-related impairments of the individual patient. Subjective complaints should be considered although they cannot, of course, be evaluated objectively. Aggravations must be treated with caution.

Objective assessment can be based on clinical findings (s. fig. 4.21), enzymatic and mesenchymal activity (s. tabs. 5.15; 5.23), serological or immunological findings (s. tabs. 5.17; 5.20), and liver function tests (s. tab. 5.14), (s. fig. 5.2). Ultrasound, colour-encoded Doppler sonography, elastography or even CT give an impression of the morphological structure of the liver, especially in cases where patients refuse to have a biopsy. The assessment programme should also contain psychometric tests. (s. pp 210–214)

The term **reduction in earning capacity** is used in civil law to assess claims payments. It denotes the difference between the income earned before the accident happened and afterwards, i.e. the actual and proven pecuniary loss is determined.

The term (severe) **disability** was defined by the World Health Organisation (WHO) in 1980. It contains guidelines for protecting severely disabled persons by law. The principle of abstract damage assessment applies when determining the degree of disability. A small part of the labour market should be kept open for severely disabled persons.

The above statements only serve as general criteria for a physician’s evaluation of patients with liver disease. More detailed information is usually available from the insurance provider. Thus it is desirable that medical practitioners cooperate closely with sociomedical specialists, making it possible to deal directly with any application for compensation, disability pension, etc.

Although there are **guidelines** for evaluating the reduction in earning capacity, the actual degree of disability may be assessed differently depending on the existing disease. In the individual case, the physician can propose percentage values concerning the disability which are higher or lower than the recommended rate. • The assessment of chronic hepatitis B and C is of great importance (H. SELMAIR et al., 1998), and it should be made according to the aetiological-morphological nomenclature. (s. pp 714–716) (s. tab. 40.18)

Altogether, **three criteria** are important in the assessment of a liver disease:

1. its effects on the patient’s capacity for work
2. its connection with a specific damaging event
3. its rehabilitation potential

Medical evaluations are simply opinions of an advisory nature; they have to be assessed by administrative and legal experts before a final decision can be made. • The physician, however, is responsible for the medical determination of a disease and the resulting diagnosis of *unfitness for work*.

| | |
|--|---------|
| Functional hyperbilirubinaemia | 0–10% |
| Acute viral hepatitis | 100% |
| Asymptomatic HBsAg carrier status | 0% |
| Chronic active hepatitis | |
| – low inflammatory activity | 20–30% |
| – moderate inflammatory activity | 30–40% |
| – severe inflammatory activity | 50–70% |
| – fibrosis (low → severe) | 20–60% |
| Scarred liver without complications (depending on the functional reduction) | 20–40% |
| Chronic cholangitis | 20–100% |
| Fatty liver disease | 0–10% |
| – with hepatitis (low → severe) | 20–100% |
| Fatty cirrhosis | 40–100% |
| Cirrhosis, compensated | |
| – inactive (stable) | 40% |
| – moderately active | 50% |
| – distinctly active | 60–100% |
| with severe functional reduction | 80–100% |
| with shunt surgery | 60–100% |
| Cirrhosis, decompensated | 80–100% |
| Liver lobe resection | > 50% |
| Tumour resection | 100% |
| Liver transplantation (after consolidation lasting two years with 100% DOD/REC, and later on no less than 60%) | 100% |
| Primary liver cell carcinoma (within the first five years of consolidation, the REC remains at 100%) | 100% |

Tab. 40.19: Guidelines for assessing reduction in earning capacity (REC) and degree of disability (DOD) in liver diseases. • If the hepatological picture cannot be classified in relation to a diagnosis shown in the above table, it should be described and classified according to its functional disturbances in line with the above diagnoses

8.5 Self-help groups

In most countries, there are numerous self-help groups for liver patients. Participation in such self-help groups is generally beneficial. They are highly valued for their constant availability and their counselling competence. As a rule, the patient can remain anonymous and all counselling is strictly confidential. Moreover, this useful service is offered free of charge. Self-help groups provide the participants with information on all important topics (including the latest developments) by means of printed material, special meetings and reports in the media; in addition, they facilitate a mutual exchange of experience among the patients.

The wish and the hope expressed by a Babylonian haruspex (a diviner whose predictions are based on inspecting the entrails of sacrificed animals) in the following sentence, which he inscribed as a repeating stereotype on a clay model of a sheep's liver (ca. 2000 BC) (s. fig. 1.1), is dedicated to all patients suffering from liver disease and also to all users of *"Hepatology – Textbook and Atlas"*:

"May your liver be smooth"

**"In the heart the physician grows,
from God he proceeds ...
The highest ground of all remedies is love."**

**Theophrastus Bombastus von Hohenheim,
known as PARACELSUS (1493–1541)**
